Case Assessment and Interpretation

Introduction

This article describes a fundamental piece of work that is transforming the practice of forensic science and its application to criminal justice. This relatively new approach, described as case assessment and interpretation (CAI), has had a significant impact upon the forensic science profession, challenging the basis of expert opinion given in past times. It has also led to changes in the application of forensic science beyond the profession and into the working environment of police forces, prosecuting authorities, and the courts. However, some of the changes in thinking and practice implied by CAI have not yet been implemented fully. Much more needs to be done, including changes to the way in which the adversarial system integrates scientific evidence into the process of criminal justice, to maximize the utilization of forensic science through effective application of CAI.

The development of CAI was driven not only by serious questions raised about the quality of expert opinion but also by the growing requirement to manage limited forensic science resources in the most appropriate and cost-effective way. It has led to further thinking on how forensic science could continue to develop in the future.

Quality of Expert Opinion

Over the past 30 years, there has been a history of dubious or misleading expert opinion being adduced in courts of law. Setting to one side the issue of the technical competence of experts, a key cause of unsafe opinions has been the unsatisfactory way in which experts have arrived at, and communicated, opinions. It is our view that an understanding of the nature of expert opinion is necessary for judges and juries to make informed decisions based on the evidence given by experts. We also suggest that an understanding of the nature of expert opinion will only be achieved when all parties in the criminal justice system agree on the nature of the role of the expert. By "role", we do not mean what the expert should do in terms of examination but rather how expert opinion fits with, and is incorporated into, the criminal justice process.

There may well be differing views on the expert's role and, in the English and Welsh jurisdiction, only limited guidance has been given by the courts on that role. The Appeal Court of England and Wales [1] considered two cases in which experts had obtained DNA profiles from samples of semen recovered from the complainant in each of the two cases. The experts reported matches with the defendants in each of the two cases and, in answer to questions in court, had given a view on the likely origin of samples of semen. The Appeal Court judgment made it clear that, in cases where the issue is the origin of a questioned sample of semen, the forensic scientist should not give an answer to a question of the form "How likely is it that the semen originated from Mr X?". That question was solely for the jury to try to answer as, unlike the expert, they would be in possession of all the available evidence, not just the scientific evidence of a DNA match. The role of a scientist who was called to give expert evidence in court was to help the jury to reach that decision. In principle, the guidance from the Appeal Court can be applied not just to the issue of the source of a recovered sample of DNA but to any scientific evidence that addresses the source of any recovered material. Instances of dubious expert evidence being adduced in court include many examples where this principle has been overlooked and has lead to questionable opinion being given. The application to other forensic disciplines is desirable and, in a recent ruling in the case against Barry George, their lordships explicitly mention CAI as a fundamental tool to evaluate the contribution of forensic evidence in the context of the case [2].

Cost-Effective Forensic Science

It is probably a safe assumption to say that the vast majority of law enforcement agencies worldwide

have limits on their financial resources and on the number of personnel available for crime investigation and criminal trial proceedings. It is also probably the case that, in most countries, police and court services are centrally funded from the public purse and are required to operate in efficient, effective, and economic ways. As forensic science services are usually provided as a subsidiary of the police, local authority or court service, similar requirements will be placed on them. In contrast, England and Wales have moved to a commercialized forensic science sector where the police, prosecution, and defense pay directly for forensic science services. Whatever the arrangements are, law enforcement agencies will almost certainly have legal, political, and social requirements to investigate crime and to bring prosecutions. A major issue for these agencies and their suppliers is how to balance the requirement to provide "value for money" while, at the same time, finding and bringing criminals to justice and exonerating the innocent. Furthermore, whatever be the form of customer–supplier relationship, decisions have to be made, both strategically and within individual cases, on the course of action that should be taken. In forensic science, these decisions are made routinely by scientists, police, and lawyers when they are considering, for example, which items should be examined in individual cases. How these professionals make such decisions and whether they have any formal guidance to do so are key considerations.

The "CAI" model is intended to guide decision-making and to provide a framework for safe, robust opinions. While the guidance was developed in the English and Welsh jurisdiction, we believe the basic principles are just as appropriate to any other jurisdiction.

History

The Development of Interpretation

The manner in which forensic scientists interpreted their findings was largely unchanged for most of the twentieth century, primarily relying on personal experience and personal opinion. In the sense that it was usually unclear to anyone else how the expert arrived at an opinion, such opinion could be hard to understand and to challenge. In addition to this lack of transparency, there was, and still is, a fundamental issue with the way in which forensic science was perceived and used by all parties in the Criminal Justice System.

It has been recognized for some time that forensic science, while having a key role to play in many cases, does not fit well with the adversarial system of justice in the United Kingdom.

This lack of fit can be explained in a number of ways but the following two differences are perhaps the most fundamental and most revealing:

1. Scientists, through their professional training, seek the truth impartially and objectively. In contrast, the adversarial system is more a "contest" during which the side that puts forward the more persuasive argument usually wins. It is not uncommon in a trial involving evidence of opinion for each side to bring more than one forensic expert to support their proposition. Although recent guidelines in the English/Welsh criminal jurisdiction have allowed for pretrial resolution of differences between experts, in practice this does not always take place. Scientists are commissioned by either prosecution or defense and are given a specific issue to address. Often the scientist working under instructions from the prosecution is unsighted of the defense until they, the prosecution-commissioned scientist, are giving their evidence. Occasionally, they may only become aware of the defense after their court appearance. Making a balanced assessment of the scientific findings in these situations is difficult if not impossible – the forensic scientist can address either only the prosecution proposition or an assumed, possibly inappropriate, alternative on behalf of the defense.
2. Scientists are comfortable with uncertainty and with thinking in probabilistic terms. In contrast, the prosecution seek certainty in order to prove their case "beyond reasonable doubt" and may seek to present forensic science as clear and incontrovertible evidence. The jury also may have difficulty in understanding scientific evidence that provides anything less than certainty. The expectations of forensic science, heightened by extensive media coverage, can, and has in the past, lead to pressure being put on the scientist to overstate his or her evidence.

Overstating the value of evidence has been a key issue in a number of miscarriages of justice in which forensic evidence has been discredited. High-profile

examples in the United Kingdom include R v Preece, R v Ward, R v Power, Hill and others, and R v Clark. It could be argued that in these cases, the expert was either biased, whether knowingly or not, or incompetent. Bias is perhaps difficult to avoid (*see* **Interpretation: Observer Effects**), particularly when trying to operate in a system not designed to determine the truth and in which, in an adversarial jurisdiction, experts are commissioned by one side or the other. In comparison, competence can be defined as having attained a particular level of technical ability in the analytical methods used. As such, technical competence can be, and is, tested to assure quality of results. However, we suggest competence requires more than just a certain level of technical ability. Competence in forensic science requires, in addition to technical skills and knowledge, a particular level of interpretative skill. We would argue that application of a robust interpretational framework would help to improve competence and to counteract bias. The question is, do we, as an international forensic science community, have such a framework?

Beginning in the 1980s, a small number of scientists within the forensic science profession began arguing that a more robust, more transparent way of interpreting findings was provided by a likelihood ratio (LR) approach within a Bayesian paradigm (reference [3] was, perhaps, the first example in the forensic science literature). The logical approach provided by the LR took many years to gain understanding and acceptance by the general forensic science community but is now, arguably, close to being accepted as "main-stream" practice. We return to this in the section Underpinning Philosophy.

The Development of a Competitive Market Place for Forensic Science

During the 1980s and 1990s, reviews of various services provided by UK Government Departments had identified improvements to help increase efficiency, effectiveness, and economy. A main political theme of the time was the introduction of practices and experiences from the private sector that were perceived as offering more business-like ways of working. The provision of forensic science services was not excluded from this review and various reports all dealt with ways of improving the delivery of forensic science [4].

Emerging from one such review was a proposal for direct payment by the police and prosecution for the services provided by forensic science organizations. The aim of the new arrangement was to achieve a more direct relationship between the ever-increasing demand for forensic science services and the resources available to deliver forensic science. If "customers" believed they really needed more forensic science services, and these services were seen as worth paying for, then forensic science providers could increase their level of resources, in terms of personnel, equipment, and range of services. On the other hand, if customers decided that the service was not worthwhile, the resources of forensic science should decrease.

A corollary of direct charging was that it gave police forces freedom to purchase forensic science from other providers in the private sector rather than from a central government agency.

The Forensic Science market place in England and Wales was thus born.

"Value for Money" and Bayes Theorem

The introduction of direct charging provided a stimulus to examine further how scientists operated within cases, particularly the way in which scientists made decisions on which items to examine and which tests to employ (Case Assessment), and the way in which they interpreted their findings (Interpretation). It was an opportunity to explore how scientists thought about a case and to understand and capture, in a formal way, how the more effective, more efficient scientists operated in practice. From this work, a model was developed to provide a framework intended to guide scientists in making good decisions [5–8]. The model was based on the logic of Bayesian thinking, particularly focusing on evaluation of LRs, and was developed and refined through workshops with practitioners across all main-stream disciplines of forensic science. Meetings were also held with a sample of police and prosecution personnel to explore implications in the criminal justice system. We return to this topic in the section The CAI Model.

Underpinning Philosophy

Dealing with Uncertainty – Bayes Theorem

How do we make good decisions when faced with a series of options? How do we choose which course of action will give best benefit?

We make these sorts of decision every day of our lives. What we eventually decide to do in a particular situation will depend on many factors including our experience, our instincts, our habits, our finances, the available information, and the constraints of rules, regulations and laws. However, underpinning all of this is the influence of the way in which we think – our style of thinking.

For many everyday situations, most of us are probably guided by our own instinctive feeling on which will be the best course of action – we do not think too long or too hard about the problem. For slightly more difficult problems, we check out our thinking with a trusted friend or colleague, or we carry out some research to obtain further information. For particularly difficult or profound problems, we may well carry out a long analysis of the situation and think through the pros and cons of the various options: we will try to take a rational decision based on data, knowledge, and understanding.

In the forensic field, it can be argued that scientists have tended to make decisions in an instinctive, heuristic way – "This course of action has worked in the past for me and therefore I will apply it in this particular case". For some, this can be an effective way of working, particularly if the scientist is good at analyzing their experiences, at learning from those experiences, and at being able to recall, at appropriate times, the lessons learned. However, we have all seen scientists whose instincts are not the best – their proposed course of action would lead to inefficient, ineffective, or even incorrect outcomes. In fact, we have all, at some time, probably experienced this situation ourselves! But even with the best of instincts, sometimes instinctive judgments let us down – better decisions could have been taken if we had had more background information and a clearer understanding of the requirements and likely outcomes.

The elegance of Bayes theorem is, for some, its simplicity in showing how new information can be incorporated in a logical, robust manner to help change a personal view on the probability that an uncertain event actually occurred. There are numerous works that explain Bayes theorem in detail – we refer readers to a relevant article (**Evidence Interpretation: a Logical Approach**) in this encyclopaedia and to other references that are written in a forensic context [9–11]. We do not intend to reiterate here an explanation of Bayes theorem, but we reproduce some formulae simply to help the reader understand this article. We base our notation on that provided in reference [12].

A classic example where Bayesian thinking can be applied to good effect is in the field of medical diagnoses. Consider the situation in which a person who has just been told he had tested positive for HIV. What is the probability that he actually has the disease, given he has a positive test result? For this example, we use the following notation:

Let H_1 be the proposition that he has the disease.
Let H_2 be the proposition that he does not have the disease.

Note that these two propositions are mutually exclusive (they both cannot be true at the same time) and that they are exhaustive (there are no other propositions to be considered).

Let R be the positive test result.
Let I be any other background information that may have a bearing on the probabilities.

One other symbol is the vertical conditioning bar | which can be read as "given". The probability assignment will be based, or conditioned, on some assumption(s) or piece (s) of information.

We will use what is known as the *odds form of Bayes theorem* to evaluate the probability that the person has HIV. Bayes theorem can be written in various forms but the odds form is most relevant to our medical example and to judicial proceedings. The odds form can be written as follows (formula 1.16 in [12]):

$$\frac{\Pr(H_1|R,I)}{\Pr(H_2|R,I)} = \frac{\Pr(R|H_1,I)}{\Pr(R|H_2,I)} \times \frac{\Pr(H_1|I)}{\Pr(H_2|I)} \qquad (1)$$

It is called the *odds form* because we are dealing with the ratio of two probabilities – the probabilities of each of two mutually exclusive, exhaustive propositions, H_1 and H_2. The ratio of two such probabilities is known as *odds*.

The left-hand side of the equation is the odds that he has the disease, conditional on the test result. It is the result of the multiplication of two expressions. The first of these two, $\Pr(H_1|I)/\Pr(H_2|I)$, is again a ratio of two probabilities but, contrary to the left-hand side of the formula, the probabilities are not conditional on the test result – they are derived from information obtained before the result of the test is known.

They are therefore known as the *prior probabilities*. The second expression, $\Pr(R|H_1, I)/\Pr(R|H_2, I)$, is known as the *likelihood ratio* (*LR*) and is the ratio of two probabilities:

1. the probability that the test would be positive, given that *he has* the disease (H_1) and
2. the probability that the test would be positive, given that *he does not* have the disease (H_2).

It is called a *likelihood ratio* because, simply, it is the ratio of two likelihoods (or probabilities). It can be seen as a measure of the weight, or impact, of the test result in helping to decide whether or not he has the disease.

Considering each of the terms, what data would inform the probabilities? The prior probabilities would be informed by the relative frequency of occurrence of the disease in the population of which the man is a member. The numerator of the LR would be informed by knowledge of the sensitivity of the test – the number of times a positive test result would be seen in samples from people who are known to have HIV. The denominator would be informed by knowledge of the specificity of the test – the number of times a positive result would be seen in samples from people who are known not to have the disease.

If robust estimates of the prior probabilities and the two probabilities of the LR are not available then a false inference could be made from a positive test result.

Bayes Theorem is eminently suited to problems such as the diagnosis of disease but we are more concerned with judicial proceedings. Instead of H_1 and H_2 to represent our propositions, we use H_p and H_d to represent the propositions of the prosecution and defense respectively. Instead of R, we use E to represent the test result. Formula 1 then becomes

$$\frac{\Pr(H_p|E, I)}{\Pr(H_d|E, I)} = \frac{\Pr(E|H_p, I)}{\Pr(E|H_d, I)} \times \frac{\Pr(H_p|I)}{\Pr(H_d|I)}$$

We referred earlier to the role of the forensic scientist in court. The odds form of Bayes theorem helps to clarify the scientist's and the jury's (in some jurisdictions, the judge's) role. The jury/judge concern themselves with the *prior* and *posterior probabilities*; the scientist concerns herself with an evaluation and communication of the *LR*, $\Pr(E|H_p, I)/\Pr(E|H_d, I)$. That role for the scientist has been described elsewhere as that of an "*evaluator*" [13]. This view of the respective roles fits well with the guidance offered by the Appeal Court in the Barry George case [2].

A major concern among some scientists, however, is the feeling that you cannot apply Bayes unless you have hard data to inform *likelihoods* (the probabilities for the scientific findings – the test results and observations). A discussion of this issue is beyond the scope of this article and we refer readers to one reference for further discussion [14]. Suffice it to say here that we believe it is helpful to consider likelihoods not as a precise number but more as a reflection of the scientist's belief that she would obtain a particular test result or observation given the truth of each of the competing propositions. This belief would be informed not only by whatever "hard" data there were but also by the scientist's own knowledge and experience. In that sense, likelihoods are subjective and are open to test and challenge.

Full Form of Bayes Theorem. We have seen how the odds form of Bayes theorem can be applied in judicial proceedings but, in investigations prior to a suspect being apprehended, there will be no propositions put forward by prosecution or defense. Indeed, the police investigator may have no idea of what has happened. Recent work has explored this distinction between investigative and judicial situations [13] and other work has demonstrated how Bayesian models may be applied to investigations [15–16]. What is clear is that the odds form of Bayes is not suited to investigative problems but that the fuller form has much potential. In "*investigative*" mode, the scientist's role may well be to provide possible explanations (propositions) for findings and, if feasible, posterior probabilities for these explanations. The scientist's role in investigations, in contrast to the role in a judicial context, may well include consideration of *prior probabilities* for explanations as well as *likelihoods* for the findings given the truth of the explanations.

The Nature of Opinion

Published work mentioned earlier on the nature of opinions [13] attempts not only to categorize opinions according to Bayes theorem, but also categorizes opinions in terms of a "hierarchy of issues" that a scientist may address. The scientist is encouraged to decide in advance, and in consultation with the clients, the level of issue to be addressed. The

scientist formulates the specific issues within the case, beginning with "offense" level, proceeding down through "activity" level and "source" level to "subsource" level. There are very few instances, if any, in which the scientist, as an evaluator, should address the "offense" level and experience has shown that, while scientists may feel more comfortable with "subsource" and "source" level issues, addressing the higher "activity" level provides the court with a much more valuable, more appropriate service. "Activity" level is the level that we would encourage all practitioners to consider. If, after consideration, the scientist does not feel able to address "activity", then the limitation of "source" and "subsource" opinions, and the possibly misleading impressions that may be given, must be made clear to the client and court. For further information on the topic, we refer the reader to the earlier references [6, 13] and to some specific case examples [17].

The categorization into "investigative" or "evaluative" opinion, together with the use of the hierarchy of issues, has helped to describe the different mode of operation of forensic scientists in the different phases of a criminal investigation and subsequent trial. We believe this will bring a new clarity and a common understanding of the contribution of forensic science to the Criminal Justice System.

The CAI Model

Many practitioners will have encountered situations in which police investigators submit large numbers of items, for example a wardrobe of clothes, with a request that the laboratory "do a full forensic examination". This type of request may have been due to a variety of reasons including:

police officers not being aware of the potential evidence types and their value;
police officers' desire to "cover all angles";
prosecution's desire to "cover all angles";
scientists' demands to see everything in a case;
local procedures; and
the seriousness of a case.

All these reasons may be justifiable in any one particular case. However, before any scientific work is started, serious consideration of the underlying reasons for doing the work must be made by all parties involved.

First, even if all items were to be examined, which tests should be used? Second, can the considerable expenditure of valuable resources, time and funding be justified?

The answer to the first question has usually been within the domain of the scientist. Police officers have been, and some still are, largely unaware of the specific scientific tests that are available let alone their applicability or usefulness. Some officers may have an awareness of, for example, DNA profiling but will not be able to specify the type of DNA-profiling tests that can be done. Police officers have tended to leave the choice of tests to the scientist, believing that the scientist will know best what to do. Scientists, on the other hand, tend to commission only those tests that are available in-house within their own organizations, and possibly just within their own building! They would tend to select those tests that appear to have served them well in the past, or that have been recommended and used by more experienced colleagues, or that are written down in set procedures for their organization. Their choice of test may have been determined more by technical considerations than by the needs of the case.

The second question – "can the expenditure be justified?" – is one that came to the forefront of people's thinking in the early 1990s with the move to Agency status of the main forensic science provider in England and Wales, the Forensic Science Service (FSS). As a result of major changes in the way the FSS and its customer police forces interacted, both customers and providers focused more on "value-for-money" forensic services. Police forces were required to obtain best value from their providers. Furthermore, the FSS had a vested interest in operating in an efficient, effective, and economic manner – it did not intend to waste resources and was required to "balance its books". In the early phases of this new relationship, attempts were made to monitor measures of performance such as the length of time to complete a case, the cost of a case, the effectiveness of the outcomes, the numbers of items examined, and the number of tests completed. Most of these measures are relatively straightforward to compile, but one measure that has been difficult to track is the effectiveness of the scientific outcome. It may seem a straightforward task to do so, but no robust, easy-to-apply system has yet been developed to assess the effectiveness of the scientific outcome. Attempts have been made [18–20] in specific areas but there remain

large gaps in knowledge and understanding on this aspect of performance.

The CAI model, as mentioned earlier (Section "Value for Money" and Bayes Theorem), was developed to provide a framework that would help scientists devise cost-effective examination strategies for the client [5]. The underpinning, logical structure of the framework was Bayes Theorem and, particularly, use of the LR to assess weight of evidence. Through workshops on case studies with groups of leading practitioners, the model was applied to the majority of case types within forensic science and was refined as more was learnt about the functioning of the model in different situations. The model comprised a series of key stages that followed the natural course of a case. For each stage, there was a series of questions that the scientist could ask to help develop the examination strategy and interpret the outcomes of tests. These questions can be captured in the form of an aide-memoir to help prompt the scientist – an example is shown in the Appendix. Such aide-memoirs have been found to be useful in the training of new practitioners as well as in offering a permanent, auditable record of the decision-making process within a case.

The key stages of the model are as follows:

define the customer requirement;
assess how forensic science can help;
agree on a case examination strategy;
carry out examination;
interpret the results; and
communicate the test results and opinions.

The emphasis of the model is in understanding the issues in a case and devising the examination strategy before any substantive work is carried out. This approach contrasts with earlier practice in which little attention may have been given to these aspects. Furthermore, the model forces the scientist to articulate her expectation before any material is recovered, hence avoiding any *post hoc* rationalization once the material has been found and analyzed.

The model encourages practitioners to communicate with the customer and to understand the following:

1. what is at issue or is uncertain;
2. the date by which the scientific information is required; and
3. the financial budget of the customer.

Having taken these aspects into consideration, the scientist can devise an appropriate strategy, consult again with the customer and gain her approval, or otherwise, for the examination to go ahead. During the communication between scientist and customer, the scientist can take the opportunity of educating the customer on likely outcomes and their evidential value, thereby managing the customer's expectation. Only when approval to proceed has been gained, should the scientist commence substantive work.

The model is not a rigid procedure. Rather it is a guide, a set of useful questions that can be asked. Neither is it a straight-through process to be followed from start to finish with no diversion. Real-life cases tend to be more complex, and the model allows for "looping back", or revisiting stages, in the light of new information, changing circumstances or surprising findings.

Some practitioners would argue that the model reflects just what they had been doing for many years, and we would agree with that view. However, development of the model helped to explore and capture the elements of good forensic science practice and, for the first time, to record formally that practice.

Case Example – a "Simple" Transfer Case

Case Circumstances

A vehicle used in the commission of an armed robbery has been found abandoned. Tape lifts were taken from the driver's seat and submitted along with the outer clothing – a sweater (item S) and a pair of jeans (item J) – taken from a suspect. The police request simply a "comparison of fibers".

Stage 1: Define the Customer Requirement. The model encourages the scientist to check, at the very beginning of a case, whether she has enough information to help her understand the key issues in the case. If the issues are "evaluative", has sufficient information on the key elements of the circumstances been provided to (i) help formulate propositions and alternatives, and (ii) inform probabilities for obtaining findings? If the issues are "investigative", the scientist needs to understand what would be the key investigative questions to address.

In this case, the scientist would probably want to know the following, for example:

- Do the police suspect this man of being the driver at the relevant time?
- What is the prospective charge against him?
- What strength of evidence will be required for charging, if not already charged, or for prosecution?
- How long had the car been in the possession of the robber/s?
- What did the lawful driver wear while driving the car?
- When were the suspect's items of clothing and the tape lifts taken?
- What happened in the intervening period?
- What does the suspect allege as an alternative?
- By when do the police need any information?
- What is their budget?

This list is not necessarily exhaustive and there may well be other queries that the scientist would have. However, obtaining answers to this list would help the scientist begin to formulate an examination strategy. We will assume the following answers:

Do the police suspect this man of being the driver at the relevant time **– yes**
What is the prospective charge – **unlawful taking of a motor vehicle**
What strength of evidence is required – **suspect has been charged but there is very little other evidence against the suspect and so strong evidence would be required to proceed with the charge; if strong evidence is not forthcoming, the charge will be dropped**
How long had the car been in the possession of the robber/s – **about 1 hour**
What did the lawful driver wear while driving the car – **unknown**
When were the suspect's items of clothing and the tape lifts taken **– both about 1 hour after car abandoned**
What happened in the intervening period – **suspect: unknown activity; car: no-one else had access to the car**
What does the suspect allege as an alternative – **he says he was not the driver and has never been in that vehicle**
By when do the police need any information – **suspect bailed to reappear in three weeks time**
What is their budget – **maximum of £3000 (~€4500)**

This additional information helps the scientist to understand the issues in the case and to take into account the timeliness and budgetary requirements of the police.

Specifying the key issues in a case may not be an easy task and requires significant care, analytical skills and effective, two-way communication. The first consideration is whether the issue is "evaluative" or "investigative". As there is a suspect, and he is giving an alternative explanation, the issue would seem to be "evaluative" and, considering the circumstances of the case, the key issue could be phrased as follows:

Is the suspect the person who drove the vehicle at the time of the robbery?

Following the guidance we discussed earlier, this issue can be classified as "activity" level – the level that is the more valuable level from a court's perspective.

Stage 2: Assess How Forensic Science Can Help. As the issue has been identified as "evaluative", this stage of the model requires the scientist to consider the LRs of all possible outcomes of the various potential examinations. One way of evaluating LRs is through the development of tables based on pairs of relevant propositions that come directly from the specified issue. Following our earlier notation, we will let H_p represents the prosecution proposition and H_d the defense proposition. In our case example, the following, competing propositions have been generated from the specific, activity-level issue:

H_p – The suspect is the person who drove the vehicle at the time of the robbery.
H_d – The suspect is not that person; someone else drove the vehicle.

Provided these propositions are mutually exclusive and exhaustive in the context of the case, the scientist can attempt to evaluate LRs for the different examinations. In this case, there is a choice of examining

both items;
just one of the items; or
neither of the items.

We will assume for the moment that there is only one examination technique available. We will also assume that the scientist has carried out a short preview examination to assess how well the garments

shed fibers and to determine the fibre type and color. On the basis of the scientist's knowledge of transfer, persistence and detection of the garment's fibers and on their background levels on vehicle seats, let us assume the scientist has developed the LR tables as in Tables 1 and 2 for the two garments.

There is the potential for much discussion amongst practitioners around the issue of how a scientist assigns the probabilities. However, as mentioned earlier, we leave that topic for discussion elsewhere. Assuming the tables are a fair reflection of probabilities, it can be seen that the LRs in Table 1 are spread more widely and are of greater magnitude generally than those in Table 2. Therefore, whatever the outcomes of the two examinations, examination for fibers like S will be the more informative, the more probative – the LR for each outcome in Table 1 "pushes" one way or the other the prior probability of the suspect having driven the car. The LRs in Table 2 either do not change that prior probability or change it only by a small amount.

Furthermore, considering the likelihoods for obtaining the outcomes, there is a greater chance of obtaining useful outcomes that point the "right" way in Table 1 rather than in Table 2. From Table 1, we can see that, if the police really have the "right" person, i.e., the conditioning is on H_p being true, then there is a combined 98% probability (0.05 plus 0.25 plus 0.68) of obtaining an outcome (LRs of 5, ~30, and 340 respectively) supporting this proposition, i.e., the results point the "right" way. There is, however, a 2% probability that, even though the police have the "right" man, the scientist will obtain an outcome (LR of 1/49) that supports the defense proposition, i.e., the result points the "wrong" way. On the other hand, if the police have the wrong man, i.e., the conditioning is on H_D being true, then there is a 98% probability that the outcome (1/49) would point that way, thus supporting the defense proposition.

If the same analysis is carried out for Table 2, we can see that, if the suspect is the "right" man, there is only a 2% probability of obtaining an outcome (*LR* of 4) that would support significantly that proposition.

This method of comparing the benefits of different strategies can be applied not only where there is a choice of items from one suspect but to any situation in which there is a choice to be made. Examples include cases in which there is a choice of several tests that can be applied to the same item, cases in which there is a choice of evidence types and cases in which there is potential for two-way transfer.

Table 1 This describes the probabilities for all the potential outcomes of examination of the seat tape lifts for fibers matching those of garment S

Outcomes from examining tape lifts for fibers matching S (E_S)	Pr [E_S|H_p,I]	Pr [E_S|H_d,I]	LR
1. No fibers matching S	0.02	0.98	1/49
2. Few fibers (1–5) matching S	0.05	0.01	5
3. Moderate number of fibers (6–20) matching S	0.25	0.008	~30
4. Many fibers (>20) matching S	0.68	0.002	340
	1	**1**	

Table 2 This describes the probabilities for all the potential outcomes of examination of the seat tape lifts for fibers matching those of garment J

Outcomes from examining tape lifts for fibers matching J (E_J)	Pr [E_J|H_p,I]	Pr [E_J|H_d,I]	LR
1. No fibers matching J	0.2	0.4	1/2
2. Few fibers matching J (1–5)	0.3	0.35	~1
3. Moderate number of fibers matching J (6–20)	0.3	0.2	1.5
4. Many fibers matching J (>20)	0.2	0.05	4
	1	**1**	

We must point out that the two tables have been evaluated as two independent tests. To evaluate the potential strength of carrying out both tests, we would need to reappraise the results of the second test based on the outcome of the first.

Of course, there are not only benefits, but also costs and limitations. Let us assume that the examination in Table 1 would cost £4000 and would be completed within two weeks while the examination in Table 2 would cost £2000 and would be completed in three days. Both examinations meet the timeliness requirement of the police but only examination 2 is within their target budget. However, examination 1 is the only one of the two examinations that has a potential of providing significant evidence – the outcome of "many" fibers matching in Table 1 provides the largest LR in the two tables and would be reported with a verbal qualifier of "moderately strong" evidence, using one published verbal scale [8]. None of the other outcomes would be as strong. So, while examination 2 would meet the cost and speed requirements of the police, it does not have the potential to provide the strength of evidence that the police say they need.

The information on benefits, costs, and limitations of the various strategies can form the basis of a dialogue between the forensic science provider and the police/prosecution/defense/court customer.

Stage 3: Agree A Case Examination Strategy. Depending on the nature of the relationship between customer and provider, and on the seriousness or complexity of the case, there may be a requirement on the provider to contact the customer to discuss and agree a case examination strategy. The CAI model captures this contact as a formal step to emphasize that the final decision on which tests on which items to commission rests with the customer.

Stages 4–6 Carry out Examination; Interpret the Results; and Communicate the Test Results and Opinions. These stages are what may be viewed as the traditional work of a forensic scientist. The main difference in the CAI model from traditional procedures is the recognition that opinion should be communicated in the form of an LR, if offering an "evaluative" opinion, or as a list of explanations or posterior probabilities if "investigative".

We will assume in this case that, notwithstanding the cost and potential strength of evidence, examination of the seat tape lifts for fibers like garment S was commissioned. Let us also assume that the result of the examination was 12 matching fibers, outcome 3 in Table 1. There will be different ways of communicating an opinion based on this outcome and its associated LR. One way could be as follows:

In my view, the finding of such a number of matching fibers on the seat tape lifts is approximately 30 times more likely if the suspect, rather than someone else, was the person who drove the vehicle at the time of the robbery.

This could be followed by a further paragraph expressing the (log of the) magnitude of the LR. The following example uses again a published verbal scale [8]:

The findings provide moderate support for the view that it was the suspect, rather than some other person, who drove the vehicle at the time of the robbery.

An "Investigative" Case

As described earlier, cases requiring so-called "investigative" opinion may well not involve a suspect. There will not therefore be an alternative proposition and, if there is uncertainty about the details of the crime, there may not be a police/prosecution proposition about what happened at the scene. An LR table, as shown in the first case example of an "evaluative" issue, cannot be developed. The "investigative" forensic scientist is therefore in a different position from the "evaluative" forensic scientist and will operate with a different mind-set and therefore in a different role. While this role will still, neccessarily, involve identifying the issues, it will focus on those areas of forensic science that will provide the most useful information to help move the investigation forward. Usefulness could be based on various measures including the speed of provision of the information, the potential of the proposed examination to reduce uncertainty for the police investigator, and the cost of the examination. The aim of the "investigative" scientist would be to provide useful explanations for the observations made at the scene or on the victim. If possible, the scientist would also rank these explanations in order of their probability.

In terms of application of the CAI model, the "investigative" scientist would consider and recommend the examination that would have the best chance of providing the most useful information within the time and budgetary limits of the police.

Wider Implications

For CAI to be applied effectively, not only must the scientists have the ability to apply this approach, but also each *organization* involved in the forensic process has to play their part. This means each organization having a common understanding of the scientist's role and having supportive procedures in place. These procedures can be categorized under the following headings: **communications and awareness; quality; and organizational support**.

Communications and Awareness

A key element of CAI is that of establishing the customer's requirements (as set out in The CAI Model section). This requires effective and efficient communication and discussion with the customer – police, prosecuting team (i.e., police and prosecuting authority) or defense.

Once the customer's requirements have been established, and the scientist has assessed the case, the scientist needs to communicate to the customer whether or not forensic science can assist. If it can, what are the chances of a helpful outcome (one way or the other); and what is the best examination strategy. At this stage, an estimate of the charges and the time scales for the examination can be agreed. Once the examination is completed, then further communication is required to explain the result or to carry out more work if needed.

To enable all this dialogue to take place in the first place requires collaboration and excellent communication on a case-by-case basis between the forensic science provider and the agencies involved. In England and Wales, in order to facilitate these communications, National and Local Tripartite Protocols have been agreed among the police, forensic science providers, and the Crown Prosecution Service. These protocols make clear the responsibilities of each of the agencies and set out processes that will support the required communications. The identification, at the earliest stage, of the key issues to be addressed is a key element of these protocols.

All parties in the forensic process should be aware of the needs of each of the others. Police and lawyers should be aware of what forensic science can provide and also its limitations. Lawyers and judges should understand how the forensic scientist is interpreting the evidence and how their approach fits with the rest of the nonscientific evidence and either augments or diminishes it. Forensic scientists should also develop their understanding of their customers' investigative and legal requirements.

Quality

In order to apply CAI effectively, forensic scientists need a good understanding of the Bayesian approach and an ability to assess probabilities based upon relevant data that have been documented and, preferably, published. They also need to understand and apply the concept of the hierarchy of issues [6, 7] and be comfortable with the difference between "investigative" and "evaluative" opinion [13]. Every practicing forensic scientist should be able to demonstrate competence in these skills to managers, external assessors and the courts. Provider organizations should set standards against which performance can be audited and validated as part of their quality management. Accreditation bodies should also assess performance against the principles underpinning CAI although as yet there are no international standards for forensic science.

Organizational Support

Apart from training and continuous professional development, any organization that provides forensic science should support its practitioners. Management should ensure that protocols and systems are in place to enable practitioners to communicate with personnel in other agencies. They should build CAI into their internal processes.

Organizations should ensure that sufficient reliable data are available to practitioners to enable them to assess probabilities. This requirement is ongoing and should shape future research programs. The application of CAI should also shape the future service provision by the forensic science provider. At a corporate level, customer communication and awareness programmes should also include CAI elements.

Further Consequences

Source- and Activity-Level Evidence

As we saw earlier, a very useful concept that emerged from the early work on CAI was that of the Hierarchy of Issues and the idea of subsource, source and

activity level propositions. This has provoked further thinking on how forensic evidence should be interpreted and presented, and has highlighted the potential overvaluing of some evidence if it is evaluated solely at source or, even worse, subsource.

Staged Reporting

The application of CAI provides the potential for a staged approach to forensic examinations – an approach sought by other partners in the Criminal Justice System.

Forensic science can provide limited information at early stages in the criminal justice process in order that the prosecution team can ask the right questions of the suspect or even to assist in putting charges to a suspect. Depending on the response of the suspect at each stage of the process, more detailed forensic work can be carried out to address specific issues as they arise – the suspect's response will frame the alternative proposition considered by the scientist and, hence, may influence the magnitude of the LR. An admission of guilt or a "guilty plea" at any stage in the investigation could eliminate the need for lengthy and costly forensic examinations thus reducing the time and cost of forensic intervention.

Factual versus Evaluative Reporting

A further corollary of CAI and staged reporting is the provision of factual reports that do not include evaluation or opinion but simply state the results of the forensic examination. Examples of this are as follows:

> "DNA from the blood on the murder weapon matched the DNA from the suspect."
> "A large amount of semen was found on the internal vaginal swabs."
> "Twenty-five fragments of freshly-broken glass, falling into two distinct groups or types, were recovered from the jacket'."
> "The white powder in possession of the suspect was found to be cocaine."

Factual reports should only be provided when the police and prosecuting team have clear understanding of what is being provided and would usually be part of a staged approach to the forensic investigation.

One key benefit of factual reporting is a result of interpretation of the findings being limited to the analytical or "source/subsource" level. This may bring some savings in cost and time if, for example, there is a "guilty" plea or the forensic science evidence is not disputed. However, it must always be understood by the police and lawyers that such reports do not involve higher level interpretation or expert opinion in its true sense and that there has been no assessment of the weight or value of the findings.

Development of a commercial market place and the procurement of forensic services

Although a market place for forensic science has been established in England and Wales, it is currently unregulated (see later) and is still in its early stages of development. Indeed forensic science itself continues to develop as new technology stretches the limits of forensic knowledge and interpretation. Arguably, the development and use of CAI has demonstrated the true value of forensic science as an interpretative discipline that can be applied to any technology that provides results or observations. Note that we are drawing a distinction between the *provision* of test results and the *interpretation* of test results within the CAI framework. The authors believe that when working as "evaluators", forensic scientists should interpret results at the highest level possible. To do anything less could leave the interpretation to those less able to do so, with dangerous consequences and potential miscarriages of justice of the kind referred to earlier in this article.

One of the consequences of the development of what is currently an unregulated market place is the move by the police to demand, as paying customers, test results on items preselected by them. This has two further consequences. First, there is the potential for forensic science to be applied only from a prosecution viewpoint. Second, test results may not be interpreted in the most robust and effective way, even if there is any interpretation at all – the judge and jurors, alone, will be left to make sense of the results or to advance from subsource/source issues to activity issues, perhaps under the conflicting persuasion of the prosecuting and defending lawyers.

Regulation of forensic science

Although there is no regulation of the market place in England and Wales, a government initiative to develop a regulatory framework for forensic science

practice is well underway. A Forensic Science Regulator has been appointed and will oversee the end-to-end forensic process from scene/suspect examination through laboratory work to the presentation of evidence in court. This should include the way in which tests are commissioned, how to avoid bias, and the delivery of interpretation within, we believe, the CAI framework in all cases where possible.

Strong representation from forensic providers is keeping the regulation of expert opinion firmly on the agenda so that standards will be maintained and overseen by the Regulator.

Clarification of Roles in the investigative and evaluative stages of Crime Investigation

The development of CAI has led to questions being asked about the role of forensic scientists, crime scene examiners, and police and lawyers in crime investigation. It has also lead to the concept of investigative and evaluative forensic science discussed earlier. It is right to say that our understanding of these "phases" of forensic science is still work in progress. However, what is emerging is that once an individual is called upon to provide expert opinion, whatever their role or job description may be or whatever organization they may belong to, there are benefits from operating within the CAI framework.

Changes to the Adversarial System of Justice

It is within the adversarial system itself that some of the most fundamental changes need to take place to enable forensic scientists to apply CAI effectively. It is beyond the scope of this article to expand in detail on this subject although many of the main points have been discussed earlier.

Perhaps the central issue for the adversarial system to address is the recognition of forensic science as a tool for enabling truth to be ascertained rather than a tool for prosecution or defense to win their case. Many changes to the process have been recommended from various reviews in England and Wales – few, if any, have been implemented fully. It is maybe the case that a full understanding of the true nature of forensic science is lacking by the key players. Indeed, before CAI and its underlying principles were developed, the forensic science profession itself was unclear. Now, however, with the growing appreciation of the power of CAI and a confidence that that brings, perhaps the profession itself can, with a stronger resolve, make its voice heard and bring about the much-needed changes.

Appendix : A step-by-step checklist for Case Assessment and Interpretation (CAI)

1. Define the customer requirement
   - What are the case circumstances – timings, witness statements, allegations, medical and other specialist evidence?
   - What are the uncertainties – with what aspects of the case does the customer need help?
   - Is there a suspect? Has he/she been charged? What is the charge?
   - What strength of evidence is required – for charging or for prosecution?
   - What are the customer's deadlines – statutory requirements; other needs?
   - What is the budget?
   - Do you have sufficient information to help identify the key issues in the case? If not, try to obtain it.
2. Assess how forensic science can help
   Based on your understanding of the case circumstances:
   - Are the issues investigative and/or evaluative?
   - What level in the hierarchy of issues (sub-source/source/activity/offense) will you be addressing?
   - What type of opinion (explanation/posterior probability/ single likelihood/likelihood ratio) will you be offering?
   - If investigative, develop list of possible explanations with, if possible, realistic prior probabilities. Considering the tests available and the likelihoods of the different outcomes of the tests, decide which tests on which items have the best chance of providing the most effective information to help direct the investigation.
   - If evaluative, specify a relevant pair of propositions based on prosecution and defense positions. Develop likelihood ratio tables for the different items/tests, previewing items if necessary. Identify the relative cost-effectiveness of the different examinations.

3. Agree on a case examination strategy
   - Contact customer and explain rationale and manage customers' expectations
   - Discuss options
   - Agree purpose of examination and the examination strategy
4. Carry out case examination strategy
   - Do the tests
5. Interpret the results
   - If investigative, revisit your list of explanations. If providing posterior probabilities, incorporate the likelihoods for the findings with the prior probabilities, and revise list in order of posterior probabilities. If not offering posterior probabilities, then simply revise list and ensure all possible, feasible explanations are given.
   - If evaluative, compare results with previous assessment and refine the likelihood ratio.
6. Communicate
   - Check your "conclusion" agrees with your "purpose" as agreed in the case strategy. Convey to the customer your findings and conclusion in the most appropriate way.
   - Ensure the strengths and limitations of your opinion are clearly set out and understood by the customer.

Acknowledgments

We wish to thank all our colleagues, both within the profession of forensic science and in the wider scientific, police and legal community, for their help and support over many years during the development of the ideas presented in this article. In particular, our colleagues in the initial and subsequent CAI development teams have been a source of inspiration and support – our special thanks go to Ian Evett, Jim Lambert, Roger Cook, Christophe Champod, Stella Jones, and Gareth Booth.

Ceiling Principle: DNA

Introduction

The National Research Council (NRC) committee was assembled in 1990 to assess the general applicability and suitability of using DNA technology in forensic science. The NRC Report [1] provided recommendations in six areas related to the DNA typing process: technical issues, statistical interpretation, laboratory standards, databanks and privacy, legal issues, and societal and ethical issues.

Assessing the probability of observing a particular multilocus genotype is a pursuit that is only attempted in forensic science. At the time of the NRC deliberations, this was already a controversial issue and a fundamental reason for the committee's existence. However, the NRC recommendations in the area of statistical interpretation actually provoked further controversy, rather than allaying it. Arguably the most controversial recommendations were those known as the *ceiling principle* and *interim ceiling principle*.

Much of the early debate surrounding DNA evidence interpretation involved the need to account for population substructure in statistical estimates. Owing to population-level differences in allele frequencies, statistical estimates can vary depending upon the source of population data. In a criminal case it is not usually known what database is the most appropriate to apply as this depends on, firstly, being able to assess the community of persons that had opportunity to commit the crime, and secondly, to have access to a representative database of this community.

At its simplest, it was the belief in population heterogeneity and its potentially discriminating effect on statistical evidence that led to the justification for the ceiling principle. It was believed that the ceiling principle would yield conservative estimates, even for a substructured population, provided the allele frequencies used in the calculation exceed the allele frequencies in any of the population subgroups. To apply the ceiling principle, the upper bound for the frequency of each allele is required, irrespective of the population of origin. The largest frequency in any of these populations, or a fixed figure of 5%, whichever is larger, should be taken as the ceiling frequency. The ceiling frequencies are then multiplied using the product rule to obtain the genotype frequency. This product of maximal frequency values serves as an upper bound for the product of all other unknown frequencies. To determine the frequencies themselves, the NRC recommended that random samples of 100 persons be drawn from each of 15–20 populations that each represents a relatively homogeneous genetic group.

Both the population genetic and statistical basis of the ceiling principle recommendation and the study proposed by the NRC were subsequently criticized in the literature (see for example [2–6]). It also caused conjecture in court by undermining the use of population-specific estimates [7, 8] or provoking significant controversy that it failed the general acceptance test and was ruled inadmissible [9]. In the

second report produced by the NRC [10], the ceiling method was described as unnecessarily conservative and was abandoned in favor of recommended methods to obtain population-specific frequency estimates that account for population subdivision.

Chain of Possession of Tangible Evidence

Laying the Foundation for Admission of Physical Items

The chain of possession of tangible evidence, sometimes also referred to as the *chain of custody*, must be proved before such evidence, or testimony based thereon, can be admitted in court. This requirement exists especially in adversary systems of justice, though courts in civil law countries adhere to a similar, though more relaxed, rule. Today, chain of possession evidence is often still referred to as *proof of the chain of custody*, but the older term is somewhat disfavored because of the possible confusion its use creates with custody of a defendant in a criminal case. As in the decisional case law, we use the two terms here interchangeably.

Proof of the chain of possession requires evidence (i) that the item itself is connected to the controversy

being litigated, and (ii) that the physical evidence has not been tampered with or altered. Thus, the party seeking to introduce evidence of the analysis of physical evidence must show to the court that the physical item itself was, in fact, derived or taken from the particular person or place alleged. The process of satisfying this preliminary evidential rule is also referred to as *laying the foundation* for its admissibility.

The requirement of showing that proper proof of custody was maintained finds its origin in the need to prevent the courtroom use of evidence that may have been improperly altered, contaminated, or substituted between the time of its original discovery and trial.

Laying the foundation for proof of integrity is of particular importance in criminal cases. To satisfy the rule, the proponent of the evidence must call, to the stand, each person who has had possession of the physical item from the moment it was first obtained or discovered to the time of trial. In civil cases, when a break in the chain of possession has occurred, that fact is often said to affect only the weight to be accorded the evidence, and not preclude its admissibility. In criminal cases, by contrast, the unbroken chain of possession must be established with some measure of certainty. Where there exists a serious break in the chain of possession, its admission may be deemed prejudicial error requiring reversal of a conviction.

When dealing with forensic examinations by experts, the chronicle of proof of custody includes testimony of the initial possessor of the specimen or object, of its transportation to and receipt at the laboratory, the method of storage at the laboratory prior to analysis, and retention, whenever feasible, of either the original item or the unused portion of the specimen or object after its examination and analysis, all the way up to the time of the production of relevant testimony at the trial. This is a laborious process that may necessitate the presence of many witnesses who have little to offer the court beyond the testimony needed to establish the chain of possession. For that reason, such testimony is often dispensed with through a stipulation entered into by the counsel, who may agree to limit the testimony on possession to that of the person who originally obtained the item and the expert who examined it.

Where physical evidence has been transmitted through the mail by a law enforcement agency to a laboratory facility, it is obviously impossible to know which postal employees handled the specimen during shipment. For that reason, courts also dispense with the requirement that all persons who may possibly have been in contact with evidence be called as *witnesses*.

Identification and Marking of Evidence

In a criminal case where proof of possession is important, initial acquisition testimony must reflect that the investigator obtained an item, identified it, and placed it in the appropriate sealed container after marking it for identification. Tangible items that are not consumed in the analysis are marked for identification by the analyst as well, and secured until the time of trial. Customs vary in law enforcement and laboratory facilities as to the exact procedures and documentary requirements personnel must follow when dealing with the possession of evidence.

Defendant's guilt in a criminal case must be established by proof beyond a reasonable doubt. However, the law does not require that proof of a chain of possession be established by such a high quantum of evidence. If an unbroken chain of possession cannot be established, the court determines whether the break affects the possible validity of the expert's findings. If the broken link has no affect on the expert analysis, courts usually decide that the evidence can be used. Practicalities of proof do not require a party offering physical evidence to negate the remotest possibility of substitution or alteration. All that needs to be established is a reasonable certainty that there has been no wrongdoing. The courts do not require proof of the impossible.

When it comes to solid objects, such as guns or ammunition, a break in the chain of possession of some hand-to-hand transfers that cannot be accounted for by documentary evidence will not likely affect the item's admissibility, since missing evidence of a transfer of the weapon or ammunition is not likely to affect the expert's examination of striation evidence.

When Evidence Is Not Available

There are instances when the actual item itself is no longer available, or has been inadvertently destroyed, and all that is left is the expert's report of the examination. When destruction is inadvertent, courts are unlikely to be overly sympathetic to

the defendant's argument that he has been denied due process because he was unable to engage his own expert. While there are court cases where the unaccounted-for absence of the physical item itself has resulted in the expert's analysis being excluded from the trial, such cases occur infrequently.

The possibility of alteration, contamination, or destruction is far greater when dealing with extremely minute quantities of suspected narcotics, biological evidence such as a blood stain or semen stain, and other trace evidence. Marking a container may not be sufficient proof of lack of tampering where an unsealed container may have been handled by unknown third persons.

For example, assume that an undercover agent purchased a foil packet said to contain PCP (phencyclidine), placed the evidence in his wallet, and thereupon adjourned to a party where drugs were used, sleeping thereafter in a dormitory-like setting where his trousers were accessible to other persons while he slept. This is clearly a situation where courts may likely consider that a fatal break in the proof has occurred and the evidence will be denied admissibility.

When a substance, such as contraband narcotics, is tested in a forensic laboratory and is thereafter altered or consumed during testing, or destroyed after testing pursuant to law, judges are likely to hold that there is no break in the chain of custody requiring exclusion of expert testimony based thereon. The same result will occur when items analyzed have been returned to a rightful owner who was wrongfully deprived of his property so that these items cannot be exhibited in court. It must be remembered, however, that even where a link in the custodial chain is deemed not to affect admissibility of opinion evidence, the physical absence of the item at trial may well affect the jury's belief in the expert's testimony.

ANDRE MOENSSENS

Chemical, Biological, Radiological, and Nuclear Investigations

What is CBRN?

CBRN is an acronym for chemical, biological, radiological, and nuclear and is a term usually used to describe the threatened, intended, or actual use of harmful CBRN material in warfare or against civilians or economic targets. The malicious use of CBRN agents against individuals, human populations, animals, plants, and infrastructure is an enduring and increasing concern.

Malicious Use of CBRN Agents in History

Some CBRN agents developed or used in state-sponsored military programs have been described as weapons of mass destruction (WMD) and their use is not new. Persian, Greek, and Roman literature refer to the use of chemical and biological weapons for military purposes pre-400 BC. Over the two millennia chemical and biological agents have been maintained as a prominent military strategy and were used in both the First and Second World Wars. In the final stages of the Second World War, nuclear weapons quickly became the weapon of choice for mass destruction. Since then, WMDs have served primarily as military deterrents.

The Geneva Protocol of 1925 banned the use of chemical weapons in warfare. A number of nations, including the United States and the former Soviet Union, continued to develop and stockpile significant quantities and varieties of these types of weapons well into the twentieth century. The Biological and Toxins Weapons Convention (BWC) of 1972 and the Chemical Weapons Convention (CWC) of 1997 banned the production and stockpiling of biological and chemical agents for nonpeaceful purposes. There is no corresponding convention related to nuclear weapons that would unilaterally ban production and stockpiling of nuclear material. Instead, the Nuclear Non-Proliferation Treaty, which entered into force in 1970, aims at preventing the spread of nuclear weapons and weapon technology from the original five nuclear weapons states (United

States, Russia (formerly Union of Soviet Socialist Republics), United Kingdom, France, and China) to nonnuclear weapon states.

A number of signatories to the BWC and the CWC continue to work with these agents for research purposes to describe the geographic distribution and variation, or as part of their defensive military programs for the development of medical countermeasures, or more controversially, for risk analysis [1]. The exact nature and extent of most historic state WMD programs remains classified, though clues can be gained from the testimonies of defectors such as Ken Alibek who was involved in the biowarfare program of the former Soviet Union that continued after they signed the BWC in 1972 [2].

The former Iraqi regime under Saddam Hussein developed and used chemical weapons against Iran and its own citizens in the 1980s. Following the first Gulf War in 1991, Iraq's alleged continued development and stockpiling of both chemical and biological weapons instigated the invasion by Western coalition forces in 2003. The extent, nature, and current status of Iraq's WMD program has not been fully understood.

CBRN terrorism is the use of these agents by individuals or groups motivated by religious, political, ecological, or other ideological objectives [3]. With the occurrence of the 2001 terrorist attacks on the World Trade Center and the "Amerithrax" incidents, governments have refocused attention on CBRN agents as the interest in such weapons grows within terrorist organizations. There has been significant media discussion of al-Qa'ida's plans to acquire and use cyanide, mustard, anthrax, and botulism, and in 2004 Jordanian officials disrupted an al-Qa'ida plot to release toxic chemicals in Jordan against the United States and Jordanian security interests. In 1984, a large outbreak of salmonellosis was investigated in Oregon, USA, and was subsequently found to be intentionally caused by a religious group in an attempt to influence local elections [4]. More recently, the Aum Shinrikyo cult used sarin gas against Japanese civilians in 1994 and 1995 [5].

The use of these agents for murder, extortion, or revenge is a criminal offence. A notable example are the "Amerithrax" attacks involving *Bacillus anthracis* spores sent through the post in October 2001 [6]. Five people subsequently died from the disease anthrax. Forensic and microbiological investigation revealed that the *B. anthracis* used was the Ames laboratory strain [7]. This has led to media speculation that the agent was sourced from a US laboratory and the perpetrator likely to be an experienced laboratory worker with access to hazardous biological agents. Other examples include the documented cases of theft and black market trading of highly enriched uranium or plutonium from the former Soviet Union [8].

Inadvertent release of hazardous CBRN agents may result in injury, death, or significant economic damage. Such events would also be subject to police investigation. For the forensic investigator, the issues surrounding the hazards of the scene and the handling of evidence would be the same as for a terrorist event.

Chemical, Biological, Radiological, and Nuclear Agents

Related entries provide further detail on investigations involving specific CBRN agents (*see* **Biological Agents**; **Chemical Warfare Agents**; **Nuclear Forensics**). CBRN are described here in brief.

Chemical warfare (CW) agents include nerve, blister, blood, and pulmonary (choking) agents [9, 10]. Traditional CW agents such as VX, sarin, and tabun interfere with the normal transmission of neurotransmitter signals within the body and at high doses cause convulsions, loss of consciousness, and death within minutes. Many commercially available pesticides can have similar effects as nerve agents. Blister agents tend to be debilitating rather than lethal, causing effects immediately (Lewisite) or many hours (sulfur mustard) following exposure. Typical symptoms include severe pain, blistering of the skin, and burning of the eyes. Blood agents, including hydrogen cyanide and cyanogen chloride, are absorbed into the blood through inhalation and act by preventing cells from using oxygen. Symptoms may not appear for several hours following a low-dose exposure and include nausea, weakness, and anxiety, with loss of consciousness and death following exposure to high concentrations. Cyanide is found in many natural products and is used for many industrial purposes. The pulmonary (choking) agents, including chlorine gas and phosgene, are so called because the alveoli in the lungs are burned by the strong acids that are produced as the gas comes in contact with water inside the lung tissue. The damage induces edema, resulting in "dry land drowning". Pulmonary agents induce symptoms 2–24 h following exposure.

The biological agents that can be used as weapons are either living organisms (pathogens, including bacteria and viruses) or are nonliving toxins [9, 11]. Bacteria and viruses work by infecting the host, replicating and inducing disease through direct damage to cells or by producing toxins that interfere with normal cellular function. The range of diseases caused by biological agents is enormous and requires the consideration of numerous variables when contemplating how to respond to potential biological releases. Depending on the route of exposure, different disease forms may be produced, with symptoms appearing hours (toxins) to weeks or even years (pathogens) following infection. Further, unlike chemicals, radionuclides, and toxins that are self-limiting, many of the living biological agents cause contagious diseases that can spread from host to host and prolong the disease outbreak. In addition, host susceptibility and immunity are important factors in determining whether exposure to a biological agent will cause disease. Many of the important biological agents are zoonotic pathogens, meaning they can infect both humans and animals, and others are spread by vectors, including fleas, ticks, and mosquitoes, making their natural "reservoirs" difficult to eradicate. Biological agents such as *B. anthracis* (causing anthrax) and *Francisella tularensis* (causing tularemia) do not normally spread from host to host. *Yersinia pestis* (causing plague) can easily spread from person to person when the disease manifests as the pneumonic form, but is rarely spread when manifested as the bubonic form. The *Variola* virus (causing smallpox) has been globally eradicated and as a result population immunity is low to nonexistent. Biological toxins including botulinum (causing botulism, produced by the bacterium *Clostridium botulinum*) and ricin (derived from *Ricinus communis*, the castor bean plant) can cause lethality at extremely low doses.

Many naturally occurring elements are radioactive or have radioactive isotopes that emit ionizing radiation in the form of alpha, beta, or neutron particles and gamma rays [12, 13]. The effect of radiation exposure is dependent upon the type of radiation, dose, and the route of exposure. External exposure occurs when the subject is exposed to radiation emitted from a source (radioisotope) that is deposited either on the surface of a person or is in close proximity to a person. Internal exposure occurs when a radioisotope is inhaled or ingested, or gets inside the body through wounds, cuts, or injection. Highly penetrating, long-range radiations like gamma or neutrons are the main concern for external exposure, whereas weakly penetrating, short-range radiations like alpha and beta particles are the main concern for internal exposure. Many radioisotopes emit more than one form of radiation. For example, radioactive isotopes cobalt-60 and cesium-137 decay by emitting beta particles, accompanied by gamma radiation. Uranium-235, uranium-238, radium-226, americium-241, and polonium-210 decay by emitting alpha particles and accompanying gamma radiation. Low doses of radiation may not cause immediate symptoms but may increase the likelihood of cancers later in life and increase susceptibility to infection by pathogens. High radiation doses cause severe illness and often lead to death.

The malevolent use of radioactive materials by terrorists might be in the form of an improvised nuclear device (IND), a radiological dispersion device (RDD), such as a "dirty bomb", or a radiological emission device (RED).

Nonstate Acquisition, Production, and Use of CBRN Agents

CBRN agents have distinct properties and capacity to cause profound effects on individuals, society, and the environment, making them attractive weapons to terrorists and criminals. Their effects can be seen immediately or years after release, producing a spectrum of illnesses, from rapid lethality, transient incapacitation to lifelong, chronic disease. They can be targeted to individuals (assassination and murder) or to populations (mass casualties and economic disruption). Because many of these agents occur infrequently or are unseen in nature, medical and veterinary practitioners and environmental protection agencies may have limited experience in recognizing them in the event of a deliberate release, limiting treatment and further enhancing the spread/contamination by the agent, and reducing the capability of law enforcement to locate and adequately examine a crime scene.

To date, all known nonstate-sponsored CBRN attacks have been committed by cults, sects, or individuals using crude preparations and/or delivery methods. In spite of the apparent attraction of CBRN terrorism, there have been no confirmed CBRN attacks by known terrorist groups such as al-Qa'ida, which questions the feasibility of this attack strategy [14]. Developing and deploying CBRN material

requires access to source material and the appropriate technical skills to produce harmful quantities of agent while minimizing the likelihood of the operator being inadvertently harmed by the agent. In spite of this, publicly available anarchist and terrorist literature describe methods for the production of some harmful chemical and biological agents and some source materials can be purchased over-the-counter or occur naturally in the environment. For example, radioactive sources that could be used for malevolent purposes can be purchased or stolen from medical institutions or industrial sites.

Recognizing a CBRN Scene

Indicators of a CBRN terrorist attack include mass casualties with symptoms typical of exposure to a CBRN agent and claims of responsibility. The covert release of CBRN agents, particularly biological and radiological agents, may only be recognized as a result of affected people presenting for medical treatment. Misdiagnosis and delayed diagnosis, including failure to consider an "unusual" cause, such as an act of terrorism, reduce the likelihood that a terrorist event will be detected and investigated. Locating the site of the release and the source of the agent used may require a combined effort by law enforcement investigators and public health epidemiologists, who are expert at tracing the source of disease outbreaks. The collaborative interaction between law enforcement and public health officials following the biological attacks in the United States in October 2001 involving *B. anthracis* was an important measure in the response to this act of bioterrorism [15]. Chemical weapons are more likely to produce immediate effects, so identifying the crime scene and the type of weapon used is often more straightforward.

Efforts by law enforcement agencies to identify and interdict planning processes for CBRN terrorism is a key pillar in preventing CBRN attacks. In these cases, law enforcement agencies are required to recognize the indicators of a CBRN production/preparation facility (clandestine laboratory), as well as other indicators of planning, such as recruitment of scientists from universities or legitimate laboratories and acquisition of laboratory equipment and terrorist training literature/recipes. Crime scene investigators need to be aware of the indicators of clandestine laboratories involved in the preparation of materials other than illicit drugs. Key indicators include dedicated equipment (centrifuges, glassware, and autoclaves), unusual laboratory chemicals (agar, culture media, and chemical precursors), and possible dispersion devices (explosives, gas cylinders, and pressurized sprayers). Relatively simple "back yard" laboratories might allow the preparation of some simple biological and chemical agents, while more complex laboratories, requiring commercial laboratory equipment, would be required to prepare most biological and CW agents, particularly if large-scale or high-purity preparations are the desired end product. It is technically infeasible to manufacture radiological material in a clandestine laboratory as such preparations require access to a nuclear reactor. Nevertheless, the assembly of an RDD using illicitly acquired radioactive material and conventional explosives might be achieved in a clandestine laboratory. Specific laboratory equipment for safe handling of radioactive materials will most likely include lead bricks for shielding during storage/preparation and radiation detectors.

Responding to a CBRN-Contaminated Crime Scene

The greatest concern to the investigator is the hazards of the CBRN environment. Law enforcement agencies with technical expertise in CBRN agents use information gathered from the crime scene to determine the likely impact and risks to crime scene examiners and the general public [16]. The need for personal protective equipment (PPE) can severely limit the capability of crime scene investigators to gather appropriate and adequate evidence. If CBRN agents have been released in a public place, there will be pressure to rapidly decontaminate the site to limit the potential to have further impact on the environment and to restore normal operations. The greatest challenge presented to investigators following a covert act of CBRN terrorism may be identifying and containing the crime scene. Further, there may be multiple crime scenes, including where the agent was manufactured and the site(s) of release.

A number of field-deployable detectors and screening kits exist that can rapidly identify the presence of explosive, radiological, chemical, and biological agents at a CBRN scene, though the accuracy and sensitivity of these kits for specific

agents is highly variable. With that said, detectors and kits are constantly evolving and improving [17–19].

Safety within the CBRN Crime Scene

Operating in a CBRN crime scene is hazardous and requires the use of PPE. Four types of PPE are usually described, with "level A" offering the most protection to "level D" offering the least. In selecting the most appropriate PPE to use, investigators must weigh up the degree of protection over flexibility and utility. For example, level A suits, which are the fully encapsulated airtight chemical resistant suits, can only be used for approximately 20 min at a time. Fatigue and heat are the major risk factors to the user. Safe operation requires extensive training and practice.

In addition to the use of appropriate PPE, particular care must be taken with procedures to avoid contamination outside the "hot zone". In the analysis of a crime scene involving CBRN or other hazardous material, the crime scene is divided into three zones: the "hot zone" is the hazardous region of the crime scene where evidence is collected, the "warm zone" is the boundary between the hot and cold zone where decontamination takes place, and the "cold zone" marks the outer perimeter of the incident site (the safe zone). Material and persons should not leave the warm zone unless they are fully decontaminated. If there is potential that the agent has been widely dispersed, the distance between the cold zone and the hot zone may be significant. For investigators using highly restrictive PPE, such as a level A fully encapsulated suit, it may not be possible to perform effective examination of an extensive hot zone following a CBRN incident. In these cases, it may require multiple entries into the hot zone to collect adequate evidence. In some cases, it may be more practical to use robotics to survey and collect evidence from within the hot zone.

Collecting Evidence (Sampling)

The CBRN agent itself will need to be examined as evidence, as well as other material, including equipment, computers, and documents. In addition, the crime scene will need to be examined for standard evidence, including DNA, fingerprint, hair, fiber, and handwriting.

When collecting evidence within the hot zone, crime scene investigators should work in pairs, using the "clean man/dirty man" approach where one person handles the contaminated items (the "dirty man"), whereas the other (the "clean man") only handles unused items and is responsible for stand off recording, including photography [20]. The clean man/dirty man approach reduces the likelihood of cross-contamination between samples and also enhances the safety of the operators within the hot zone. A number of factors need to be considered in the decision making that takes place around the collection of evidence from within the hot zone and the significance of different factors will vary from case to case [21]. In all the cases, a strategy of approach to the crime scene should be developed prior to entry to maximize effective use of the limited time within the hot zone. Crime scene examiners need to prioritize the types of items to collect, where to sample within the scene, how much CBRN material to collect and determine the types of vessels that are suitable for the storage and/or transportation of CBRN samples. As CBRN agents may not be visible to the naked eye, a collection approach that maps the crime scene may be required. A number of field detectors for chemical and radiological agents will allow the scene examiner to precisely determine the location of the agent for sampling, though this is not the case for biological agents. Further, adequate samples will need to be collected from within and around the crime scene to determine the background levels. These data will also be important for site remediation and for declaring that the previously contaminated site is clean.

An effective forensic investigation relies on ensuring the integrity of the evidence from collection to analysis and through to trial. For CBRN investigations, integrity is considered on multiple levels, including maintaining the physical integrity of the CBRN agent, as well as avoiding compromise through inadvertent contamination and the breaking of chain of custody. Many CBRN agents are unstable, so sampling, packaging, and transportation should be performed in a manner that best maintains the integrity of the material, while minimizing risk of accidental exposure to investigators and laboratory staff. Some standards exist, including from the American Society for Testing and Materials (ASTM) International [22]. Following a covert release, critical evidence, particularly clinical samples from the affected individuals, may have been collected and

analyzed without law enforcement involvement or adherence to chain-of-custody principles. Furthermore, detailed analysis of esoteric CBRN agents may not be within the realm of analyses performed in police forensic laboratories, which will require evidence to be referred to medical, military, research, or even private industry laboratories which may not have the same accreditation standards as standard forensic laboratories.

Evidence Storage

The rarity and nature of CBRN criminal and terrorism events means that investigations tend to be extensive and protracted. This may necessitate long-term storage of the agents and contaminated items, including biological specimens, computers, and vehicles. Many CBRN agents, or the solvents in which they are collected, can react with standard evidence storage containers (notably plastic bottles or bags), potentially resulting in the loss of evidence and harm to people and the environment. In addition, some plastics in storage bags and tubes can absorb chemical and biological agents, thus reducing the yield of agent for analysis or altering its properties. As most CBRN agents are unstable, they will degrade over time, losing their viability or potency and even changing their chemical properties. In some cases, it is possible to treat the agents to minimize loss (such as freezing, drying, or immobilizing in a matrix), but all of these treatments will alter the properties of the agent from its original condition.

Most standard forensic laboratories and law enforcement agencies do not have appropriate facilities for safe, long-term storage of CBRN agents and contaminated items [23]. These items may need to be stored in facilities dedicated to the analysis or research of specific material, where capacity to store large or multiple items may be lacking. Consideration must be given to maintaining security, evidence integrity, and chain-of-custody for storage of CBRN items in facilities that are not managed by law enforcement agencies.

Finally, once evidence has been processed and is not longer needed, specific arrangements must be made for the safe destruction and/or disposal of CBRN agents and contaminated items. The crucial factor that must be considered at the time of destruction is whether the item will be required for criminal proceedings. It may be the case that the destruction of the contaminated evidence may be in breach of the local, state, federal, or international legal requirement to provide this to the legal defense lawyers in the case of a criminal trial. Due care and attention must be taken when disposing of the contaminated evidence with the legal ramifications considered prior to this action.

Impact of CBRN Agents on Standard Forensic Evidence

The CBRN agents themselves, particularly radiological and chemical agents, can damage or destroy critical evidence, including biological evidence (DNA, hair, and fingerprints), as well as documents, computer data, and other reactive material. Standard forensic analysis for DNA, fingerprints, and handwriting from evidence gathered from a CBRN crime scene will be unsafe if evidence is not handled with physical protection or decontaminated. Most forensic laboratories do not have facilities that allow physical examination of contaminated evidence, so decontamination is often the only option. Chemical, heat, and irradiation methods used for decontamination can significantly alter surface materials as well as affect the integrity of latent fingerprints, DNA, and the characteristics of writing inks and dyes [24–31].

Forensic Analysis of CBRN for Intelligence

Specific disciplines are required for the direct examination of CBRN agents and their production/preparation processes, providing information that can be used for the attribution of CBRN crime or to exonerate the innocent. As with any forensic field, the application and interpretation of data is critical in excluding a particular source as the origin of the sample, as well as attributing the sample to a particular source. This is particularly important in discriminating malicious use of CBRN agents from natural causes.

"Microbial forensics" is the scientific discipline dedicated to analyzing evidence from an actual or threatened bioterrorism act, biocrime, or inadvertent microorganism/toxin release for attribution purposes, as well as to exonerate the innocent [32]. The forensic examination of microbial agents will be most effective if there is sufficient basic scientific information concerning microbial genetics, evolution, physiology,

and ecology of the agent [33]. Apart from providing greater confidence in the data for attribution purposes, understanding the "microbial background" of relevant geographic areas is critical for determining the source of the biological agent for consequence management and for remediation.

The analysis of chemical reagents, chemical degradation products, and equipments found at the scene can determine the types of agents being manufactured and the preparatory method. Chemical trace analyses, including isotopic ratios and mass spectrometry, are not only useful for chemical tracing but can support microbial forensics to determine the origin of source material (such as toxic plants) and the origins of growth media.

"Nuclear forensics" is the branch of science that seeks to examine the nature, use, and origin of intercepted illicit nuclear or radioactive materials. The analysis seeks to produce a characteristic energetic "signature" for the material as evidence for attribution. It can be applied to investigations involving the malevolent use of nuclear materials and is instrumental in determining adherence to international safeguards for illicit trafficking. Nuclear forensic analyses aim to provide legally admissible evidence that could lead to prosecution of the offenders involved with trafficking of the illicit material. Thus, it assists law enforcement agencies in the fight against illicit trafficking in nuclear and radioactive material in order to minimize and/or eliminate the likelihood of such materials being used by terrorists.

Chemical Warfare Agents

Introduction

Toxic industrial chemicals (TICs) are also referred to as *toxic industrial materials* (*TIMs*). TICs are the hazardous industrial chemicals that are manufactured, stored, transported, and used throughout the world. TICs include chemicals in the gas, liquid, or solid state. They can be chemical hazards including but not wholly biological hazards such as carcinogens, reproductive hazards and, corrosives or physical hazards such as being flammable, explosive, or reactive. In addition to their commercial uses, TICs have been used as stimulants for chemical weapons, where they can aid in determining the effectiveness of respirators, detectors, and other defensive measures. Concern arises periodically, however, that TICs could be used

directly by individuals or groups for chemical terrorism or could be diverted by nations into use in the production of chemical weapons [1].

A TIM is any substance that, when supplied in a given quantity, produces a toxic effect [2]. TICs and TIMs are produced in substantial amounts for legitimate purposes. A classic example is chlorine gas, which is used in multiple industrial applications such as water purification, sanitization, disinfection, bleaching, and in the manufacture of plastics.

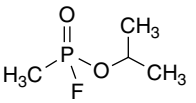
Chemical warfare agents (CWAs) are a subset of TICs. There are no legitimate nonoffensive uses for CWAs. The specific chemical compounds of concern are detailed in the schedules issued by the Organization for the Prohibition of Chemical Weapons (OPCW). The chemical weapons convention (CWC) developed three lists of chemicals that are monitored and regulated under the CWC. The Schedules 1 and 2 chemicals as outlined in the CWC are listed in Tables 1 and 2, respectively.

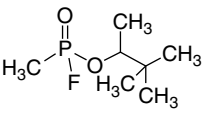
The following criteria were used to determine whether a toxic chemical or precursor should be listed in Schedule 1:

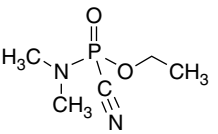
1. It has been developed, produced, stockpiled, or used as a chemical weapon as defined in Article II of the CWC.
2. It poses otherwise a high risk to the object and purpose of the CWC by virtue of its high potential for use in activities prohibited under the CWC because one or more of the following conditions are met:
   a. It possesses a chemical structure closely related to that of other toxic chemicals listed in Schedule 1, and has, or can be expected to have, comparable properties.
   b. It possesses such lethal or incapacitating toxicity as well as other properties that would enable it to be used as a chemical weapon.
   c. It may be used as a precursor in the final single technological stage of production of a toxic chemical listed in Schedule 1, regardless of whether this stage takes place in facilities, in binary munitions, or elsewhere.
3. It has little or no use for purposes not prohibited under the CWC.

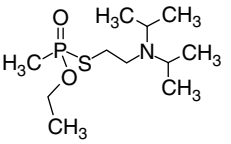
The following criteria were used to determine whether a toxic chemical or a precursor should be listed in Schedule 2:

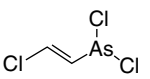
- It poses a significant risk to the object and purpose of the CWC because it possesses such lethal or incapacitating toxicity as well as other properties that could enable it to be used as a chemical weapon.
- It may be used as a precursor in one of the chemical reactions at the final stage of formation of a chemical listed in Schedule 1 or Schedule 2, part A.
- It poses a significant risk to the object and purpose of the CWC by virtue of its importance in the production of a chemical listed in Schedule 1 or Schedule 2, part A.
- It is not produced in large commercial quantities for purposes not prohibited under this the CWC.







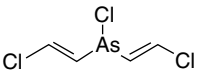


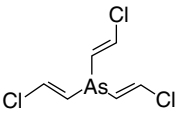


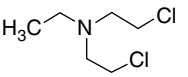
A toxic chemical is described by the OPCW as "Any chemical which through its chemical action on life processes can cause death, temporary incapacitation or permanent harm to humans or animals. This includes all such chemicals, regardless of their origin or of their method of production, and regardless of whether they are produced in facilities, in munitions or elsewhere" [3]. Chemical warfare (CW) should therefore be considered as combat that utilizes the toxic properties of chemical substances to kill, injure, or incapacitate an enemy.

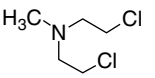
This article provides an overview of CWAs, their detection in the field, and the laboratory-based methods required for the forensic analysis of a suspected CWA. It does not cover the effect of CWAs on traditional evidence or decontamination of traditional evidence. CWAs are organized into several categories according to the manner in which they affect the human body, which also affect the types of analysis used to identify the material. CWAs are also classified according to their persistence, a measure of the length of time that a chemical agent remains effective after dissemination. The names and number of categories vary slightly from source to source, but in general the basic classes of CWAs are identified in Table 3.

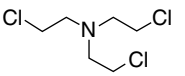
Analysis for CW Agents

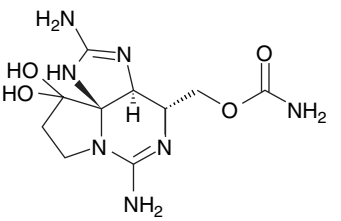












CWAs can be analyzed by numerous methods each of which has varying degrees of success. There are a number of issues that need to be taken into consideration when analyzing CWAs, from the chemistry

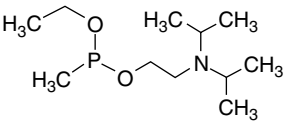
Table 1 Schedule 1 chemicals

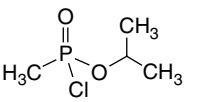
A.	Toxic chemicals		CAS registry number
1.	*O*-Alkyl (≤C10, incl. cycloalkyl) alkyl (Me, Et, *n*-Pr or *i*-Pr)-phosphonofluoridates,		
	e.g., Sarin: *O*-isopropyl methylphosphonofluoridate		107-44-8
	Soman: *O*-pinacolyl methylphosphonofluoridate		96-64-0
2.	*O*-Alkyl (<C10, incl. cycloalkyl) *N*, *N*-dialkyl (Me, Et, *n*-Pr or *i*-Pr) phosphoramidocyanidates		
	e.g., Tabun: *O*-ethyl *N*, *N*-dimethyl phosphoramidocyanidate		77-81-6
3.	*O*-Alkyl (H or <C10, incl. cycloalkyl) *S*-2-dialkyl(Me, Et, *n*-Pr or *i*-Pr)-aminoethyl alkyl(Me, Et, *n*-Pr or *i*-Pr) phosphonothiolates and corresponding alkylated or protonated salts		
	e.g., VX: *O*-ethyl *S*-2-diisopropylaminoethyl methyl phosphonothiolate		50782-69-9
4.	*Sulfur mustards*		
	2-Chloroethylchloromethylsulfide		2625-76-5
	Mustard gas: *bis*(2-chloroethyl)sulfide		505-60-2
	Bis(2-chloroethylthio)methane		63869-13-6
	Sesquimustard: 1,2-*bis*(2-chloroethylthio)ethane		3563-36-8
	1,3-*Bis*(2-chloroethylthio)-*n*-propane		63905-10-2
	1,4-*Bis*(2-chloroethylthio)-*n*-butane		142868-93-7
	1,5-*Bis*(2-chloroethylthio)-*n*-pentane		142868-94-8
	Bis(2-chloroethylthiomethyl)ether		63918-90-1
	O-Mustard: *bis*(2-chloroethylthioethyl)ether		63918-89-8
5.	*Lewisites*		
	Lewisite 1: 2-chlorovinyldichloroarsine		541-25-3

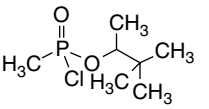
(*continued overleaf*)

Table 1 (*continued*)

A.	Toxic chemicals		CAS registry number
	Lewisite 2: *bis*(2-chlorovinyl)chloroarsine		40334-69-8
	Lewisite 3: *tris*(2-chlorovinyl)arsine		40334-70-1
6.	*Nitrogen mustards* HN1: *bis*(2-chloroethyl)ethylamine		538-07-8
	HN2: *bis*(2-chloroethyl)methylamine		51-75-2
	HN3: *tris*(2-chloroethyl)amine		555-77-1
7.	Saxitoxin		35523-89-8
8.	Ricin		9009-86-3







B.	Precursors		CAS registry number
9.	Alkyl (Me, Et, *n*-Pr or *i*-Pr) phosphonyldifluorides, e.g., DF: methylphosphonyldifluoride		676-99-3
10.	*O*-Alkyl (H or <C10, incl. cycloalkyl) *O*-2-dialkyl(Me, Et, *n*-Pr or *i*-Pr)-aminoethyl alkyl(Me, Et, *n*-Pr or *i*-Pr) phosphonites and corresponding alkylated or protonated salts e.g., QL: *O*-ethyl *O*-2-diisopropylaminoethyl methylphosphonite		57856-11-8

Table 1 (*continued*)

A.	Toxic chemicals		CAS registry number
11.	Chlorosarin: *O*-isopropyl methylphosphonochloridate		1445-76-7
12.	Chlorosoman: *O*-pinacolyl methylphosphonochloridate		7040-57-5

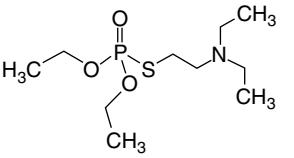
of the specific agent to the matrix that the agent is to be analyzed in. Analysis of an unknown chemical sample can yield significant information from the type of CWA used, the method of manufacture utilized to produce the CWA, as well as the presence or absence of degradation products. The synthetic method used can be identified through the presence of route-specific reaction markers. This information can give an indication of the sophistication of the manufacturing process, the level of purity of the final material, and some detail on precursors used. In turn, this provides information about the synthetic laboratory, the equipment, and the knowledge and skills of the chemist(s) involved.

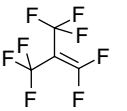
Identification of degradation products provides an estimate of the time since the chemical agent had been manufactured and the length of time since its dissemination. Identification of the CWA, its precursors, reaction markers, and degradation products is crucial in an investigation to establish links between the agent(s), manufacture method, location of manufacture and, if possible, the person, persons, or group responsible. Rapid identification of the agent and other toxic compounds assists in developing a successful decontamination procedure for victims and evidence.

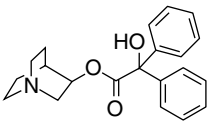
The persistence of an agent at the site of release is dependant upon many factors including the type of agent used, the location of the release, the climatic conditions, the mode of dissemination, and whether decontamination procedures have commenced. With this in mind, the presence of the CWA in its original form cannot always be expected. Degradation products may be present; however, it is likely that these will be compromised and unlikely to be in pure form.

The analysis of an unknown sample, either in a laboratory or at a crime scene, should take into consideration preparation of the unknown sample prior to analysis, which will then assist in deciding what chromatographic or spectrometric technique should be utilized. In general, chromatographic techniques are applied within specific detectors and certain spectrometric techniques are used to identify a number of chemical candidates.

Presumptive Analysis – Detectors for CWAs







There are a number of handheld electronic detectors and colorimetric indicators that are utilized for presumptive identification of CWAs, TICs, and TIMs. Detector responses are used to establish what procedures are to be used in order to respond to a specific chemical incident.

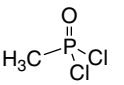
Some examples of detection principles utilized in the identification equipment are

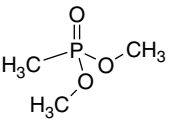
- colorimetry
- electrochemical analysis
- ion mobility spectrometry (IMS)
- flame photometry
- photoionization
- enzyme-based techniques.

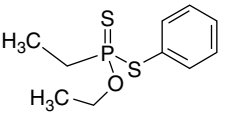
Described below are examples of these types of technologies and a brief overview of the chemistry behind the detection methodology [4]. One of the greatest limitations of all of the methods described below is the limited capability to decontaminate equipment. Each technique or piece of equipment should be decontaminated in such a way that this

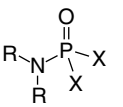
Table 2 Schedule 2 chemicals

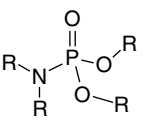
A.	Toxic chemicals		CAS registry number
1.	Amiton: *O*, *O*-diethyl *S*-[2-(diethylamino)ethyl] phosphorothiolate and corresponding alkylated or protonated salts		78-53-5
2.	PFIB: 1,1,3,3,3-pentafluoro-2-(trifluoromethyl)-1-propene		382-21-8
3.	BZ: 3-quinuclidinyl benzilate (*)		6581-06-2

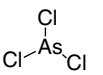


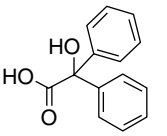


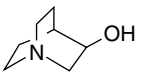


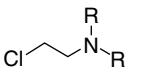


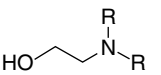


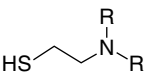


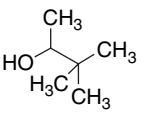












B.	Precursors		CAS registry number
4.	Chemicals, except for those listed in Schedule 1, containing a phosphorus atom to which is bonded one methyl, ethyl, or propyl (normal or iso) group but not further carbon atoms, e.g., Methylphosphonyl dichloride		676-97-1
	Dimethyl methylphosphonate		756-79-6
	Exemption: Fonofos: *O*-ethyl *S*-phenyl ethylphosphonothiolothionate		944-22-9
5.	*N*, *N*-Dialkyl (Me, Et, *n*-Pr, or *i*-Pr) phosphoramidic dihalides		
6.	Dialkyl (Me, Et, *n*-Pr or *i*-Pr) *N*, *N*-dialkyl(Me, Et, *n*-Pr, or *i*-Pr)-phosphoramidates		
7.	Arsenic trichloride		7784-34-1
8.	2,2-Diphenyl-2-hydroxyacetic acid		76-93-7

Table 2 (*continued*)

A.	Toxic chemicals		CAS registry number
9.	Quinuclidin-3-ol		1619-34-7
10.	*N*, *N*-Dialkyl (Me, Et, *n*-Pr, or *i*-Pr) aminoethyl-2-chlorides and corresponding protonated salts		
11.	*N*, *N*-Dialkyl (Me, Et, *n*-Pr, or *i*-Pr) aminoethane-2-ols and corresponding protonated salts		
	Exemptions: *N*, *N*-dimethylaminoethanol and corresponding protonated salts		108-01-0
	N, *N*-Diethylaminoethanol and corresponding protonated salts		100-37-8
12.	*N*, *N*-Dialkyl (Me, Et, *n*-Pr, or *i*-Pr) aminoethane-2-thiols and corresponding protonated salts		
13.	Thiodiglycol: *bis*(2-hydroxyethyl)sulfide		111-48-8
14.	Pinacolyl alcohol: 3,3-dimethylbutan-2-ol		464-07-3

action will not compromise the detector. For example, the full submersion of a detector that draws air into the detector may have a disastrous effect on the detector.

Colorimetric Detectors

Colorimetric detectors are based upon a color change either in the visible or ultraviolet spectrum, which occurs in the presence of the target agent. These colorimetric indicators are the fastest, cheapest, lightest, and easiest type of detector. A number of Western military forces employ two types of paper colorimetric measurements, commonly referred to as *M8 and M9 detection paper*.

The main limitation of the identification papers is that they have to be in intimate contact with a liquid sample to work. Neither M8 nor M9 paper detects CWAs in the vapor phase. These papers are highly subject to false positives from common household materials including pesticides, smoke, petrol, strong bleaches, acid, and common solvents.

The M8 paper, as seen in Figure 1, detects and also differentiates between V-type nerve agents (e.g., VX), G-type nerve agents (e.g., sarin and soman), and H-type vesicants (e.g., sulfur mustard). The beige paper contains two dyes and an acid–base (pH) indicator. Together, these change to yellow when in contact with liquid sarin, green when in contact with liquid VX, and red when in contact with a liquid mustard agent. The principal difference between M8 and M9 paper is that M9 paper shows only a generic red spot when there is a positive indication of any CWA [5].

Electrochemical Detection

Electrochemical or chemiresistor detectors work on the principle that an electrical current changes when a CWA is present. The most common mechanism for an electrochemical gas sensor is a conducting wire or filament that is coated with a reactive material that oxidizes rapidly when it comes into contact with a chemical such as a CWA. The oxidation of the surface material exposes the conducting wire to air and the electrical resistance increases substantially.

Table 3 CW agents and their physical properties, which include the mode and rate of action

Properties of chemical warfare agents									
	Chemical and physical properties (at 20 °C)								
Agent class	Chemical agent name; formula	Symbol	CAS number	Appearance	Odor	Rate of detoxification	Eye and skin toxicity	Routes	Physiological action	Rate of action
Choking	Chlorine; Cl_2	CL	7782-50-5	Greenish yellow gas or amber liquid	Pungent, suffocating, bleach-like odor	–	–	Inhalation; skin absorption (liquid, vapor); ingestion	Respiratory poison; bronchitis and accumulation of fluid in the lungs; liquid causes burns and blisters	Rapid
	Phosgene; $COCl_2$	CG	75-44-5	Colorless gas (foglike in initial concentration – becomes colorless as it spreads)	Newly mown hay, highly toxic suffocating odor	Not detoxified; cumulative	Mild eye irritation	Inhalation	Damages and floods lungs	Delayed; immediate irritation in high concentration; low concentration no ill effects for 3 h or more
Blister (vesicants)	Phosgene oxime; $Cl_2C=NOH$	CX	1794-86-1	Colorless solid or liquid	Intense, penetrating, disagreeable and violently irritating odor	–	Violently irritating to eyes; low concentration cause tearing, inflammation and temporary blindness; liquid on skin is corrosive	Inhalation; skin absorption (liquid, vapor); Ingestion	Violently irritates mucous membrane of eyes, nose, and lungs	Rapid; immediate effects on contact

Sulfur mustard; $(ClCH_2CH_2)_2S$	HD	505-60-2	Colorless when pure, but normally a yellow to amber oily liquid; thickened agent has viscosity similar to honey	Garlic- or mustardlike odor; color and/or odor may vary for thickened agent	Very low; repeated exposures of HD are cumulative in their effects	Eyes very susceptible to low concentration; skin less so	Inhalation; skin absorption (liquid, vapor); ingestion	Blisters; destroys tissues; injures blood vessels	Delayed – 4–6 to 24 h to days (up to 12 days in rare cases)
Nitrogen mustard; $CH_3CH_2N(CH_2CH_2Cl)_2$	HN-1	538-07-8	Oily colorless to pale yellow liquid; salts are solid	Faint fishy or musty odor	Not detoxified; cumulative	Eyes susceptible to low concentration; less toxic to skin, incapacitation requires higher concentration	Inhalation; skin absorption (liquid, vapor); ingestion	Blisters; affect respiratory tract; destroys tissues; injures blood vessels	Delayed action – 12 h or longer
Nitrogen mustard; $CH_3N(CH_2CH_2Cl)_2$	HN-2	51-75-2	Pale amber to yellow oily liquid; salts are solid	Fruity odor in high concentrations. Low concentrations fishy odor similar to "soft soap"	Not detoxified	Toxic to eyes; blisters skin (greatest blistering power of nitrogen mustards in vapor form)	Inhalation; skin absorption (liquid, vapor); ingestion	Similar to HD; bronchopneumonia may occur after 24 hours	Skin effects delayed; 12 h or longer
Nitrogen mustard; $(ClCH_2CH_2)_3N$	HN-3	555-77-1	Colorless to pale yellow liquid which darkens during extended storage; salts are solid	Butter almond odor	Not detoxified; cumulative	Eyes very susceptible; skin less so	Inhalation; skin absorption (liquid, vapor); ingestion	Similar to HN-2	Serious effects same as for HD; minor effects sooner
Lewisite; $ClCH{=}CHAsCl_2$	L; L-1	541-25-3	Colorless to brownish liquid; thickened agent has viscosity similar to honey	Geranium-like odor; no odor when pure; thickened agent odor may vary from unthickened	Body does not detoxify L	Even limited concentrations causes extreme irritation of eyes; Intimate contact exposure causes severe corneal damage; same blistering action on skin as HD	Inhalation; skin absorption (liquid, vapor); ingestion	Similar to HD plus may cause systemic poisoning	Rapid; more rapid than N-mustards

(*continued overleaf*)

Table 3 (*continued*)

Properties of chemical warfare agents									
	Chemical and physical properties (at 20 °C)								
Agent class	Chemical agent name; formula	Symbol	CAS number	Appearance	Odor	Rate of detoxification	Eye and skin toxicity	Routes	Physiological action	Rate of action
Blood	Hydrogen cyanide; HCN	AC	74-90-8	Colorless liquid that is highly volatile	Bitter almonds or peachy kernels odor; not detectable by all individuals, even at lethal concentrations	Rapid; 0.017 mg $kg\,min^{-1}$	Moderate	Inhalation; skin absorption (liquid, vapor); ingestion	Interferes with use of oxygen by body tissues; accelerates rate of breathing	Very rapid; incapacitation within 1–2 min; death can occur in 15 min after receiving lethal dose
	Cyanogen chloride; CNCl	CK	506-77-4	Colorless gas and liquid (liquid below 12.8 °C)	Pungent biting pepperish odor; odor can go unnoticed because of discom-fort/irritation to mucous membranes	0.02–0.1 mg $kg\,min^{-1}$	Low lachrymatory; highly irritating to eyes, upper respiratory tract, and lungs; can cause dry land drowning	Inhalation; skin absorption (liquid, vapor); ingestion	Chokes, irritates, causes slow breathing rate	Immediate intense irritation; systemic effect believed to be due to CK conversion to AC in the body
	Arsine; AsH_3	SA	7784-42-1	Colorless gas	Mild garlic like odor	–	None	Inhalation	Damages blood, liver, and kidneys	Delayed action – 2 h to as much as 11 days
Nerve	Tabun; $C_2H_5OP(O)(CN)N(CH_3)_2$	GA	77-81-6	Clear, colorless to brown liquid	None when pure; impurities may give a faintly fruity odor	Slight but definite	Very high; much greater through eyes than skin but liquid penetrates skin easily	Inhalation; skin absorption (liquid, vapor); ingestion	Cessation of breath and death may follow	Very rapid
	Sarin; $CH_3P(O)(F)OCH(CH_3)_2$	GB	107-44-8	Clear, colorless liquid	None	Low; essentially cumulative	Very high; much greater through eyes than skin but liquid and vapor penetrates skin easily; lethal dose is 1.7 g per person	Inhalation; skin absorption (liquid, vapor); ingestion	Cessation of breath and death may follow	Very rapid; death usually occurs within 15 min after absorption of fatal dose

Vomiting	Soman; $CH_3P(O)(F)OCH(CH_3)C(CH_3)_3$	GD	96-64-0	Clear, colorless to brown liquid; thickened agent has viscosity similar to honey and may vary in color	Slight camphor odor and gives off a colorless vapor	Low; essentially cumulative	Very high; much greater through eyes than skin but liquid and vapor penetrates skin easily; lethal dose is 0.35 g per person on bare skin	Inhalation; skin absorption (liquid, vapor); Ingestion	Cessation of breath and death may follow	Very rapid; death usually occurs within 15 min after absorption of fatal dose
	VX; $CH_3P(O)(OCH_2CH_3)SCH_2CH_2N-[CH(CH_3)_2]_2$	VX	50782-69-9	Clear, colorless to amber oily liquid; similar in appearance to motor oil; thickened agent has viscosity similar to honey	None	Low; essentially cumulative	Extremely toxic by skin and eye absorption; does not injure but penetrates rapidly; about 100× potent as GB	Inhalation; skin absorption (liquid, vapor); ingestion	Produces casualties when inhaled or absorbed	Very rapid; death usually occurs within 15 min after absorption of fatal dose
Riot control (tear)	Adamsite; $C_6H_4(NH)(AsCl)C_6H_4$	DM	578-94-9	Light yellow to green crystals	No pronounced odor; vapors are irritating	Quite rapid in small amounts; incapacitating amounts lose their effects after about 30 min	Irritating; relatively nontoxic	Inhalation; ingestion	Like cold symptoms plus headache, vomiting, nausea	Very high; requires only about 1 min to temporarily incapacitate at a concentration of 22 mg m^{-3}
	Chloroacetophenone (mace); $C_6H_5C(O)CH_2Cl$	CN	532-27-4	Colorless to gray crystalline solid	Sharp irritating floral odor, similar to apple blossoms	Rapid; effects disappear in minutes; high concentration may cause skin irritation but usually disappears within a few hours	Temporary severe eye irritation; mild skin irritation	Inhalation	Lachrymatory; irritates respiratory tract	Instantaneous

(*continued overleaf*)

Table 3 (*continued*)

Agent class	Properties of chemical warfare agents									
	Chemical and physical properties (at 20 °C)									
	Chemical agent name; formula	Symbol	CAS number	Appearance	Odor	Rate of detoxification	Eye and skin toxicity	Routes	Physiological action	Rate of action
Incapacitating	2-Chloro-benzylidene malono-nitrile; $ClC_6H_4CH{=}C(CN)_2$	CS	2698-41-1	White crystalline solid; may also appear as a 1% solution in trioctylphosphite	Burnt to create colorless gas with pungent pepperlike odor	Quite rapid; incapacitating dosage loses effect in 5–10 min	Highly irritating; nontoxic	Inhalation; ingestion	Highly irritating; but nontoxic	Very rapid (max. effects in 20–60 s)
	Pepper spray (Oleoresin Capsicum); Capsaicin: $(CH_3)_2CHCH{=}CH(CH_2)_4CONHCH_2C_6H_3$-4-(OH)-3-($OCH_3$)	OC	8023-77-6 (404-86-4; capsaicin)	Varies depending on manufacturer; typically amber to light red appearance; mixture may include dye (capsaicin: orange red liquid or dark red solid)	Slight ethereal odor	–	Highly irritating	Inhalation; local eye/skin impacts	Highly irritating	Instantaneous
	Buzz; $(C_6H_5)_2C(OH)CO_2C_7H_{12}N.HCl$	BZ	6581-06-2	White crystalline solid	Odorless	From and ICt50 dose severe effects last 36 h; mild effects last 45 h	–	Inhalation; skin absorption (sld); ingestion	Fast heartbeat, dizziness, vomiting, dry mouth, blurred vision, stupor, and increasing random activity	Delayed action – 1–4 h

Figure 1 Example of M8 paper (http://www.saferamerica.com/productDetail.asp?categoryID=19&productID=365) [Reproduced with permission from Safer America.]

The change in current or increase in temperature is indicative of CWA exposure.

Other electrochemical detectors employ chemically selective membranes, which allow only certain chemical types to pass (CWAs), those that are required to complete a circuit. A change in the current or resistance of the solution on the detector side of the membrane indicates the presence of a CWA.

A newer type of chemiresistor instrument uses a quartz or silicon substrate that is coated with a conducting polymer. The degree of current change is dependent on the chemistry of the absorbing agent. The polymers provide limited specificity, so that the various classes of CWAs can be differentiated. The response time for electrochemical sensors is generally very fast, for example less than a minute, and often the measurement can be completed in seconds. This type of detector is limited to the detection of chemical vapors, and as such the detector response will be affected by the chemical properties of the agent in the environment. Figure 2 shows an example of an electrochemical detector.

Ion Mobility Spectrometry

Material deposited on a surface can be analyzed using IMS. The sample is rapidly thermally desorbed and the resultant vapors passed, via the inlet liner, into the ionization chamber. In the ionization chamber, a radioactive source generates ions from the sample. The ionized species are then electrically trapped at a gating grid so that all ions enter a drift tube at the same time. Inside the tube, the ions move through the drift tube toward the collector electrode under the influence of the electric field and against a drift flow. Included are small amounts of the internal calibrant 4-nitrobenzonitrile for explosives or nicotinamine for illicit drugs and CWAs. The ions travel at different speeds and arrive at the collector electrode with characteristic drift times. The drift times are inversely proportional to the characteristic reduced mobilities of the ions. CWAs, TICs, TIMs, illicit drugs, and explosives can be identified by analyzing directly the ratio of drift time to that of the internal calibrant. Figure 3 contains a schematic of the important features of an IMS.

The Ionscan 500DT manufactured by Smith Detection (http://www.smithsdetection.com/eng/1526.php) is an example of the IMS instrument, which is designed for fast and effective presumptive test. The instrument is extremely sensitive, with detection limits in the order of nanograms for detecting CWAs, TICs, TIMs and illicit drugs and down to picograms for explosives. A "positive" result is generated when an ion reaches the detector with a "drift time" similar to that of one of the standards. This generates a presumptive positive for the presence of CWAs, TICs, TIMs, illicit drugs, or explosives.

IMS is relatively specific; however, there are still compounds that can produce a false positive reading. A positive IMS result is strong indication that a

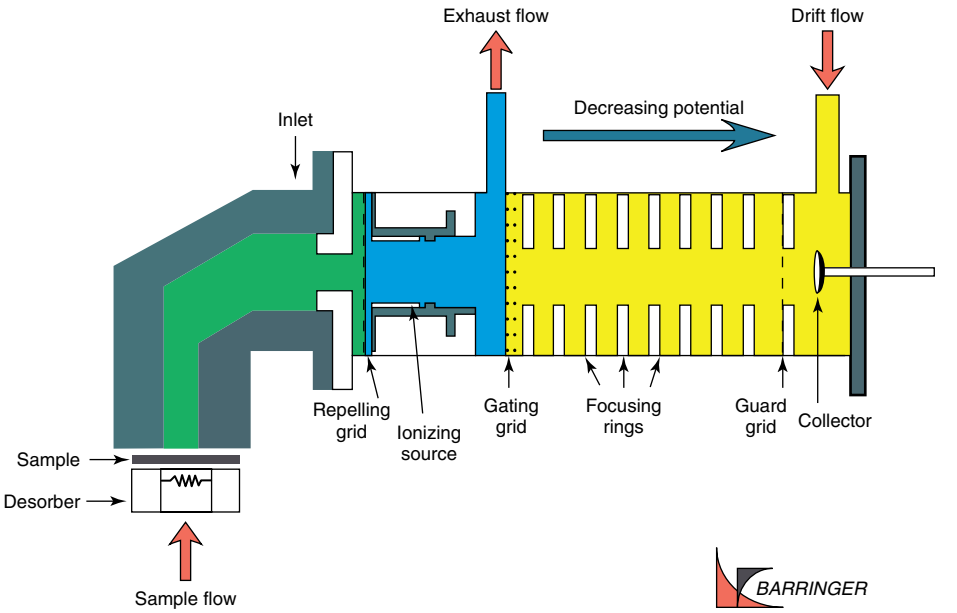

Figure 3 Schematic of the important features of an IMS

Figure 5 CAM portable IMS system, manufactured by Smiths Detection (http://www.smithsdetection.com/eng/CAM.php) [Reproduced with permission from Smiths Detection.]

particular target chemical is present; however, independent analysis by gas chromatography/mass spectroscopy (GC/MS) and/or gas chromatography/mass spectroscopy/dual flame photometric detection (GC/MS/DFPD) is required for confirmation. Figures 4 and 5 show examples of portable IMS systems used for CWA detection.

The downside of these technologies is that the detectors can be overwhelmed by high concentrations of the agent, then requiring several minutes of exposure to clean air in order to clear the agent from the detector so it can be returned to use.

Flame Photometry Detectors

In flame photometric detection (FPD) a small sample is ignited in a hydrogen flame, and the characteristic emission spectrum produced serves as a fingerprint for the atoms in the compounds analyzed. A quantitative reading of the amount of a certain element, such as phosphorous or sulfur, in a sample can be detected. Optical filters can be selected for specificity of a target material. A light-detecting element, typically a photodiode, recognizes patterns that correspond to CWAs, TICs, and TIMs. FPD detectors identify compounds in a vaporous state and as such are affected by the chemical properties of the agent in question, i.e., the vapor pressure of an agent at a specific temperature. To overcome this, scrapings from a surface can be taken and heated with the vapors collected and analyzed. An FPD detector can also

Figure 6 AP4C portable FPD system manufactured by Proengin (http://www.proengin.com/index.php?option=com_content&task=view&id=25&Itemid=32) [Reproduced with permission from Proengin.]

be combined in a laboratory setting with a GC to improve complex mixture separation. An example of a portable FPD unit is shown in Figure 6. FPDs are less influenced by high concentrations of an agent.

Photoionization Detectors

Photoionization detectors (PIDs) use ultraviolet light to ionize vapor or gas samples. A detector measures the amount of ions on the basis of a change in electrical current. PID systems are highly quantitative when compared with a calibrated, known sample and provide excellent sensitivity in such situations. Popular PID systems have very limited specificity, are highly subject to false positives in unknown or mixed environments, and are costly pieces of equipment. Nonetheless, for applications such as leak testing, PIDs are appropriate.

The limitation of the PID is that the compounds of interest must have an ionization potential less than the voltage of the lamp. If the ionization potential is greater than the voltage of the lamp, they will not be detected. PIDs can also be susceptible to failure and quenching in high humidity; for this reason a water vapor filter is normally fitted when in use. An example of a portable, handheld PID is shown in Figure 7.

Enzyme-Based Techniques

Enzyme or immunoassays approaches have been utilized for military and commercial CW detectors. Some enzyme-based CW detection systems exploit the tendency of organophosphate nerve agents to bind to acetylcholinesterase as a detection technique. Enzyme-linked immunoassays have been developed, much like the biological warfare agent counterpart,

Figure 7 Handheld PID MiniRAE 2000 manufactured by RAE Systems Inc. (http://www.raesystems.com/products/MiniRAE2000_986.html) [Reproduced with permission from RAE Systems Inc.]

with specificity for G-type nerve agents. Other systems exploit the natural enzyme that catalytically hydrolyzes or breaks down in the presence of water. Organophosphorous hydrolase can be incorporated into handheld assays or tickets. A pH sensitive probe reacts to change in acidity due to the hydrolysis of G-type nerve agents. The response can be as simple as a colorimetric pH indicator changing from red to blue, or a potentiometric electrode.

One of the limitations for the enzyme-based screening is the time taken for the assay to produce a result. The response time can be critical in cases where the agent can compromise the personal protective equipment being used by the first responder. A further limitation of the enzymatic assay is that it generates a result for a single source or location. This requires that another detector is utilized to detect the point source of contamination prior to using the enzymatic detection system. An example of an enzyme-based identification system is shown in Figure 8.

Presumptive testing is used by first responders and forensic members in the field in order to safely respond to an incident. Presumptive screening of a scene can also assist in determining the possible point of release of an agent, thereby increasing the likelihood of obtaining good-quality samples for analysis. Conformational testing is required to be

Figure 8 Nerve agent vapor detector enzymatic indication system manufactured by Anachemia Canada, Inc. (http://www.anachemia.com/engnew/frame/product4.html) [Reproduced with permission from Anachemia Canada, Inc.]

undertaken in a laboratory to confirm the presence and use of CWAs.

Laboratory-Based Analysis

For definitive analysis of CWAs, a range of sophisticated laboratory-based instrumental techniques have been developed and standardized for laboratory confirmation. The aim of this analysis is to confirm through scientific processes the presence and type of CWAs or TICs through a more comprehensive understanding of the manufacturing process and degradation products produced. The complete unequivocal analysis of the samples can take considerable time. Mesilaakso [6] described an analytical strategy for the analysis and forensic identification of CWAs.

The analytical strategy displayed below should not be considered all-encompassing. Additional instrumental methods can be utilized for the identification of the process used to manufacture the agent. Potentially, the location of manufacture of the agent, or precursors, can also be determined. One such method is stable isotope ratio mass spectrometry (IRMS). IRMS has been utilized for profiling illicit drugs, and to a lesser extent explosives, to identify the location of manufacture or production.

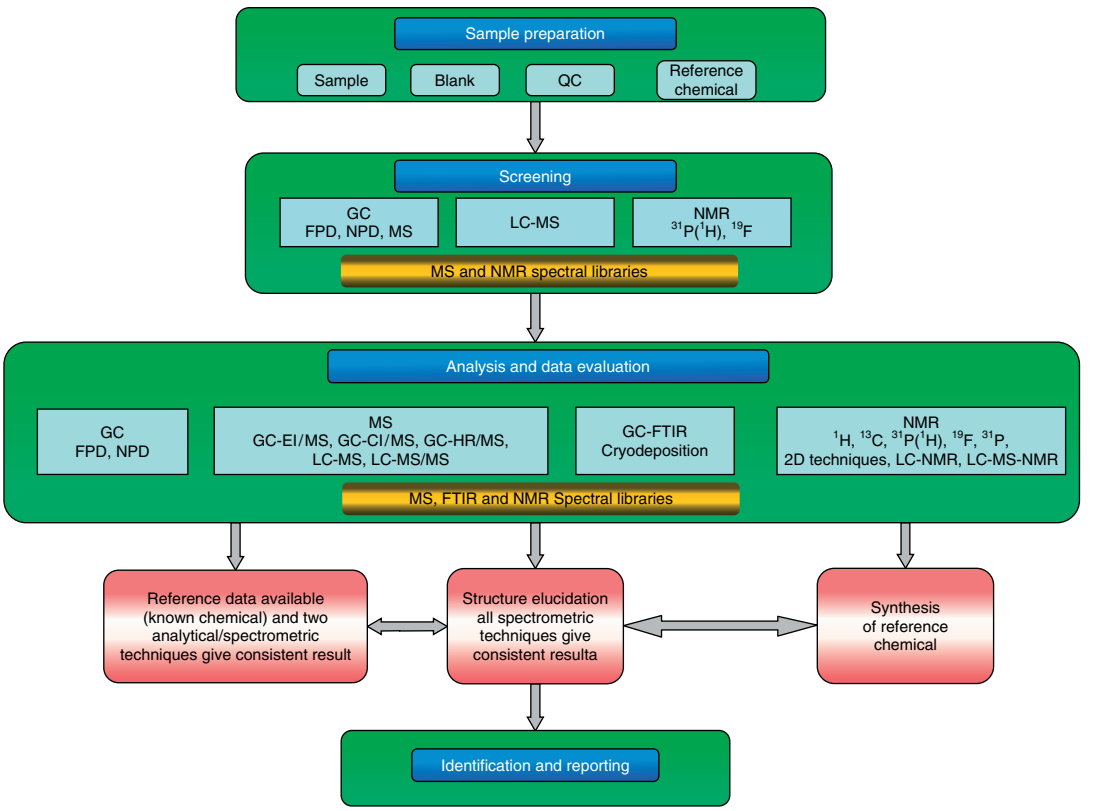

Figure 9 Analytical strategy for the analysis of CWAs

It is possible that this method could be used in the identification of CWAs and other TICs and TIMs. Figure 9 is a simplified version of these procedures.

Sample Collection

The collection of good samples is one of the most critical parts of a successful analysis. The location of the samples and their movements should be detailed and recorded throughout the entire sample collection, transportation, and analysis stages of the investigation. Having centralized laboratories capable of testing and analyzing CWAs is imperative. These laboratories should be equipped to track the continuity of the sample and maintain the chain of custody. The chain of custody for the evidence in a case relating to the use of a CWA will be closely examined and could jeopardize the case because of technicalities.

Sample Preparation

The accurate analysis of CWC-related chemicals depends on the collection of high-quality samples and well-planned and effective sample preparation procedures that are suited to the methods of analysis. The preparation of samples for analysis requires a thorough understanding of the behavior of the various types of chemicals in different sample matrices, both before and during the sample preparation, and an awareness of the limitations of the chosen instrumental method of analysis. Samples and prepared subsamples need to be appropriately labeled, and preparation procedures should follow endorsed standard procedures. Continuity of all samples and subsamples must be established

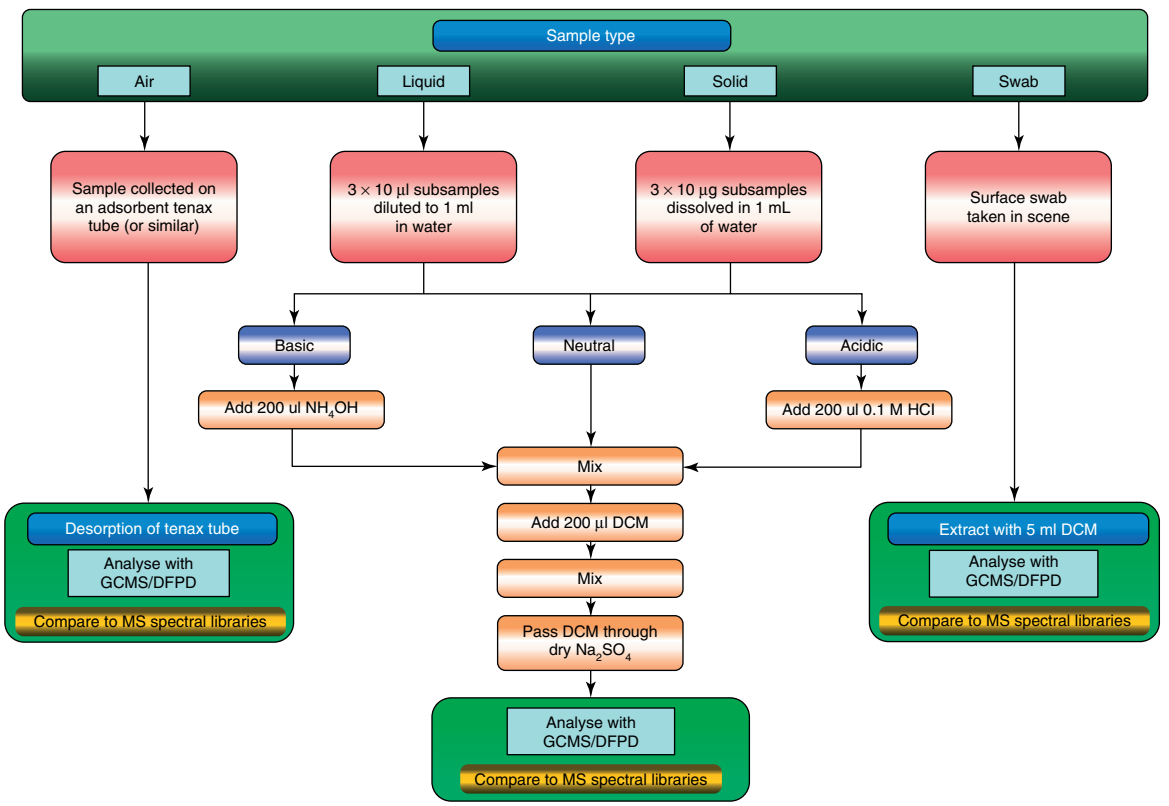

Figure 10 Example of a possible sample preparation protocol

and maintained during the analytical aspect of the investigation.

There are specific methods to be utilized for different sample types, such as air, aqueous liquid samples, soil samples, wipe samples, activated charcoal samples, concrete samples, paint, rubber, and other polymeric samples. Figure 10 is an example of possible sample preparation steps that could be utilized in the case of a suspected CWA, which are aimed at producing a presumptive identification only.

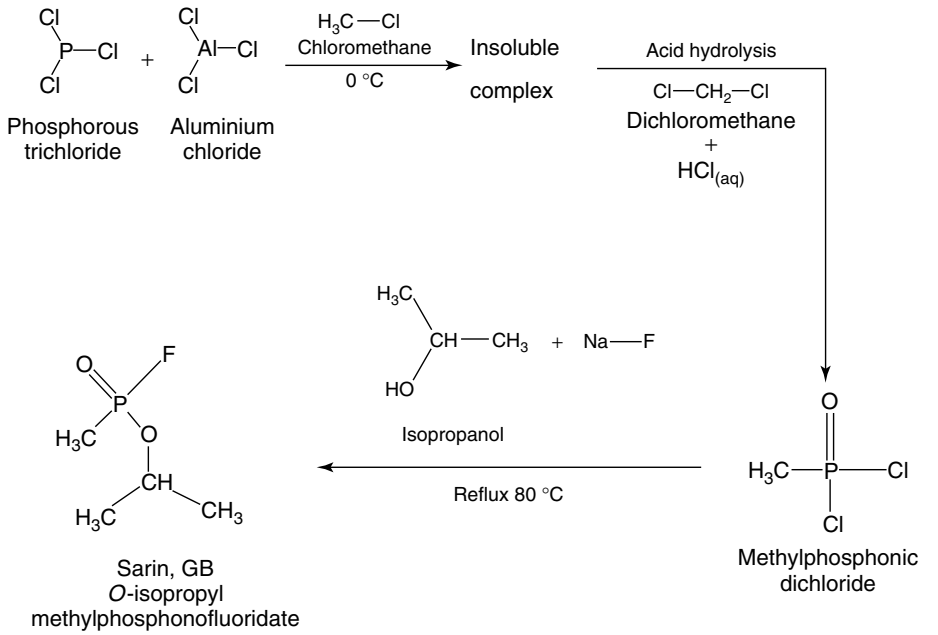

Figure 11 An example of a synthesis method for the nerve agent sarin (GB) [7]

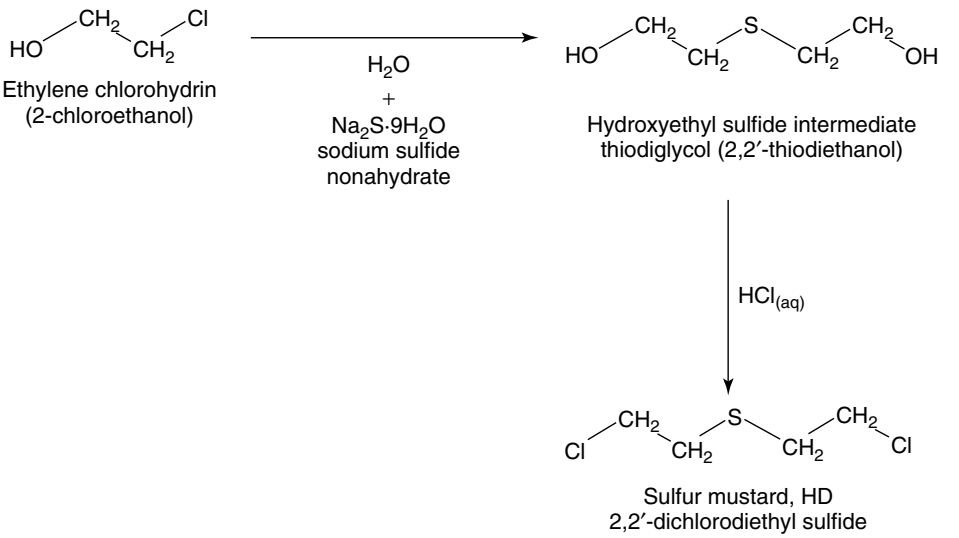

Figure 12 An example of a synthesis method for blister agent sulfur mustard (HD) [7]

Each sample matrix presents a unique set of challenges that must be met in order to maximize the recovery of the agents while minimizing matrix interference. With such difficult sample matrices, a substantial amount data analysis will be required to identify the compound(s) of interest. A common tool that has been used for deconvolution of complex data files is automated mass spectral deconvolution and identification system (AMDIS) created by the National Institute of Standards and Technology (NIST). This data analysis package enables complex mixtures that cause coeluting chromatographic peaks to be resolved, at least to an extent, into their component parts. This does not mean that a less rigorous chromatographic method is acceptable, but in cases of complex mixtures there is a greater probability that the component compounds could be identified.

Once all the analysis and data interpretation have been completed, a report will be issued. This may require the presentation of all the analytical data to a court, or at least made available to the defense team. With this in mind, scientists working in this area must be prepared for the court and should fully understand the procedures, instruments, and data analysis packages used to prepare the final report, as they may have to explain them to the judiciary.

Synthesis of CWAs

During the analysis of a particular CWA, reaction intermediates and markers from the synthetic process utilized may be identified. Examination of these reaction markers will assist in establishing the synthetic method utilized, which, in turn, will assist in the investigation of a CW-related incident. The absence of reaction markers is a critical finding, as this would indicate that a competent scientist produced the material of interest and knows that there is a requirement to purify the final product.

As an example of possible synthesis processes for CWAs, sarin and sulfur mustard have been chosen, and one process for each of these CWAs is detailed below. As can be seen from these synthetic pathways, the overall production of these two CWAs is not overly technical or challenging for an individual who

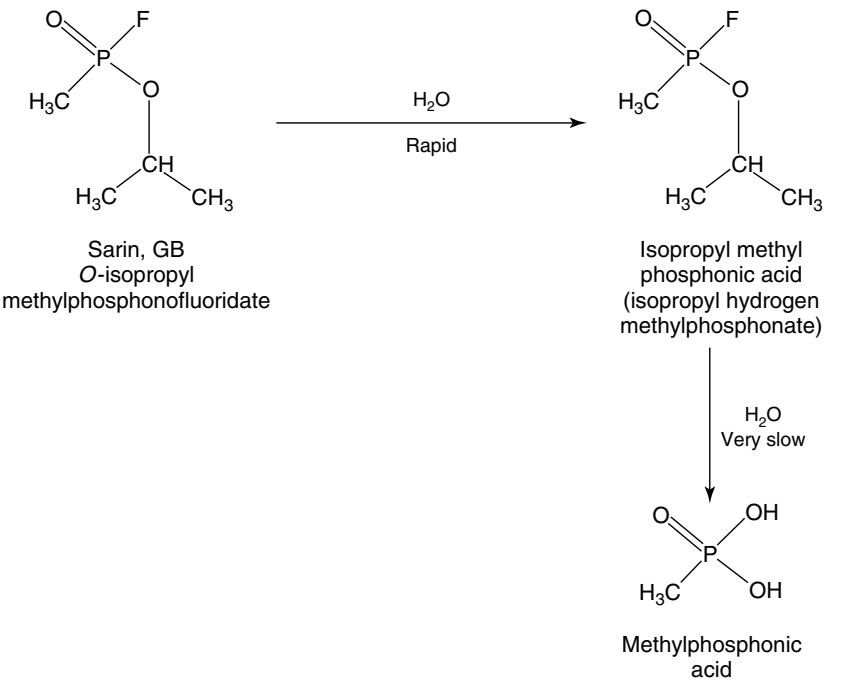

Figure 13 An example of a sarin (GB) hydrolysis [8]

has basic undergraduate chemistry training or experience. Having access to suitable protective equipment or decontamination equipment is not really required. Figures 11 and 12 are examples of possible synthetic routes for sarin and mustard.

Degradation of CWAs

When a CWA is exposed to the atmosphere, it will commence degradation to form more stable compounds. Some of the degradation products

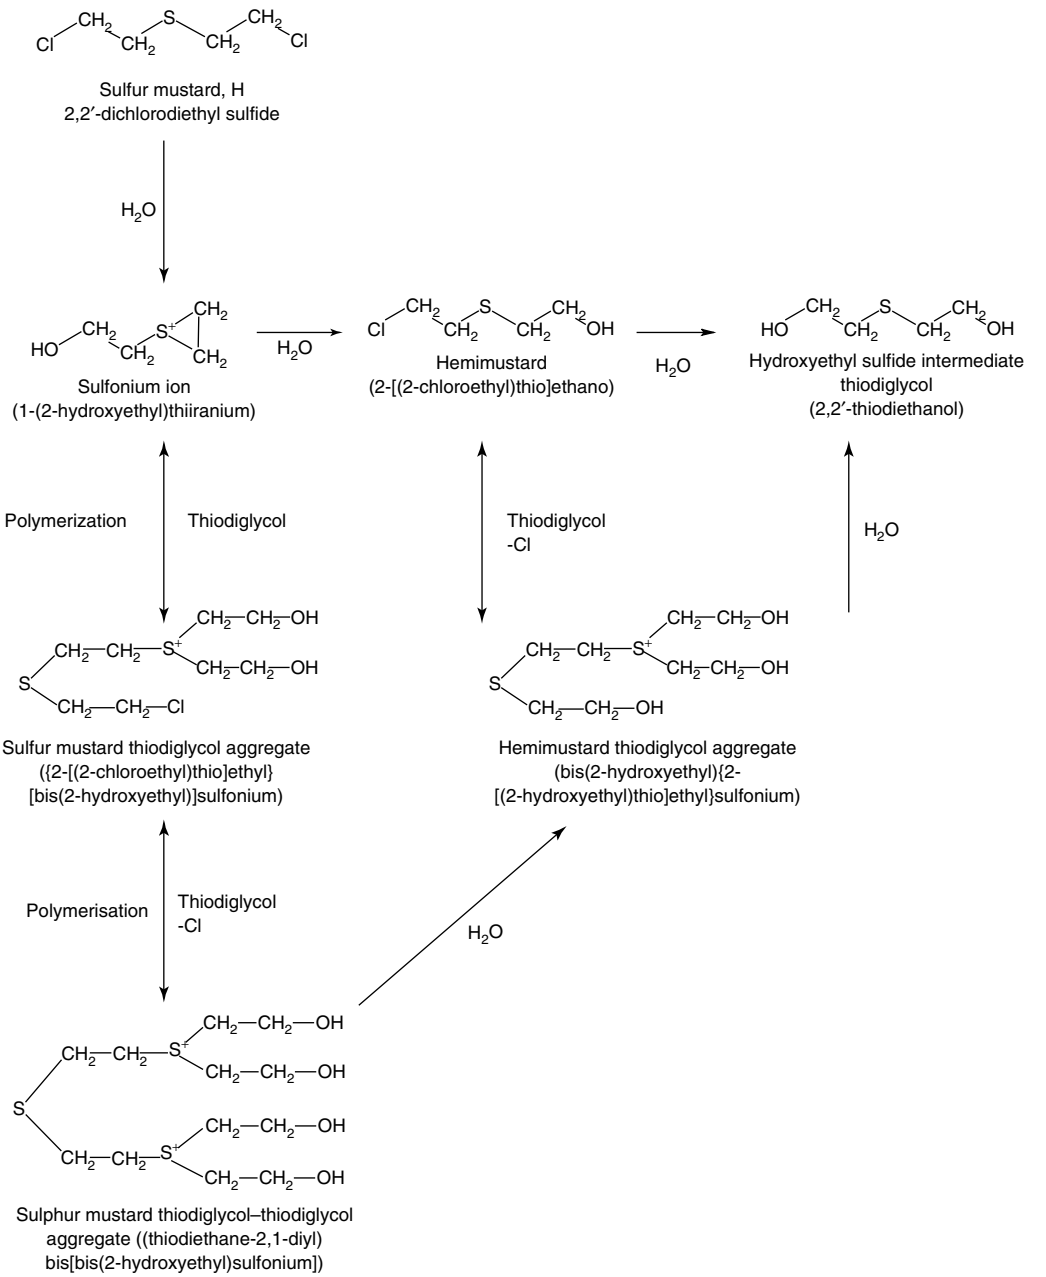

Figure 14 An example of sulfur mustard (HD) hydrolysis [8]

formed will have a degree of toxicity; however, as the degradation pathway progresses, the toxicity of the final product decreases. Examples of the degradation (hydrolysis) in water for sarin and sulfur mustard are shown in Figures 13 and 14, respectively.

Sarin hydrolyzes rapidly to isopropyl methyl phosphonic acid and then slowly to an inert, stable product, methylphosphonic acid. A publication by the Stockholm International Peace Research Institute (SIPRI) detailed the hydrolysis of sarin in water and reported the half-lives of sarin in water at different temperatures and pHs (Table 4) [9]. In this report, it has also been identified that the half-life of sarin was greatly affected by the salt concentration of the water (Table 5). It is possible that, if the environmental conditions are known, the ratio of the hydrolysis products and sarin will give an indication of the time since manufacture for the agent.

Table 4 Half-life of sarin in water (h) [9]

	pH				
Temperature (°C)	6.5	7.0	7.5	8.0	9.0
0	8300	2650	830	265	26.5
10	1870	591	187	59	6.0
20	461	146	46	15	1.5
25	237	75	24	7.5	0.8
30	125	39	12.5	4	0.4

Reproduced from Ref. 9. © Taylor and Francis Group, 1985

Table 5 Rate of hydrolysis of sarin due to salinity [9]

Water condition		Half-life of sarin (h)
Sea water	pH = 8.0, temperature = 25°C	0.4
Distilled water	pH = 7.9, temperature = 25°C	7.5

Reproduced from Ref. 9. © Taylor and Francis Group, 1985

Table 6 Hydrolysis rates and half-lives for sulfur mustard [9]

Water condition	Observations
Saturated solution of sulfur mustard (temperature = 20°C)	110 min for 99% hydrolysis
Saturated solution of sulfur mustard (temperature = 50°C)	4 min for 99% hydrolysis
Distilled water (temperature = 25°C)	Half-life 8.5 min
Salt water (Temperature = 25°C)	Half-life 60 min

Reproduced from Ref. 9. © Taylor and Francis Group, 1985

Table 6 details the hydrolysis rates and half-lives for sulfur mustard under various water conditions. The hydrolysis rates and half-lives vary considerably and appear to be shorter in fresh water; this is commonly not the case, as the hydrolysis of mustard is surface controlled [9]. Although the hydrolysis rate for sulfur mustard is rapid, during hydrolysis sulfur mustard has the capacity to form polymeric thiodiglycol structures. These thiodiglycol polymers have the capability of producing a stable impervious "heel" that protects the bulk of the chemical agent. Trapp [9] reports the formation of this protective phase or "heel" in water where there is no turbulence. Trapp [9] attributes this fact as the reason for injuries when Japanese chemical weapons were recovered from ocean dump sites in 1962 and 1970 [9]. It should be noted that as thiodiglycol is both a precursor and a degradation product, care must be taken when interpreting the analytical results obtained from the analysis of a sulfur mustard sample.

Child Sexual Abuse

Introduction

The forensic aspects of the sexual abuse of children is one part of the very broad topic of child maltreatment. The forensic investigation of child sexual abuse requires the cooperation of a diverse group of professionals, including emergency room staff, pediatricians and other primary care physicians, law enforcement, social service personnel, and a variety of mental health professionals. Psychiatrists, psychologists, and other mental health professionals may evaluate children for forensic or legal purposes, either in private practice or as part of an interdisciplinary team. Forensic evaluators may assist the court in determining what happened to the child and make recommendations regarding placement or treatment. Evaluators may be asked to assess the credibility of a child who allegedly was sexually abused. In civil law suits, mental health professionals may testify about the cause, nature, and extent of the child's psychological injuries.

Definitions

Sexual abuse of children refers to sexual behavior between a child and an adult or between two children, when one of them is significantly older or when coercion is used. The perpetrator and the victim may be of the same sex or the opposite sex. Sexual behaviors may include touching of breasts, buttocks, and genitals, whether or not the perpetrator or victim are undressed. They may also include exhibitionism, fellatio, cunnilingus, and penetration of the vagina or anus with sexual organs or objects. Sexual abuse may involve behavior over an extended period of time or it may be an isolated incident. Developmental factors must be considered in assessing whether sexual activities between two children are abusive or normative. In addition to touching, sexual abuse also refers to *sexual exploitation of children*, for instance, engaging in prostitution of minors or activities related to pornography depicting minors.

The *Diagnostic and Statistical Manual of Mental Disorders,* Fourth Edition, Text Revision (*DSM-IV-TR*) [1] addresses the classification of child maltreatment in the article, "Other Conditions That May Be a Focus of Clinical Attention," and in the section, "Problems Related to Abuse or Neglect." There are separate diagnoses for physical abuse of a child, sexual abuse of a child, and neglect of a child. Also, there are separate numerical codes depending on whether the focus of attention is on the perpetrator of the abuse or the victim of the abuse. These conditions and problems are listed on Axis I of the multiaxial assessment of *DSM-IV-TR.*

In federal law, child sexual abuse means the employment, use, persuasion, inducement, enticement, or coercion of any child to engage in, or assist any other person to engage in, any sexually explicit conduct (or simulation of such conduct for the purpose of producing a visual depiction of such conduct) or the rape (and in cases of caretaker or interfamilial relationships, statutory rape), molestation, prostitution, incest with children, or other form of sexual exploitation of children. A variety of legal definitions and guidelines regarding child sexual abuse exists at the state level, so clinicians should be aware of the terminology and criteria used in their own locale.

Epidemiology

Each year the Children's Bureau, an agency within the Department of Health and Human Services, collects data on child maltreatment. The results are published in an annual document called *Child Maltreatment* [2]. The agency estimated that during 2005, about 3.3 million allegations of child abuse and neglect comprising 6.0 million victims were reported to child protective services. Of the allegations that were screened in and investigated, about 25% were considered substantiated or indicated and about 55% were considered unsubstantiated. The substantiated or indicated cases were distributed as follows: neglect, 63%; physical abuse, 17%; sexual abuse, 9%; psychological abuse, 7%; and medical neglect, 2%.

The data were analyzed for patterns of maltreatment by the sex and age of victims. Rates of many types of maltreatment were similar for male and female children, but the sexual abuse rate for female children was higher than that for male children. Examining the age distribution of victims, the 0–3 age group had the highest victimization rate, and the rate of victimization declined as the age of the victims increased. For example, the abuse rate for infants (age 0–3) was 16.5 per 1000, while the rate for children

(age 4–7) was 13.5 per 1000. The highest rate of sexual abuse, however, was in the young adolescent (age 12–15) group, with 17.3% of all victims suffering sexual abuse *versus* only 8.9% in the 4–7 age group. All these figures are approximations because the actual amount of abuse is unclear.

Perpetrators and Patterns of Child Sexual Abuse

There is enormous diversity among those who perpetrate child abuse [3]. Perpetrators come from diverse backgrounds in terms of *age, sex, mental capacity*, and *socioeconomic status*. Family members are often perpetrators of sexual abuse. Other times, the perpetrator may be a person entrusted with the care and well-being of a child such as relatives and baby-sitters. Both men and women are perpetrators of sexual abuse. Sometimes sex offenders themselves are children or adolescents – for example, older siblings abusing younger siblings or adolescents who rape peers. Finally, one must include mentally ill or especially mentally retarded persons who may be the perpetrators of child sexual abuse without a clear understanding of their own behavior. Perpetrators may commit child sexual abuse only once in their life or they may serially abuse scores or hundreds of children. Some perpetrators may be attracted to children of a particular gender, age, and physical appearance; others may prey on children at large in a rather indiscriminate manner.

Intrafamilial Pattern of Abuse

Incest may be strictly defined as sexual relations between close blood relatives, for example, between a child and the father, uncle, or sibling. Incest may be defined more broadly to include sexual intercourse between a child and a stepparent or stepsibling. Although father–daughter abuse is the most common form of incest, it may also involve father and son, mother and daughter, and mother and son. Healthy, self-confident children refuse the intrusions either directly (via oppositionality and temper tantrums) or indirectly (through silence and distancing maneuvers) or by adopting any strategy that causes the offender to refrain.

Intrafamilial sexual abuse – as well as other sexual abuse that occurs over a period of time – frequently evolves through five phases [4]:

- **Engagement phase**

The perpetrator induces the child into a special relationship.

- **Sexual interaction phase**

The sexual behaviors progress from less to more intrusive forms of abuse.

- **Secrecy phase**

The perpetrator threatens the victim not to tell.

- **Disclosure phase**

The abuse is discovered accidentally (when another person walks in the room and sees it), as a result of the child's reporting it to a responsible adult, or because the child is brought for medical attention and an alert clinician asks the right questions.

- **Suppression phase**

The child may often retract statements of the disclosure because of family pressure or because of the child's own mental processes. That is, the child may perceive that violent or intrusive attention is synonymous with interest or affection.

Close Associate Pattern of Abuse

The perpetrator of sexual abuse may be a person who is not a parent or relative, but is entrusted with the care and well-being of a child. This group of perpetrators may include family friends, neighbors, baby-sitters, scout leaders, clergymen, and other religious leaders. In this circumstance, the pedophilic perpetrator typically grooms the child over a period of time. He or she gains the friendship of the child through enjoyable activities and gifts, introduces sexual activities that may seem innocent and even pleasurable, and progresses to more intrusive activities. This type of sexual abuse has a pattern that is similar to the five phases of intrafamilial sexual abuse.

School is another setting where the close associate pattern of sexual abuse may take place, with the perpetrators in this case being teachers, coaches, counselors, or principals. Both boys and girls may be victims. While this type of abuse may take the form of coerced sexual activities, often, especially for adolescents, it may appear to be a consensual relationship between an underage student and a teacher or other staff. Of note, corporal punishment by school personnel still occurs in some states and

localities. This form of punishment, which usually consists of adult's hitting the child's buttocks with a wooden paddle, may be perceived as a sexual assault by some children.

Stranger Sexual Abuse

Children may be abducted and sexually abused by strangers, which often involves more violence than abuse by a family member or close associate. A perpetrator may observe a playground and identify a child who is not closely supervised. In this way, a pedophile may molest hundreds of children before he is apprehended. For each child victim, this is usually a single, isolated experience. A solo sex ring is a form of child sexual abuse that involves one adult perpetrator and multiple child victims, who may know about each other's sexual activities with the perpetrator.

With the proliferation of computers and the Internet, cyberspace has become a fertile ground for pedophiles to perpetrate their crimes on children [5]. This may include pedophiles' producing and trading child pornography over the Internet; interacting with minors through chat rooms, often with the goal of luring them into sexual activities; and outright trafficking of children for sexual purposes.

Clinical Features of Child Sexual Abuse Victims

Sexually abused children manifest a variety of emotional, behavioral, and somatic reactions [6, 7]. These psychological symptoms are neither specific nor pathognomonic since the same symptoms may occur without any history of abuse. The psychological symptoms manifested by abused children can be organized into clinical patterns. Although it may be helpful to note whether a particular individual falls into one of these patterns, this in itself is not diagnostic of sexual abuse.

- **Anxiety symptoms**

This includes fearfulness, phobias, insomnia, nightmares that directly portray the abuse, somatic complaints, and posttraumatic stress disorder.

- **Dissociative reactions and hysterical symptoms**

The child may exhibit periods of amnesia, daydreaming, trancelike states, hysterical seizures, and symptoms of dissociative identity disorder.

- **Depression**

This may be manifested by low self-esteem and suicidal and self-mutilative behaviors.

- **Disturbances in sexual behaviors**

Some sexual behaviors are particularly suggestive of abuse, such as masturbating with an object, imitating intercourse, and inserting objects into the vagina or anus. In contrast to these overly sexualized behaviors, the child may avoid sexual stimuli through phobias and inhibitions.

- **Somatic complaints**

This includes enuresis, encopresis, anal and vaginal itching, anorexia, bulimia, obesity, headache, and stomachache.

Approximately one-third of sexually abused children have no apparent symptoms. On the other hand, the following factors tend to be associated with more severe symptoms in the victims of sexual abuse: greater frequency and duration of abuse, sexual abuse that involved force or penetration, and sexual abuse perpetrated by the child's father or stepfather. Other factors associated with poorer prognosis are the child's perception of being less believed, family dysfunction, and lack of maternal support. Of note, multiple investigatory interviews appear to increase symptoms.

Evaluation Process

A forensic evaluation emphasizes collecting accurate and complete data to determine – as objectively as possible – what happened to the child. The data collected in a forensic evaluation must be preserved in a reliable manner through audiotape, videotape, or detailed notes. The results of the forensic evaluation are organized into a report that will be used in the court and read by attorneys, a judge, and others. From the psychiatric and psychological perspective, the interview is usually the primary source of information and the physical examination is secondary. In practice, children who may have been sexually abused are interviewed first and later given a physical examination and other tests.

In addition to interviewing the child, the evaluator obtains a history from the parents (separately, in most cases) and other pertinent informants. In the evaluation of suspected sexual abuse, the examiner should consider the possibility that the parents or other informants are not telling the truth. For example, the mother may wish to avoid the discovery of father–daughter incest by blaming the child's genital injury on another child or a stranger. In another scenario, the mother may fabricate an allegation of incest when the child had never been abused at all, for example, to gain advantage in a child custody dispute. The first version protects a father who is guilty; the second version implicates a father who is innocent.

The examiner should determine how the allegation originally arose and what subsequent statements were made [8]. Determine the emotional tone of the first disclosure (e.g., whether it arose in the context of a high level of suspicion of abuse). Determine the sequence of previous examinations, the techniques used, and what was reported. Try to determine whether the previous interviews were likely to have distorted the child's recollections. If possible, review transcripts, audiotapes, and videotapes of earlier interviews. Seek a history of sexual overstimulation (lax attitudes toward nudity and sexual activity in the home), prior abuse, or other traumas. Consider other stressors that could account for the child's symptoms. The examiner should also ask about exposure to other possible male and female perpetrators.

A psychosocial history should be collected and organized that includes

- symptoms and behavioral changes that may be related to the alleged abuse;
- confounding variables such as psychiatric disorder or cognitive impairment that may need to be considered;
- the family's attitude toward discipline, sex, and modesty;
- developmental history from birth through periods of possible trauma to the present;
- family history, such as earlier abuse of the parents, substance abuse by the parents, spouse abuse, and psychiatric disorder in the parents; and
- underlying motivation and possible psychopathology of the adults involved.

Collateral information may be useful in verifying allegations of sexual abuse, and thus the evaluator should consider requesting pertinent information from the following, after obtaining authorizations: protective services, school personnel, other caregivers (e.g., baby-sitters), other family members (e.g., siblings), the pediatrician, and police reports.

The Child Interview

Several structured and semi-structured interview protocols have been introduced that are designed to maximize the amount of accurate information and minimize mistaken or false information provided by children. These approaches include the cognitive interview, which encourages witnesses to search their memories in various ways such as recalling events forward and then backward. The interview protocol developed at the National Institute of Child Health and Human Development (NICHD) includes a series of phases and makes use of detailed interview scripts [9]. The stepwise interview (outlined below) [10] is a funnel approach that starts with open-ended questions and, if necessary, moves to more specific questions.

In interviewing children who may have been abused, it should be possible to follow a standard protocol and also be flexible, considerate, and generally supportive. As when seeing any patient, the evaluator must size up the situation and use techniques that are likely to help the youngster become comfortable and communicative. One victim might need a favorite object (e.g., a teddy bear or a toy truck); another might need to have a particular person included in the interview. Some children are comfortable talking; others prefer to draw pictures. The child might make important comments while chatting during the break time instead of during the structured interview.

Interview Process

The interviewer of the allegedly sexually abused child should remember the following principles [8]:

- audiotape or videotape the interview, if possible;
- use a minimum number of interviews (perhaps two or three), as multiple interviews may encourage confabulation;
- avoid repetitive questions, either/or questions, and multiple questions and try to avoid leading and suggestive questions;

- use restatement, that is, repeat the child's account back to the child (which allows the interviewer to see if the child is consistent and ensures that the interviewer understands the child's report);
- conduct the examination without the parent present (if the child is very young, consider having a family member in the room);
- use an examination technique that is appropriate to the child's age and developmental level, such as drawings and play re-enactment; and
- determine the child's terms for body parts and sexual acts; do not educate or provide new terms.

Interview Content

The interview should not take the form of an interrogation. Note the child's affect while discussing these topics and be tactful in helping the child manage anxiety. Young children may not be able to report all of the relevant information. The examiner should explore the following:

- whether the child was told to report or not report anything;
- who the alleged perpetrator was;
- what the alleged perpetrator did;
- where it happened;
- when it started and when it ended;
- number of times the abuse occurred;
- how the child was initially engaged and how the abuse progressed over time;
- how the alleged perpetrator induced the child to maintain secrecy;
- whether the child is aware of specific injuries or physical symptoms associated with the abuse;
- whether any photography or videotaping took place?

The Stepwise Interview

The usual clinical interview may need some modification for evaluating a child who may have been abused. The stepwise interview [10], which is primarily intended for forensic evaluations, consists of the following components.

- **Build rapport**

Build rapport and informally observe the child's behavior, social skills, and cognitive abilities.

- **Ask the child to describe two specific past events**

This step assesses the child's memory and models the form of the interview for the child. Ask nonleading, open-ended questions in the pattern that will occur through the rest of the interview.

- **Establish the need to tell the truth**

Reach an agreement with the child that in this interview only the truth will be discussed, not "pretend" or imagination. Explain to the child that it is fine not to know the answer to a question. It is fine to correct the interviewer.

- **Introduce the topic of concern**

Start with general questions such as, "Do you know why you are talking with me today?" Proceed, if necessary, to more specific questions such as, "Has anything happened to you?" Drawings may help initiate disclosure.

- **Elicit a free narrative**

Once the topic of abuse has been introduced, the interviewer encourages the child to describe each event from the beginning without leaving out any details. If abuse has occurred over a period of time, the interviewer may ask for a description of the general pattern and then for an account of particular episodes.

- **Pose general questions**

The interviewer may ask general questions to elicit further details. These questions should not be leading and should be phrased in such a way that the child realizes an inability to recall or lack of knowledge is acceptable.

- **Pose specific questions if necessary**

Asking specific questions in a careful way may yield helpful clarification. For example, the interviewer may follow-up on inconsistencies in a gentle, nonthreatening manner. Avoid repetitive questions or appearing to reward particular answers in any way.

- **Use interview aids if necessary**

Anatomical dolls may be useful in understanding exactly what sort of abusive activity occurred. The dolls are not used to diagnose child abuse, only to clarify what happened.

- **Conclude the interview**

Toward the end of the interview, the interviewer may ask a few leading questions about irrelevant issues (e.g., "You came here by taxi, didn't you?"). If the child demonstrates susceptibility to the suggestions, the interviewer must verify that the information

obtained earlier was not contaminated. Finally, the child is thanked for participating in the interview. However, the child should not be complimented or rewarded, since that may communicate that the child has given "the correct answer" to the interviewer.

Physical Examination

A forensic medical examination is usually performed by a pediatrician, preferably one with special expertise in child sexual abuse. The examination consists of a general physical examination with a focus on the genital and anal areas. A comprehensive examination must direct attention to all aspects of the victim's health status, including maturity, developmental assessments, and a review of systems [11–13].

After sexual abuse, labial and perineal tissues may manifest abrasions, contusions, lacerations, petechiae, and edema. Examination may reveal bloodied tissue, genitorectal tears, and infected secretions. On the other hand, scarring after sexual abuse may be minimal or not evident if vaginal penetration has been gentle, consensual, or gradual. Vaginal and rectal tissues rapidly heal after injury and abrasions can be repaired within several days. Thus, the lack of physical findings may indicate either a return to normalcy after rapid healing of minor lesions or abuse perpetrated in a manner that left no material evidence. In other words, a normal genital examination does not mean the child was not sexually abused. Most victims of child sexual abuse have a normal or nonspecific genital examination.

Serious injuries to the penis – such as scaldings and partial amputation – produce noticeable scars. The more common traumas – hematomas, abrasions, and lacerations – are superficial injuries and heal rapidly without scarring.

Anal findings include dilation with loss of anal–rectal tone, flattened rectal rugae, lacerations, and wedge-shaped and linear scars. Acute trauma may result in swelling and spasm secondary to submucosal hemorrhage. Most rectal injuries, massive or minor, heal quickly and nearly completely, leaving little evidence of abuse. Rectal irritants – such as pinworms, lichen sclerosis, atopic dermatitis, and rare hematological disorders – may be present in a child, and should be considered as part of the differential diagnosis of anorectal lesions.

Special Tests and Laboratory Examination

When sexual abuse is suspected, the victim requires evaluation for sexually transmitted diseases (STDs) [14]. If the examination occurs within 72 h of the alleged abuse, the clinician should consider cultures of the genital, anal, and oral mucosa. The following STDs are essentially diagnostic of child sexual abuse unless they were acquired perinatally: gonorrhea, syphilis, and *Chlamydia trachomatis*. Positive serology for the human immunodeficiency virus (HIV) is diagnostic of child sexual abuse unless it was acquired perinatally or by blood transfusion. The following STDs raise suspicions of child sexual abuse and should ordinarily be reported to protective services: herpes simplex virus in a genital location unless there is a clear history of autoinoculation; *Trichomonas vaginalis*; and condylomata acuminata or anogenital warts. However, infants and young children may acquire anal and genital warts perinatally. Or course, pregnancy is diagnostic of child sexual abuse, as is the presence of semen or sperm acid phosphatase.

Determining the Validitiy of a Case of Sexual Abuse

The psychiatric evaluation of youngsters who may have been sexually abused involves assessing the child's credibility. Although generally children tell the truth when they talk about abuse, sometimes children make false denials (saying they were not abused, when actually they were) or false allegations (saying they were abused, when actually they were not) [15].

Possible Explanations of Denials of Abuse

A false denial or retraction may occur for several reasons. The child may have been pressured by the perpetrator or family members to recant the allegation. The pressure may consist of bribery, mockery, or threats of injury. The child may be protecting a parent or other family member, even without external coercion. The child might be frightened or distressed by the investigation and decide to withdraw participation. For instance, an interviewer could induce a false denial by asking overly challenging questions. A child may be inhibited by shame or guilt; the child

may mistakenly assume responsibility for what happened. Finally, the child may have "accommodated" to the abuse, consciously or unconsciously, instead of objecting to it.

Possible Explanations of Allegations of Abuse

A false allegation of abuse may also occur for several reasons [16]. For example, sometimes a false allegation arises in the mind of a parent or another adult and is imposed on the child, and this may happen in several ways. The parent may have misinterpreted an innocent remark, a neutral piece of behavior, or a benign physical condition as evidence of abuse and induced the child to endorse this interpretation. The parent and child may share a *folie à deux* or the child may simply give in and agree with a delusional parent. A parent may have fabricated the story and induced the child to collude in presenting it to the authorities. Also, previous interviewers may have asked leading or suggestive questions. An interviewer who believes abuse occurred may unwittingly shape a child's responses until the child validates the interviewer's assumptions.

A false allegation of abuse may also occur through unconscious or nonpurposeful mental mechanisms in the child. For example, a young child may confuse fantasy with reality. Although rare, older children and adolescents may experience delusions about sexual activities in the context of a psychotic illness. False allegations occur through the mental mechanisms of misinterpretation (when the child misunderstood what happened and later reported it inaccurately) and miscommunication (when the child misunderstood an adult's question and the adult may later misinterpreted or took the child's statement out of context). Also, through the process of confabulation, the child may fill gaps in his memory with whatever information makes sense to him at the time.

A false allegation of abuse may occur through conscious or purposeful mental mechanisms in the child such as lying. Some children engage in pseudologia or pathological lying, the enthusiastic proliferation of falsehoods that may have no obvious motivation. Through the mechanism of innocent lying, younger children may make false statements without appreciating their serious implications because that seems to be the best way to handle the situation they are in. Through deliberate lying, children may choose to avoid or distort the truth for some personal advantage. This happens more with older children and adolescents.

Finally, through the mechanism of perpetrator substitution, the child may have actually been sexually abused and exhibits symptoms consistent with abuse but identifies the wrong person as the perpetrator, resulting in a false allegation. The child may do this to protect the actual offender or the child may displace the memories and accompanying affects onto another individual.

Prognosis After Child Sexual Abuse

Neurobiological Consequences of Child Sexual Abuse

Both severe physical abuse and repeated sexual abuse may cause changes in the child's developing brain that persist into adulthood [17–19]. Adult survivors of abuse are more likely to have abnormalities of their electroencephalograms (EEGs), which indicate limbic irritability. They are more likely to have a variety of changes in the structure of the brain as visualized by magnetic resonance imaging (MRI), including decreased volumes of the anterior cingular cortex, cerebellum, hippocampus, and amygdala. Decreases in the midsagittal area of the corpus callosum have been found in both children and adults with trauma histories. These neurobiological effects of persistent child maltreatment probably mediate the behavioral and psychological symptoms that follow abuse, such as increased aggressiveness, heightened autonomic arousal, depression, and memory problems.

Psychosocial Sequellae of Child Sexual Abuse

In a forensic context, psychiatrists and psychologists are sometimes asked to predict or estimate the prognosis of a child who has been sexually abused. In conducting such an assessment, the evaluator should rely as much as possible on research, not one's personal opinion or speculation [20]. Children who have been sexually abused are more likely as adults to have problems with anxiety, depression, suicidality, substance abuse, and chronic medical problems compared with children who were not

sexually abused [21–23]. These long-term effects of sexual abuse are not inevitable, however. The psychological effects of sexual abuse and other traumas may be affected by the child's genetic makeup as well as by the amount and nature of support from the nonabusive persons in the child's life [24].

Chronic severe abuse can lead to a syndrome known as *complex posttraumatic stress disorder* (*PTSD*) or disorder of extreme stress not otherwise specified (DESNOS). This disorder, which has been proposed for inclusion in the *DSM-V*, is characterized by alterations in the following: ability to modulate emotions; identity and sense of self; ongoing consciousness and memory; relations with the perpetrator and others; physical and medical status; and systems of meaning. The core of this disorder is a breakdown in the ability to regulate internal states.

Child Sexual Abuse Accommodation

Introduction

The child sexual abuse accommodation syndrome (CSAAS) has no specific definition. It is a clinical concept that was first introduced by Ronald C. Summit, M.D [1] in 1983. Dr Summit utilized the syndrome to explain some of the atypical behaviors of children who have been the victims of sexual abuse (*see* **Child Sexual Abuse**; **Assault: Sexually Motivated**). He postulated that children who have been sexually abused often present with a number of peculiar characteristic features. These peculiar features might account for the conflicting details of the alleged abuse as presented by these children. These peculiar characteristics frequently evoke skepticism in adults about the actuality of the abuse upon eventual disclosure. This in turn results in further stigmatization of the child who is often accused of "lying, manipulating, or imagining by parents, courts, or clinicians."

Dr Summit explained that the conceptual basis of the syndrome arose from his attempt to foster better understanding of sexually abused children by clinicians. He stated that his main motive for the syndrome was to encourage clinicians to be more empathetic and supportive of abused children. He asserted that better understanding of children who have been sexually abused would lead to improved clinical interventions to help them to recover from the psychological impact of abuse.

In his original article, Dr Summit reported that the majority of the theoretical basis for the syndrome was drawn from the studies of female victims of sexual abuse. This was attributed to the fact that females were more likely to be sexually abused than males by adult male caretakers. Moreover, males were less likely to admit to being victims of sexual abuse. However, he indicated that the syndrome can be present in male victims since the response of children to the experience of being sexually abused is the same irrespective of their sex.

Over the years, the CSAAS has been a source of great dispute within the medicolegal community. The term syndrome is most commonly applied during the prosecution of alleged perpetrators of child sexual abuse. There have been attempts by several child sexual abuse "experts" to utilize the syndrome as the theoretical proof for the occurrence of sexual abuse in the absence of more incriminating evidence. This has led to intense dissent by the opposing school of thought which believes that there is no uniform set of characteristics that identifies the children who have been the victims of sexual abuse. The controversy regarding the authenticity of the syndrome has resulted in some skepticism amongst courts and Juries. The overall result has been the lack of uniformity in the verdict of legal battles concerning the applicability of the syndrome.

Clinical Characteristics

Dr Summit described five categories of behaviors that can be observed in the children who have been sexually abused that might lead to alienation upon disclosure of their abuse. These five categories of behaviors represent the discernible phases of the CSAAS. He characterized the first two sets of characteristics as "preconditions [1]" that are required for sexual abuse to occur. The remaining three categories of behaviors are usually observed after the abuse has been established. They represent "sequential contingencies [1]" that are required for the abuse to continue over a prolonged period of time without disclosure by the child. These categories of behaviors also explain the child's hesitation to reveal the details of the abuse when it is finally discovered by others. The five categories of the CSAAS described by Dr Summit include the following:

- secrecy;
- helplessness;
- entrapment and accommodation;

- delayed, conflicted and unconvincing disclosure;
- retraction.

Secrecy

Dr Summit theorized that the initial goal of an adult who is engaged in the sexual abuse of a child is to ensure that the child does not spontaneously report the abuse to other trusted adults. This often involves an initiation period during which the perpetrator attempts to create a common emotional link between the child victim and the perpetrator.

The establishment of a common shared secret, the integrity of which is maintained by various psychological techniques, is the initial weapon of the perpetrator. Some of the psychological techniques utilized by the perpetrator include threats, intimidation, blackmail, and rationalization. The perpetrator ensures that the abusive acts occur only when he is alone with the child. The perpetrator also ingrains a belief in the child that the shared act is a secret that "must never be shared with anyone else [1]".

According to Dr Summit, the combination of the perpetrators' psychological manipulation and the child's inherent vulnerabilities results in significant internal conflict for the child. The child's predicament is also compounded by the fact that she has little understanding of the concept of sex. Furthermore, any attempt by the child to disclose the abuse is often welcomed by "adult disbelief and suspicion of the child's motives [2]". As a result, the child becomes afraid of being blamed for the abuse. She might also worry that other trusted adults would not be capable of protecting her from possible retaliation by the perpetrator. Finally, the child develops a sense of isolation and helplessness. This in turn leads to chronic "self-blame [1]" with the resultant effect of a lifetime of "self-imposed exile from intimacy, trust, and self-validation [1]".

Helplessness

Dr Summit asserted that contrary to the expectations of adults, sexually abused children are usually physically incapable of resisting their abusers despite being opposed to the abuse. This is due to the tremendous amount of psychological power that most abusers have over the child. This usually precludes the need for physical force. Dr Summit emphasized that an imbalance of power exists between the perpetrator and the abused child. Most abusers are individuals who occupy important positions of trust and control in the child's life. He cited studies that suggested that a child was more likely to be sexually abused by close relatives such as their fathers, stepfathers, and other important caretakers. Although it was easy for the child to resist "strangers, weirdos, and kidnappers [1]", it is often not so easy to resist important caretakers within "an authoritarian relationship [1]." As such, sexually abused children often quietly succumb to the abuse without putting up any resistance.

Dr Summit challenged the common assumption by adults that a child's failure to resist or report sexual abuse suggests that the child was a consenting partaker in the abusive relationship. Especially erroneous is the suggestion that the abused child might have initiated the abuse by some seductive and sexually provocative behavior. He emphasized that the perpetrating adult was solely responsible for "any clandestine sexual activity" with a trusting child who is usually helpless in resisting the abuse. This helplessness is created by the psychological position of power that the perpetrator often occupies in the child's life.

Entrapment and Accommodation

Dr Summit hypothesized that child sexual abuse is often repetitive and occurs over a prolonged period of time. The perpetrator often experience some initial regret, guilt, or fear of discovery that leads to a resolution to stop the abuse. However, the "forbidden quality of the experience [1]" and the ease with which the abuse is achieved leads to a compulsion to repeat the acts. If the child does not receive help or protection from the abuser, she finally alters her mental state so as to continue to survive the act while maintaining her emotional well-being.

Dr Summit explained that the child accommodates to the abuse by learning to accept the abuse. This is achieved by mentally shifting the burden of blame from the perpetrator to the child. The child experiences significant internal conflict due to the contradiction between the perpetrator's image as a loving and protective caretaker versus the unfathomable nature of their acts of betrayal. Being unable to deal with the pain, the child succumbs to the mental torture and turns the blame on herself. She accepts the responsibility for the acts and makes attempts to continue to be "good" so as to ensure that she continues to

receive the abusing adult's love and protection. This she achieves by continuing to yield to the perpetrators sexual demands as well as by maintaining the code of secrecy and silence. The battled for internal control is often evident in the behavior of abused childs, which are usually characterized by "self-punishment, self-mutilation, selective restructuring of reality and multiple personalities [1]." The child then manifests these conflicts by an increased potential for suicidal behavior, sexual promiscuity, and frequent attempts to escape from the pain of abuse by running away.

Dr Summit postulated that the psychological reaction of male victims is often different from that of female victims of child sexual abuse. Unlike female victims, male victims usually externalize their internal conflict by becoming outwardly aggressive, violent, and antisocial. The male victim is more likely to view his abuse as mutually beneficial, which might lead to a continued wish for an "idealized relationship" with the perpetrating adult. This might ultimately lead the male victims to engage in their own acts of sexual molestation of other children or adults.

Delayed, Conflicted, and Unconvincing Disclosure

Dr Summit surmised that reporting sexual abuse is "the exception rather than the norm [1]." Most cases involving young children are reported either following incidental discovery by a third party or as a result of "sensitive outreach and community education [1, 3]" by child protective agencies. This usually happens when another concerned adult such as a schoolteacher or a neighbor observe physical or behavioral changes in the child that leads to suspicion. Upon questioning, the child might then hesitantly reveals the details of the abuse to investigating authorities. Dr Summit asserted that in adolescents, disclosure might occur following a period of intense conflict between the child and her family. As the adolescent victim matures and seeks outside relationships, the perpetrator (who is most often the father) becomes possessive and imposes strict rules aimed at "protecting" the child from "the dangers of outside peer involvement [1]." The child responds to this attempt to limit her freedom by becoming delinquent. This in turn leads to harsh punishment from the perpetrator. Anger and resentment then develops in the child, due to the inability to gain freedom. Disclosure usually occurs following an episode of severe punishment by the perpetrator. However, because of accommodation to the child's maladaptive pattern of delinquent behavior prior to disclosure, her credibility is questioned. The child's timing of disclosure after several years of abuse is often interpreted as retaliation for reasonable discipline issued by the perpetrator. This notion is reinforced by the lack of corroboration of the child's story by other family members.

Dr Summit described an alternative pattern of accommodation involving adolescents who divert their anger into positive avenues. Rather than becoming delinquent, these girls are usually successful both in their academic and personal lives. They are usually high achievers who are very popular with teachers and peers. When they finally decide, due to internal conflict, to disclose the details of their abuse, their story is often greeted with disbelief. The rationale is that it is impossible for a child to adjust so well after such a sordid experience.

Retraction

Dr Summit asserted that a child often reverses her initial reports of sexual abuse once the abuse has been reported to investigative and prosecuting authorities. At the initial point of disclosure, the child is not aware that her report has very grave consequences for her family. However, as the investigation proceeds and prosecutors and family members pressurize the child, she begins to question the wisdom in pursuing a course that could lead to the end of her family unit, as she has always known it. In an attempt to protect her family, the child assumes the role of a martyr and retracts her initial report. She then concocts an explanation that she had made up the story because she was angry about being punished by the perpetrator. In earnest, the child assumes the role of the villain while letting the perpetrator of the hook. Dr Summit cautioned, "Unless there is special support for the child and immediate intervention to force responsibility on the father, the girl will follow the 'normal' course and retract her complaint."

Historical Controversy Involving the CSAAS

Following the publication of Dr Summit's article in 1983, the CSAAS has been embroiled in legal controversy. At one point, the controversy was so intense that Dr Summit wrote in 1992, "The CSAAS is a clinical observation that has become both elevated as

gospel and denounced as dangerous pseudoscience [4].” This controversy arose from an initial misunderstanding of the scope and purpose of the CSAAS.

After Dr Summit published his epic article in 1983, there was some excitement in the legal community. This excitement was greatest amongst prosecutors and other authorities involved in the prosecution of perpetrators of child sexual abuse. The syndrome was misunderstood and considered to be analogs to the battered child syndrome (*see* **Battered Child Syndrome**), which described the classic physical and radiological findings associated with the children who have been the victims of prolonged, severe physical abuse. Since Kempe and his colleagues [5] expounded the features of the battered child syndrome in 1969, it has been a useful tool in the successful prosecution of child physical abuse cases. Hence the initial fantasy was that the CSAAS would achieve similar status in sexual abuse cases. However, the point missed was that the CSAAS was developed as a tool to assist clinicians to better understand the unusual presentation of some children who have been the victims of sexual abuse and not as a diagnostic tool. Unlike the battered child syndrome, the CSAAS does not present a set of physical or psychological characteristics that can help to confirm that a child has been sexually abused. Rather, it represents a set of observations that can help adults to better understand certain unusual aspects of child sexual abuse such as delayed disclosure and retraction after initially reporting details of the abuse.

The rash of expert witness testimony utilizing the CSAAS as proof of child sexual abuse resulted in skepticism amongst jurist and jurors. The fact that the syndrome was not widely understood and accepted within the psychiatric community did not help its reputation. The result was that there were many prolonged legal battles in various jurisdictions, which were settled in courts of higher authority in many states. Although no legal arguments involving the syndrome has ever been addressed by the United States Supreme Court to date, it has been the center of contention in numerous cases addressed by some state supreme courts.

Legal Applications of the CSAAS

In the United States, the CSAAS has been utilized mainly in the criminal prosecution of child sexual abuse cases. There is no indication that it has ever been the central issue in any civil disputes to date.

Judicial opinion on the admissibility of the CSAAS varies depending on jurisdiction and its legal application. The two most common standards for admitting expert testimony in the United States are the Frye test [6] and the Federal Rules of Evidence (FRE) 702 (*see* **Expert Opinion: United States**; ***Frye v. United States***; **Evidence: Rules of**; **Alcohol: Behavioral and Medical Effects**) [7]. The Frye test requires that the scientific basis for expert testimony be generally acceptable within the relevant field. On the other hand, the FRE 702 allows expert testimony if it will “assist the trier of fact to understand the evidence or to determine a fact at issue”. It outlines four requirements for admissibility of expert testimony based on the case of *Daubert v‘ Merrell Dow Pharmaceuticals, Inc* [8] (Daubert standard) (*see* ***Daubert v. Merrell Dow Pharmaceuticals***) namely

1. The scientific theory or technique has been tested.
2. The scientific theory or technique has been subjected to peer review and publication.
3. The scientific theory or technique has known or potential error rates and is subject to standards controlling its existence and maintenance.
4. The scientific theory or technique has general acceptance in the relevant scientific field (the Frye test).

Most of the legal analysis of the admissibility of the CSAAS has been related to its admissibility under the Daubert standards.

Admissibility to Support a Claim of Sexual Abuse

Many high courts in the United States have rejected expert testimony that utilizes the CSAAS to support a child’s claim of being sexually abused. In *State v. Foret* [9] a man was convicted of attempted molestation of a juvenile under his control, based on expert testimony that utilized the CSAAS to support the truthfulness of the victim’s claims. The conviction was affirmed by the Louisiana Court of Appeals but rejected by the Louisiana Supreme Court following a Daubert analysis. The Louisiana Supreme Court reasoned that the CSAAS was based on psychodynamic theories that are difficult to test. The court also noted that the CSAAS was not developed as

a diagnostic test for the detection of sexual abuse and that it was not generally accepted within the field of clinical psychology and psychodynamic theory from which it was developed. Similarly, the New Jersey Supreme Court rejected expert testimony that presented the CSAAS as substantive evidence that child sexual abuse occurred in *State v. J.Q* [10]. In that case, which involved the allegations by two sisters that their father sexually abused them, the court pointed out that the CSAAS was not diagnostic of child sexual abuse. Rather, the court suggested that expert testimony would have been admissible if had it had been used to demonstrate that delayed reporting and later recantation of an allegation of sexual abuse was not inconsistent with a history of such abuse.

Finally, in *Commonwealth v. Dunkle* [11], the Pennsylvania Supreme Court ruled that the CSAAS was not admissible for any legal purpose because it had not gained general acceptance in the particular field in which it belonged and because its symptoms were not specific to children who have been sexually abused.

Admissibility for Rehabilitation of Victim Credibility

Legal opinion varies on the admissibility of the CSAAS for the rehabilitation of the credibility of a victim of child sexual abuse. The majority view is that it is admissible for this purpose. The Delaware Supreme Court in *Wheat v. State* [12] addressed admissibility of the CSAAS to rehabilitate the credibility of a child victim of sexual abuse. In that case, a man was accused of sexually abusing his 10-year-old stepdaughter. The victim later recanted the abuse following pressure from the perpetrator's ex-wife, but insisted during trial that she was abused. Expert witness testimony was used by the prosecution to demonstrate that it was not unusual for children who have been the victims of sexual abuse to recant their stories under pressure from family members. The perpetrator appealed the jury's guilty verdict on grounds that expert testimony on the CSAAS should not have been admissible. Although the Delaware Supreme Court reversed the conviction, it ruled that expert testimony on the CSAAS to assist in rehabilitating the victim's credibility was admissible as it assisted the jury to better understand the behavioral characteristics of sexually abused child especially as it relates to the recantation of their initial claims of abuse.

On the other hand, the Pennsylvania Supreme Court rejected the use of the CSAAS in the rehabilitation of victim credibility in *Commonwealth v. Dunkle*. It ruled that victim credibility was the sole responsibility of the trier of fact and that was outside the domain of expert witness testimony.

Summary

The CSAAS was conceptualized to help mental health practitioners to better understand the abnormal behavioral characteristics of children who have been sexually abused. It has been misunderstood by some as diagnostic of child sexual abuse. This has led to its misuse in the prosecution of child sexual abuse cases. The overall effect is that it is now viewed with skepticism by some legal authorities. When properly applied, it can be used to rehabilitate the credibility of a child sexual abuse victim. It can also be used to assist Juries to better understand the contradictions in the victim's behavior. The general consensus is that it is not admissible as proof that allegations of abuse are true.

Children: as Defendants

Introduction

In the past, numerous legal systems, including the United States', have recognized that juvenile offenders should be treated differently than adult offenders, particularly with regard to criminal responsibility.[a] Despite a lack of systematic research to support this notion, these legal systems recognized that because of juveniles' developmental immaturity, they were inherently more impulsive, exhibited worse judgment, and were therefore less blameworthy than adults who committed similar acts. Through the concept of "penal proportionality", they were subsequently subject to less harsh penalties. Society's withholding of certain privileges until youth reached certain ages provided additional implicit support for this line of reasoning and the eventual establishment of a separate juvenile justice system to both adjudicate and rehabilitate juveniles.

The first juvenile court in the United States was established in 1899 in Chicago by the Illinois legislature and Progressive reformers. These reformers viewed juveniles as having diminished (or absent) culpability and more malleable, "unformed character" than adult offenders. Therefore, the juvenile courts initially focused primarily on rehabilitation rather than the other penal objectives, namely incapacitation (i.e., the protection of society), deterrence (both specific (that offender), and general (other potential offenders)), and retribution. *Parens patriae* (literally "parent of the state") rather than *police power* was the operative doctrine. Proceedings were typically less adversarial and more informal than in adult criminal court and tended to focus on the nature of the offender rather than the offense itself. Prosecutors, defense attorneys, and judges often worked in a collegial manner in order to serve the best interests of the youth. Because the court fashioned itself strictly rehabilitative and proceedings were considered civil rather than criminal in nature, due process protections were generally not considered important.

In their first 65 or so years of existence in the United States, juvenile courts generally operated unfettered by constitutional mandates that applied to adult criminal court proceedings. Judges had a great deal of discretion with regard to almost every aspect of delinquency proceedings (including the ultimate disposition of youths adjudicated delinquent) and there were some abuses of power. Because of these abuses, the lack of due process protections in juvenile court proceedings was challenged in a number of court cases in the 1960s. The U.S. Supreme Court's ruling in *In re Gault* (1967) extended due process protections to delinquency proceedings [1]. The subsequent (and necessarily altered) version of the juvenile justice system probably acknowledged more accountability in youths than its prior incarnation. Nonetheless, the special character and mission of the juvenile justice system were, for the most part, preserved.

However, over the past 20 years, there has been a fundamental change in the way juvenile defendants are viewed by and subsequently have interacted with the legal system. What happened and why? In the late 1980s, there was a marked increase in the rate of crimes committed by juveniles, particularly homicide. Over time this led to a change in the public perception of minors involved in the juvenile justice system. These youths began to be seen as budding psychopaths who needed adult punishment rather than troubled children in need of rehabilitation. Catchy slogans such as "adult time for adult crime" and "old enough to do the crime, old enough to do the time" were promulgated.

Subsequently, a great deal of public pressure was put on state and federal legislators to use juvenile courts (and adult criminal courts) as mechanisms for social control (i.e., protecting the public) rather than rehabilitation of juvenile offenders. Juveniles began

to be transferred (also known as *waived*) to adult criminal court at much higher rates. There they faced adult sentences potentially as harsh as life without parole or death (at least until the 2005 US Supreme Court decision in *Roper v. Simmons*) [2]. Those lucky enough to remain under juvenile court jurisdiction faced much stiffer sanctions there (e.g., in California, incarceration up to age 25). In short, juveniles were forced to negotiate an increasingly unforgiving juvenile justice system or an adult criminal justice system that was not designed or prepared to deal with them. The latter did not have experience with the unique challenges that psychosocial immaturity and "unformed character" presented with regard to the adjudicative process (which encompasses all proceedings from initial arrest through sentencing) and criminal responsibility.

Although the proverbial pendulum may have started to swing back over the past decade because of a variety of factors [3], this sort of thinking is still evident in a great many jurisdictions.

There has been a positive, albeit unforeseen result of society's shift to a more punitive stance toward juvenile offenders: renewed attention has been brought to juveniles' developmental immaturity and its subsequent potential effect on their abilities to understand and participate meaningfully in the adjudicative process (a general definition of adjudicative competence). Concerns about juveniles' adjudicative competence certainly existed previously (particularly after the *Gault* decision). However, because of the less adversarial nature of juvenile proceedings and the less severe penalties faced by juveniles in the past, the potential effects of their developmental immaturity on the fundamental fairness of the adjudicative process were not thoroughly explored and quantified until quite recently. Recent studies have raised serious doubts about many juvenile defendants' abilities to understand pretrial and trial proceedings and to participate meaningfully in their defense, particularly those who are young and have lower IQs [4].

With this background in mind, we can now consider what light the existing, mostly recent, literature can shine on the topic "children as defendants" by considering the following questions:

- What are the characteristics of almost all juveniles that make their negotiating the current legal systems (both juvenile courts and adult criminal courts) potentially difficult?
- What are additional characteristics of juveniles likely to become involved with the justice system that may make their navigating the same legal systems even more daunting?
- How do (or should) these characteristics or limitations affect different components of the adjudicative process (including disposition/sentencing)?

Adjudicative Competence and Culpability: Limiting Factors

The juvenile adjudicative process can be started and completed in either juvenile court or adult criminal court and movement between the two venues is not uncommon (e.g., a juvenile initially under juvenile court jurisdiction can be transferred to adult criminal court or *vice versa*) (*see also* **Juvenile Justice: Transfer to Adult**). Typically, those minors transferred to (or "directly filed on" in) adult criminal court are 13- to 17-year-old and have been charged with serious crimes. If convicted, they face potentially lengthy sentences. "Amenability to treatment" or "rehabilitative potential" is usually cited as the most important criterion in determining "juvenile fitness" (i.e., whether a minor remains under juvenile court jurisdiction). However, issues of culpability are implicit in the decision to try a minor in adult criminal court (i.e., if a minor is facing adult sanctions, he must be as responsible for his actions as an adult).

Numerous features of juveniles (some of which are listed below) may influence their adjudicative competence and culpability. Obviously, given the potential jeopardy juveniles face in adult criminal court, it is extremely important to consider these factors in order to protect these defendants' various trial-related rights (e.g., 6th and 14th Amendment rights, right to be competent to stand trial, etc.) and to ensure that the punishment meted out is consistent with the blameworthiness of the perpetrator. However, these factors also need to be considered even in minors who remain under juvenile court jurisdiction. Although these individuals may be facing less serious sanctions, the aforementioned features are, in most cases, more descriptive of these younger juveniles and/or have a larger impact on their adjudicative competence and culpability.

General Developmental Immaturity

Society has long recognized that juveniles are generally more impulsive, more susceptible to peer pressure, more prone to immediate gratification, and more likely to engage in risky behavior than adults (*see also* **Juvenile Justice: Adolescent Development**). For this reason, individuals are generally precluded from participating in certain activities until they reach certain ages (e.g., driving, entering into contracts, serving in the military, and consuming alcohol).

Recently, researchers have begun to define more precisely particular domains of "impairment", quantify the degree of these impairments by age, and examine how these impairments may affect the adjudicative process and potentially impact criminal responsibility. Most adolescents manifest deficits in the following areas:

1. **Risk appraisal:**

Adolescents tend to discount and undervalue risk.

2. **Time perspective:**

Adolescents tend to care more about short-term consequences than long-term consequences and are less "future-oriented" than adults.

3. **Peer influence:**

Adolescents are much more likely than adults to be subject to and succumb to peer influence.

4. **Abstract thinking:**

Children and adolescents' perceptions and decisions may be based on overly concrete ideas; they may view rights as discretionary or conditional as opposed to automatic and inalienable.

5. **Perceived autonomy:**

Children and adolescents' lack of perceived autonomy can manifest itself as passivity, inattention, or compliance with authority.

6. **Stability of "character":**

Coherent integration of various elements of identity does not occur until early adulthood under the best of circumstances; adolescent antisocial behavior is extremely common and only a small percentage of adolescents continue this behavior into adulthood [5].

With regard to the above, Fried and Reppucci [6] demonstrated that resistance to peer influence, temporal perspective, and risk appraisal all had nadirs at approximately age 15–16. Interestingly, this is approximately the age at which the arrest rate peaks for both violent and nonviolent crime.

Neuroimaging has also proved a powerful tool in providing an anatomical explanation for at least a portion of these impairments. For example, Gogtay *et al.* [7] showed that central nervous system pruning in children and adolescents (a proxy measure of neuroanatomical maturity) proceeded in a parietal-to-frontal direction and that pruning continued until at least age 21 (this was the oldest individual examined). He also noted that the dorsolateral prefrontal cortex (sometimes referred to as the "superego" of the brain) did not *start* to prune until the end of adolescence. Bartzokis *et al.* [8] found that myelin volumes in the frontal and temporal lobes (another measure of neuroanatomical maturity) did not peak until age 45–50.

Mental Disorders

Youths in the juvenile justice system evidence much higher rates of mental disorders than youths in the general population. Approximately 66% of juvenile pretrial detainees or delinquents meet the Diagnostic and Statistical Manual of Mental Disorders-Fourth Edition (DSM-IV) criteria for a mental disorder (including substance abuse/dependence or conduct disorder), though not all of these individuals require treatment [9].

In their meta-analysis studies involving juvenile justice populations, Otto *et al.* [10] noted high prevalence rates of mental disorders (see Table 1). Similarly, in a more recent study, Teplin *et al.* (see Table 2) noted relatively high rates of specific mental disorders in youth in Cook County, Illinois juvenile detention facilities.

Table 1 Prevalence of mental disorders amoung youth in the juvenile justice system

Conduct disorder	50–90%
ADHD	19–46%
Substance abuse	25–50%
Personality disorders	2–17%
Mental retardation	7–15%
Learning disorders	17–53%
Mood disorders	32–78%
Anxiety disorders	6–41%
Psychoses and autism	1–6%

Table 2 Six-month prevalence and odds ratios (ORs) of *DSM-III-R* diagnoses by sex with and without diagnosis-specific impairment criteria[a]

Disorder	Male, % (95% CI) ($n = 1170$)		Female, % (95% CI) ($n = 656$)		Female–Male ORs (95% CI)	
	Diagnosis	Diagnosis with impairment	Diagnosis	Diagnosis with impairment	Diagnosis	Diagnosis with impairment
Any of the listed disorders	66.3 (61.6–70.7)	63.3 (58.6–67.8)	73.8 (70.1–77.1)	71.2 (67.5–74.7)	1.43 (1.09–1.88)	1.43 (1.10–1.87)
Any except conduct disorder	60.9 (56.2–65.5)	59.7 (54.9–64.3)	70.0 (66.2–73.5)	68.2 (64.4–71.8)	1.49 (1.15–1.94)	1.45 (1.12–1.88)
Any affective disorder	18.7 (15.2–22.8)	16.1 (12.8–20.0)	27.6 (23.6–32.0)	22.9 (19.0–27.2)	1.66 (1.20–2.29)	1.55 (1.09–2.20)
Major depressive episode	13.0 (10.0–16.6)	11.0 (8.3–14.5)	21.6 (17.8–25.9)	18.9 (15.2–23.2)	1.85 (1.27–2.70)	1.88 (1.25–2.82)
Dysthymia	12.2 (9.3–15.8)	9.9 (7.3–13.2)	15.8 (13.1–18.8)	12.5 (10.2–15.3)	1.34 (0.93–1.95)	1.31 (0.87–1.96)
Manic episode	2.2 (1.1–4.3)	2.0 (1.0–4.1)	1.8 (1.0–3.2)	1.2 (0.6–2.4)	0.81 (0.33–1.99)	0.58 (0.21–1.63)
Psychotic disorders	1.0 (0.4–2.6)	–	1.0 (0.5–2.1)	–	0.98 (0.30–3.25)	–
Any anxiety disorder	21.3 (17.6–25.6)	20.7 (17.0–24.9)	30.8 (27.2–34.6)	28.9 (25.5–32.7)	1.64 (1.22–2.20)	1.56 (1.16–2.10)
Panic disorder	0.3 (0.1–0.6)	0.1 (0.0–0.4)	1.5 (0.8–2.7)	1.0 (0.5–2.0)	5.65 (2.04–15.65)	8.13 (2.01–32.85)
Separation anxiety disorder	12.9 (9.9–16.5)	10.8 (8.1–14.2)	18.6 (15.7–21.9)	16.3 (13.6–19.4)	1.55 (1.08–2.21)	1.61 (1.10–2.34)
Overanxious disorder	6.7 (4.6–9.7)	5.9 (4.0–8.7)	12.3 (9.9–15.1)	11.5 (9.2–14.2)	1.95 (1.23–3.10)	2.06 (1.27–3.35)
Generalized anxiety disorder	7.1 (4.9–10.2)	6.4 (4.3–9.4)	7.3 (5.6–9.6)	6.8 (5.1–9.0)	1.03 (0.63–1.69)	1.07 (0.64–1.79)
Obsessive-compulsive disorder	8.3 (6.1–11.3)	–	10.6 (8.4–13.2)	–	1.31 (0.86–2.00)	–
Attention-deficit/hyperactivity disorder[b]	16.6 (13.3–20.5)	11.2 (8.5–14.6)	21.4 (18.4–24.8)	16.4 (13.7–19.5)	1.37 (0.99–1.89)	1.55 (1.07–2.25)
Any disruptive behavior disorder	41.4 (36.8–46.2)	31.4 (27.2–36.0)	45.6 (41.4–49.8)	38.0 (33.9–42.2)	1.19 (0.92–1.53)	1.33 (1.02–1.75)
Oppositional-defiant disorder	14.5 (11.4–18.2)	12.6 (9.8–16.2)	17.5 (14.7–20.6)	15.1 (12.5–18.1)	1.25 (0.89–1.76)	1.23 (0.86–1.76)
Conduct disorder	37.8 (33.3–42.6)	24.3 (20.5–28.5)	40.6 (36.5–44.8)	28.5 (24.6–32.8)	1.12 (0.86–1.46)	1.24 (0.92–1.67)
Any substance use disorder	50.7 (45.9–55.5)	–	46.8 (42.6–51.1)	–	0.86 (0.66–1.11)	–
Alcohol use disorder	25.9 (21.9–30.4)	–	26.5 (22.6–30.9)	–	1.03 (0.76–1.40)	–
Marijuana use disorder	44.8 (40.1–49.6)	–	40.5 (36.8–44.4)	–	0.84 (0.65–1.08)	–
Other substance use disorder	2.4 (1.7–3.4)	–	6.9 (4.1–11.4)	–	3.00 (1.57–5.74)	–
Both alcohol and other drug use disorders	20.7 (17.0–24.9)	–	20.9 (18.0–24.2)	–	1.01 (0.75–1.38)	–

[a] CI indicates confidence interval. Ellipses indicate that diagnosis and diagnosis with impairment are identical because the diagnosis criteria for psychotic dis obsessive-compulsive disorder, and substance use disorders include impairment

[b] Attention-deficit/hyperactivity disorder is without the criterion of onset before age 7 years because caretaker information is not available and self-resymptoms before age 7 years unreliable

Many youths with these mental disorders will meet minimum thresholds for adjudicative competence and criminal responsibility. However, these disorders frequently impact both the effectiveness of these youths' participation in the trial process and their culpability, particularly when considered in conjunction with their baseline developmental immaturity.

Generally, mental disorders have been thought to have less impact on the adjudicative process than developmental immaturity. Many scholars postulate that this is because psychotic disorders are relatively rare in minors (with a mean age of onset in the late teens or early 20s), whereas developmental immaturity is almost ubiquitous in juveniles. In a later section, we will examine how different mental disorders may impact specific stages of the adjudicative process.

Substance Use Disorders

Youths in the juvenile justice system have rates of substance use disorders (i.e., abuse or dependence) approximately 25 times higher than youths in the general population (50 *vs.* 2%) [9, 11]. Comorbid psychiatric disorders are the rule rather than the exception. As with adults, acute intoxication, withdrawal phenomena, and substance-induced psychiatric disorders (which may include psychotic disorders) can affect various stages and aspects of the adjudicative process. However, because youths' brains are still developing and immature, substance use may impact their capabilities even more than adults.

Effects related to substance use may also impact juveniles' culpability. Although acute intoxication generally disqualifies a defendant from utilizing the insanity defense, it may be germane to questions of mitigation or diminished capacity/actuality (i.e., did the defendant form the intent required to be convicted of the crime? (e.g., "premeditation" for first-degree murder)). Youths who demonstrate "settled psychosis" (i.e., psychotic symptoms that persist after acute intoxication) could potentially utilize the insanity defense.

Intelligence

For a variety of reasons, the average IQ of youths involved in the legal system is at least one standard deviation (i.e., 15 points) below that of youths in the general population. Most studies have found the mean IQ of juvenile justice populations to be 80–85. In a study of juvenile adjudicative competence, Ficke *et al.* [12] found that their 9- to 16-year-old detained study participants had an average IQ of 73. According to Otto's data, the rates of mental retardation (i.e., an IQ $\leq$ 70 and particular deficits in adaptive functioning) are approximately three to eight times higher than the rates in the general population.

Obviously, sub-average intelligence can have a significant impact on both the adjudicative process and culpability. The latter was recognized explicitly in the 2002 U.S. Supreme Court decision in *Atkins v. Virginia* [13], which banned the execution of the mentally retarded on Eighth Amendment grounds.

Other Factors

In addition to higher rates of substance use disorders and other mental disorders, youths in the juvenile justice system also have higher rates of head trauma, prenatal exposure to drugs and alcohol, attachment disorders arising from problems in infancy, dysfunctional and chaotic families and neighborhoods, and exposure to violence and abuse. It has not been systematically established whether or not these factors independently and appreciably impact either these individuals' ability to participate meaningfully in the adjudicative process or their culpability. However, it is certainly reasonable to suspect that these factors may exacerbate or even cause deficits in these domains.

Effects of Selected Factors on Different Aspects of the Adjudicative Process and Culpability

Arrest and Interrogation

Because of their developmental immaturity and lack of experience, youths are likely to view their rights (e.g., the "right to remain silent") as conditional and discretionary rather than automatic and inalienable. They are also more likely to trust and obey authority figures. These observations are not surprising. Juveniles' abilities to think abstractly may not be fully developed (e.g., they may be unable to conceptualize a "right") and children are frequently socialized both to "tell the truth" and believe that "the police are your friend." This trust and lack of sophistication

may not adversely impact these youths in their everyday lives and may in fact serve them well. However, these same characteristics can become liabilities in dealing with a police interrogation, particularly if the youth is charged with a serious crime.

In the previously cited MacArthur study, when youths were faced with a hypothetical interrogation situation, approximately 50% of 11- to 13-year-olds was their best interrogation choice ("talk/admit" rather than "talk/deny" or "remain silent") [4]. In the same study, only 15% of 18- to 24-year-olds thought this was the best option. Similarly, Grisso [14] found that only 40% of adolescents recognized that they would not have to make statements about their offense even if a judge ordered them to do so.

Other Pretrial Proceedings and Trial

Age (a proxy for developmental maturity), intelligence, and mental disorders can all significantly impact a juvenile's understanding, reasoning, and appreciation related to pretrial proceedings and the trial itself. The MacArthur study found that age and IQ were the variables most closely tied to scores on a standardized competence assessment instrument (the MacArthur Competence Assessment Tool-Criminal Adjudication (MacCAT-CA)). Approximately 30% of 11- to 13-year-olds and 19% of 14- to 15-year-olds scored below the "clinically significant impairment" threshold on the MacCAT-CA and would likely have been found incompetent. Over 50% of 11- to 13-year-olds in the "detained" sample with IQs between 60 and 74 scored below this threshold [4].

In addition to age, intelligence, and psychotic disorders, numerous other untreated or inadequately treated mental disorders in juveniles can also significantly impact pretrial and trial proceedings. For example:

Attention-Deficit/Hyperactivity Disorder (ADHD):

Juveniles may not be able to adequately attend to conversations with their attorneys or to court proceedings. Their courtroom demeanor may also be adversely affected.

Social Anxiety Disorder:

Juveniles may not even agree to meet with their attorneys and may have extreme difficulty tolerating open court.

Depression:

Juveniles may not have the motivation to defend themselves. In the past (i.e., before *Roper v. Simmons*), suicidality had been a factor in some death penalty cases.

Pervasive Developmental Disorders (e.g., Autistic Disorder, Asperger's Disorder):

Juveniles may appear to lack remorse or empathy for the alleged victim (can also be factor at sentencing/disposition).

Culpability

All of the aforementioned factors may diminish juveniles' culpability and subsequent deserved punishment. Researchers are beginning to uncover evidence of the neurobiological basis of this developmental immaturity and are gathering evidence about adolescents' impaired decision making in hypothetical criminal situations. In response to both this growing database and recently rediscovered common sense notions about the psychosocial immaturity of juveniles, courts and legislatures are beginning to reassess how minors interface with and are treated by the juvenile justice and adult criminal justice systems.

A variety of individuals can consider any or all of these factors at various junctures in the adjudicative process: the police when they initially detain the youth; the district attorney when he or she decides whether to file charges in juvenile or adult criminal court; the judge when determining whether to divert the juvenile's case to "drug court" or "mental health court;" the trier of fact when they decide about issues related to diminished capacity/actuality (more germane for substance use issues); and the same trier of fact when considering mitigating factors at sentencing. Hopefully, research and evidence rather than politics and fear will drive these individuals' decision processes.

Minors in Adult Criminal Court: Final Thoughts

It is important to note that some degree of adolescent antisocial behavior is normative. Arrest rates for violent and nonviolent crime peak around the age of 16 or 17, decrease quickly and linearly until age 30, and then continue to decrease each year thereafter,

albeit more slowly [5]. What does this mean? Adolescent antisocial behavior generally does not persist into adulthood and is, by definition, "adolescent-limited". As contingencies change and neurological maturation progresses, the vast majority of adolescents are able to desist from their criminal behavior. However, there is a small subset of individuals who engage in "life-course-persistent" antisocial behavior.

Incarcerating individuals for lengthy periods imposes a tremendous cost on society, both directly (e.g., cost to house inmate) and indirectly (e.g., institutionalization, loss of employment opportunities because of criminal record). These costs may be justified in order to protect society or serve other legitimate penological interests. However, it is questionable whether indiscriminately incarcerating minors for extended periods serves these penological interests. Is severe, inflexible punishment (i.e., retribution) a legitimate penological objective if the actor is less blameworthy (or, in extreme cases, not culpable at all)? Is incapacitation necessary if the antisocial behavior is likely to cease even without specific interventions?

Essentially, we must learn to be more selective in waiving juveniles to adult criminal court. How can this be accomplished? We need to become more sophisticated in our understanding of the genesis and maintenance of juvenile antisocial behavior. We need to develop and employ instruments that can more accurately predict which juveniles are likely to continue offending as adults (particularly violently offending). We need to examine the validity and predictive value of the concept of juvenile psychopathy. Research in this area is ongoing and will hopefully lead to more just legal outcomes for minors, help protect the general public and preserve the dignity and integrity of the legal process.

End Notes

[a.] For sake of ease, the terms *child, adolescent, youth, juvenile*, and *minor* are used interchangeably in this article. However, the reader should note that each has a slightly different definition and connotation. The terms *criminal responsibility* and *culpability* are also used interchangeably with the same caveats.

Children: as Witnesses

Each year, thousands of children participate as witnesses in the legal system. Although they may bear witness to many types of crimes, in the criminal courts they are most often involved as alleged victims of child sexual abuse (CSA). In fact, despite constituting only 10% of the 3 million annual reports of child maltreatment to child protective services, CSA cases account for the majority of criminal trials in which children testify. Child victim testimony is often the main evidence in CSA cases. Thus, child witness accuracy is of great concern to psychologists, lawyers, judges, and society as a whole. As is true for eyewitness testimony generally, inaccurate accounts by children can lead to false convictions. Yet if accurate accounts are disregarded because of the witness's age, guilty perpetrators could be free to commit future crimes. Of course, both undiscovered cases of actual abuse and convictions based on false accusations are serious injustices. It is therefore important to understand, from a scientific perspective, the accuracy of child eyewitness testimony.

Research on Children's Testimony

Research conducted at the beginning of the 20th century led to the conclusion that children were particularly unreliable, highly suggestible witnesses. However, much of the early research lacked ecological validity and was arguably not fully applicable to actual legal cases involving children. Eighty years later, with an increase in CSA reports (including high profile convictions of day care providers who were accused by preschoolers of ritualistic sexual abuse but later exonerated), psychological interest in children's eyewitness accuracy and suggestibility drastically increased (*see* **Children: Suggestibility of**). Some researchers were most concerned about the need to obtain reports of child abuse from actual child victims who needed protection but were reluctant to disclose abuse, whereas other researchers were most concerned about controversial cases resting upon possibly false accusations fanned by forensic interviewers' suggestive and widely criticized interview techniques. Scientific research on children's eyewitness testimony has clarified many of the issues of concern surrounding children's memory and suggestibility, although some topics remain subject to scientific debate. Important recent research that is more directly applicable to cases involving child witnesses can help ensure that accurate testimony is provided in true cases as well as false cases of child abuse.

Modern researchers have discovered a host of factors that influence child witness accuracy, including child age and individual differences, social circumstances, interview characteristics, and so forth. An important goal is to understand these factors, and use this understanding to aid the legal system by, for example, developing interview techniques that encourage accurate eyewitness reports from children.

Researchers have examined children's eyewitness testimony abilities by questioning children about documented traumatic and nontraumatic events. Studies reveal that younger children, especially preschoolers, are typically more suggestible than older children and adults; that is, on average, younger children are more likely to incorporate into their own reports incorrect information contained in an interviewer's questions.

Eyewitness memory can be affected by children's level of stress at the time of the event or at the time of recall. Children are particularly prone to error, for example, when they are young (e.g., 3- to 4-years-olds); exposed to misleading questions asked by a biased, coercive, or intimidating interviewer; positively reinforced for incorrect responses; asked to identify strangers from target-absent photo lineups; and asked about peripheral details of events or about events that happened in the distant past. An issue of scientific and applied interest is whether false suggestions actually change children's memory or simply their reports of an event (i.e., social compliance). Both might be possible. In documented controversial multivictim CSA cases that were arguably false,

anecdotal evidence reveals that some alleged victims recanted their claims years later, recalling that they were pressured to make accusations and lied rather than having false memories, but others maintained their allegations. Experimental research has shown that when questioned in extremely suggestive ways, some children appear to incorporate the misleading and inaccurate information into their memory, although many do not (e.g., when confronted with the truth about an event).

Child Forensic Interviews

Researchers have been successful in translating research findings into useful methods for interviewing suspected child abuse victims. In particular, research has led to the creation of developmentally appropriate, research-based forensic interview protocols. The acceptance of such protocols by social service and law enforcement agencies has made highly suggestive interviews the exception, not the norm, in actual forensic investigations of child abuse. Forensic interviews, often one of the earliest interactions between the alleged abuse victim and the legal system, are used to determine whether the child has been abused and to gather information about the circumstances surrounding the abuse. Information gained from this interview is critically important in determining case disposition, from taking no action in unsubstantiated cases, to removing children from possible harm in the home and/or pursuing a case to trial in substantiated cases. There are a number of forensic interview protocols, including the Step Wise Interview, the National Institute of Child Health and Human Development (NICHD) child interview protocol, and others, but all share basic elements such as recommending that children be questioned with developmentally appropriate language and with open-ended, nonleading questions to the extent possible. Many use a phased approach, starting with introductory phases – such as introduction and rapport building, a developmental assessment (including learning the child's names for different body parts), a discussion of interview guidelines of truth versus lie – before moving to open-ended prompting designed to obtain a child's narrative description of the events under investigation, and then more specific or cued recall follow-up questions, if necessary. The use of props during the interview, such as anatomically detailed dolls, anatomical drawings and diagrams, dollhouses, and puppets is usually discouraged altogether or at least until the end of an interview that has not yet yielded a disclosure. Even then, their use is recommended in conjunction with nonleading questions.

Generally, child forensic interviewers are trained to remain objective and use open-ended questions to improve child witness accuracy. For example, forensic investigators allow children to recall information freely in response to open-ended, nonleading questions (e.g., "What happened while you were in the house?"); then follow up with more specific or focused questions about the details children mentioned. Forensic interviewers use socially supportive interviewing techniques, which include building rapport with the child and providing emotional warmth and support throughout the interview while remaining neutral. Research demonstrates that children questioned in a socially supportive manner are more resistant to misleading questions than those questioned in an intimidating way. This is a particularly useful finding to the field of forensic interviewing, because unlike a child's age, cognitive development, or temperament, the interviewer's social support is easily controlled.

Some interview techniques are controversial; for example, multiple interviews of children over time rather than once. In actual cases, however, children sometimes disclose after several interviews. Research illustrates that multiple, highly misleading and coercive interviews can erode children's accuracy over time, although they do not necessarily do so. Multiple interviews conducted in a recommended manner can result in increased accuracy.

Accommodating Children's Testimony in the Forensic Context and Courtroom

Child advocacy centers (CACs) can aid children who find themselves involved in the legal context. CACs are "one-stop shops" where children who are victims of alleged maltreatment can often receive services from social workers, police officers, prosecutors, and physicians all at one location. Forensic interviews are conducted at these locations by trained interviewers, and the interview is observed by authorities (e.g., police and prosecutors) from behind a one-way mirror to ensure that all necessary questions are asked. In some jurisdictions, interviews are videotaped, and

these tapes can be used under certain circumstances at preliminary hearings or trials. CACs potentially decrease the number of times children need to be formally interviewed. By centralizing the resources and investigation, CACs aim to reduce child stress and provide necessary services as fast as possible.

Many legal cases involving children are resolved through confessions, settlements, and plea bargains. Only a relatively small percentage of cases go to trial. For those cases that do continue to trial, a number of hearings will be held, some of which may involve the children testifying. Testifying in court can be stressful for adults, not to mention for vulnerable children. Facing the accused perpetrator, experiencing harsh and confusing cross-examination designed to discredit their accounts, and having to provide testimony about personal and possibly embarrassing events in open court are just some of the factors contributing to children's fears and anxiety about the courtroom. Studies have shown that testifying multiple times is associated with emotional distress in both the short and long term, especially in severe intrafamilial CSA cases. Furthermore, although testifying can be helpful for some children, for others it may cause a delay in emotional recovery. There is also concern about how the stress caused by courtroom testimony will affect children's memory reports and accuracy. Several procedural reforms have been studied as potential ways to make testifying less stressful for children while bolstering the accuracy of their memory reports, with the additional goal of promoting fair trials for defendants.

One way to reduce many children's fears and anxiety is to allow them to present testimony in a manner that does not require them to face the defendant. Several methods to avoid face-to-face confrontation have been studied. Special legal exceptions sometimes allow adults who recount a child's out-of-court statements to testify in place of an alleged child victim. In light of Crawford v. Washington, however, the child must to be available for cross-examination at trial. Such testimony is considered hearsay. Videotaped forensic interviews of children are also considered hearsay evidence; presenting the videotape at trial can reduce anxiety in children by preventing them from having to testify in open court. However, at least in the United States, in light of the Crawford v. Washington decision, if the hearsay statements are made to an "authority", they are deemed "testimonial" and cannot be entered as evidence in criminal court trials unless the child also appears. In contrast, in many other countries, such hearsay is regularly admitted without the need for children to take the stand.

Child testimony via closed-circuit television (CCTV) has also been proposed to protect children from seeing the defendant face-to-face. This technique can reduce children's anxiety as well as increase their memory report accuracy. The US Supreme Court ruled that this method can be used at trial after a case-by-case determination by the judge, at least in certain CSA cases. Using CCTV for children is quite limited in the United States, although it is more common in several other countries (e.g., the United Kingdom).

Jurors' Reactions to Child Witnesses

From a legal perspective, even if children's memory reports are sometimes flawed, as long as fact finders (e.g., jurors) can reach the truth, justice is served. From the initial police investigation and forensic interview to the courtroom, adults must decide whether children's reports are accurate. Research shows that many adults have a difficult time making this judgment. This is not surprising, because adults are often poor detectors of lies and truth, accuracy and inaccuracy. Researchers have studied factors aside from actual accuracy that influence adults' perceptions of children's credibility, with the goal of understanding how jurors make decisions in cases involving child witnesses. This research reveals that victim, juror, and case characteristics all influence jurors' judgments. For example, in CSA cases, jurors in mock trial studies often perceive younger children and children with mild intellectual disabilities as more credible than older children and children without disabilities, because young and disabled children are believed to be particularly honest, sexually naïve, and lacking in the cognitive abilities thought to be necessary for fabricating false charges. If highly suggestive interviewing of young children is demonstrated, however, younger children's credibility may fall below that of older children. Juror characteristics, such as gender, also influence perceptions of children's accuracy. Compared to men, women on average have more empathy for child victims, react more negatively to CSA, and believe children's reports more often. In turn, women tend to

be more punitive in their case judgments than men. Furthermore, when made known to fact finders, certain defendant characteristics, such as having a record of past offenses, can also increase the likelihood of convictions.

Courtroom factors also influence jurors' judgments. For example, courtroom innovations such as allowing children to testify via CCTV rather than in open court can lower jurors' belief in children's testimony. Children may appear more distant or perhaps more relaxed when testifying in this alternative manner, in the latter case, violating jurors' expectations that actual child victims will be upset during testimony. Expert testimony from psychologists can be useful in educating jurors about such issues.

Future Directions in Child Witness Research

The newest research directions include work focused on understanding individual differences in children's eyewitness memory and their responsiveness to various forensic interview techniques. For example, research has shown that some children may benefit more from socially supportive interviewing techniques than others. Most likely to benefit are children who have a low level of social support from friends and family, are insecurely attached to their caregiver, and are highly reactive physiologically to stressful situations. Research has also begun to use sophisticated neuroscience methods to understand the physiology of memory and suggestibility. In addition, researchers are currently addressing controversies regarding the ways in which children initially disclose CSA, and whether children delay and recant accusations. That is, although the media often focus on false reports of child abuse, a larger problem likely is that most abused children never disclose that they were sexually abused. Evidence of nondisclosure comes, for example, from research on nondisclosure in cases where there is incontrovertible evidence of abuse, such as the child having a sexually transmitted disease. Due to lack of disclosure, most cases of CSA are never investigated by authorities. Children fail to disclose, for example, because they are embarrassed, afraid of losing their family, afraid of retribution, or because they do not even understand that the abuse is wrong. Further, some children who disclose may later recant, especially children who are younger, who have experienced intrafamilial abuse, and who have unsupportive caregivers.

Because individual differences exist across children in disclosure and memory, it is essential that the legal system is flexible in providing a supportive environment in which children can testify fully and accurately, based on children's abilities and needs. The court must carefully guard these young witnesses while still protecting the rights of those accused.

Children: Cross-Examination of

see Cross-Examination: Impact on Testimony

Children: Suggestibility of

Within the field of psychology and law, the term *children's suggestibility* typically refers to the extent to which internal and external factors can inadvertently or intentionally induce children to adopt and incorporate misinformation into their memory reports. Concerns about children's suggestibility are common in legal cases that rely heavily on children's eyewitness memory, such as in prosecutions of child sexual abuse and in custody cases involving allegations of child maltreatment. (*see* **Children: as Witnesses**).

Such concerns are especially prominent when there is no evidence aside from the child's statements and when the child may have been questioned in a leading manner (e.g., by a parent, clinician, or forensic interviewer). Although researchers debate the extent to which suggestion actually alters memory (e.g., having an existing memory overridden by a new one, or creating a brand new but false memory for an event that never took place), it is clear that individuals' eyewitness memory reports are susceptible to adverse effects of social influence. Either way (from memory change or social influence), a false report can result.

Both adults' and children's reports about their eyewitness memories can be altered or affected through the use of suggestive techniques, but young children (e.g., preschoolers) are, on average, especially vulnerable to the effects of misinformation and suggestion. However, children in general tend to be less suggestible about negative taboo events than positive or neutral events, although it is still possible to mislead at least a subset of children about highly negative incidents, including ones that are implausible. Children's increased resistance to suggestion about negative events is especially relevant in a forensic context because, in the legal system, children are typically asked to provide eyewitness reports about negative experiences.

The length of time between an event and the first interview, as well as the number of subsequent interviews, may influence children's suggestibility and thus the accuracy of their reports. When memory is still fresh, resistance to suggestion is increased, albeit not eliminated. In terms of accuracy, it is best for children to be interviewed as quickly as possible after the event by a trained neutral interviewer. However, if children have been severely traumatized, the optimal delay may be less clear. Although repeated interviewing can increase the amount of information provided, it can also increase suggestibility if, for example, children's memory is weak and multiple misleading influences are placed on the children.

Suggestibility and Interview Techniques

To reduce suggestibility in the forensic setting, it is important to conduct appropriate interviews with children. Although children may fall victim to suggestive influences in the home (e.g., by emotionally motivated or well-intentioned caregivers) or in other contexts outside of a legal setting, clinicians, lawyers, and forensic interviewers should attempt to obtain accurate information by reducing misleading questions in child interviews. Researchers have examined interview techniques that contribute to children's suggestibility, and specifically to children's false reports. Researchers have also evaluated ways to question children about events in non or less-suggestive manners in hopes of developing optimal interview strategies for child witnesses.

In regard to interview techniques that contribute to children's suggestibility, several examples are provided here: First, false information presented before or after a target memory event can lead to a child having more difficulty remembering the actual (i.e., true) details. If an interviewer presents false information to a child after a target event, the child might incorporate some of this false postevent information into his/her memory report of that target event. One explanation for this phenomenon relies on the notion of "source monitoring error." The child misattributes the source of the false information to actual experience and then incorporates the false information into his/her memory report. Adults are susceptible to source monitoring errors as well. When it occurs, child and adult witnesses might not be consciously aware of this type of memory error.

A second example of an interview technique that can contribute to children's suggestibility concerns indirect parental or peer pressure. Children can feel pressure to conform to or agree with authority figures as well as with peers. As a result, children can be susceptible to an interviewer's implication

of parental and peer statements. If a child witness is told by the interviewer that his/her parent said something happened or that all of the child's classmates said it happened, the child witness might try to conform his/her answers to the interviewer's suggestions.

A third method of potentially influencing a child's memory report in a negative way is referred to as *stereotype induction*. This involves, for example, telling a child that the accused is a "bad" person. A parent or interviewer might tell the child that someone was arrested, and "only very bad people get arrested," which may imply to the child that the person must have done horrible things. Giving children negative stereotypes about individuals can influence the children's memory reports in a way that is consistent with the stereotype.

Turning now to ways to question children in less-suggestive manners, although currently the United States does not have generally accepted, national interview guidelines, there are best practice guidelines that have emerged from decades of research in the field of children's suggestibility. Open-ended, free recall questions are considered the least suggestive and have been empirically shown to result in the most accurate information. Thus best practice guidelines typically preference such questions. However, in the forensic context, young children often fail to provide lengthy narrative responses to these types of questions. According to best practice guidelines, after free recall, more specific cued recall questions can be asked followed, if necessary, by more direct questions (the "funnel approach"). It is considered best to avoid yes/no questions, especially with young children. It is also recommended that all interviews be videotaped so that fact finders and experts can evaluate the extent to which interviews are potentially suggestive. Some countries have national interview guidelines. For instance, Israel uses the National Institute of Child Health and Human Development (NICHD) protocol which relies on establishing rapport with the child, practicing answers to (innocuous) free recall and open-ended questions, and introducing the target event in a neutral, nonsuggestive way; the interviewer waits until the end of the interview to use specific, option-posing questions, if such questions are deemed necessary.

Another widely used interview technique that attempts to reduce adverse effects of suggestion while promoting accurate and complete reports is the revised cognitive interview (CI). Originally developed for adults, this interview also has a rapport building phase and then relies on having the interviewee engage in "mental reconstruction" of the target event. Next, the witness is asked to free recall the event from beginning to end, and then in reverse order from the end to the beginning (change order). Last the interviewee is asked to recall the event from someone else's perspective (change perspective). However, concerns have been raised about young children's ability to perform the last two steps (change order and change perspective). Consequently, revised CI interviews for children have often excluded either or both of these steps. Both the NICHD and revised CI protocols are useful in reducing suggestibility in interviews with children aged four years and older.

Props, dolls, and human figure drawings can help children by serving as external retrieval cues, but such aids can also be suggestive in nature. Critics of such retrieval tools are concerned that dolls and props themselves are misleading, especially if they are used to suggest inaccurate information. Research on these aids indicates that overall they enhance children's reports by increasing the amount of accurate information provided, but that they also increase the number of errors in memory reports depending in part upon the child's age. Younger children, especially, might be too cognitively immature to understand the dual representation required to effectively use such retrieval tools. Of note, critics have argued that, use of anatomically detailed dolls may heighten suggestibility by prompting the child to demonstrate sexual acts with the dolls; these acts may be mistakenly interpreted as evidence of child sexual abuse.

Individual Differences

Individual traits of children may predict increased susceptibility to suggestion. It should be emphasized, however, that individual differences among children are often inconsistently associated with suggestibility, and the predictive power of such differences is typically too weak for legal purposes (i.e., many children would be misclassified). That said, language ability has been shown to be associated with suggestibility, perhaps especially in younger children. Children with more developed language skills tend to be more resistant to suggestive questions. With better language

skills, children may be more capable of understanding the questions and of understanding instructions that they do not always have to agree with the interviewer. In contrast, children with mental retardation are more highly susceptible to suggestive questioning, although even here, the research literature is mixed.

Parental attachment may influence how a child thinks and talks about negative events. Parents who are more avoidant in their attachment style may be less likely to talk with their children about negative life experiences. Research has shown that parental avoidant attachment predicts errors in children's memory reports of stressful events. Moreover, for child victims of sexual abuse, emotional support from parents after the child discloses the abuse is associated with more accurate reports (years later in adulthood) compared to that of children whose parents were more avoidant and attempted to minimize or ignore their child's disclosure.

Children's inhibition skills (e.g., ability to ignore irrelevant stimuli) are also associated with their memory reports. Children with deficient inhibition skills evince weaker overall memory and more inaccuracies in the information they provide to both direct and misleading questions. Thus, such children are more likely to be susceptible to suggestive techniques.

Trauma and Suggestibility

Several laboratory and field studies have examined children's memory of and suggestibility about events that are negative and even traumatic. Results from such studies have been mixed in terms of whether children are more suggestible about stressful than neutral events, or less so. Some theories of stress and memory suggest that trauma victims might repress traumatic events and in doing so have no memory for the traumatic experiences, only to have such memories reawakened later; other theorists contend that such memories have a high likelihood of being false. Some research indicates that trauma victims are especially attentive to trauma-related stimuli and remember their trauma experiences quite well, rather than repressing memory of them. When suggestibility has been studied in actual child abuse victims, their performance is generally comparable to that of nonabused control children, although some forms of psychopathology may be associated with greater error.

Conclusions

Overall, suggestive techniques are of most concern when they lead to false reports against innocent people. There is evidence that such techniques, in the extreme, can lead to false memories of entire events that never occurred. It is important to note that the inaccuracies resulting from suggestibility would likely be inaccurate details that are intermingled with an accurate memory report (e.g., mistaking the color of a car in an accident that actually occurred). However, exposure to multiply suggestive techniques over a long period of time could potentially lead vulnerable children (e.g., certain preschoolers) to create false memories of entire events that never occurred. Fortunately, children, even young ones, can be resistant to suggestive techniques, perhaps especially when they are reporting about personally significant negative experiences.

When child witnesses are involved in the legal system, their memory reports may be relied upon to prosecute those who commit crime. It is important to reduce, as much as possible, children's suggestibility errors, and false memory reports to ensure that innocent defendants are not wrongfully convicted. At the same time, children's suggestibility should not be overstated. Children often can resist false suggestions and maintain accuracy in the face of misinformation and the use of suggestive techniques. However, even then, the child's credibility as a witness may be damaged as a result of concerns about children's suggestibility.

Civil Commitment

Introduction

Mental illness can have a profound effect on one's thought process. Delusions (*see* **Delusions**) and hallucinations (*see* **Hallucinations**) can create frightening situations from which a person may feel the only escape is to strike out. Depression and catatonia can produce such devastation that a person can no longer feed or clean himself. Such altered realities can also impair one's ability to make rational decisions. Thus, civil commitment as we currently know was born out of the need to involuntarily hospitalize mentally ill patients who are assessed to be a danger to themselves or others while maintaining respect for their civil rights.

In 1403, the world's oldest psychiatric hospital, the Bethlem Royal Hospital of London (a.k.a. Bedlam), first opened its doors. Over three centuries later, the first psychiatric asylum in the United States was established. The number of institutions throughout the industrialized world continued to expand until, in the 1950s, over 550 000 individuals in the United States, and 150 000 in England were maintained in public facilities due to their mental illness [1, 2]. Because of the advent of psychotropic medications, the promise of community mental health centers and funds supposedly allocated for this care, the number of institutionalized patients was declined to about 70 000 and 30 000, respectively, in the 1980s and 1990s [1, 2].

During this same period, an increasing awareness developed that all citizens, including those suffering from mental illness, should receive equal protection under the law. Previously, civil commitment laws were created to make the process as simple and convenient as possible [3]. On the basis of their status, patients subject to civil commitment may have lost other civil liberties, including the right to marry, manage their property, or carry a driver's license [4, 5]. Often, civil commitment merely required the presence of mental illness and a need for treatment. These criteria were fueled by the idea of *parens patriae*, which refers to a government's obligation to care for its citizens. Historically, the other primary reason for civil commitment is supported by a country's police powers. The government has an obligation to protect its citizens and doing so may require the detention of a mentally ill individual who, due to his illness, is perceived to present a danger to others.

Over the past several decades, we have seen a shift in the role of civil commitment. This may again be altered on the basis of the public's perception of the relationship between mental illness and violence, especially following national tragedies such as the Virginia Tech massacre, in which a mentally ill individual killed 32 people and wounded 25 before killing himself [6].

Inpatient Civil Commitment

The Criteria

Though countries, and even individual states, have established their own unique procedures for civil commitment, there are several themes that are common to most. The first is the requirement of mental illness. There does exist, however, some discrepancy in how mental illness is defined. Some countries or states specifically exclude diagnoses such as substance use disorders, dementia, mental retardation, or personality disorders [3]. In the 1992 US Supreme Court case *Foucha v. Louisiana*, the court decided that it was unconstitutional to hold a not guilty by reason of insanity (NGRI) acquittee (*see* **Insanity: Defense**; **Interrogation**) in the hospital based on his risk of violence secondary only to his antisocial traits [7]. However, England and Scotland do permit the detention of patients whose dangerousness stems from the existence of a personality disorder [8, 9].

When patients are civilly committed, they are placed in a hospital setting. Without the presence of mental illness (which presumably can be ameliorated with treatment), hospitals would simply serve as an

alternative to incarceration. In 1975, the US Supreme Court, in *O'Connor v. Donaldson,* held that "a State cannot constitutionally confine *without more* a nondangerous individual who is capable of surviving safely in freedom by himself or with the help of willing and responsible family members or friends." [10] (emphasis added) In this decision, "more" is commonly construed as a reference to treatment. In the United Kingdom, based on the 1985 court case *Regina v. Hallstrom* [11], the focus of civil commitment rests on the intention to treat patients' mental illness [9].

In addition to the presence of mental illness, there are often three main potential criteria for civil commitment. The first is the risk of danger to self. This may be manifested in form of a suicide attempt, an overt suicidal threat, or behavior that indicates that one intends to harm oneself (e.g., writing a suicide note or stocking up on medication known to be lethal in overdose), which may occur despite a patient's denial of suicidal thoughts. The second criterion is the risk of danger to others, similar to the first criterion in that both actions and thoughts allow for a patient to be civilly committed. The final criterion for civil commitment often refers to a patient's gravely disabled condition or inability to care for self. This alludes to the patient's inability to provide for his own basic needs, such as food, shelter, clothing, medical care, and personal security [12] secondary to mental illness. On the basis of this assessment and prediction, the clinician is given both the power and responsibility of placing a person, at least temporarily, in an inpatient facility potentially against his will.

The Process

Once a mental health care provider has made the decision to civilly commit a patient, there exists a standardized procedure to which the clinician must adhere. Though the criteria are often the same, the logistics of civil commitment vary between countries and states.

The United States. In the United States, there exists a delicate balance between psychiatry and the law during the commitment process. All states allow for emergent commitment of patients meeting the aforementioned criteria with little to no involvement of the court system. Therefore, commitment is primarily based on the assessment of the clinician and occurs swiftly. At this time, the patient is provided with the potential duration of the confinement and the point in time when access to counsel and a hearing is granted [3]. This access must occur following an often brief and well-circumscribed period, which can range from 48 h [13] to 15 days (with the requirement of a second opinion by another psychiatrist) [14].

The second step in this process involves long-term detention and does require judicial approval. Patients who require only brief stabilization may be discharged before their cases reach court. On the basis of the holding in the Supreme Court case, *Addington v. Texas* [15], the decision to civilly commit must be founded on clear and convincing evidence, which is an intermediate level of proof between preponderance of the evidence (civil) and beyond a reasonable doubt (criminal). The landmark high water mark for the rights of civil committees is based on the 1972 court case *Lessard v. Schmidt*; the patient is eligible for all the same constitutionally protected due process rights afforded to criminal defendants [16]. Among different states, the initial commitment often extends from 90 to 180 days and may be renewed if necessary after the expiration of that period [3].

The United Kingdom. Civil commitment in the United Kingdom can be enacted to ensure both patients' health and the safety of those around them and is based on an intention to treat patients' mental illness [11]. In England and Wales, a patient can be involuntarily hospitalized, assessed, and treated for a period up to 28 days. If appropriate, after this evaluation period, a patient may be detained for a (renewable) period up to six months based on the consensus of two medical opinions. In Scotland, detention beyond the 28 days evaluation period must be sanctioned by a Mental Health Review Tribunal, which consists of a lawyer, a psychiatrist, and a third person with experience in handling mental health issues. In Northern Ireland, the initial evaluation period is only seven days, and this may be extended for another seven days if necessary.

Other Nations. In 1997, Applebaum [17] authored a review of the state of civil commitment worldwide. In the decade following the change from treatment to dangerousness-based commitment in the US, several other nations followed suit (including Austria,

Belgium, Germany, Israel, the Netherlands, Northern Ireland, Russia, Taiwan, and Ontario, Canada). However, many nations, including Sweden, Finland, France, Greece, and Italy, have opted for laws more similar to the British model that is based on the need for treatment. Applebaum noted that there is data to support the idea that, regardless of the laws, both courts and doctors will follow their moral compasses and civilly commit those patients that need psychiatric intervention. This appears to be an international phenomenon.

The Dual Role Dilemma. Mental health professionals are frequently called upon to serve as both the patients' treatment providers and their forensic evaluators in regard to their eligibility for civil commitment. Potential conflicts that may arise include a disruption in the therapeutic alliance and inappropriate access to patients' information. In other words, patients may not have chosen to reveal certain information to someone acting solely as a forensic evaluator. Therefore, patients may feel that their own psychiatrists testified "against" them [18].

Outpatient Civil Commitment

After deinstitutionalization created a push for increased psychiatric care in the community, civil commitment was no longer restricted to the inpatient setting. In the United States, in 1966, the court of appeals for the District of Columbia heard the case of *Lake v. Cameron* and decided that a nondangerous, civilly committed person should not have to be confined to an inpatient facility if less restrictive alternatives were available [19]. In 1999, the state of New York again brought attention to outpatient civil commitment when it enacted Kendra's Law, named after a woman who was pushed onto the subway tracks by a schizophrenic man [20]. To be eligible for outpatient civil commitment according to this law, an adult must be mentally ill and unlikely to survive safely in the community without supervision but unlikely to comply with treatment and have a history of treatment noncompliance and violent acts [20]. Many states have adopted similar laws, but enforcement occurs only in the counties opting to do so (California, Ohio, etc.).

Interventions for those people who are committed on an outpatient basis include options such as monitored medication use, required participation in individual or group therapy, mandatory presentation to day hospital programs, or residence in certain supervised living environments [21]. The United Kingdom also emphasizes the use of the least restrictive alternative, and jurisdictions have rules and resources in place to allow for outpatient civil commitment [9].

Other Factors Affecting Civil Commitment

Incompetence

Competence refers to one's capacity to function in a particular domain at a particular time. There are many specific types of competence with various standards. On the basis of evidence often collected by mental health professionals, the ultimate decision on competence is usually made by a judicial body (*see* **Capacity Assessment**).

Most cases of civil commitment involve the hospitalization of a patient who does not want such an intervention. Because the safety of the patient or others may be in serious jeopardy, it might be immaterial if the person is felt to be capable of making the decision in this case. Competency does become an issue, however, if the person meets commitment criteria and requests a voluntary admission but appears incapable of making that decision. This scenario renders civil commitment as the only viable option. On the basis of the 1990 US Supreme Court case *Zinermon v. Burch*, if a patient is suspected or known to be incompetent regarding his ability to sign himself in to the hospital, he cannot voluntarily do so. The Court noted that allowing an incompetent individual to voluntarily hospitalize himself when he is unable to consent to admission is a deprivation of his civil liberties [22].

In the case of incompetent patients, the presence of a guardian alters the procedure for hospitalization. In general, a guardian is a court-appointed individual who maintains control over other's property or person. Some guardians, referred to as *conservators* or *guardians* of the estate, only make decisions related to their wards' estates. For those persons deemed by the court to be globally incompetent, general guardians (or guardians of the person) are responsible for all of their decision making. This, of course, includes the decision to sign into a hospital or accept and refuse treatment.

Guardians may make decisions for their wards based on two different models. In the *best interest* standard, guardians base their decisions on what they judge would be in the best interest of their wards. Alternatively, in the "substituted judgment"

standard, guardians base their decisions on how their wards might have acted in the same situation if they were competent. With the second model, the guardians' task is simplified greatly if their wards (while competent) draft advanced directives outlining their wishes if the occasion arises in which they become incompetent [23]. However, it is important to recognize that these advance directives (and even the decision of the guardian) can be overridden by the civil commitment laws, which serve to protect both the patient and the community [24].

Forced Medications

As noted above, the capacity to determine the need for hospitalization and the capacity to make decisions about medical treatment are often two distinct types of competency. In 1980, the Utah legislature (United States) codified that, in order to civilly commit a patient, hospitalization must be the least restrictive alternative and the patient is incompetent to consent to treatment [25], and therefore, a civilly committed patient has no right to refuse medication [26].

Special Cases Related to Civil Commitment

Minors

Merely on the basis of their age, minors are generally considered incompetent to make legal decisions, whether or not they meet the criteria of a given competency. Parents (or the state) are recognized as their legal guardians and are therefore often responsible for their decision making (*see* **Parental Rights and Prerogatives**). On the basis of a 1967 case (*In re Gault*), the US Supreme Court stated that due process is required for juveniles [27]. Twelve years later, *Parham v. J.L. and J.R.* came before the court. This was a class action suit seeking to place civilly committed children in less restrictive environments. However, the Supreme Court declined to grant children the same procedural due process rights granted to adults who faced the possibility of civil commitment [28]. This decision served as an acknowledgment of parental authority over the civil liberties of minors.

Insanity Acquittees

Much as it did for minors, the US Supreme Court made a special exception for those found NGRI. In 1983, they heard the case of *Jones v. U.S.*, in which a man presented a successful insanity defense for shoplifting, was hospitalized and then requested to be released after he was hospitalized for the length of time equivalent to what his sentence would have been if he had been convicted. The Court rejected his argument, deciding instead that hospitalization is not a sentence but includes treatment, the NGRI acquittee may be confined indefinitely, and the burden of proof to prove lack of dangerousness rests on the acquittee [29].

Inmates

Over the past several decades, the US Supreme Court has heard major cases regarding the rights of mentally ill prisoners in regards to civil commitment. The outcome of *Baxstrom v. Herald*, decided in 1966, stated that the equal protection clause of the 14th amendment was violated if an inmate was civilly committed following a period of incarceration without review [30]. This decision lead to the movement of 969 "criminally insane" prisoners from the custody of the New York Department of Corrections to state civil hospitals; this was informally known as *Operation Baxstrom* [31]. Interestingly, only 26 of those people returned to forensic psychiatric hospitals over the next four years [32]. The second of these cases was *Vitek v. Jones* [33]. This decision stated that the rights of due process are applicable when inmates are transferred from the facility in which they are incarcerated to a psychiatric hospital for treatment. More specifically, they have the right to notice the transfer, an adversary hearing, and the availability of legal counsel [33].

Canada enacted a postconviction commitment law in 1997. In lieu of sentencing offenders that the court considers dangerous, this law allows for their indefinite confinement in federal or state institutions. This law applies to various crimes that can cause significant harm to the victim; however, 90% of those committed under this law are sex offenders [34].

Sexual Offenders

Sex offenders pose a particular challenge in regard to civil commitment, given that they are typically difficult to treat and may pose a great risk to others if they reoffend. This issue was addressed by the US Washington State Supreme Court in 1993. According to *In re Young and Cunningham*, the court decided

that the state law allowing the civil commitment of sexually violent predators with mental abnormalities or personality disorders was constitutional in some cases. Since the commitment was civil (not criminal), it did not violate a defendant's double jeopardy or ex post facto rights [35]. This issue made its way to the US Supreme Court in 1997 in *Kansas v. Hendricks*. The outcome was similar, when a 5-4 Court decided that the state of Kansas' civil commitment of sexual offenders did not violate substantive due process and the double jeopardy/ex post facto clauses. Furthermore, they noted that failure to offer treatment does not indicate that the law is merely punitive [36]. Some argue that this decision overextended the reach of civil commitment laws [37, 38] and places psychiatrists in the difficult situation of using psychiatric services for social control. One author went on to state that other selected classes of people, notably substance abusers, may be in jeopardy of serious consequences from this decision [38].

Abuses of Civil Commitment

In the nineteenth century, the case of Mrs E.W.P. Packard came to light when she published a text chronicling her difficulties. In 1839, she married a Presbyterian minister with whom she had six children. After she began to explore other religions, her husband had admitted her to an Illinois State Hospital for the Insane in 1860, where she was diagnosed with "monomania" and "moral insanity". Though she was released in 1863 and ultimately declared to be sane, she discovered she had no legal rights for her children or her property. Because of her experience, she dedicated her life to lobbying for asylum reform and women's rights [39].

This obvious violation of civil rights occurred over a century ago, but abuses of the power of civil commitment have occurred far more recently. When Khrushchev rose to power in Communist Russia, he moved political dissidents from labor camps to psychiatric hospitals in effort to make these revolutionaries appear better treated with the added benefit of making them seem "crazy" and unworthy of support [40, 41]. Prior to the fall of this regime, Western psychiatrists had the opportunity to directly examine the state of psychiatry in the Soviet Union and confirmed the presence of such activities [42]. In China, those who openly challenge the government are labeled as mentally ill and placed in special forensic hospitals known as *Ankang*. Only recently, China has become more open in allowing outsiders to investigate their forensic facilities [43].

Civil commitment exists as a delicate balance between psychiatry and the law, weighing a need to protect the patient and his community with his rights as a citizen. Commonly, patients are eligible for civil commitment if: (i) they are mentally ill and (ii) they are at risk of harming themselves or others. Each jurisdiction may go about civil commitment in a slightly different way, and a variety of laws have emerged. These laws are modified in special cases, such as those involving minors, insanity acquittees, inmates, and sex offenders.

Civil Law Systems of Justice

The legal systems that exist in countries outside the English-speaking world are frequently referred to as *civil law systems of jurisprudence*. They are also referred to as *inquisitorial systems* or *investigative systems*. Civil law systems are based alternatively on the French Napoleonic Code, or on the Roman law from which the Napoleonic Code was in turn derived. Civil law systems stand in contrast to the adversary or common law systems, which developed predominantly in the English-speaking world.

Civil law systems are based on a search for truth that requires a judicial official, called an *examining magistrate* (or *juge d'instruction*) to investigate whether a crime has been committed. At the conclusion of this investigation, which may in some

celebrated or notorious cases be years in duration, a file or *dossier* will have been compiled. This *dossier* will contain all of the relevant statements and evidence that have been collected and examined. The *dossier* will also include the magistrate's conclusions about the strength of the evidence and recommendations for further action. When the investigation results in finding sufficient cause to establish that a crime has occurred, and that a specific person has committed that crime, the magistrate's file will recommend that the individual be placed on trial.

Cocaine

History

Cocaine is a psychotropic drug prepared from coca that is found in the plant, *Erythroxylon coca*, which grows principally in the northern South American Andes and to a lesser extent in India, Africa, and Java. The plant, which may reach 3 m, favors higher elevations (up to 1800 m) because at lower elevations (below 500 m), the alkaloid content is significantly diminished due to more rapid growth. Coca leaves may first be harvested about 2 years after the time of planting. Then, depending on the altitude, the leaves may be harvested up to three times a year. The leaves are dried and converted into a coca paste, which is eventually used to produce cocaine hydrochloride (cocaine HCl). The yields from 100 kg of coca leaves are about 1 kg and 800 g, respectively, for coca paste and cocaine HCl.

In the mid-nineteenth century Carl Wöhler, the chemist who synthesized urea, had coca leaves imported to Germany and presented them to his graduate student, Albert Niemann, to analyze. Niemann was the first to successfully isolate cocaine from the coca plant. From the 1860s until the turn of the century, cocaine appeared in various elixirs and tonics purported to have "magic" properties. One of the more famous preparations was Vin Mariani, a mixture of wine and cocaine that received celebrity endorsements from Pope Leo XIII, US President McKinley, Thomas Edison, Auguste Rodin, and Jules Verne. The original Coca-Cola® beverage contained a coca-based syrup supplemented with caffeine and was marketed as a tonic and headache remedy. In 1884, the year Sigmund Freud popularized the drug in his famous treatise "Über Coca", Carl Koller became the first physician to use cocaine as a topical anesthetic in ophthalmological surgery. As cocaine abuse began to be viewed as a problem, its sales became restricted. Legitimate medical use is almost exclusively limited to topical administration as a local anesthetic in ear, nose, and throat surgery (as the HCl salt in 10–20% solutions) and in ophthalmological procedures (as a 1–4% solution). Cocaine is one of the most common illicit drugs of abuse. It is estimated that over 34 million Americans aged 12 or over have tried the drug, with about one million current users [1].

Cocaine Abuse

Cocaine is sold on the street in the form of the hydrochloride salt and crack. The salt form varies considerably in purity and is typically diluted with a variety of cutting agents. The cocaine powder supplied by dealers is often clumpy and first needs to be chopped. This is usually achieved using a mirror with a razor blade, after which the cocaine is arranged into thin lines about 30–60 mm long and 2 mm wide resulting in an average dose of 25 mg and then

snorted through a straw or "tooter". Alternatively, cocaine may be snorted from a "coke spoon" or "bullet", a device in which a vial containing cocaine may be inverted over a closed chamber into which the cocaine falls and may then be rotated for convenient snorting. A single long fingernail may serve as a natural "coke spoon".

Crack is a free base form of cocaine that produces a characteristic crackling sound when smoked. It is prepared by adding baking soda to aqueous cocaine HCl and heating it to remove the water. After heating, the mixture is cooled and filtered, and the free base cocaine precipitates into small pellets or "rocks." These "rocks" can then be smoked in a crack pipe. Crack pipes range from elaborate glass pipes to a soda can with a hole. A typical "rock" weighs about 20 mg and costs US$10–20 (2008), making this form of cocaine much less expensive, per unit, than the salt form that is typically sold for around US$100 per gram.

Pharmacology and Pharmacodynamics

Mechanism of Action and Effects

Cocaine (methylbenzoylecgonine) is an ester of benzoic acid and the amino alcohol, methylecgonine, and is chemically, but not pharmacologically, related to atropine. Cocaine is used medicinally as a topical local anesthetic but is structurally different from other local anesthetics by virtue of its tropine moiety (Figure 1). However, as other local anesthetics, cocaine consists of a hydrophobic and hydrophilic regions and contains ester linkages that allow the body to hydrolyze and deactivate the drug.

As a local anesthetic, cocaine's most important mechanism of action lies in its ability to block sodium channel conductance and thereby to increase the threshold required to generate an action potential. Cocaine has additional actions that make it unique from other local anesthetics, including its ability to block reuptake of the neurotransmitters norepinephrine, dopamine (DA), and serotonin. Norepinephrine (noradrenaline) is responsible for the classic adrenergic effects observed with cocaine use including mydriasis, vasoconstriction, hypertension, tachycardia, and tachypnea. However, the euphoric effects of the drug are mediated by DA, the neurotransmitter that stimulates the reward centers in the brain. After an acute dose of cocaine, DA concentrations in the brain become elevated, as cocaine prevents the reuptake of DA into the presynaptic neuron. This results in increased extracellular DA concentrations resulting in chronic stimulation of the DA receptor in the postsynaptic neuron. During this period, the user experiences the desirable behavioral effects of cocaine including intense euphoria, psychic energy, heightened sexual excitement, and elevation of mood. When DA is depleted, the central stimulatory effects (rush) are followed by depression (crash). Therefore, chronic cocaine users repeatedly administer cocaine (binge) to maintain increased synaptic levels of DA. The positive reinforcement of the rush *versus* the negative reinforcement of the crash is the principal reason for the development of cocaine abuse.

The time course for the high in humans parallels that of the cocaine concentration in the reward centers of the brain. For equivalent plasma cocaine concentrations, smoked cocaine induced significantly greater self-reports of "high" than intranasal cocaine and showed a trend for greater effect than intravenous cocaine [2]. This study demonstrates the importance of speed of cocaine delivery into the brain on its reinforcing effects and how crack cocaine can be even more dangerous than the salt.

Toxicity

There appears to be a good correlation between peak plasma cocaine concentrations and peak pharmacologic and behavioral effects [3]. Because the "high" is related to plasma concentration, not the dose, it is easy to understand how self-administration of toxic amounts of cocaine occurs during a binge.

The most common clinical manifestations following acute cocaine intoxication include profound central nervous system (CNS) stimulation with psychosis and repeated grand-mal convulsions, ventricular tachyarrhythmias and respiratory dysfunction with Cheyne-Stokes breathing, and ultimately respiratory paralysis. Other symptoms include mydriasis, hypertension leading to hypotension, and small-muscle twitching. Cocaine's ability to increase muscular activity and vasoconstriction may produce extreme hyperthermia.

A significant number of cases presented to emergency departments have been associated with a cocaine-induced psychosis, now commonly called

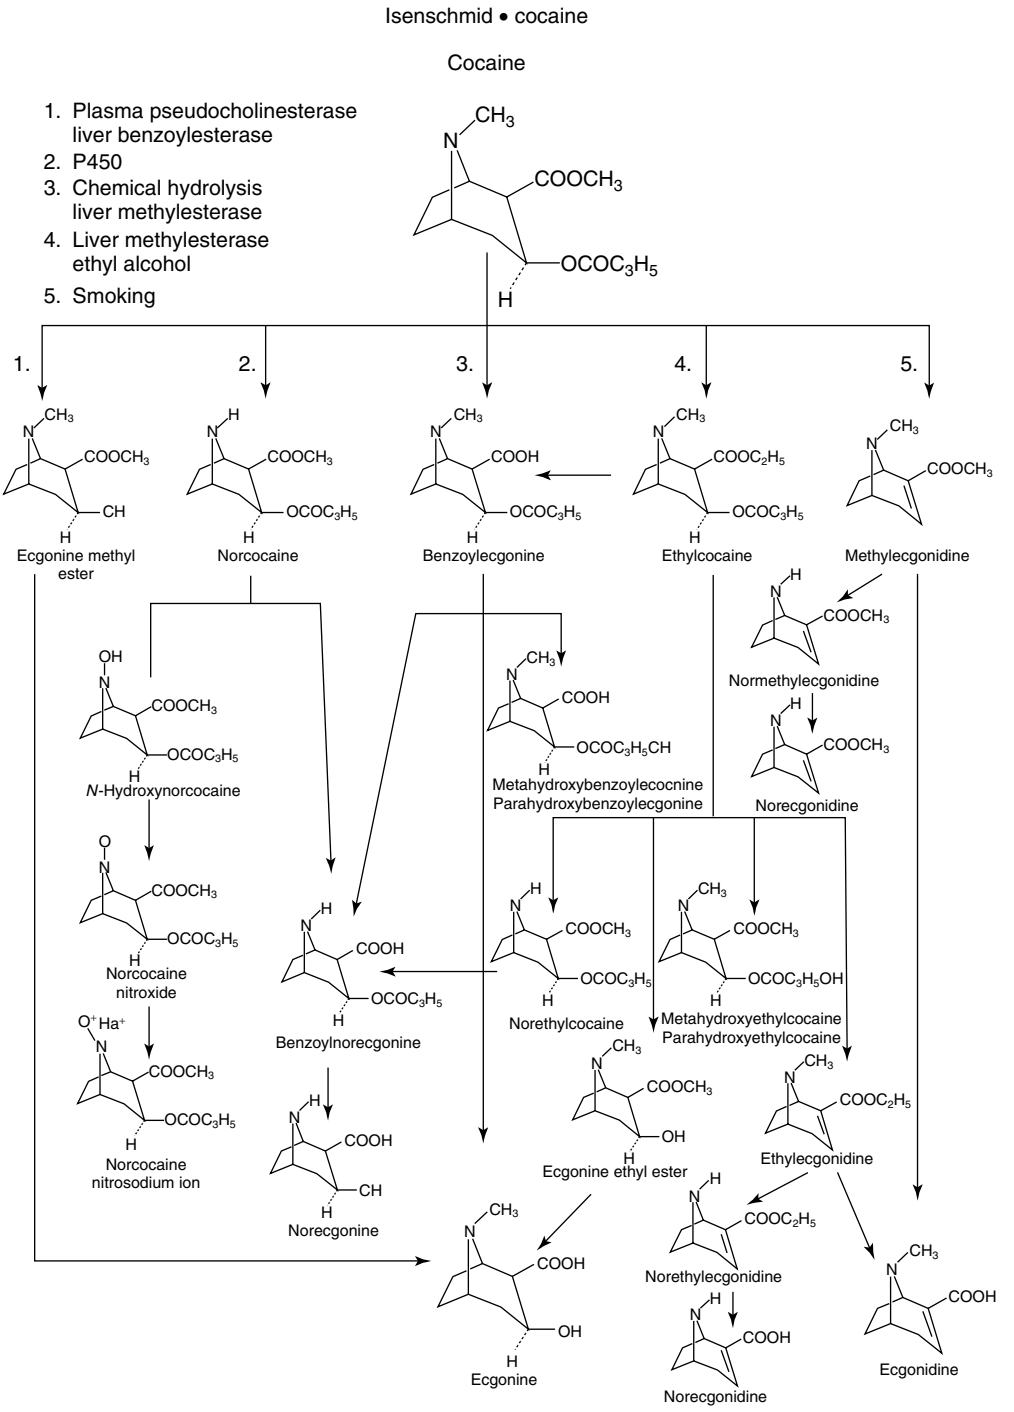

Figure 1 Pathways in the metabolism of cocaine. Cocaine, in *Principles of Forensic Toxicology*, B. Levine, ed, AACC Press, Washington DC, p. 221) [Reproduced with permission from AACC Press. © 1999.]

cocaine-induced excited or *agitated delirium*. This syndrome is characterized by severe hyperthermia (104–108 °F), extreme agitation and delirium, respiratory arrest, and sudden death. These individuals exhibit bizarre and violent behavior and extreme strength and are frequently seen running around – often naked – shouting, fighting, breaking things, and causing injury to themselves and/or others. Law enforcement is frequently called to respond to this type of situation and attempt to restrain the individual. In some cases, stress from restraint may result in catecholamine surges on an already sensitized myocardium, resulting in arrhythmias and possible death.

Cocaine can injure cerebral arteries and an acute hypertensive episode following a single dose in a chronic user can cause the vessels to rupture. Even though acute tolerance to the cardiovascular effects of cocaine has been shown to occur, during a cocaine "binge" the chronic cocaine user may self-administer more cocaine than the cardiovascular system can tolerate.

Pharmacokinetics

Absorption. Cocaine may be self-administered intranasally, by smoking, intravenously, and orally. Cocaine is usually not administered orally because low bioavailability results in reduced euphoric effects due to inefficient delivery to the brain. The intravenous route of administration, sometimes called *mainlining*, is the only route that consistently produces 100% drug bioavailability. Despite varied bioavailability of cocaine when administered intranasally or smoked, the convenience of these two routes of administration, and the latter's rapid, intense onset of effects, makes them the most commonly used.

Metabolism. Cocaine is metabolized primarily to benzoylecgonine and ecgonine methyl ester by different mechanisms (Figure 1). The mechanisms of cocaine metabolism are not straightforward due to complex *in vitro* and *in vivo* reactions.

Stability studies support the long-held findings that cocaine is metabolized to ecgonine methyl ester via enzymatic hydrolysis by pseudocholinesterase and to benzoylecgonine via spontaneous hydrolysis at physiological and alkaline pH [4]. However, cocaine can also be metabolized by liver esterases. Liver methylesterase catalyzes the conversion of cocaine to benzoylecgonine and the transesterification of cocaine to ethylcocaine (also known as *cocaethylene*), if cocaine is used with ethanol [5]. In the absence of ethanol, this enzyme hydrolyzes cocaine exclusively to benzoylecgonine. In the presence of both cocaine and ethanol, transesterification of cocaine to ethylcocaine occurs about 3.5 times faster than hydrolysis to benzoylecgonine [6]. As ethylcocaine is an active drug, it can contribute to cocaine toxicity. A separate and distinct human liver esterase, benzoylesterase, was found to catalyze the conversion of cocaine to ecgonine methyl ester but not ethylcocaine [5]. Both benzoylecgonine and ecgonine methyl ester are further metabolized to ecgonine.

Minor metabolites of cocaine include norcocaine, an *N*-demethyl metabolite of cocaine produced by liver cytochrome P-450 that received considerable study because of its conversion into a hepatotoxic metabolite [7]. In humans, however, reports of hepatotoxicity attributed to cocaine use are rare. Methylecgonidine (anhydroecgonine methyl ester) has been identified as a unique cocaine metabolite in postmortem blood and urine after smoking cocaine [8]. Related metabolites, ecgonidine, and norecgonidine methyl ester have been identified in urine specimens [9]. Other metabolites of simultaneous cocaine and ethanol users include ethylecgonidine and ecgonine ethyl ester. Hydroxylated metabolites of cocaine are found primarily in the urine [10].

Plasma Concentrations. Many pharmacokinetic studies have been performed with cocaine. Most studies performed were limited to single-dose studies with measurement of only the parent drug. Although considerable interindividual variation between subjects has been reported, several observations could be made. When bioequivalent doses of cocaine were administered by the intravenous and smoked routes, similar absorption and elimination curves for cocaine were obtained [3, 11]. When two different doses were given by the intravenous, smoked, or oral routes, intrasubject data indicated that mean peak plasma cocaine concentrations were dose related [11, 12]. When cocaine was administered intranasally, the dose and mean peak plasma concentration showed a poor correlation due to dose-dependent bioavailability by that route [13] with delayed peak plasma concentrations [3]. Similar delays in peak cocaine concentrations were observed oral cocaine administration [12].

On the basis of a review of the literature, typical peak plasma cocaine concentrations in most single-dose pharmacokinetic studies by the smoked (up to 100 mg), intravenous (up to 64 mg), and intranasal (up to 100 mg) routes averaged between 0.2 and 0.4 mg l^{-1} [14]. Of course, when cocaine is abused, it is rarely administered as a single dose. In the limited controlled studies that have examined the pharmacokinetics of cocaine following multiple doses, cocaine concentrations of up to 1–2 mg l^{-1} have been measured after smoked, intravenous, and oral administration without adverse effects [14].

After intravenous and smoked administration, cocaine follows first-order elimination using both one- and two-compartment models. On the basis of the literature, the average half-life for cocaine, for both routes of administration, was about 60 min and was usually not dose dependent [14]. After intranasal administration, cocaine pharmacokinetics have generally been described by one- or two-compartment models with first-order input. On the basis of the published data, the average absorption half-life for cocaine was 12 min and the average elimination half-life 84 min [14]. Dose-dependent kinetics has been reported in a few studies, which follows high intravenous and intranasal doses [13, 15].

Benzoylecgonine appears in the plasma within 15–30 min following cocaine administration by the intravenous, smoked, and intranasal routes of administration [3, 16, 17] On the basis of a single-dose pharmacokinetic study with sampling times sufficiently extended to study the pharmacokinetics of benzoylecgonine in plasma, the average formation half-lives for intravenous, smoked, and intranasal routes of administration were 34, 29, and 112 min, respectively [3]. Peak plasma benzoylecgonine concentrations usually occurred within 90 min after smoked and intravenous cocaine administration and were about half the peak cocaine concentration. After intranasal cocaine administration, peak benzoylecgonine concentrations were not reached until 3 h and were about twice that of cocaine and remained elevated for the next 5 h. This was consistent with the delayed absorption after intranasal administration during which time significant metabolism of cocaine may occur. In all routes of administration, the rate of benzoylecgonine elimination was slow compared to its rate of formation, accounting for its accumulation in plasma while cocaine concentrations were decreasing. The elimination half-lives for benzoylecgonine were 347, 324, and 213 min, respectively, after intravenous, smoked, and intranasal routes of administration.

The appearance of ecgonine methyl ester in blood after the administration of cocaine is not well understood. In some studies, only trace amounts of ecgonine methyl ester were detected in the blood [3, 16]. However, in other studies, ecgonine methyl ester could be detected in the blood at significant concentrations, although generally at much lower concentrations than benzoylecgonine [12, 18–20]. Factors that may play a role in the appearance of ecgonine methyl ester in blood include cocaine stability, route of administration, chronicity of use, and enzymatic reactions not yet identified. Some of these factors have been reviewed [21], but further research is still needed.

Excretion. Cocaine and its metabolites are excreted into the urine almost exclusively by simple filtration. In a study where urine specimens were collected for 3 days after six subjects were administered a single dose of cocaine by intravenous (25 mg), intranasal (32 mg), and smoked (42 mg) routes of administration, the mean percentage of the total dose recovered over 3 days was 45, 57, and 25%, respectively [10]. Cocaine concentrations declined to below detectable limits within 24 h (detection limit = 0.001 mg l^{-1}). Benzoylecgonine and ecgonine methyl ester were frequently detected at low concentrations (<0.025 mg l^{-1}) through 72 h.

Interpretation of Results

Blood

To attempt interpretation of cocaine and metabolite concentrations in blood, a large number of factors must be considered. A search of the literature suggests that cocaine concentrations of <0.30 mg l^{-1} are generally considered clinically therapeutic [14]. However, therapeutic, toxic, and lethal cocaine concentrations clearly overlap as observed by clinical and postmortem studies. Tolerance or reverse tolerance can play a significant role in the poor correlation observed. In a study of 130 patients presenting to an emergency room with acute cocaine toxicity, the mean plasma cocaine concentration was 0.34 mg l^{-1} and ranged from undetectable to

3.92 mg l^{-1}. The median cocaine concentration in these patients was only 0.07 mg l^{-1}. However, the mean and median benzoylecgonine concentrations in these patients were 1.57 and 1.06 mg l^{-1}, respectively. There was no correlation between the cocaine and metabolite concentrations in these patients and their clinical state or their outcome. The degree of symptoms of toxicity – most notably hyperthermia, heart rate, and psychosis – did provide a better predictor of a patients' outcome [22].

Other complicating issues include underlying pathology and the instability of cocaine in blood. In unpreserved blood, studies have shown that cocaine is rapidly hydrolyzed by plasma butyrylcholinesterase almost exclusively to ecgonine methyl ester [23]. The addition of sufficient sodium fluoride, while inhibiting enzymatic hydrolysis of cocaine to ecgonine methyl ester, does not prevent spontaneous hydrolysis of cocaine to benzoylecgonine. The rate of hydrolysis of both esters has been shown to be temperature and pH dependent, with higher temperatures and pH increasing the rate of hydrolysis.

In postmortem cases, additional complications are the competing factors of postmortem redistribution and release with cocaine hydrolysis [24]. Studies conducted with blood collected from the same cadavers at different times did not show predictable changes in cocaine concentrations. This leads to the conclusion that the usefulness of postmortem cocaine and metabolite concentrations after death may be limited especially since therapeutic, toxic, and fatal cocaine concentrations overlap. Studies conducted by other investigators have found similar results [25].

Urine

Urine is the most commonly utilized specimen for detecting cocaine use and can easily be analyzed for the presence of cocaine and metabolites, typically benzoylecgonine. There are few interpretive concerns for positive results, once alternative medical explanations are ruled out, since drug concentrations cannot be correlated to impairment. Generally, benzoylecgonine may be detected for 2–4 days using a 300 ng ml^{-1} cutoff concentration depending on dose, frequency of use, urinary pH, clearance, and hydration. Prolonged positive immunoassay results from 5 to 10 days have been reported after compulsive cocaine use with continuous positive results for up to 16 days [26, 27].

Other Specimens

Cocaine and metabolites may be detectable in hair for considerably longer periods of time than that in urine. For this reason, analysis of hair may be useful in determining a past history of cocaine use. Cocaine is present at higher concentrations than benzoylecgonine and ecgonine methyl ester in hair. Many important issues related to hair testing are still being studied including environmental contamination, washing techniques, sex or racial bias, specimen adulteration, quality-control procedures, proficiency testing, and the establishment of cutoff concentrations. Hair testing may be useful in postmortem cases where no other specimen is available and drug history is desired.

Saliva (oral fluid) may be a useful specimen for the detection of recent cocaine use in clinical studies, workplace testing, and roadside sobriety tests. Generally, a good correlation between saliva and plasma cocaine concentrations has been observed [28]. It offers the distinct advantage of collection by direct observation without any invasive procedure. It is important to develop standardized collection protocols for the collection of saliva because there is a risk for collecting a contaminated specimen from the oral cavity, especially shortly after cocaine administration. The saliva-to-plasma-cocaine ratio can also be affected by saliva pH and saliva flow rate after stimulation.

Methods of Analysis

For most purposes, analysis of cocaine and metabolites involves an initial test (screen) to rule out the negatives, and a second test to confirm positive initial findings. Immunoassays are commonly used for screening purposes because they are readily amenable to large-batch analysis, are relatively sensitive, and require little or no sample preparation. Because most immunoassays are targeted to detect benzoylecgonine, they are particularly well suited for screening urine specimens. There are several types of immunoassays on the market. Depending on the immunoassay selected, analysis of blood and tissue homogenates may be performed either directly or after protein precipitation and/or solvent extraction.

Confirmatory testing is usually accomplished using a chromatographic separation technique, followed by detection using a variety of available

detectors. Before cocaine and its metabolites can be analyzed using chromatographic techniques, the drugs must first be isolated from the biological matrix. This may be accomplished either by liquid–liquid or solid-phase extraction procedures for which there are many available procedures. For forensic purposes, chromatographic separation and detection is usually performed using gas chromatography-mass spectrometry or liquid chromatography-mass spectrometry. This ensures that there is adequate sensitivity and selectivity in the confirmation test. More recently, tandem mass spectrometry has been utilized using both chromatographic techniques. Depending on the techniques used, some metabolites, such as benzoylecgonine, require derivatization before they can be analyzed.

Compulsion

Introduction

According to the *Oxford English Dictionary* [1], compulsion is an "action, or an act, of compelling, or the condition of being compelled; constraint, obligation, coercion," and an "insistent impulse to behave in a certain way, contrary to one's conscious intentions or standards". Compulsion is thus defined by the presence of a force, either external or internal, that tends to impose behavior upon an individual.

External force may include coercion by others, as invoked in the affirmative defense of duress. A reasonable person confronted with a stranger brandishing a gun and instructed to steal a candy bar would likely perform the criminal act rather than risk losing his life. External force also operates in compulsory legal enforcement of treatment such as involuntary hospitalization for mental illness (*see* **Civil Commitment**) or in "leveraged" [2] forms of outpatient treatment such as outpatient commitment or court-mandated treatment as a condition of probation, though Bonnie and Monahan argue that the "coercive" aspect of these measures has been overemphasized [3].

External force also includes legal directives which an individual specifies while competent and which are later applied at a time when he is no longer competent. This is the case in *psychiatric advance directives*, where the individual creates a statement indicating his preferences for treatment at a future time when he no longer has the capacity to make a rational decision. In this way, the person places himself under a binding compulsion that he has formulated while lucid.

Internal forces leading the individual to act are comprised of complex phenomena within a wide range of psychopathology (*see* **Psychopathology: Terms and Trends**, and are also comprised of motivations and drives on a continuum with normal. Internal compulsion is thus more difficult to prove as a matter of fact, and is likely to require expert evaluation by a mental health professional. Whereas the presence of external compulsion is demonstrated through physical evidence and witness testimony according to an objective standard (a reasonable person would feel compelled), internally compelling forces are subjective, in that they are specific to the individual, arising from particular circumstances and beliefs that may be delusional or otherwise the product of psychopathology.

Involuntariness

The mental health field, and particularly the medical specialty of psychiatry, is distinguished by the fact that it is common to treat patients on an involuntary basis. The ability to assess the need for civil commitment is an essential skill of the psychiatrist. Psychiatrists hold significant power to limit the liberty of individuals with mental illness, and the ethics of the use of compulsory measures is necessarily an ongoing subject of reflection in the field.

Whether in the treatment setting or in a forensic evaluation, the assessment of an individual's ability to control his behavior is among the most difficult tasks for a mental health professional. Authors writing in the psychoanalytic tradition have defined compulsion as "a form of behavior to which the subject is obliged by an internal constraint [4]." Clinically, compulsion may be accompanied by anxious struggle against the impulses, with anxiety increasing the more the individual refrains from the compulsive behavior.

A related concept is the "repetition compulsion," in which the person is seized by an "ungovernable" tendency to put himself into "distressing situations, thereby repeating an old experience", [4] which he does not consciously recall. Freud began developing this concept prior to World War I, and formulated it explicitly in 1920 in his work *Beyond the Pleasure Principle* [5]. On the basis of his observation that soldiers returning from war had nightmares of their traumatic experiences, Freud concluded that mental functioning was not entirely guided by wish fulfillment (pleasure), but that the psyche included repetition of painful, unpleasant experiences that emerged as though forced upon the individual against his bidding. Psychoanalysts have not reached a consensus regarding explanations for this phenomenon, but agree that it exists [4].

Other accounts of compulsion as an involuntary phenomenon include biological explanations of temperament as a quantitative effect [6, 7] of the person's amount of instinctual drive. Social conventions, such as peer pressure in adolescents, or values such as cleanliness and purity in religious cultures, may become internalized by an individual and act as coercive forces within him. Whether it is attributed to the

force of unconscious meanings or to the compelling nature of social values or biological factors, the drive to act is experienced by the individual as surpassing his conscious control. In the study of pathological conditions such as addiction, controversy exists regarding the degree of control that the person ultimately has.

A Phenomenon of Mind and Behavior

The concept of internal compulsion is present in the definition of a wide variety of psychopathological conditions. A classic description of pathological compulsion is that of a person with obsessive-compulsive disorder who is unable to stop washing his hands, and does not know why. However, compulsion is also experienced by individuals with eating disorders, tics, pathological gambling, compulsive shoplifting, fire-setting, and uncontrolled buying. There is some evidence that these disorders are related to obsessive-compulsive disorder at the biological and psychological level [8]. Dermatological conditions may give rise to and result from compulsive behavior, such as hair pulling, itching, and scratching [8]. Individuals with personality disorders, such as borderline personality disorder, may experience the compulsion to self-injury. In some personality disorders as well as attention-deficit hyperactivity disorder, bipolar disorder, and posttraumatic stress disorder, the individual may manifest impulsive behavior, driven by a compulsion that may or may not be associated with a specific idea.

Impulsive Behavior

A definition of impulsivity as "a predisposition toward rapid, unplanned reactions to internal or external stimuli without regard to the negative consequences of these reactions to the impulsive individual or to others [9]," crosses many diagnostic categories. Impaired impulse control is included in the DSM-IV [10] symptom criteria of disorders such as antisocial personality disorder, borderline personality disorder, substance use disorders, attention-deficit hyperactivity disorder, and bipolar disorder [9]. One study suggests that impulse-control disorders were present in over 30% of psychiatric inpatients [11]. These disorders may be a common complication of other major psychiatric disorders, requiring specific treatment focused on these impulse-control symptoms [11].

There is some evidence that entering an altered state of consciousness ("dissociation") and a decreased ability to express feelings through words ("alexithymia") are associated with impulsive behavior, particularly self-mutilation in patients with a history of sexual abuse [12]. Impulsive behavior has also been studied in the context of violence and aggression (*see* **Aggression**), where the distinction between unplanned (impulsive) and planned aggressive behavior has been conceptualized as a basis for different treatment and different patterns of risk for future violence. "*Threat-control override*" [13] symptoms such as believing that thoughts are being inserted into one's mind, or voices that instruct the individual to perform wrongful acts, may result in actions that the person finds difficult to resist [14].

Addiction

Addictive behavior (*see* **Addictions**) is often invoked as a paradigm of compulsion, since nowhere is the drive to act more apparent than in the repeated intake of harmful substances, despite knowledge of the consequences. However, controversy exists as to the mechanism of the repeated behavior and the degree to which individuals have control and therefore responsibility for acting on their addictive impulses [15].

The choice to act on the compulsion to use illegal drugs has been viewed as a balance between pleasure-seeking tendencies and rational control. *Reward-related learning* is one theory that emphasizes neurobiological mechanisms that underlie pleasure-seeking behavior, which entail the creation of patterns that become reinforced even when the behavior no longer results in pleasurable outcomes [16]. *Impaired inhibitory control* seeks to explain repeated compulsive behavior as an abnormality of the brain circuits that regulate inhibition. In this model, a failure to inhibit compulsive behavior is a stronger factor than the strength of the drive for pleasure or the compulsion to act. Decreased ability to refrain from acting on impulses is thereby related to an inability to delay action to obtain satisfactions that are only possible at a later time [17]. This way of viewing the individual's choices as a balance between two systems governing motivation and control has been subject to criticism, because it does not take into account the impact of emotions in guiding decisions [18]. Mood and emotional state may tip the balance in a transient

manner, beyond the intensity of desire or the capacity to control or inhibit impulses.

Economic theories entail the construction of models for determining thresholds for choosing a particular action. In this perspective, the magnitude of the reward and the time to obtain the reward are factored into a system of relative values. For example, if the reward of graduating from college takes four years and requires abstinence from illegal drugs, whereas the reward of obtaining a small amount of pleasure through intoxication only takes 10 minutes to achieve, the individual may choose the more rapid and immediate satisfaction, even though the reward is smaller. In the theory of *delay discounting* or *hyperbolic discounting* the value of the long-term reward is diminished or "discounted" relative to the immediacy of the short-term satisfaction [19]. One way of treating this problematic is *choice bundling*, in which rewards are grouped and become sufficiently large in the person's mind as to override the desirability of short-term satisfaction of an impulse [19]. If multiple positive long-term outcomes are reinforced as a combination, their heightened value may make the immediate gratification no longer worthwhile. In this theoretical framework, the individual's self is viewed as a "population" with competing interests that require bargaining to arrive at a decision. Alliances or coalitions between interests and goals that share the aim of avoiding adverse short-term outcomes such as compulsively abusing illegal drugs may override the anticipated satisfaction that the individual seeks in using them [19].

Ego depletion is a concept in which the ability to control one's behavior is considered to be a resource that can become exhausted ("depleted") under conditions that require either strenuous or prolonged effort [20]. In psychoanalytic theory, the ego is the part of the psyche that is responsible for regulating drives in accordance with social norms. Depletion of the ego is thereby understood as a process in which the individual encounters increasing difficulty in regulating his choices. This was initially demonstrated through psychological experiments in which the ability to sustain concentration on a task was decreased when the task was immediately preceded by another strenuous exercise requiring self-control [20]. Further elaboration of the theory through experiments has led psychologists to distinguish between *autonomous* and *controlled* regulation of choice. These latter experiments suggest that choices that are made autonomously or spontaneously in accordance with the subject's personal desires are less fatiguing than controlled choices that are made under conditions where the subject is told that he must follow a particular rule that is imposed [21]. Although this distinction is logical, one unanswered question that is relevant for treatment is how self-regulation that is initially made under controlled or imposed conditions may become, over time, more spontaneous for the individual. Clinically, persons who attempt to change their patterns of behavior require intensive effort when first modifying their habits, and may gradually integrate these changes in a more personalized and automatic manner, particularly when they remove themselves from an environment that may contribute to depletion of self-control [22].

Subjective Experience of Coercion

Individuals placed under the compulsion of externally imposed measures react in a wide variety of ways. Prison inmates may adapt to their forced surroundings by embracing their identity as criminals among other criminals, in a process known as *prisonization* [23, 24]. When faced with conditions that are beyond their control, individuals may attempt to gain control by complying in a manner that they believe to be of their own choosing, such as volunteering to perform work while in prison or maintaining good behavior to obtain early release. A common reaction to imposed conditions that are perceived as coercive is that of rebellion. Although disobeying the parameters of confinement is counterproductive for the individual and paradoxically results in increased enforcement, a person may experience satisfaction in transgressing the limits of imposed constraint.

Court-mandated mental health and substance abuse treatment presents particular conceptual difficulties. Mental health treatment and substance abuse programs are most effective when the patient is motivated for treatment. External compulsion to adhere to treatment appears to run contrary to this principle. Many patients are compliant with the requirement for treatment only for the time that it is mandated by the Court. However, others initially comply owing to external compulsion and discover that treatment is of value to them. In these latter cases, an injunction for treatment serves to introduce the individual over a significant period of time to the treatment, which he is then able to make his own.

An individual's degree of awareness of internal compulsion may depend on what form of psychopathology is present. Persons who experience an internally compelling force such as addiction or impulsivity sometimes develop techniques, either spontaneously or learned through treatment, to oppose the compulsion. These individuals may describe intense psychological discomfort in their awareness of a struggle to resist acting on the compulsion. Persons who fail to refrain from acting on their impulses may experience distress and shame at not following their own rules and values.

Applications in Legal Proceedings: Does Free Will Matter?

A fundamental principle of law is that of the reasonable person's choice in action [25]. This is most clearly present in assessing *mens rea* in determinations of responsibility in criminal proceedings. At the opposite end of the spectrum, strict liability assigns responsibility even in the absence of awareness of wrongdoing. The controversial area of unconscious motivation implies a choice without awareness, and is generally excluded from legal proceedings, though formulations of some factors below the level of the individual's conscious awareness may contribute to criminal mitigation.

Although the topic of compulsion seems to imply an understanding of the problem of free will, and the question of whether actions are freely willed or not has been explored extensively by numerous authors in different disciplines, ranging from philosophy and sociology to neuroscience, the concept of free will has only limited relevance in legal adjudications. Pockett outlines three main positions with regards to free will. The *compatibilist* view posits that "in the absence of external (and arguably also internal) compulsion, acts are said to be freely willed [26]." The *libertarian* view requires that action be initiated consciously to be free. The *incompatibilist* view, between compatibilist and libertarian views, relies upon the determinism of physical laws and therefore implies that either there is no place for conscious initiation of action, or that if there is a role for consciousness, it is subsumed to unconscious processes. Pockett reviews experiments that suggest that actions are initiated prior to the individual's awareness of action, and proposes that, although legal decisions currently rely upon the compatibilist view (absence of compulsion indicates choice and therefore responsibility), scholars may wish in the future to examine whether a more accurate definition of intent should include unconscious motive. Kroeber presents the historical background of this debate regarding physical determinism and concludes that although there may be physical (and biological) laws governing behavior, civil and human laws cannot be understood in these terms. He suggests that individuals under the law are presumed to be aware of their actions incompletely but to the best of their ability, and are therefore responsible [27].

Morse presents an overview of the debates regarding free will in the legal context [25], and concludes that the concept of free will has no place in forensic mental health assessment. He points out that legal decisions do not require an evaluation of the underlying cause of behavior, including whether or not the action was a product of free will. He argues that the compatibilist position is the relevant measure of volition, in that in the absence of compulsion, an individual is deemed responsible. The law assumes that individuals are rational subjects, and this rationality or lack thereof is appreciated at the level of individual behavioral differences independent of the metaphysical question of what type of cause underlies the behavior and whether or not the action was freely chosen in the sense of being initiated at a conscious level [25].

Conclusion

Compulsion is an abstract concept that pertains to diminished voluntary control over one's actions, owing to a force that may be externally imposed or which arises internally in the context of pathological mental conditions. Psychiatric disorders characterized by reduced impulse control or addictive patterns may contribute to behavior that brings the individual to the attention of the legal system, through criminal charges or civil suit. Although many different theories exist to explain a person's reduced control over behavior, further empirical research is required to describe the phenomenon fully and to synthesize the findings of disparate approaches. Whether external or internal, compulsion may induce suffering in the individual under its sway. In legal proceedings, compulsion is assessed on the basis of the individual's ability to exercise reason and the presence or absence of force, rather than on the basis of metaphysical

considerations of free will or the ultimate biological, social, or chemical causes determining action.

Compulsion Defense

Introduction

The law acknowledges that circumstances exist which may reduce or even exculpate an individual's behavior that would otherwise be considered criminal (*see also* **Insanity: Defense**). The fundamental principle that individuals may have genuine excuses for their acts, otherwise unacceptable in society, has its precedent in early social norms as well as in the history of criminal law. Nonetheless, few instances in the law elicit as much ambivalence as when individuals present themselves free from criminal responsibility due to unusual circumstances or states of mind. The most extreme example of the incapacity to be held criminally culpable, such as mental illness in the insanity defense, may be easier to intuitively accept as a legal standard because of the obvious deviations from common human experience.

The defenses of excuse, including coercion and compulsion, however, offer complex legal challenges that stem, in part, from their uncertain acceptance by society for psychological and scientific reasons. The circumstances of the criminal acts in compulsion defenses are such that we can readily imagine our own emotional and behavioral responses were we to face the same the terrible choices as the unfortunate defendant.

Society's mixed feelings regarding such defenses have perhaps contributed to the frequent confusion around their legal definitions and, as a result, the landscape of legal doctrine regarding such defenses is sometimes unclear. With advances in neuroscientific research in recent decades towards understanding the foundations of mental functioning and resulting human behaviors, there has also been heightened attention to its potential role in law rulings. Consequently, the legal principles of intention, choice (free will) and consciousness have been more closely scrutinized through the lens of neuroscience fueling an ongoing debate about its impact and in legal proceedings.

Definition of Compulsion Defenses

The word "compulsion" is defined in the Merriam-Webster Law Dictionary as "an act of compelling (as by threat or intimidation), specifically, 'coercion"' or "the state of being compelled, specifically 'Duress"'. A "compulsion defense" as a legal concept is vague in its definition because it is not a uniformly accepted term of art. Rather, the category of "compulsion defense" encompasses, according to some experts, distinct subbranches including defenses of "duress", "necessity", and "self defense" (the last of which will not be addressed in this review.) Here, the specific legal terms "duress" and "necessity" will be briefly discussed with respect to their distinctive uses as well as the relationship to the other related legal concepts of "excuses" and "justifications".

Duress

"Duress" is a defense accessible in the federal court system and also in several states. It excuses criminal conduct where "the actor was under an unlawful threat of imminent death or serious bodily injury, which threat caused the actor to engage in conduct violating the literal terms of the criminal law." Otherwise unlawful conduct caused by such duress will excuse the crime in question "unless that crime consists of intentionally killing an innocent third person" [1]. The historical rule of the common-law defense of duress does not apply to a charge of murder and thus far no federal courts have ruled on its admissibility as a defense to felony murder.

A defense of "duress" derives from the proof that a defendant was subjected to undue pressure or unusual circumstances outside of the defendant's control. An individual who commits an otherwise illegal act as a result of a threat of death or serious injury may affirmatively assert a defense of duress or coercion, thereby excusing him from criminal liability. A defendant exercising a defense of duress must bear the burden of proof being a preponderance of evidence. If the defendant is successful, some courts may give the prosecution the burden of persuading the jury that the defendant did not meet the elements of the defense.

Due to the heterogeneous nature of the legal criteria within statutory law and the variations among jurisdictions, the following elements represents a synthesis of common elements for the definition of duress: (i) an immediate threat of death or serious bodily injury to the defendant (The defendant must not merely perceive a threat, but must be actually faced with such a threat), (ii) a well-grounded

fear that the threat would be carried out; and (iii) no reasonable opportunity to avoid the threatened harm, (iv) any reasonable person in the defendant's position would have also committed the otherwise criminal act.

In practice, raising the defense of duress is seldom permitted during criminal prosecutions and, even where allowed to be presented to the fact finder, even less often successful in its outcome. In part this is due to the lack of agreement with respect to a fundamental legal theory or argument that would allow society to permit individuals to engage in unlawful behaviors. Also, the unclear nature of the law regarding these defenses reflects society's mixed feelings about the moral and emotional issues that underlie the issues of excuse and justification for otherwise criminal behavior. As reflection of this uncertainty, there has been sporadic attention in legal research for these issues except in cases of felony murder or where the issue of developmental dysfunction (e.g. Mental Retardation) is involved.

Necessity

The defense of "necessity" is distinguished from the defense of duress with respect to its legal criteria, although both constructs are seldom utilized in their essential forms. Commonly understood, the "necessity" defense is thought to pertain to threats from nature and its environment, while the duress defense has been relegated to circumstances in which the threats are considered man-made.

The necessity defense is raised when a defendant is faced with a naturally caused set of circumstances before being faced with a "choice of two evils". The necessity defense is often understood to be considered a "justification" defense based on the assumption that the individual chooses the lesser of two harms. The theory of "harms reduction" or "balance of harms" proposes that the harm caused by the individual's illegal act is less than were the actor to obey the law. An example would include an individual fleeing from an oncoming tornado and breaking into another residence's basement cellar for self-protection.

Conceptually related legal concepts include "justification" and "excuse" defenses. In such defenses, which also have been variably interpreted by legal scholars, the defendant has fulfilled the "mens rea" component of the criminal act, but has offered a conceivable argument as to why he should not receive punishment. In distinguishing a "justification" defense, the proposed argument is that an unlawful act was committed for the greater social interest. In contrast, an "excuse" defense asserts that specific circumstances prevent the individual from making a voluntary or free choice. A common example would include the insanity defense that is grounded in the individual's mental incapacity to make a reasoned decision.

In further clarification, one might consider the defense of "justification" to rest upon the nature of the criminal acts and the "excuse" defenses to depend upon the nature of the individuals who commit them. While there is no categorical distinction between the theories of "excuse" and "justification" when attempting to apply these constructs, duress is more commonly thought of as an "excuse". Some point to the absence of the underlying theory of "lesser of two harms" when clarifying duress from necessity. In further contrast between, the burden of the former lies with the defendant's affirmation while the burden of a justification defense would more expectedly rest upon the responsibility of the prosecution to prove its absence. In practice, these distinctions are artificially drawn and more often defenses are a combination of the two.

The Question of Neuroscientific Research on Issues of Criminal Responsibility

An analysis of criminal defenses based on internal [e.g., biological] and environmental variables that may potentially exculpate an individual would be ultimately unsatisfying without a brief mention of scientific research that has begun to challenge the underlying principles of our legal processes and systems. Advances in our understanding of the brain and its functioning have been increasingly focused on some of the most subtle and complex issues of the human experience, particularly, the empirical description of human consciousness and the notion of "free will".

These issues, once reserved for debate within the fields of philosophy and theology, are now receiving widespread attention for their potentially profound effects on legislation and case law. At the heart of one particular debate is the presumption of an individual's voluntary or "free" decision-making capacity that is a fundamental principle in the adjudication of criminal

responsibility. Scientific research has progressively attempted to break down and analyze the neurophysiological mechanisms behind such assumptions of "free will" and conscious intent, thereby raising questions about the nature of the law's authority.

Central to this neuroscientific discussion of "free will" was a series of experiments, developed by Benjamin Libet in 1983, in which attempted to trace the temporal relationships between an individual's conscious intent and the associated voluntary movement. Fundamental to Libet's work, was the previous determination of the "readiness potential" (RP), an electrophysiological measurement that, during an individual's decisional sequence, occurred hundreds of milliseconds before the recording of a voluntary movement.

In his experiments, Libet connected a series of electroencephalogram (EEG) electrodes to the scalp and mastoid areas of human subjects as well as an electromyography (EMG) electrode attached to their forearms. When the subjects were asked to move their arms, an EMG potential was recorded and a trigger signal was transmitted to the EEG recorder. Subjects were asked to watch a rotating spot of light on a cathode ray oscilloscope and were subsequently instructed to report on the position of the light at the moment of their being aware of wanting to move. This moment of first awareness was labeled "W" while the actual moment of movement was labeled "M". Approximately 40 trials of the EEG sweeps from the EMG recorder were then averaged.

Interestingly, the findings included averaged recordings of RPs occurring approximately 400 ms prior to "W" [the moment of first awareness] which itself preceded the measurements of "M" by approximately 200 ms. Libet's work demonstrated that measurable brain activity preceded not only voluntary movement but the individual's conscious awareness of that intent to move. Libet eventually hypothesized a "veto" function which would allow the conscious cessation of the unconscious decision in between moments "W" and "M".

Libet's work has been the source of extensive controversy; for its reliability, validity and its implications in legal standing. Using the ramifications of Libet's own work, critics have emphasized the confounding nature of other variables such other unaccounted events that affected his experiment. This would theoretically include the notion that the subjects' experience from the experiment's inception [e.g., when the subjects were first informed of the nature and details regarding the experiment's instructions] had created corresponding neural correlates to that experience and may have also effected the measurements of brain activity during recording.

Nonetheless, subsequent research in England [2] seemed to corroborate some of Libet's work, neuroanatomically mapping activity to three localized brain structures including the dorsal prefrontal cortex, the intraparietal sulcus and the presupplementary motor area. This and other similar research has subsequently underscored the issue that intentionality may truly commence before the individual's conscious awareness and, strangely, that the individual's attention to the preceding "absence" of awareness of the thought may actually catalyze the action itself. Alternatively understood, brain activity initiates a decision-making process before the conscious mind becomes aware of its intentions.

For some, these and similarly replicated results have reignited the age-old debate over the existence of "free will", a presumption upon which our modern legal system is commonly thought to rest. Instead, the implications of neuroscientific explorations have lead some, such as Daniel Wegner, to postulate that human behavior is derived from "determined and mechanistic processes". Such a position asserts that human behavior is more complex and comprehensively accounted for by the nuances of biological and neurophysiological processes that exist outside the human consciousness than by the reliance on the "incomplete" experience of our conscious will.

Some thinkers convincingly argue that these cellular and biological processes are shaped by previous environmental and emotional experiences which become part of the brain's "hard-wiring". These neurobiological representations then serve as activated cognitive substrates during future decision-making that are then triggered by similar environment stimuli of stressful situations or hard decisions.

Such research has raised the issue of the increasingly complex interplay between consciousness and unconsciousness during a decision-making processes. Do individuals freely make conscious and rational decisions for themselves and what are the forces (e.g., internal, environmental) that may shape the individual's rational choices and conscious behaviors?

Another neurobiological perspective on the process of decision-making is found in the research of Antonio Damasio who has explored the neural

basis of emotions and their inextricable relationship with the frontal lobe, the center of conscious control of human behavior. Damasio's work argues that emotions, as biologically represented in the limbic system, have profound influence over the regulation of an individual's decision-making processes. Damasio argues in his "Somatic Marker Hypothesis" that emotions arise from an integration of "somatic markers", direct signals from the body that are cognitively represented in the brain (particularly the ventromedial prefrontal cortex) and are recruited for, among other higher functions, the regulation of "rational" decision-making processes.

The above examples of neuroscientific research and the profound issues of morality they have been proposed to address are not offered to represent an established or cumulative body of evidence. Rather, these explorations are meant to underscore the scientific community's rapidly growing efforts at revealing the complex nature of the intersection between biology and human behavior. The interface of neuroscience and the law proves to be an exciting yet far from determined relationship.

Computer Animation and Simulation Evidence

Introduction

The presence and implementation of multimedia devices in the courtroom has become an increasingly common sight, in recent years.[a] Especially true in today's world, multimedia technology involves the extensive use of computer-generated visual products. Visual representations of key testimony and evidence both simplify and expand the ability of attorneys and experts to educate juries about complex information. Computer animations and simulations are two highly effective examples of visual techniques that break down dense information into manageable and compact segments. This technology served as one of the first types of computer-driven and created evidence introduced into the American legal system.

One significant reason for the relatively early use of computer animations and simulations is the immediate impact such evidence has on jurors. Additionally, animation and simulation was inexpensive compared to other multimedia options available 20 years ago [1].[b] While the humble beginnings of computer-generated evidence in the courtroom were mainly restricted to airline and vehicular accident scene reconstruction, the present technology has litigants employing animations and simulations in all manner of civil and criminal trials. Software is now interactive allowing experts to make adjustments during testimony and advanced enough that complex processes such as chemical reactions and machinery operations can be represented with relative ease.[c] To better understand why animation and simulation can be so important to a party's case, this article provides a brief explanation of how these technologies are viewed in the context of the courtroom,

including their influence on crime and accident scene processing.

Animation vs. Simulation

While computer animations and simulations may appear interchangeable on the surface, the construction methods and intended purposes of each differ. Computer animations are created in a two-step process that results in moving images much like those seen in animated movies. First, three-dimensional representations of all objects/locations to be included in the animations must be documented and then the images must be designed to move in a way that accurately represents the scene or information one is trying to show [2]. At this point, the still frames are strung together and played back in a set sequence; this results in a moving picture. Computer simulations, on the other hand, use both animation and mathematical computation to produce an illustrated presentation of possible outcomes predicted by a computer based on certain preset parameters [3].[d]

For instance, in an accident reconstruction simulation, facts about the accident are entered into the computer, which are then generated into probable outcomes based on assumptions the computer is programmed to apply. Specifically, alternative conclusions can be hypothesized, such as the wearing of a seatbelt, weather conditions, time of day, etc. Once a simulation is produced, it is converted into a graphic animation that can be stored on a CD or computer hard drive.[e]

Current Technology

As the use of computer-generated evidence has increased over the past 15 years, the methods used to collect the necessary information to formulate the recreations have advanced as well. The most up-to-date technology developed for crime and accident scene reconstruction involves the use of a device called a *total station*, which utilizes forensic mapping technology to coordinate and collate the pertinent data [4].

The total station is composed of four parts: a theodolite, an EDMI, an optical prism, and a data collector. A theodolite is an instrument that measures angles on horizontal and vertical axes. An EDMI (electronic distance measuring instrument) measures distance via infrared diode. The optical prism reflects the light emitted by the EDMI, and the data collector captures the measurements generated by the EDMI and theodolite and adds graphic attributes. These measurements are then fed into a forensic mapping program that converts the data into a diagram of evidence locations through a polar coordinate system.

When an investigator wants to use this system to record an accident or crime scene, an investigator will hold a pole, with the optical prism attached to the top, over the evidence to be documented. The infrared diode on the instrument is focused on the prism and reflected back, which allows the data collector in the machine to record the distance, angle, and elevation of the evidence. The operator presses a button to record the evidence and assigns it a code. He can then move on to the next location. Once all the sites at the scene are recorded, the information can be downloaded to a laptop on-site and later converted to an animation or simulation for use in court.[f]

Case Examples

In addition to the technical differences between animations and simulations, there is also a legal distinction applied by courts that determines the evidentiary function the moving images will have in the case presentation. If the images are merely presenting a moving illustration of testimony, then it is considered demonstrative evidence and referred to as an *animation*. The standard of admission for animation demonstrative evidence is fairly low requiring only that the evidence be relevant, accurate, and the probative value outweighs the possibility of prejudice [5]. On the other hand, if the images are meant to convey evidence to a jury, it is called a *simulation* and treated as substantive evidence subject to admission standards under *Daubert* or *Frye* [6].

While computer animation made its start in civil litigation, the first reported use of animation in an appellate criminal case was *People v. McHugh* [7]. The defendant, charged with second-degree manslaughter and driving while intoxicated, attempted to enter, into evidence, a computer recreation of his version of the events. The state argued that the evidence should be evaluated by the court via a pretrial *Frye* hearing as scientific evidence to ascertain if the mathematical formulas and techniques used in the computer program were reliable and generally accepted in the scientific community. The court,

however, did not view the recreation as scientific evidence and compared the presentation to a hand or mechanically drawn diagram. As an aid comparable to a drawing, the method of production is not the controlling factor in determinations of admissibility. Additionally, the court described computers as "mechanical tools – receiving information and acting on instructions at lightning speed" and held that the evidence was admissible provided it was relevant, accurate, aided the jury in understanding testimony and the expert was properly qualified.

Somewhat surprisingly, there are still courts that have not specifically decided if this type of evidence is admissible, despite the infiltration of computers into myriad aspects of daily life. A 2006 decision by the Pennsylvania Supreme Court, *Commonwealth v. Serge*, presented this question as an issue of first impression [8]. A defendant appealed the commonwealth's use of a computer-generated animation that depicted the state's version of the events that led to the murder of the defendant's wife. The information produced in the animation was based on physical and forensic evidence and was viewed by the trial court as a demonstrative aid for the jury to better understand the purported sequence of events. As a preliminary matter, this court noted that computer-generated evidence is just another mode of expressing information traditionally done through drawings or diagrams and as such, should not be held to a different or higher admissibility standard than other types of demonstrative evidence. Further, the court acknowledged that while this evidence may be more persuasive to a jury, that fact alone is not sufficient to warrant its exclusion. Thus, the court evaluated the evidence under the demonstrative evidence standard for admission: authentication, relevance, and probative value. The crucial prong for purposes of this case was whether the probative value of the computer-generated evidence outweighed its prejudicial effect. The court determined that the content of this presentation was not inflammatory beyond the extent inherent to a depiction of murder. The court specifically pointed to the following factors in not finding prejudice: (i) the absence of sound, (ii) no facial expressions, (iii) lack of life–life motion, (iv) no transition between scenes to create a story line, and (v) no images of blood or other injury. Therefore, the trial court properly allowed the admittance of the recreation animation.

While the admissibility requirements for computer animation are not complex, there are cases in which animations are not admitted into evidence. In *Dunkle v. State*, the state introduced four computer animations reenacting a murder based on statements made by the defendant and witnesses and physical evidence found at the scene [9]. The different scenarios presented to the jury were intended to dispute the defendant's version as inconsistent with the evidence. The animations placed the victim and gun in the same place but varied the location and actions of the defendant. The court questioned the accuracy and relevancy of the asserted sequences of events because the state had little physical evidence to go on in forming its version and the inconsistent statements of the defendant about the crime made it almost impossible to determine what story the state was arguing against. Consequently, it held that the admissions were improper and their admission was not harmless error. Further, the court acknowledged the strong impression and air of truth digital recreations give to juries and found the prejudice these animations would create due to the unsupported assertions that outweighed any relevancy or probative value they could have. Upon retrial, this court also required the trial court to issue instructions to the jury explaining the limited purpose of the reenactments as constructed illustrations of an expert's testimony and not substantive of the events that actually occurred.

By contrast, an example of the much more stringent admission requirements for computer simulations is illustrated in *State v. Sipin* [10]. In this case, the admissibility of a computer simulation was tested under the *Frye* standard for novel scientific evidence. The defendant was charged with vehicular homicide, and the state wanted to use an accident reconstruction simulation to show that the defendant was driving at the time of the accident using a simulation software program called *PC-Crash*. Specifically, the computations input into the program were supposed to produce the body movements of the multiple vehicle occupants during a multivehicle accident. The defendant objected to its introduction asserting that the state's expert had not validated the accuracy of the program for the predictive outcomes formed.

An accident reconstructionist expert produced two validation studies on the accuracy of the predictive simulations in car accidents. The first assessed the program's ability to predict accident-related information such as tire marks and speed against real world

data. The second looked at the body movement of a pedestrian hit outside of a vehicle during an accident. No validation study was produced that examined its accuracy in ascertaining the movement of multiple bodies within a car during an accident, and this program had never been used in a Washington court to predict interior movement in a comparable event. The expert supported his use of the program by arguing that the kinetic principles used to predict body movement inside and outside a vehicle do not differ and stated that there was not a debate in the scientific community about the ability of the program to calculate interior movement.

In determining whether scientific evidence meets the *Frye* standard of admissibility, the proponent must show that the science is generally accepted as valid among members of the relevant scientific community. Further, the application of the science at issue must be proper and accurate. In the case at bar, the court held that the application of the PC-Crash program to assess the body movement of interior occupants during a multivehicle crash was not proper. Manuals from the manufacturer explicitly warned of limitations the program had in calculating interior movement in accidents occurring at speeds in an excess of 40 kilometres per hour. Further, a multibody software option developed by the manufacturer to predict movement during accidents had preset physical parameters that constrained the predictive capabilities of the program. Also, a distributor of PC-Crash and a software programmer who worked on accident reconstruction programs both testified that PC-Crash was not sophisticated enough to produce accurate predictions for accidents of this type. Finally, the defendant produced three papers that argued against the accuracy of the program. These things in combination indicated to the court that there was not a consensus in the scientific community on the accuracy of PC-Crash and, consequently, it held that the simulation was inadmissible.

End Notes

[a.] In fact, some organizations are actively promoting and supporting the integration of technology into the courtroom, hoping to enhance the ability of the legal system to achieve justice. See the Center for Legal and Court Technology at William & Mary Law School. http://www.legaltechcenter.net

[b.] However, the cost of computer-generated evidence can easily add up to tens of thousands of dollars depending on the complexity of the reconstruction or process being depicted.

[c.] See Animators at Law (www.animators.com) for examples of animation representing biological processes, machine operation, and accident recreation.

[d.] Put simply, animations recreate real past events based on known facts, and simulations combine facts from past events with assumptions about various ways the events could/should have unfolded.

[e.] Under the category of animation, there is another type of computer-generated motion image known as *recreation animation*. This differs from basic animation in that it relies on scientific data to form the moving representation and is not limited to reproducing eyewitness testimony. The information put in is culled from facts determined after the occurrence of the illustrated event. Thus, some assumptions are made about the sequence of events and impact of forces, but it does not create predictive outcomes found in computer simulations.

[f.] Numerous software programs exist that can work in conjunction with total stations to create 3-D images. Some of these include Crime Zone, iWitness, and MapScenes.

Computers

Introduction

Computer forensics is a fast growing area. In businesses and in law enforcement, the number of people involved is growing rapidly. Computer forensics can be described as "the use of specialized techniques for recovery, authentication, and analysis of electronic data with a view to present evidence in a court of law".[a] Within law enforcement, some of the objectives are to find information that might contribute to an insight into what has happened in an investigation, and who was responsible. Important issues are that the data on the seized computers are not altered and that a clear chain of evidence is documented.

Traditionally, a distinction is made between computer forensics (hard drives), mobile phone forensics, and video. Nowadays, mobile phones and personal digital assistants like the IPAQ or Blackberry are like computers with a hard drive and therefore are dealt with in mostly the same way. Standard software mostly used within law enforcement for these products are "Encase", "Ultimate Toolkit", XRY, and Tulp 2G (developed at the Netherlands Forensic Institute).

Digital video is still a different field because, although they are basically like computers with a hard drive, the problem with proprietary systems is so great that different techniques need to be used.

Multimedia

The popularity and ubiquity of mobile devices is immense and growing in an exponential way. There are systems and capabilities that would have been more akin to a computer in the past. Hand-palm computers and phones but also MP3-players, iPods, PS3, and even navigation systems are used for multimedia storage. The possibility to connect anything with everything and going online adds to three trends:

1. Data storage on an ever-growing number of different digital devices;
2. Growing volume of storage (especially due to the increase in photo and video shooting); and
3. Online storage is a network attached storage (NAS) where computers can access storage at file level over a local area network (LAN), a wide area network (WAN), or the Internet.

Storage is of two main forms: primary storage (local random-access disk storage and secondary storage (offline, sequential-access storage, e.g., magnetic tape).

There is a division to be made on the different types of storage media. Mostly, they are divided into three categories: magnetic, optical, and electronic, with each a total different technology.

1. Magnetic storage media
   - magnetic tape
   - floppy disks, Zip drive, JAZ drive, etc.
   - hard disk
2. Optical media
   - CD-R
   - CD-RW
   - DVD
   - DVD-RW
   - DVD+RW
   - DVD-RAM
   - Blu-Ray
3. Electronic storage media, which is used in digital cameras – video cameras and various types of MP3 players and portable gaming devices. With some of these devices "card readers" may be obtained as an accessory
   - Compact Flash (CF)
   - Ultra CF
   - SmartMedia
   - Memory Stick
   - MultiMediaCard (MMC)
   - xD Picture Card
   - PocketZIP
   - Microdrive
   - USB thumb drives
   - SIM cards (in mobile phones)
   - Portable navigation systems (e.g., TomTom wherein the newer systems have 20 GB hard drive mounted with 12 GB of the available memory).

There are also specialist gaming devices, wherein memory sticks are used as extendible memory, PSP, Playstation 3 and newer models of the Sony Ericsson mobile phones.

Hard Disks

For the majority of systems, tools such as FTK (http://www.accessdata.com/) and Encase (http://www.

guidancesoftware.com/) or the Linux variants of dd, for example, rdd, http://sourceforge.net/projects/rdd provide the necessary means to image and analyze hard drives. Special care has to be taken with redundant array of independent disks (RAID) systems, the technology where large amounts of DATA are being stored and which need to be secure and quickly accessible. Each array is seen by the computer system as a single hard disk even if there may be 2, 3, 4 or more physical hard disks in the system. RAID systems mostly use level 0–5 or a combination of them and mostly use SCSI disks as a base but there are controllers which use IDE/SATA. Special care has to be taken with acquiring and analyzing RAID systems, for example, drive order, block size, and direction of rotation. With networks, the aim here is to capture information (data) that moves over a network and make sense in a forensic way. A much-used forensic tool here is that from EnCase Enterprise, among other tools, which do in-depth analysis and network monitoring and detecting tools.

Systems such as Apple are taking an increasing share of the market due to popularity of their products, e.g., Ipod, Imac, Macbook (Pro) and the newly arrived iPhone. More Apple computers are coming to homes and businesses with a lot of them replacing Unix desktops and with the possibility for running multiple operating systems, it is getting increasingly popular and used more and more as a platform. This means that more such systems are involved in forensic examinations.

Securing Data from a Macintosh Computer

As most documentation has been written about Windows machines, this document concentrates around the newest technologies concerning the Macintosh and will give a brief explanation of the use of FireWire Target Disk Mode (TDM). TDM is a technology, which enables Macintosh computers to act as an external, Firewire hard disk. The advantage is that a Macintosh research computer could investigate and secure the data of another Macintosh computer in a forensically safe way.

Investigators should be very aware that the data is probably written onto the system under investigation when it includes installed FAT or NTFS partitions. These partitions are installed with BootCamp, for example, which is a standard tool of Mac OS X. This is caused by the FireWire connection, which is not write blocked in any way.

It should be noted that EnCase (versions 6.X) includes a write-blocker option within the Tools menu, but experts (e.g., the New York Forensic Department of the New York State Police and the FBI) have not (scientifically) endorsed that tool yet. Until now, there are no so-called "White Papers publications" on this method of write blocking. It is obvious that trusting on changing registry settings is venturing on thin ice. For this reason, it is *not* recommended to use TDM in combination with a Windows research computer.

A useful tool to secure a Macintosh computer is to use a LiveCD facility. There are various CDs available of which the EnCase Linen CD is a good example. For example, with this CD a Macintosh computer can be secured (in server mode) via a network connection (cross cable). Another Unix-oriented boot CD is Ubuntu, which makes copy of the hard disk via DD (*disk dump*, a Unix program to copy and convert files.)

It is very important when booting a system with a boot CD (to avoid writing actions on the Macintosh computer) that the computer is switched on with the CD placed in it (or insert it simultaneously during computer start-up) with the "option" key (i.e. Alt key) pressed. Within a few seconds, the Mac will show a list of bootable devices. You will then select your boot CD and start DD (a command line utility) to make a copy of the system that is under examination. Mac forensic users could also use, among others, the Macquisition Boot DVD. When used properly and observing the procedures correctly, the Macintosh research computer will not access the filesystem or other available data.

For a digital forensic examiner with a Macintosh research computer, TDM is an extremely useful tool. Its procedure is as follows.

Check whether the Mac system under investigation is switched off. When it concerns an Apple laptop, connect the AC power supply.
Boot the system while pressing the "Option" key. This may have the following outcome: a list of bootable devices or you will see a prompt for the FirmWare password. In the latter case, it is impossible to use TDM.

Use a Fire Wire cable to connect the research computer with the system under investigation. If it concerns a Mac, it is not necessary to switch off your own research system.
Switch on the system under investigation and immediately press the "T" key and keep it pressed until the FireWire icon appears. The hard disk of the system under investigation will now be available on your research computer (preferably a Mac) and will appear by using the Explorer (PC) or it will appear on your desktop (Mac).
When you have finished your investigation you will drag the icon of the system under investigation from your research Mac to the waste paper basket, select "put away" when Mac OS9 is concerned or "eject" from the file menu under Mac OS X.
Switch off the system under investigation by pressing the power switch.
Remove the Fire Wire cable from the systems.

Important Notes

On the Mac research computer->Disk Arbitration should be switched off on the research system. Disk Arbitration is a daemon (background process) in OS X, which mounts filesystems automatically. For example, mounting your USB memory stick and after this it will appear on your desktop.

Disk Arbitration will mount the available volumes in a read/write mode, which is not desirable in a forensic investigation. This could be avoided by switching off Disk Arbitration on the Mac.

Another important addition (made by Apple) further explains as follows:

Fire Wire Target Disk Mode functions on internal ATA drives only. TDM only connects with the master ATA drive on the Ultra ATA bus. TDM does not connect with a Slave ATA, ATAPI, or SCSI drives available on the system. This means that it is impossible to connect to a system in which more drives have been installed of the aforementioned types. If it is known that there are two or more hard disks in the system, it is probably better to use the Live CD method to switch on and acquire the system (read the part on the EnCase LinEn CD and Macquisition Boot DVD).

Note BootCamp:
If a system is switched on by pressing the "Option" key and a drive appears with "Windows" on it, then BootCamp has been installed.

Note EnCase Unallocated clusters:
If Unallocated clusters are only seen after acquiring a Mac hard disk with the help of EnCase, then "H+" within these clusters should be sought. "H+" is at the start of a sector and marks the beginning of a partition. After this, by going back two positions in EnCase this can be marked as a partition and EnCase will now display the data/volumes.

Note EnCase partitions:
EnCase will often show partitions without any information. These are the so-called driver partitions.

During the investigation of a system, it is very important to test the research tools and validate the results with other research tools before evidence is brought to court.

Phones and PDAs

XRY, TuLP2G, Neutrino, PDA analyzer + PDA Express, and Paraben Device Seizure are examples of tools used for examining phones and PDA's.

PDA's and mobile phones nowadays have more and more the same functionality and have added the possibility to be used as Mp3 players, camera's, Internet (WiFi) connectivity and also as gaming platforms. Nokia is re-releasing the N-Gage phone as a gaming platform and Sony Ericsson has plans to release a gaming phone not to mention the recently added iPhone and new generation iPod touch by Apple.

Furthermore, we have to be aware that the same way laptop data is being protected by antivirus, firewall, and encryption software the same applies to PDA's and smart phones.

Dealing with encrypted PDAs and smart phone devices, it is best practice not to switch them off as this might result in the device not being accessible next time it is turned on. The accessible data of the device should be copied before it is switched off and therefore available to the forensic software.

The iPod, for instance, has been overlooked previously as a device where evidence could be extracted from. However, it has become clear that it can store vast amounts of data, has PDA like functions and it can be hacked and customized so it will be increasingly used in crimes.

One of the tools to analyze the iPod is EnCase by Guidance Software. Apart from being recognized by law enforcement and the courts, it does a good

job at recovering data (even deleted) from the iPod even if it has been (re-) initialized. Most of the iPod investigation can be done on a PC but when required a Mac can be used. Write blocking is in order when analyzing the iPod. It is best that for write blocking a hardware write blocker is used. When using the USB write blocking functionality in Windows XP SP2 investigators should be aware of the fact that it will allow write access to the device when it does not recognize the file system.

It is also recommended that during the investigation that the hash value[b] (a digital fingerprint of a file) is verified at various stages to ensure that the contents have not changed.

Also hard drives which contain read errors or which have been damaged are examined at forensic laboratories. When repairing hard drives one can chose to do that a specialized company or obtaining the knowledge of reparation yourself. One should have training, and it is advisable to have a collection of hard drives, in order to exchange, for example, a damaged controller.

Video

Due to the increase of digital closed circuit television (CCTV) systems in public areas, this area of work has added a complete new discipline to the forensic field workers. Very often the systems contain proprietary software, which makes it impossible to view the images with standard tools. In the worst case scenario, the hard drive with the images only work in the original machine. Also, the systems do not always have an input/output interface for making a right connection.

When dealing with CCTV systems, it is very likely that several cameras will be connected to it. Therefore, special forensic research computers with special software are needed. Examples of widely used software are IMPRESS from IMIX and and Video Investigator from Cognitech, which are forensic suites of tools that enables demultiplexing, frame averaging, duplication, video level adjustment, magnification, highlighting, and obscuring of multiple subjects and specific areas.

Challenges Ahead

- Addressing the fast growing complexity and diversity
  Different techniques and tools are needed to collect all the evidence from a device.
  An example of the wide range of knowledge demanded from forensic investigators is pointed out in the "iPod Forensic Update" [1]. In the default mode, the iPod can accept audio-, video-, and photo-based files. In the disk mode, however, it acts as a hard drive to which any type of file can be transferred through Windows Explorer, these files are not visible on the iPod while browsing it. Another example is the use of Encase on Apple computers, although a good thorough tool, there are some items it does not show.
- Storage of data online as a trend in society.
  Especially, in the child porn business both the use of encryption and central data storage (on the internet) is a growing problem. Different legislation in different countries severely restricts the investigation.
- Storage of the increasing amount of collected multimedia evidence in the law enforcement directorate itself. For this a solution has not yet been found.
- Proprietary software this is especially a problem in the camera industry, video is often stored in a proprietary software format on hardware sometime does not even have an output channel. To collect this kind of evidence means often making a copy with data loss and therefore not having an exact image. By well documenting the followed actions, the evidence is still acceptable in court;
- Vulnerability of tools (they are not well protected against viruses and Trojans) encryption is an increasing problem, as it is ever more widely used. If encryption is implemented not in the right way, it sometimes can be broken easily. However, if strong encryption is used, it will take much more effort and computing power to break the encryption. Depending on the passwords and the passphrases that have been used, one can do password guessing with dictionary attacks or try to receive the keys from the suspect.

The advantage in forensics examinations of an encrypted drive/device is that when the encrypted partition is in use special forensic tools give you the ability to obtain data and possible valuable information when the encrypted partition is unlocked. This is called a *live investigation*, which as a rule should be

done with the utmost care and procedures. Several best practice manuals exist, for example, from the Working group forensic IT from the European Network of Forensic Science Institutes, www.enfsi.eu. The live investigation can also be helpful to do a search for child pornography images at different systems without having to image the complete system, and realizing a faster response rate.

Conclusion

The challenge ahead is that the storage space grows very rapidly, and people distribute their information (encrypted) on the Internet. Furthermore, malicious software also influences the evidence, since in practice it is possible that this software is used in a distributed network without the person possessing the PC being aware of it. Also storage devices get smaller each year, and for having all digital evidence it is also important to look for other digital devices. Also, forensic laboratories will have to cope with an ever-growing storage space to several thousands of terabytes in a few years, with appropriate backup facilities.

End Notes

[a.] http://www.forensicfocus.com/

[b.] www.wikipedia.org/ A hash function takes a long string (or "message") of any length as input and produces a fixed length string as output, sometimes termed a *message digest* or a *digital fingerprint*. A hash value (also called a "digest" or a "checksum") is a kind of "signature" for a stream of data that represents the contents. One analogy that explains the role of the hash function would be the "tamper-evident" seals used on a software package.

Confession *see* Interrogative Suggestibility

Confessions: Evidentiary Reliability of

Introduction

A "confession" is any written or oral statement in which a person admits to having committed some transgression, often indicating acknowledgement of guilt for a crime. In some settings, confessions are considered necessary for absolution, social acceptance, freedom, or physical and mental health, making it easy to understand why people often exhibit an "urge to confess". In other settings, however, confessions predictably result in personally damaging consequences to the confessor – such as a loss of money, liberty, or life itself – making it difficult to understand this aspect of human behavior.

In criminal law, confession evidence is considered a highly potent weapon of prosecution, suggesting that "the introduction of a confession makes the other aspects of a trial in court superfluous" [1]. On the one hand, confessions play a vital role in law enforcement and crime control. On the other hand, they are fallible and serve as a source of recurring controversy, with questions often arising about whether a statement is authentic, voluntarily given, the product of a competent waiver of rights, and in accord with the law. For all of these reasons, confessions have been described as "troubling" [2].

Contradicting the pervasive myth that people do not confess to crimes they did not commit are numerous instances throughout American history, beginning with the Salem witch trials of 1692, in which men and women were wrongfully prosecuted, convicted, imprisoned, and sometimes sentenced to death, because of false confessions. The prevalence rate is unknown, but analyses of wrongful convictions reveal that between 14 and 25% of prisoners exonerated by DNA or other means had confessed to police. Importantly, it is clear that these discovered instances represent the tip of a larger iceberg [3–5].

After reviewing a number of past cases, and drawing on psychological theories of social influence, Kassin and Wrightsman, in 1985, proposed a taxonomy that distinguished three types of false confessions: voluntary, compliant, and internalized [6]. Still used today, this classification scheme has provided a useful framework and has since been used, critiqued, extended, and refined in subtle ways [7].

"Voluntary false confessions" are those in which people claim responsibility for crimes they did not commit without prompting or pressure from police. Often this occurs in high profile cases. When Charles Lindbergh's baby was kidnapped in 1932, 200 people stepped forward to confess. When "Black Dahlia" actress Elizabeth Short was murdered and her body sawed in half in 1947, more than 50 men and women confessed. More recently, in 2006, John Mark Karr volunteered a confession, replete with details, to the unsolved murder of young JonBenet Ramsey. There are many reasons why innocent people might voluntarily confess – such as a pathological need for attention, notoriety, or self-punishment; residual feelings of guilt; delusions of their own involvement; the perception of tangible gain, real or imagined; or the desire to protect a parent, child, or someone else.

In contrast to voluntary false confessions are those in which suspects are induced to confess through the processes of police interrogation. In "compliant false confessions", the suspect acquiesces to the demand for a confession in order to escape from a stressful situation, avoid an expected punishment, or gain a promised or implied reward. Akin to the classic forms of influence observed in social psychological studies of conformity, compliance, and obedience to authority, this type of confession is a mere act of capitulation by a suspect who knows that he or she is innocent. Psychologically, these confessions are easy to understand, as they arise whenever a suspect comes to believe that the short-term benefits of confessing – such as being left alone, fed, or released – outweigh the long-term costs associated with prosecution, the loss of reputation, and incarceration.

In the extreme, this type of false confession was seen in *Brown v. Mississippi* (1936), a case in which three Black tenant farmers confessed to murder after they were whipped with a steel-studded leather belt [8]. More recently, it was multiply illustrated in the 1989 Central Park jogger case, where five New York City teenagers confessed after lengthy interrogations, in vivid detail, each claiming he expected to go home afterward. On the basis of these confessions, the boys were convicted and sent to prison, only to be exonerated 13 years later when the real rapist gave a confession that was confirmed by the original DNA evidence [9].

"Internalized false confessions" are those in which innocent but vulnerable suspects, exposed to highly suggestive interrogation tactics, come not only to capitulate in their decision to confess but also to believe that they were culpable, sometimes confabulating false memories in the process. Gudjonsson and MacKeith argued that this effect stems from "memory distrust syndrome", whereby people come to distrust their memory, which renders them vulnerable to misinformation from external sources [10]. This phenomenon is closely related to psychological studies involving the creation of false memories for words in a list, visual images, and past experiences.

The case of 14-year-old Michael Crowe, whose sister Stephanie was stabbed to death in her bedroom, illustrates the problem. Michael had adamantly asserted his innocence, but police targeted him for suspicion. After a series of interrogation sessions, during which time Michael was deceived into thinking there was substantial physical evidence of guilt (e.g., that his hair was found in Stephanie's grasp), he concluded that he was a killer, saying: "I'm not sure how I did it. All I know is I did it." Eventually, he was convinced that he had a split personality – that "bad Michael" acted out of a jealous rage while "good Michael" blocked the incident from consciousness. The charges against Crowe were later dropped when a drifter in the neighborhood that night was found with Stephanie's blood on his clothing [11].

Recent research on the causes and consequences of police-induced confessions has focused on three processes: (i) the preinterrogation interview during which police judge people to be truthful or deceptive, (ii) the interrogation processes that lead certain suspects under certain conditions to confess, and (iii) the influence of confession evidence on judges, juries, and other decision makers.

The Preinterrogation Interview

Typically, the confrontational process of 'interrogation' is preceded by an information-gathering 'interview' designed by police to determine if a suspect is guilty or innocent. Sometimes, that initial judgment is

reasonably based on witnesses, informants, or other extrinsic evidence. At other times, it is based on a clinical impression formed during this interview. In "Criminal Interrogations and Confessions", first published in 1962 and still the most influential manual on interrogation, Inbau, Reid, Buckley, and Jayne (2001) advise police in the use of "behavior provoking questions" and observation of verbal cues, nonverbal cues, and behavioral attitudes to detect deception – they claim, at high levels of accuracy [12].

For people who stand falsely accused, this first impression often determines whether they are interrogated or sent home. Yet in laboratories all over the world, research has shown that people are only about 54% accurate in judging truth and deception; that training produces little, if any, improvement compared to naive control groups; and that police, customs inspectors, judges, psychiatrists, and other so-called experts perform only slightly better, if at all [13, 14].

Assessing performance in a forensic context, researchers randomly trained some lay participants but not others in a popular law enforcement method of truth and lie detection. These students then watched videotaped interviews of mock suspects, some guilty and others innocent, all of whom denied their involvement in various mock crimes. As in nonforensic studies, observers were generally unable to differentiate between guilty and innocent suspects. Moreover, those who underwent training were less accurate, more confident, and more biased toward seeing deception [15]. Using the same tapes, other researchers found that experienced samples of police detectives exhibited these same tendencies – a finding consistent with studies suggesting that current law enforcement training may lead police to make prejudgments of guilt, with confidence, that are frequently in error [16].

Recent studies suggest that human lie detection performance can be improved. In one research program, Hartwig and colleagues found that interviewers can increase their accuracy by withholding crime details while questioning suspects, which traps those who are guilty but not innocent in inconsistencies when these facts are disclosed [17]. In a second research program, Vrij and colleagues note that because lying is more effortful than telling the truth, interviewers who tax a suspect's cognitive load (for example, by asking challenging questions or reversing their order) can make more accurate true–false judgments by attending to effort cues – such as response hesitations or the use of simple language [18].

The Processes of Interrogation

To protect citizens against violations of their constitutional rights and to guard against wrongful convictions, American courts have set guidelines by which confessions are admitted into evidence at trial. For judges to consider on a case-by-case basis, in the context of a "totality of the circumstances", confessions are admitted if deemed voluntary but excluded if coerced.

Many years ago, interrogators used bright lights, brute force, the rubber hose, and physical intimidation to get confessions. Today, however, the police are required to warn suspects of their "Miranda" rights to silence and to an attorney and are legally prohibited from drawing confessions through violence, physical discomfort, threats of harm or punishment, or promises of leniency or immunity. Hence, the use of physical force has given way to more psychologically oriented techniques.

Observational studies have confirmed that modern police interrogation is psychologically oriented, often involving feigned sympathy and friendship, appeals to conscience and religion, confrontations with evidence, the alternation of good cop and bad cop, and other forms of trickery and deception [19]. In a recent survey, 631 police investigators reported that the tactics most frequently used were to physically isolate the suspect from family and friends, typically in a small private room; identifying contradictions in the suspect's account; trying to establish rapport in order to gain the suspect's trust; confronting the suspect with evidence of his or her guilt; and appealing to his or her self-interests [20].

Today, a number of manuals are available to train police in how to elicit confessions through interrogation. The text "Criminal Interrogation and Confessions", cited earlier, teaches the popular Reid technique (named for its founder, John Reid), a nine-step interrogation program that is essentially reducible to an interplay of three processes [21]: "*isolation*", which involves placing the suspect into a small, barely furnished, soundproofed room to increase stress, discomfort, and the suspect's desire to escape; "*confrontation*", in which the interrogator

strongly accuses the suspect of the crime, sometimes citing real or fictitious evidence to bolster the claim; and "*minimization*", in which a sympathetic interrogator morally justifies or excuses the crime, leading the suspect to infer that he or she will be treated with leniency upon confession. Once these processes elicit a suspect's admission of guilt, investigators are trained to convert that simple admission into a full and detailed narrative confession.

False Confessions

As prescribed, police interrogations should lead guilty suspects to incriminate themselves by reducing the perceived negative consequences of confessing while, at the same time, increasing the anxiety associated with continued deception. However, actual cases as well as psychological research indicate that this approach may induce innocent people to confess. As for risk factors, some suspects are particularly vulnerable to manipulation; some tactics are particularly coercive.

Dispositional Vulnerabilities

Some suspects are dispositionally more vulnerable to influence than others – and at greater risk for false confessions. Focusing on personality traits, Gudjonsson [22] has found that individuals who are prone to "compliance" in social situations are especially vulnerable because of their eagerness to please others and a desire to avoid confrontation, particularly with those in authority. Individuals who are prone to "suggestibility" – whose memories can be altered by misleading questions and negative feedback – are also more likely to confess. Most importantly, Gudjonsson notes that people who are highly anxious, fearful, depressed, delusional, or otherwise psychologically disordered are often at a heightened risk to confess under pressure.

Youth is a substantial risk factor. Statistics show that more than 90% of juveniles whom police seek to question waive their "Miranda" rights to silence and a lawyer [23]. In fact, the presence of a parent, guardian, or other "interested adult" – which many states require to protect young suspects – does not lower this waiver rate, as adults often urge their youths to cooperate with police [24]. This problem can be seen in the disproportionate number of juveniles appearing in the population of false confessors. Looking at 125 proven false confessions, for example, Drizin and Leo found that 33% involved juveniles [3].

That juveniles are vulnerable in this regard makes sense. Developmental psychology research shows clearly that adolescents are not only more compliant and suggestible than adults but that their decision-making is characterized by an "immaturity of judgment" – a pattern of behavior that is impulsive, focused on the present, and diminished in the capacity to perceive risk [25]. To the adolescent not fully focused on long-term consequences, confession may thus serve as an expedient way out of a stressful situation.

People who are intellectually impaired are also vulnerable in the interrogation room. Indeed, at least 22% of exonerees in a recent sample of false confessions were mentally retarded, as measured by conventional IQtests [3]. This result is not terribly surprising. Most people who are mentally retarded cannot fully comprehend their rights, leading some researchers to describe the "Miranda" warnings they receive as "words without meaning" [26]. People who are mentally retarded also exhibit an acquiescence response bias that leads them to say "yes" to a whole range of questions – even when an affirmative response is incorrect, inappropriate, or absurd [27]. They are also suggestible, as measured by the degree to which they are influenced by leading and misleading questions. Gudjonsson and others have found that people who are mentally retarded score higher than average on the Gudjonsson Suggestibility Scale, a commonly used test of interrogative suggestibility [22].

Finally it is important to note the paradoxical possibility that "innocence" itself may put "innocents" at risk. According to Kassin [21], anecdotal and research evidence indicate that people who stand falsely accused tend to believe that truth and justice will prevail and that their innocence will become transparent to investigators, juries, and others. As a result, they cooperate fully with police, often not realizing that they are suspects, by waiving their "Miranda" rights and speaking freely to defend themselves.

The problem is poignantly illustrated by the case of Jeffrey Deskovic, exonerated in 2006 after fifteen years in prison for a murder he confessed to while

in high school but did not commit. "Believing in the criminal justice system and being fearful for myself, I told them what they wanted to hear," Deskovic said. Certain that DNA testing on the semen would establish his innocence, he added that he confessed because "I thought it was all going to be okay in the end" [28].

Interrogation Tactics

It appears that certain aspects of interrogation, even if legal, put lead innocent people to confess. To begin with, people in general become vulnerable to influence if isolated for extended periods of time, becoming fatigued or sleep-deprived – states that induce a focus on short-term consequences in decision-making [29, 30]. Thus it comes as little surprise that whereas most police interrogations last for less than two hours, the average length of interrogation in false confession cases is 16.3 h [3].

One potentially problematic tactic, present in the vast majority of false confession cases, is the false evidence ploy. Following a US Supreme Court ruling in 1969, American police are permitted to bolster their accusations by telling suspects that there is incontrovertible evidence of their guilt (e.g., a fingerprint, blood or hair sample, eyewitness identification, or failed lie-detector test) even if such evidence does not exist [31].

Basic psychology research, in nonforensic contexts, has shown that presentations of false information – via confederates, witnesses, counterfeit test results, bogus norms, false physiological feedback, and the like – can alter people's visual judgments, beliefs, behaviors, emotions, physical attraction, self-assessments, perceptions of other people, memories for observed and experienced events, and even certain medical outcomes, as seen in studies of the placebo effect. Human malleability to influence in the face of misinformation is broad and pervasive.

In the laboratory experiment, Kassin and Kiechel [32] tested the hypothesis that false evidence would lead innocent people to confess and possibly to internalize blame for outcomes they did not produce. Subjects typed letters on a keyboard in what was supposed to be a reaction time study. At one point, they were accused of causing the experimenter's computer to crash by pressing a key they were instructed to avoid. They were asked to sign a confession. All subjects were truly innocent and all initially denied the charge. In some sessions but not others, a confederate reported that she witnessed the subject hit the forbidden key. This false evidence nearly doubled the number of students who signed a written confession. As measured moments later, it also increased the number of subjects who believed they were responsible for this outcome. Follow-up studies using this computer-crash paradigm have replicated this effect even when highly negative consequences followed from the confession [33, 34].

Another potentially problematic tactic is minimization, the process by which interrogators offer moral justification or face-saving excuses, minimizing the crime and making confession seem like a cost-effective solution. Interrogators are thus trained to suggest to suspects that their actions were spontaneous, accidental, provoked, peer pressured, or otherwise justifiable by external factors. Minimization tactics lead readers of an interrogation transcript to infer that leniency will follow from confession, even in the absence of an explicit promise [35]. In a laboratory study in which college students were accused of cheating, minimizing remarks increased the rate of true confessions from actual cheaters and false confessions from noncheaters – just as effectively as did an explicit offer of leniency [36].

Confession Evidence in the Courtroom

When a suspect retracts a confession, pleads not guilty, and goes to trial, a sequence of two decisions is set into motion. First, a judge determines whether the confession was voluntary and hence admissible as evidence. Then a jury, hearing the admissible confession, determines whether the defendant is guilty beyond a reasonable doubt. But can people distinguish between true and false confessions, and what effect does this evidence have within the context of a trial?

Addressing the first question, researchers interviewed male prison inmates on videotape providing true confessions to the crimes for which they were incarcerated and concocting false confessions to crimes selected by the experimenter that they did not commit. When college students and police investigators later judged these statements from videotapes or audiotapes, the results showed that neither group

was particularly adept, exhibiting accuracy rates that ranged from 42 to 64% [37].

Mock jury studies have further shown that confession is a highly potent form of evidence and that people do not fully discount confessions even when coerced. To illustrate, researchers presented mock jurors with one of three versions of a murder trial – a low-pressure confession version, a high-pressure confession version, and a no-confession control version. Confronted with the high-pressure confession, subjects judged the statement to be involuntary and said it did not influence their decisions. Yet when it came to verdicts, this same confession significantly boosted the conviction rate – even when subjects were specifically asked to disregard confessions they thought were coerced [38].

Criminal justice statistics reinforce the point that confessions unleash a chain of adverse legal consequences – from arrest through prosecution, conviction, and prison. Archival analyses reveal that roughly 80% of innocent confessors who pled not guilty and went to trial were convicted by juries [3]. This figure led Drizin and Leo to describe confessions as "inherently prejudicial and highly damaging to a defendant, even if it is the product of coercive interrogation, even if it is supported by no other evidence, and even if it is ultimately proven false beyond any reasonable doubt" (p. 959).

A jury's reaction to confession evidence also depends on how that evidence is presented. Today, it is mandatory in Great Britain and common in many American police departments to videotape confessions for presentation in court. This policy brings many possible advantages – such as deterring police from using overly aggressive tactics, preventing voluntary confessors from later claiming they were coerced, and providing an objective and accurate record of the whole process, a common source of dispute at trial.

At present, researchers are weighing in on the "how to videotape" question, focusing on how the interrogation is staged for the camera. Lassiter and colleagues reviewed a series of studies in which they taped mock confessions from three different camera angles so that either the suspect or the interrogator or both were visible. All subjects – including mock jurors – heard the same exchanges of words, but those who focused on the suspect saw the situation as less coercive – and the suspect as more guilty – than did those focused on the interrogator [39]. Recently, these investigators found that juries and judges also appreciate the situational factors that produce confessions more when the interrogator is visible on camera than when the focus is solely on the suspect [40, 41]. Hence, it is important not only that entire sessions be recorded but that the camera adopt a neutral "equal focus" perspective that shows both the accused and interrogators.

Psychologists as Confession Experts

The problems raised by confession evidence are fundamental to criminal justice, substantial, and important. Thus, there is a great deal about this aspect of the legal system that warrants the intervention of psychologists for educational and research purposes. Intervention in this regard may take several forms, including but not limited to in-court testimony from "confession experts". In recent years, a growing number of psychologists have testified, often on behalf of criminal defendants who confessed but then retracted their statements and went to trial.

Typically, these experts testify in general terms about the social influence processes of compliance, persuasion, and obedience to authority; suggestibility effects in memory; personality and psychopathology; and other relevant phenomena; in other cases, they offer opinions concerning a specific defendant based on interviews and test results. As both the law and empirical foundations for such expert testimony evolve, it remains to be seen what impact psychological research on confessions will have on police, judges, juries, defendants, and others in criminal justice.

Confirmation Testing: Toxicology

Introduction

An axiom of the highest importance in forensic toxicology is the need to ensure that a reported result is reliable and cannot be successfully challenged in legal proceedings due to some weakness in the identification process.

The concept of confirmation testing is to use an alternative method based upon a different chemical principle than originally used to identify a substance, or group of substances. Confirmation is distinct to and should be more sensitive and specific than initial or screening tests covered elsewhere in this Encyclopedia.

What Techniques are Suitable?

Essentially all methods using some form of chromatographic separation are suitable, provided they are sufficiently different from the initial method and show very good to excellent discriminatory power.

Mass spectrometry (MS) is preferred, wherever possible, to chromatographic methods using a form of detection not capable of providing structural information. Most commonly these include "hyphenated" (one after the other) instrumental techniques in which MS is linked with gas chromatography (GC) or high performance liquid chromatography (HPLC, or often abbreviated as liquid chromatography LC) (Table 1).

Mass Spectrometry

This is generally regarded as the gold standard because of its ability to provide structural information in addition to retention time matching. Retention time matching means the coincidence, or almost coincidence, of chromatographic peaks obtained with an authentic standard and the compound being identified. The ability of a mass selective detector (MSD) to be discriminatory depends very much on the type i.e., single stage vs. tandem, the type of ionization (see below) and the compound(s) being detected.

MS is a technique in which a substance is subject to bombardment with high energy electrons in a high vacuum environment to create electrically charged particles (ions). Ionization of the substance may also be achieved by collision with other ionized small molecules. Initially the molecular ion is formed; however, the substance will often break down to smaller fragments, which provide clues as to the structural features of the original substance. The ions are separated by a mass analyzer according to their molecular weight-to-charge (m/z) ratios and each type of ion is counted (the response) by an ion detector, usually an electron multiplier. The response for all of the ions detected by the mass analyzer is compared with the response obtained from the most frequently encountered ion (the base ion), which is given a nominal response of 100%. A bar graph representation of the m/z of the detected ions against their relative abundances can then be drawn. This is the mass spectra of the substance and can be compared for identification purposes with the mass spectra of an authentic sample of the substance or an electronic mass spectral library.

When electrons are used to ionize substances and positive ions are counted, this is called *electron impact positive ion mass spectrometry* (EI-MS). When ionized small molecules such as methane (a reagent gas) are used to ionize the substance under question, it is called *chemical ionization mass spectrometry* (CI-MS). Negative ions can also be monitored and when this is used the technique is called *negative ion MS*.

Table 1 Confirmatory methods and relative discriminatory powers

Instrumental method	Relative discriminatory power[(a)]
GC-MS (full-scan EI)	Very high
GC-MS (SIM)	High
GC-MS/MS	Excellent
GC-MS (high resolution)	Very high–excellent
LC-MS (quadrupole)	Moderate–high
LC-MS/MS (and ion trap)	Excellent
GC (FID, ECD, NPD)	Moderate
HPLC (UV)	Low
HPLC (DAD)	Moderate

DAD, photodiode array detection; ECD, electron capture detection; EI, electron impact; FID, flame ionization detection; GC, gas chromatography; LC, liquid chromatography; MS, mass spectrometry;, MS/MS, tandem mass spectrometry; NPD, nitrogen phosphorus detection; SIM, selected ion monitoring; UV, ultraviolet detection

[(a)] These are relative and will also depend on compound being confirmed and application method

Some substances do not produce a mass spectra with much discriminating power e.g., the electron impact EI mass spectra of amphetamine and indeed a range of other substances which have poor mass spectra with "common" low-molecular-weight ions dominating the spectra. Under these conditions, MS is little better than a conventional detector, such as a flame ionization detector (FID) or a nitrogen phosphorus detector (NPD).

It is not possible to provide straightforward guidelines as to what constitutes a sufficiently adequate mass spectrum. Chemists and analytical toxicologists are trained to assess identification requirements. However, relatively common ions such as m/z 44, 58, 77, 91, 105 should not be used as the main identifying ions since these are found in many compounds and represent "simple" fragment ions. Rather, ions of higher molecular weight or preferably a number of ions of higher molecular weight are preferred. Drugs that have relatively simple MS include amphetamine, amitriptyline, and doxepin. These substances need to be chemically altered (derivatized) to improve MS characteristics or need to be detected by other techniques.

MS can be run under full scan conditions in which all ions from a low cutoff (often m/z 40 or 50) to the highest measurable mass (m/z 500 or more) are detected by the mass analyzer of the MS. When this occurs, any compound that is required to be identified has a "full" mass spectrum. This is preferred over "selected ion monitoring" or SIM, in which only selected ions known to be present in the suspected compound are measured. However, SIM is commonly used as a confirmatory method, and provided this is conducted properly and uses well-defined ions it can be suitably discriminatory and become a confirmation method.

Mass Spectral Matching Criteria

When performing full mass spectral matches, it is essential that the retention time (the chromatographic detection time) of the presumed substance matches that of an authentic standard. This means that an authentic standard must be run under the same conditions as the unknown sample in the same batch of analyses. All ions in the mass spectra need to be consistent with that of the authentic compound, i.e., there should be no missing ions or additional ions that do not form part of the background signals. The relative abundances of the ions should also match that of the authentic standard. A usual guide is that they should match within a relative abundance of $\pm 30\%$. Some laboratories will apply even tighter matching guidelines.

When running SIM an authentic standard must also be run in the same batch as the unknown(s). Again the retention time as demonstrated by the coincidence of the ions being monitored should match within a small allowance for measurement uncertainty and the ion ratios of the monitored ions should agree within $\pm 20\%$.

Methods to Enhance Spectral Information

When compounds provide poor mass spectral definition, they need to be run under different ionization conditions or be analyzed as a chemical derivative.

In GC other ionization conditions include chemical ionization (CI). This can be operated under positive and negative ion modes. This mode employs a reagent gas (R) in the ionization chamber (source), such as methane, isobutane, or ammonia. The reagent gas is ionized by the electrons, but since these molecules have a far higher mass than electrons, the collision energies with the compounds eluting from the GC column are far lower. This results in much less fragmentation of the target molecules and can often provide strong signals for the molecular ion, usually as $M + H^+$ or $M + R^+$ ions. As a consequence, CI is often called a *soft ionization technique*, and is required when using LC to prevent substantial ionization of the volatile buffers and solvents used. However, less structural information can be obtained than EI ionization and depending on the other techniques used it may not be sufficiently discriminatory to confirm the presence of a compound.

Alternatively, negative ions produced in the ionization process can be monitored. These will be from different structural parts of the molecule than the positive ions. Compounds with functional groups or moieties that capture electrons are most sensitive using this form of ionization, e.g., compounds containing halogen atoms or nitro groups.

The use of tandem mass spectrometry (MS/MS or MS^n) has revolutionized the discipline of MS and is now a major technique to confirm the presence of foreign substances such as drugs. In this technique, one or more ions derived from the initial ionization can be induced to fragment in a collision chamber adjacent to the mass analyzer and these further fragments characterized by a second mass analyzer. Consequently, derivative spectra are obtained. This type of MS is more discriminatory than first-generation mass spectra and is often also more sensitive and will allow ultralow detection limits to be obtained. The cost of the instrument is higher than a simple mass spectrometer, but the costs are affordable by major laboratories.

Tandem MS is particularly important when LC is used. LC has some inherent advantages over GC in that derivatization may not be required and thermal decomposition should not be a problem; however, liquid chromatography mass spectrometry (LC-MS) has been hampered by the necessity to use a soft ionization technique producing fewer ions with consequent less discriminatory power. With the advent of tandem MS, LC-MS/MS has become a very powerful technique with high discrimination. Ion trap mass spectrometers utilize a different process to generate ions compared to conventional quadrupole or magnetic sector mass spectrometers, but can also provide MS^n spectra. These are often at a lower price than tandem mass spectrometers.

Time-of-flight (TOF) MS, like other forms of high resolution MS, is another instrumental technique used in laboratories. This is more commonly used to screen samples for the presence of drugs and other compounds. It does, however, provide accurate molecular weights of ions that in association with another suitable technique can be used in confirmatory analysis.

Chromatography Tests

Traditionally, before the routine use of mass spectrometers, laboratories would use a chromatographic technique to confirm the presence of drugs based on an immunoassay. A colorimetric method or even an older chromatography technique such as thin layer chromatography (TLC) has also been used. Indeed in the developing world this practice is still being applied. Although the discriminatory process is less used than MS, a well-developed and validated chromatographic method can be suitable for those laboratories that do not have mass spectrometers.

Chromatography has various forms but is generally based on separating substances by virtue of a partitioning between two phases i.e., a stationary and a mobile or moving phase. In TLC separation of substances is caused by their relative solubility in solvents (moving phase by capillary action) and affinity for the support i.e., the stationary phase (often silica based). In HPLC this is the relative solubility of the substance between the moving liquid phase and a molecular layer (pseudo liquid phase) bound to a silica support. In GC this is a relative solubility between the moving gas phase (usually helium or nitrogen) and a micro-liquid layer coated (or even bonded) onto a silica support.

HPLC with ultraviolet (UV) or, better, photodiode array (DAD) or multiwavelength detection (MVD)

can be used to provide the second method of identification. DAD can produce some clue as to the identity of the eluting molecule provided the molecule has sufficiently distinctive UV spectra. The potential information obtained from DAD would be more useful than the simple retention time matching that would occur with a fixed wavelength UV detector. Published spectra are available for initial matching purposes. However, as for MS, direct comparison with a standard is preferred to confirm retention time matching and UV spectra under the conditions used. UV spectra of eluting substances are compared with library entries, usually electronically in a similar manner to that used for comparing MS, except that here it is the closeness of a UV spectral fit – the UV maxima and minima wavelengths and general similarity of spectra.

GC can be also used as the second method using detection systems such as FID, NPD, or electron capture detector (ECD). However, this technique is more commonly used as a screening method since it does not provide any structural information and relies exclusively on retention time matching. It is however possible to increase the discriminatory power of GC by splitting the injection into two separate columns with different stationary phases with their own detectors, usually both NPD. This arrangement produces two distinct sets of retention time data greatly facilitating identification. Laboratories have also been known to use this arrangement using an NPD and an MSD. The use of capillary columns allows better separation characteristics than HPLC since the resolving power of capillary columns is higher than that of columns used in HPLC.

Further details of how chromatography systems work and their relative advantages and disadvantages can be found in some of the reading materials.

Cutoffs

A term often used in forensic testing is cutoff. This refers to a concentration that is being applied as an effective reporting limit and is usually higher than the detection and quantitation limits of an analytical assay (see next section).

For example, it is often used in urine analysis for drugs of abuse to assist in the interpretation of the possible significance of a drug result. When testing for opiates such as morphine and codeine, a cutoff of $2000\,ng\,ml^{-1}$ will mean that most results of morphine over $2000\,ng\,ml^{-1}$ in the absence of substantial levels of codeine probably mean exposure to morphine or heroin (morphine is major metabolite of heroin). A cutoff of $15\,ng\ ml^{-1}$ of cannabis metabolite in urine will exclude most cases of passive exposure of cannabis smoke.

It should be stressed that applying cutoffs does not mean that an interpretation does not need to be performed since there may still be alternative explanations for a positive drug result than personal drug use. However, it does guide laboratories in using more relevant concentrations when performing analyses.

Extraction and Isolation Techniques

Analyses of tablets, powders, or residues usually do not require sophisticated sample isolation or purification step. Rather they involve the dilution of an accurate mass of material with a solvent such as an alcohol or simple ester (i.e., ethyl acetate) and direct injection into the analytical equipment such as an MS.

However, when dealing with biological samples, e.g., blood/plasma, urine, hair, and saliva, an isolation process needs to be employed to extract the analyte(s) from the matrix. This not only isolates the analyte(s) to facilitate some form of chromatography but also removes potential interferences from the matrix.

Isolation procedures can involve the use of solvents such as the extraction of codeine from blood using butyl chloride, or the extraction of the active substance in cannabis, Δ^9-tetrahydrocannabinol (THC) from blood using hexane. The pH of the blood (or other fluid) is adjusted prior to extraction to ensure the nonionized form of the substance is present. This assures a better recovery of the analyte(s) in the solvent. The solvent is then usually evaporated and the residue containing the drug reconstituted into a small volume of an injecting solvent. An aliquot of this extract is then injected into the chromatograph.

Other common isolation procedures include the use of solid-phase extraction (SPE) columns or solid-phase microextraction (SPME). SPE involves the use of commercial minicolumns or cartridges packed with a coated silica-based phase similar to that used

in HPLC. The sample is diluted into a buffer of correct pH and applied to the column/cartridge and the analyte(s) of interest are selectively absorbed onto the column. A wash-step removes the excess of unwanted material in the sample and a final step elutes the analyte(s) with a suitable solvent into a small tube. The solvent is either injected directly into the chromatograph or concentrated by evaporation prior to chromatography. This method is most commonly used for urine analyses for drugs of abuse.

SPME involves the use of fibers that selectively retain the analyte(s) after dipping the fiber into the sample and applying this directly to a GC. A heated injection port volatilizes the substance and introduces it to the GC column. Fibers used include dimethylpolysiloxane for low-molecular-weight compounds and volatiles, polyacrylate for polar compounds, dimethylpolysiloxane–divinyl benzene for volatile alcohols and amines, and a carbowax–templated resin for surfactants.

Another technique used occasionally is direct precipitation using methanol, acetonitrile, or other water-soluble solvents. This precipitates proteins and allows direct injection of the supernatant into a chromatograph (usually HPLC) or it becomes the first step of a further purification stage, e.g., solvent extraction.

Whatever the technique used, the overall recovery of the analyte(s) must be reproducible and efficient (>50%) (see sections on internal standards) with no chromatographic interferences caused by extraneous or co-extracted substances.

Chiral Analysis

Many drugs used in medicine and illicit drugs exist as optically active compounds i.e., existing in mirror image forms (stereoisomer) with one or more optically active (chiral) centers. Often, only one of these stereoisomers is pharmacologically active, or is much more active than the other isomer(s). For example, methamphetamine has one chiral center, with the S-configuration having the most activity as a central nervous system stimulant. Illicit methamphetamine has the S-configuration while the R-form is legally available in some countries (e.g., United States) as a weak stimulant for use as a nasal decongestant.

Since conventional chromatography does not separate stereoisomers, it is necessary to use chiral methods to distinguish the isomeric form. This can be accomplished by the use of either derivatization techniques to produce a diastereomer that can be separated on a conventional column or use of a column coated with an optically active phase that preferentially retards one isomer over another.

Quantitative Analysis

Many laboratories combine the confirmation step with a series of calibrators that enable the amount of identified substance to be quantified. Quantitative results are most useful for blood/plasma measurements, but are also useful in some applications of oral fluid, hair, and urine testing. See the respective chapters on "alternative specimens . . . " (**Hair: Toxicology**; **Oral Fluid Toxicology**; **Sweat: Toxicology**) for further details. Quantitative results provide a basis for interpretation of the possible significance of a drug presence, in terms of how much was taken, when the substance may have been taken, and what the likely effects of the substance may have been on the individual.

To achieve quantitative results, a series of calibrators are prepared at varying concentrations covering the anticipated concentration range expected for the samples. Typically this range extends from the lower limit of quantitation (LLOQ) to the highest concentration that still enables linear performance of the detector. Samples that contain concentrations of analyte(s) that exceed the highest calibrator will usually need to be repeated as a diluted sample. The response of the calibrators is calculated as a ratio of the peak area of the analyte(s) to the peak area of the internal standard IS (see below).

Performance measures of quantitative assays include the LLOQ, the linearity of the response over a concentration range, the precision of the analysis at particular concentrations over the calibration range, and the accuracy of a calibration. Typically precision should be less than ±20%, and the accuracy should be within 20% of the true concentration. Oftentimes these parameters are far tighter. For example, in alcohol analyses precisions of better than 2% can be obtained using GC techniques. These parameters all need to be properly established before an assay

is conducted on real samples and form part of the validation process.

Internal Standards

Analytical assays used for quantitative analyses must contain a marker to ensure the chromatography is adequate and any variations in extraction efficiency can be corrected. Indeed this marker, known as an *internal standard* (*IS*), should also be used in qualitative assays including confirmation assays. The IS is a substance with very similar physiochemical characteristics to the analyte(s) and is added to all calibrators and unknown samples before the start of the extraction or isolation procedure. The IS can be separated from the analyte(s) either because it has slightly different chromatographic performance (to the analyte) or it has different ions that can be selected by the mass spectrometer.

For example, if an IS in a sample chromatogram is half its usual area (or peak height), then by using the ratio of responses of the analyte(s) to the IS the concentration of the analyte(s) can still be calculated. In reality, this is no different from injecting half of the usual volume into the chromatograph since the ratio of the analyte(s) to the IS will still be the same although the individual peak areas have halved. The use of an IS therefore makes the response of any sample independent of the extraction efficiency (see the section Quantitative analysis). This improves the overall precision of quantitative analyses. It is good practice to calculate the retention time of a substance relative to the retention time of the IS as this value is independent of variations in column performance. Unfortunately this is not possible when isotopically labeled ISs are used (see below).

In the past ISs were often structurally related compounds, such as another barbiturate for a barbiturate assay, or another benzodiazepine for a benzodiazepine assay. Modern chromatographers prefer the use of stable isotopes of the analyte(s), invariably deuterated analogs. These can only be used when some form of MS is being used, since they co-chromatograph with the analyte and can only be distinguished from the analyte by the selection of the appropriate ion(s). Deuterated ISs are available for most common drugs and provide the best match with the analyte in terms of closeness of physiochemical characteristics.

Method Intelligence and Validation

All methods used in laboratories need to be properly validated prior to use such that they are fit for the intended purpose. The validation process ensures that the method is reproducible and rugged, i.e., it always works even when different analysts are using the method. The detection limits for confirmatory testing need to be well established, as well as the recovery and precision of the method at different drug concentrations. This is particularly important if the confirmatory method is also used to quantify the amount of compound in the sample. Moreover, the method should be checked for specificity by potentially interfering compounds, either for their known elution at or near selected compounds or because they are frequently coassociated with the compound(s) being confirmed.

This validation process together with its use in case work enables intelligence to be obtained of what can and cannot be detected using this method. Thus, a robust and well-developed confirmatory method will be far more useful in a laboratory than *ad hoc* or ill-defined methods.

Uncertainty of Measurement

Uncertainty of measurement is a concept used in laboratories where some form of quantitative result is being produced, or a result is compared to a decision limit, such as cutoff. It simply means that laboratories recognize that all measurements are subject to some error of measurement and that laboratories need to estimate or calculate this error and where necessary apply this to their work.

Typically laboratories will assess all steps of an assay for error of measurement, i.e., purity of substance, weighing errors, pipetting or other dilution errors, recovery of drug from a matrix, errors in determining size of a chromatographic peak, etc. If the combined error of a quantitative measurement is 10% and to show the distribution about a mean of about 95%, a coverage factor of 2 is often applied. This means that for a cutoff of $100\,\mathrm{ng\,ml^{-1}}$ the uncertainty of measurement is $\pm 20\%$ (2 times 10%) with a confidence of 95% or a coverage factor of 2.

Crime Scene Documentation

Introduction

A crime scene investigator (CSI) can be unrivaled in his ability to identify, recover, and interpret evidence, but unless he can correctly document the evidence and its passage through the various processes required, it will be useless in court.

A CSI generates several documents during an investigation. These are necessary to demonstrate the integrity of the evidence and the continuity of the chain of custody (*see* **Chain of Possession of Tangible Evidence**). In many jurisdictions, all evidence recovered by a CSI is passed on to another unit or agency. Each of these diverse entities has its own requirements for information and therefore its own documents. The design and layout of documents vary greatly between agencies and legal systems but they fall into basic categories described.

To understand the complexity of the documentation needed, it is necessary to explain the various paths that evidence takes.

Physical and Trace Evidence

When recovered and packaged, it is recorded on the following documents:

- chain of custody form (for one such example, see Figure 1);
- crime scene report (Figure 2); and
- exhibits list (Figure 3).

It may also be recorded on the following:

- photo log (Figure 4) and
- sketch of the scene.

Most departments also design a multitude of forms to document each of the following activities. Upon return to the CSI office it is also recorded in

- exhibit store register.

At a later stage, it may be transferred to a forensic science laboratory for examination and analysis, which entails the exhibit being recorded on a

- laboratory submission form.

On removal from the exhibit store and its subsequent return to the CSI unit following analysis, the items' movements in and out are recorded in the exhibit store register.

DNA Evidence

When recovered and packaged, it is recorded on the following documents:

- chain of custody form;
- crime scene report; and
- exhibits list.

It may also be recorded on the following:

- photo log and
- sketch of the scene.

Upon return to the CSI office it is also recorded in

- CSI freezer register or exhibit store register.

At a later stage, it may be transferred to a forensic science laboratory for examination and analysis, which entails the exhibit being recorded on a

- laboratory submission form.

On removal from the CSI freezer or exhibit store and its subsequent return to the CSI unit following analysis, the item's movements in and out are recorded in the exhibit store register.

Footwear, Tire, and Tool Mark Evidence

When recovered and packaged, it is recorded on the following documents:

- chain of custody form;
- crime scene report; and
- exhibits list.

It may also be recorded on the following:

- photo log and
- sketch of the scene.

Upon return to the CSI office it is also recorded in

- exhibit store register.

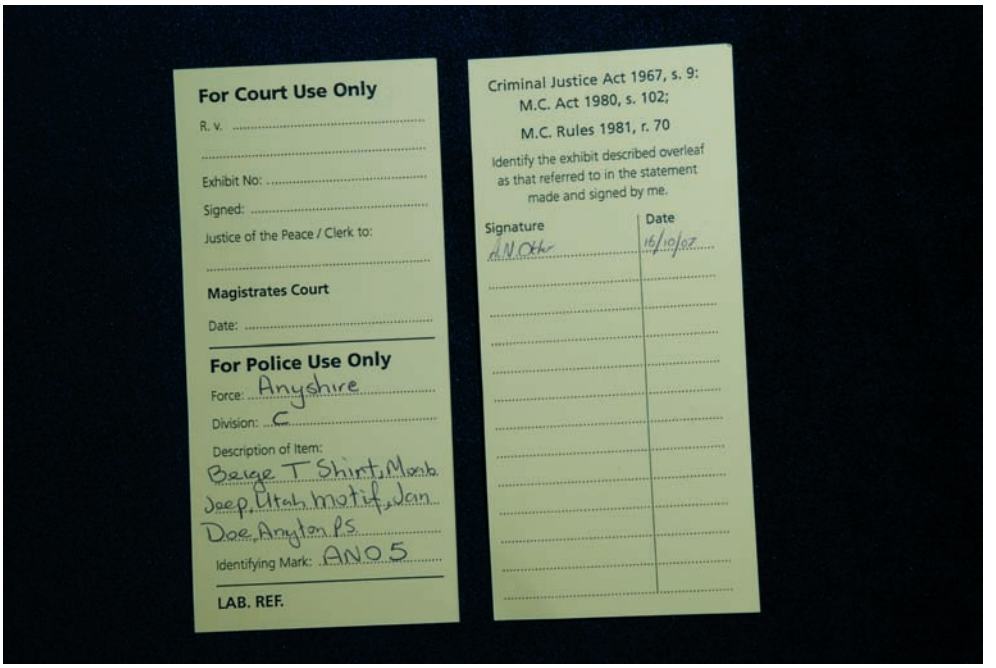

Figure 1 An example of a chain of custody document

At scene, prior to recovery by casting or other means, footwear, tire, and tool marks are photographed (*see* **Evidence Collection and Preservation: Casting**), so in addition their details are entered on an

- imaging submission form.

In addition, many police forces in the United Kingdom employ footwear analysts as part of the forensic intelligence section of their scientific support units. In those cases, a copy of the footwear mark would be forwarded to the analyst, along with a copy of the crime scene report and the copy of the exhibit would be recorded on a

- footwear submission form.

At a later stage, it may be transferred to a forensic science laboratory for examination and analysis, which entails the exhibit being recorded on a

- laboratory submission form.

On removal from the exhibit store and its subsequent return to the CSI unit following analysis, it is returned to the CSI unit, the item's movements in and out are recorded in the exhibit store register.

Photographs and Videos

When completed, films and/or disks are packaged and the following documents are completed:

- chain of custody form;
- crime scene report; and
- exhibits list.

They may also be recorded on the following:

- photo log.

They may also possibly be entered on the

- sketch of the scene.

Upon return to the CSI office, they will also be recorded on a

- imaging submission form.

And forwarded, either by hand or secure dispatch, to the relevant photographic or imaging unit.

1234	7	Evidence close-up of key ring.	Item E
1238	8	Evidence close-up of key ring with scale.	Item E

Figure 4 A typical photo log sheet [Reproduced with permission from R M Gardner.]

If patent fingerprints, they are also recorded on the following:

- photo log.

They may possibly also be entered on the

- sketch of the scene.

Upon return to the CSI office, dependent on the job description and qualifications of the CSI unit, they may be recorded on a

- fingerprint submission form.

Where the fingerprints have been photographed, they are also recorded on an

- imaging submission form.

Once fingerprints have been recovered from a scene, it is normal practice that elimination fingerprints are obtained from those persons with legitimate access.

- At this stage, agency protocols can vary considerably, so suffice to say they ensure that lifted fingerprints, photographs of fingerprints, and elimination fingerprints are collated and forwarded to the responsible unit or agency for comparison and identification, along with the fingerprint submission form.

Required Contents of Crime Scene Documents

Chain of Custody Document

When an item is recovered it must be packaged immediately and the packaging sealed to prevent any contamination from another source (*see* **Packaging and Transport**). Some packaging have the chain of custody document printed on it, or a label with the required details attached to the packaging.

In some jurisdictions this is called an *exhibit label*, while in others it may be referred to as an

evidence voucher. It should be noted that in Scotland, exhibits are referred to as *productions* as they are "produced" in court. All references to exhibits should be read as productions for the purposes of Scots law and documents include variations to include the requirement for corroboration of evidence.

Whatever its name, a chain of custody document is used to record the following details:

- Law enforcement agency.
- Basic command unit, where applicable (division, precinct, etc.).
- Description of item (This should be detailed enough to clearly distinguish similar items).
- Location recovered from (The location within a scene where the item was recovered).
- Address or scene where it was recovered.
- Identifying mark or reference (This varies between agencies. In England and Wales an identifying mark is the initials of the person recovering the item plus a chronological number starting at 1 e.g., ABC/1).
- Signature and date of person recovering and space for the signature of every other person taking possession of the item up to its presentation in court.

Whenever an item of evidence is passed on to another party, it is good practice to ensure that person signs for possession in front of the person relinquishing custody of the item. That way a CSI can be sure that if the chain of custody is broken it is not broken with them.

Crime Scene Report

While at a crime scene, it is imperative that a CSI maintain a detailed record of actions, observations, information, and evidence recovered.

A CSI not only recovers evidence but has an important part to play in the investigative and intelligence gathering processes. A crime scene report is an important part of both the investigation and intelligence gathering.

The style and layout of a crime scene report varies greatly between agencies. Even in England and Wales, with only 43 law enforcement agencies, there is little commonality of style and layout.

No matter where an agency is, a crime scene report includes the following details:

- case number and agency
- details of crime or incident
- address or scene
- details of CSI
- details of victim(s)
- details of first officer(s) attending
- date and time of incident, or time frame
- date and times CSI arrived and departed
- modus operandi and other pertinent details.

This should be as detailed as possible and include the following:

- description of the scene;
- actions and apparent actions taken by offender(s);
- point and method of entry to the scene;
- items moved by offender(s);
- items stolen by offender(s);
- items from scene not taken by offender(s);and
- items abandoned by offenders(s)

Some jurisdictions may also require that a detailed record is kept of the examination equipment and methods used.

Most jurisdictions prefer a narrative style of crime scene report, but some may have a checklist requirement for standardized information gathering for intelligence and statistical purposes. Care should be taken that a crime scene report remains an investigative tool and does not become solely a means of gathering statistical information that does not assist the investigative process.

- **Elimination actions taken or required**

This includes details of, where required, elimination fingerprints, footwear impressions, and DNA samples taken from those with legitimate access to the scene. Where elimination databases of police personnel are maintained, details of all officers attending should be included.

- **Sketch of crime scene**

Where necessary a sketch of the scene should be made and if available to an agency, professional plan drawers should be utilized to provide an exact scale plan of the scene.

List of exhibits

This should be maintained as exhibits are recovered and the details should be an exact copy of those

documented on the chain of custody document. This ensures that challenges as to verification of exhibits are minimized. Dependent on legal requirements and agency policies this may be part of the main crime scene report or a separate document (Figure 3). Legal requirements may vary but the main information recorded is the following:

- item number or identifying mark (see the section "Chain of Custody Document")
- description of item
- location recovered from
- person recovering item
- time item recovered
- signature.

If the exhibits list is a separate document, additional information such as scene, offense, and case number are required along with any other information such as search warrant number.

Where a serious incident is under investigation in England and Wales an exhibits register is maintained by an exhibits officer. This can be a CSI or experienced detective and all exhibits recovered are passed to them for documentation and secure storage. This is used to document all exhibit movements and also serves as a source of information that can guide the forensic recovery and submissions strategies (*see* **Crime Scene Management**).

Photographic Log

In many jurisdictions, it is a requirement to provide a log detailing the serial number of the camera equipment used and if a traditional film camera, the film batch number(s).

For each photograph taken, all or some of the following details are required:

- shutter speed
- film speed
- lens number and size, e.g., 55 mm
- aperture
- distance from camera to object in question and distance from reference points
- direction of photograph, i.e., north
- photographic placards and what they indicate.

Some jurisdictions may also require the height at which the camera was.

Post Scene Documentation

Once work at the scene has been completed, or in the case of a major incident where work stopped for the day, the onward movement of all evidence is required. Unlike their television counterparts, CSIs cannot simply hand an exhibit to someone, nor are they experts in all fields of forensic science. Almost everything a CSI recovers is either placed in a secure store or passed onto another unit or agency for further examination or analysis (Figure 5). This documentation is necessary to ensure a fully recorded and transparent movement of exhibits between the scene, storage, the receiving unit(s), and onward until the case is heard in court.

With several thousand agencies worldwide, it is impossible to establish a common style of documentation. As agency protocols and CSI job descriptions vary enormously some of the described documents may not be used.

Exhibits Store Register and CSI Freezer Registers

In major investigations, exhibits may be immediately dispatched to another unit or agency. However, in routine volume crime cases exhibits will normally be stored in secure locations pending decision on their submission for examination or analysis. Some agencies may have electronic registers while the majority of medium and smaller agencies use a paper-based system.

The sections requiring completion in those registers include all the details of the exhibit, which must match all the details of the exhibit marked on the evidence voucher (see the section "Chain of Custody Document" above). The last person to sign the evidence voucher must be the person who signs the item into the store or freezer. The register should include the following details for each item:

- date and time items deposited
- person depositing
- location in store/freezer
- movement from store
- time and date removed and reason (to laboratory, etc.).

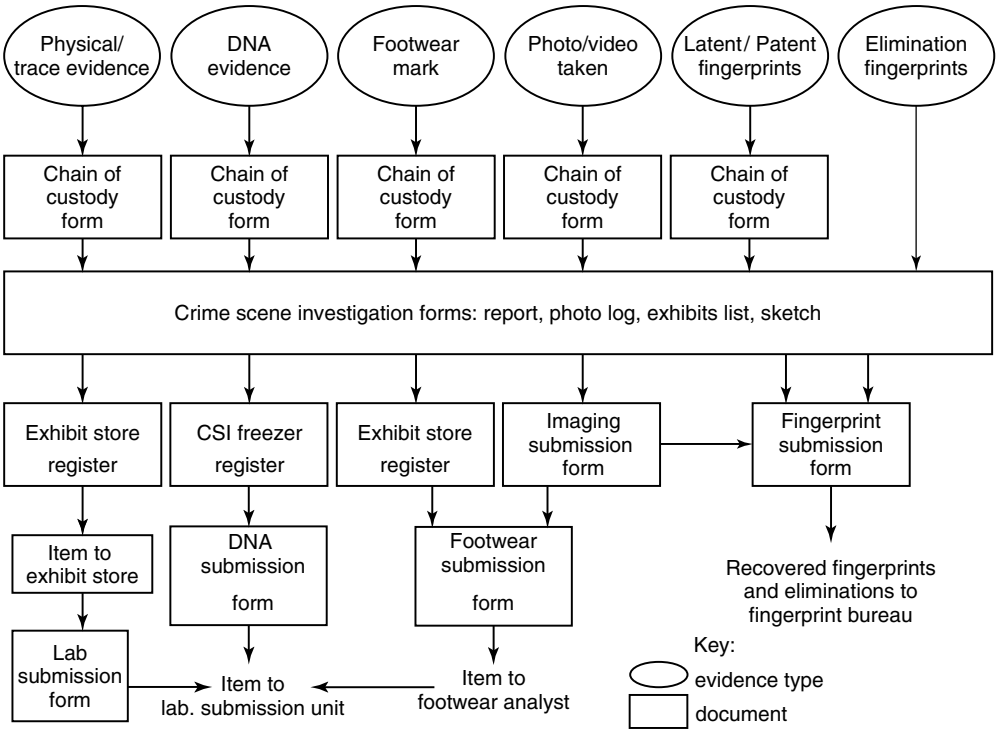

Figure 5 A typical flowchart of CSI actions and document generation

Imaging Submission Form

Once images of a scene have been made, the resultant film(s), tape(s), and disk(s) are either handed over to the imaging unit or dispatched to them via secure internal mail. This form not only documents the submission of the film(s), tape(s), and disks but the required details include such things as the following:

- CSI case number and agency
- imaging unit case number (if different)
- date and time items received
- person depositing
- person receiving
- number of working copies made and who they were provided to
- number of evidential copies made for, prosecutors, defense attorneys, jurors, and court officers.

Fingerprint Submission Form

In some agencies, a CSI may also be a latent print analyst, while in others, the latent print comparison and identification is the responsibility of a court recognized fingerprint expert. In the United Kingdom for example, police forces maintain fingerprint bureaus. Where the latent fingerprints are passed on to another unit or agency, a fingerprint submission form is required. The detail on this form varies from agency to agency but includes the following:

- agency and CSI case number
- fingerprint bureau case number (if different)
- list of lifted and photographed fingerprints
- date and time items received
- person depositing
- person receiving
- identity of persons whose elimination prints are enclosed.
- details of personnel attending scene
- results of comparison (eliminated, identified to person on record, and outstanding).

Dependent on local protocols or legal requirements, disposal of elimination fingerprints may be required.

Footwear Submission Form

Where an agency uses a footwear analyst to provide forensic intelligence on footwear impressions found at scenes a submission form is needed. The details on this form includes

- agency and CSI case number
- imaging unit case number (if different)
- footwear analysis case number
- date and time items received
- person depositing
- person receiving
- details of when entered on intelligence systems
- details of onward submission to a forensic science laboratory.

Laboratory Submission Form

When submitting items to a forensic science laboratory, it should be remembered that all forensic science interpretations are context based. Given one set of circumstances, the results of examination and analysis may refute the prosecution version of events. In another set of circumstances, the results may support the suspect's version of events. To this end the detail required on any laboratory submission form is substantial. Some details may vary but in general they include

- agency and investigating officer details
- agency case number
- CSI case number
- incident details
  - date, time, and offense type
  - full details of the offense
- details of all subjects (victims, deceased, suspects, and persons for elimination)
- occupation of subject (This could have great bearing on the interpretation, e.g., a glazing contractor could have glass on their hair clothing, some of which has the same refractive index as glass from a scene. This does not necessarily place him at the scene)
- name and signature of person delivering or dispatching the items and method used
- name and signature of person receiving
- list of exhibits, including date time and location of seizure
- previous submission reference numbers.

In some jurisdictions, where an invoice may be levied against the submitting agency, a submission form also includes the following:

- person authorizing submission.

Following receipt at the laboratory, the case is given a laboratory case number.

DNA Submission Form

In jurisdictions where DNA viable material is submitted for inclusion on a DNA database the requisite form normally contains the following details:

- agency and investigating officer details
- agency case number
- CSI case number
- incident details
  - date, time, and offense type
  - details of the offense
- name and signature of person delivering or dispatching the items and method used
- name and signature of person receiving
- list of exhibits, including date, time, and location of seizure
- previous submission reference numbers.

As can be seen from the previous lists, a considerable amount of administration effort is required of a CSI. Fortunately, in many larger jurisdictions, much of the very necessary but tedious work has been computerized, allowing several forms to be populated with the required information from a single entry or "one key" operation. This allows the CSI to simply read and sign the submission forms.

Major Incident Forms

Routine or volume crime generates substantial administration but major incidents create even more. This is necessary to demonstrate the thoroughness of the investigation.

Scene Entry Log

Before entering a scene, any personnel encounters an officer assigned to document all persons entering the

scene. In many jurisdictions, this is an informal list of personnel and times entering and departing the scene. In others, this is a formal document and includes the following details:

- *Cover*
  - offence
  - scene
  - crime scene manager
  - detailed instructions to the officer(s) on completion of the log and handover to a relieving officer.
- *Inner pages*
  - time and date
  - details of person requesting entry (instructions from Crime Scene manager should be specific about refusal of entry to all except those necessary for the examination function)
  - reason/authority for entry and reason for refusal
  - signature of person entering
  - time and date of entry to the scene
  - details of protective clothing worn
  - whether person is on a DNA/fingerprint elimination database
  - time and date of leaving scene
  - name and badge number of logging officer.

All of the above details are necessary to show that there was no contamination of or interference with the scene. Any nonpolice personnel attending the entry and exit point should have their details taken. Where no statutory power exists to compel them to provide their name etc., their vehicle license plate should be noted for future reference. This may prevent any future defense of the defendant having attended or entered the scene.

Crime Scene Manager and Crime Scene Coordinator Log

In the United Kingdom, the roles of crime scene manager and crime scene coordinator have been established for well over a decade (*see* **Crime Scene Management**). In the United States and other jurisdictions, the roles may be called a *lead CSI*. The United Kingdom and other European Union states have adopted the European Crime Scene Management Manual. Amongst the many recommendations of the manual is the need to maintain detailed logs for every scene involved in an incident and where a coordinator is appointed to oversee the various scenes, that person should also maintain a log. "Discovery" or "disclosure" legislation varies considerably and while some legislation may allow a degree of flexibility, other jurisdictions may make it compulsory that every written word in the course of an investigation has to be copied to the defense, including in some areas, a photograph of the notes on white dry wipe board. In reality, this may include a note of a family telephone number on the same piece of paper as the contact details of an official involved in the investigation, or the local pizza shop. The implications of either piece of information being divulged to the defense could present a personal security risk or the potential for an unscrupulous attorney to attempt to show that staff welfare was more important than their client's liberty.

The logs may vary in content and size but the general information is very similar.

The following descriptions of the contents outline the details required and the rationale for their inclusion.

Reference Number and Contact Details. It is a good practice and an efficient way of collating information to record the following information:

- Case reference numbers (dependent on agency guidelines).
- Details of personnel and their office phone number, cell phone/pager number. For example,
  - senior investigating officer and deputy
  - exhibits officer
  - command post senior staff
  - crime scene manager
  - CSI and lab staff
  - FME/coroners staff.

Under "discovery" or "disclosure" rules, it may be possible to withhold copies of this page from the defense and reference should be made to the applicable laws.

History of the Scene. Recording the details of all first responders ensures that if required all unidentified fingerprints, footwear marks, tire tracks, and possibly DNA can be checked against those person

for the purpose of elimination. Documenting the position of cordons and any adjustments prevent any false claims by defendants and others.

Initial Observations. Several pages are devoted to recording the details of the scene. This may seem a time consuming exercise but they are vital in transparently demonstrating that an open minded and thorough investigation has been conducted. Several pages may not be used in an investigation and are simply scored across diagonally and marked "N/A" (not applicable).

A full description of the scene would be documented, along with any approach path and the use of forensic stepping plates to facilitate activity in the scene without destroying any evidence on floors.

Any disturbance, forced entry, and items obviously foreign to the scene would be recorded.

If the scene of homicide is a residence, the details of all rooms are noted. The following should be recorded:

- Furnishing and contents.
- The status of doors and windows – open/ closed? Locked/ unlocked? Marks indicating forced entry? Keys in locks?
- Are any drapes/curtains/blinds open or closed?
- Lights – are they on? Position of switch? Does the light bulb work?
- Are sinks, washing machines and dishwashers, full, blocked or inoperative?
- Are the heating system and its timing mechanism working? What time does it switch on and off and what temperature is it set at?
- Are all utilities working in the premises?

The above may seem overly detailed but in all democracies the prosecution must prove the defendant guilty "beyond all reasonable doubt" and an inability to answer those questions later in court could prove problematic at least for the prosecution case.

Vehicle Details. When examining a vehicle, most crime scene investigators record the basic details of make, model, color, and license plate. However, all eventualities should be considered and the following details should be recorded:

- make, model, and color
- any damage
- true license plate details and any false details displayed
- chassis, engine, and vehicle identification number
- any required taxation or insurance details displayed
- odometer and trip meter readings
- fuel level and note any oil leaks
- where and when the vehicle was stolen, used in the commission of an offense and recovered
- make, model, size, and position of all tires on or in the vehicle.

The depth of detail recorded may seem excessive but later in an investigation several questions may be asked or new possible lines of inquiry opened. By recording more than the basic information most unexpected twists in a case can be dealt with. Consider the possibility of organized criminals having a decoy vehicle with an identity duplicating that of another. If all the additional details are recorded, it should be possible to demonstrate the existence of different vehicles.

Deceased Check List. In most areas of the United States, the deceased is the province of the medical examiner or coroner and not the responsibility of the CSI. In other countries, notably in the United Kingdom, it is the norm for a CSI team to assist the forensic medical examiner at the scene, attend the autopsy to record information, and recover evidence for onward movement to the necessary agencies. The autopsy would be considered a secondary crime scene.

The crime scene manager (CSM) would record details of the deceased.

- If known, their name, address, date of birth, and occupation.
- On the scene
  - the position of the body, visible marks of violence, tattoos, piercings, state of their clothing, and if areas of exposed skin have been tape lifted. Any body and air temperatures taken would be recorded
  - details of surrounding areas, including vegetation, that may affect the body
  - weapons
  - water.

At autopsy, detailed records of the clothing would be taken, as some garments may be missing or on the

body in an incorrect manner if the deceased had been stripped and redressed postmortem by the offender.

Sketch Plan. A sketch plan should be made by the CSM for easy reference.

Information from Fire Officers. Where fire is involved, many US jurisdictions call on the services of Fire Marshals or the Bureau of Alcohol, Tobacco, Firearms, and Explosives, (ATFE, formerly Bureau of Alcohol, Tobacco and Firearms (ATF)) to investigate. In the United Kingdom, a joint investigation among Fire Service, Police, and a forensic scientist would be undertaken.

The CSM would record such information from the first fire unit as

- Security of premises on arrival and any forcible entry made.
- Location and extent of burning on arrival.
- Effects of firefighting on spread of the fire and final burning pattern.
- Any relevant observations, including persons on scene.
- Weather.
- If any video surveillance equipment was fitted to fire trucks.

Scene Attendance Cross Reference. Where there are multiple scenes involved in a major investigation, the crime scene coordinator should maintain a scene attendance cross reference or matrix.

These pages have a grid or matrix with the scenes noted in separate boxes along the top and the details of the personnel attending down the left side. Where a person enters a scene, an "X" and the date of attendance are placed in the box across from their name and beneath the scene. This provides an easy and rapid check that no person has attended two scenes that could be linked by forensic evidence. This helps eliminate the possibility of cross-contamination of scenes.

Scene Records. In the United Kingdom, although the scene is managed by the CSM, it is still under the control of the senior investigating officer (SIO).

Following discussion, the SIO and CSM agree the search parameters and if necessary adjust cordons accordingly. Under the Health and Safety at Work Act 1974, they carry out a risk assessment and ensure all persons in attendance are aware of any potential risks. This could be the possibility of infected blood, sharp instruments trip hazards. Control measure to remove or reduce those risks must always be implemented. They also decide on the forensic recovery strategy. All of the above decisions are documented.

While at scene, all decisions made by the CSM, as circumstances change, are documented along with the rationale. This may seem excessive but it does ensure the transparency of the investigation. Several months or years later, a court may ask why a decision was made and with the benefit of hindsight may attract criticism. However, if, based on information available at the time, the decision was correct, any reasonable criticism can be answered.

The CSM also notes all relevant information from briefings, instructions received, instructions, and briefings given to personnel and any informal contacts and meetings. This not only ensures transparency but provides reminders about information that needs to be disseminated to staff and higher authority.

Aide Memoir

The last pages contain an A*ide Memoir* to remind the CSM of items that can easily be overlooked when multitasking.

An example of the *Aide memoir* is

Scene manager/scene coordinator to be appointed.

Scene manager to receive comprehensive briefing by officer/SIO at the scene. Ensure logs have been commenced.

Review scene preservation methods/cordons. Establish rendezvous point and car parking area.

Ensure full protective clothing, suits/overshoes worn by all personnel entering the scene and that they have a valid reason for doing so. Brief scene entry loggist on the requirements/restrictions on entry to scene.

Establish common approach path and consider stepping plates. Consider alternative routes. Consider tents, screens, sheeting and lighting, etc.

Consider closing the scene until daylight.

Commence initial scene video/still photography. Consider aerial photography.

Scene manager to decide on and arrange attendance of pathologist, forensic scientist and any other specialists.

Forensic medical examiner/pathologist to certify death.

Air/room temperatures, Meteorological Office data, heating settings, etc.

Check all electrical switches/sockets and appliances are working.

Check all gas appliances/pipes in working order.

Consider 1/2 h rectal temperatures (Not in sexual offences) and air temperatures if the body is to remain in situ for a prolonged period.

Scene manager to liaise with plan drawer(s) regarding scene requirements.

ALL firearms found to be made safe by authorized officers. Consider the attendance of a ballistics specialist.

Consider preservation of insect life on body – especially in cases of advanced decomposition or if the body may have been moved.

Consider the use of an entomologist, biologist, and anthropologist.

Complete relevant examination of the body prior to removal. Tape lift as appropriate. In cases of burning, tape lift all exposed areas of skin as it is prone to break away from body.

Bag head, hands and feet before removal. If possibility cocaine use involved paper bag on head.

Obtain samples from underneath the body. (For example, soil, carpet, etc.)

Ascertain identities of all persons entering the scene prior to introduction of control measures and obtain elimination fingerprints/footwear. Consider seizing their clothing.

Arrange removal of deceased.

Recover "fragile" evidence from entry point (for example, fibers, etc.) Tape lift contact areas on common approach paths.

Latent footwear impressions in dust. ESLA as soon as possible and always before further examinations undertaken.

Consider chemical enhancement of footwear marks in blood.

Tool/tire/footwear impressions – photograph and cast.

Blood distribution – mark and photograph. Consider attendance of scientist. Agree plan of action E.G. swab or removal of wallpaper, flooring etc.

Fingerprint examination – agree parameters with SIO. Consider use of Quasar/chemical treatment.

Arrange for extended search by operations support unit.

Consider seizure of CCTV video tapes.

Even if not apparently involved, vehicles of victims and suspects.

Crime Scene Investigation

Introduction

The basis of crime scene investigation, as with every other aspect of forensic science, is Locard's theory, sometimes called *Locard's Law*. Simply stated it is: "Every contact leaves a trace." Considering its application to a crime scene, it was described very eloquently in a US Federal Court decision (*Harris vs. United States,* 331 U.S. 145 (1947).

> Wherever he steps, whatever he touches, whatever he leaves, even unconsciously, will serve as silent witness against him.
>
> Not only his fingerprints or his footprints, but his hair, the fibers from his clothes, the glass he breaks, the tool mark he leaves, the paint he scratches, the blood or semen he deposits or collects – all of these and more bear mute witness against him.
>
> This is evidence that does not forget.
>
> It is not confused by the excitement of the moment.
>
> It is not absent because human witnesses are, it is factual evidence, physical evidence cannot be wrong; it cannot perjure itself; it cannot be wholly absent, only its interpretation can err.
>
> Only human failure to find it, study and understand it can diminish its value.

In the United States, larger agencies' workloads and crime rates can justify crime scene investigation units or even full crime laboratories. Others must rely on state and adjacent law enforcement agencies, joint task forces, officers with minimal training and experience, and even volunteers.

Around the world, the police are organized in different ways. Some countries have single national police forces, while others have local and federal agencies. Those countries following variations of Napoleonic Law (*see* **Civil Law Systems of Justice**) can have policing systems, where the uniformed patrol force, the detective force, and the magistrates who interview witnesses and suspects are responsible to different national government departments. Other countries, such as the United Kingdom, have large police forces serving one or a combination of local government areas.

In the British Isles, the examination of a crime scene is undertaken by trained police personnel, formerly police officers but now more likely to be civilian support staff. They are known variously as *scenes of crime officer* (SOCO) or now more commonly crime scene investigator (CSI). In other countries, there are various titles for the role: crime scene examiner (CSE), crime scene analyst (CSA), crime scene technician, evidence technician, forensic specialist, etc. For simplicity, the CSI is used for those who examine a "scene".

A scene is described as any premises, location, vehicle, person, or indeed an item involved in an offense or incident.

The First Officer(s) Attending (FOA)

Any officer performing this role has a responsibility to preserve the scene (*see* **Crime Scene Management**).

Actions of a CSI at a Volume Crime Scene

As Gardner [1] and White [2] correctly state, a CSI must carry out an independent assessment of a crime scene. Witnesses can be confused and provide misleading information and only by careful examination of the scene, one can arrive at a true understanding of the sequence of events. The CSI continuously reassesses a scene, based on his observations, information received, and evidence revealed during the activities of scene processing.

According to Smith [3], when a CSI attends a volume crime scene, he should be aware of the contamination risks. While no specific guidance is given, it would be prudent to follow the simple anticontamination procedures that many police forces use:

- **Always wear a face mask.**

This not only prevents accidental contamination of potential DNA sources but also protects you from any hazards due to long-term exposure to fingerprint powders.

- **Change your disposable gloves after handling individual items.**

Touching your face, adjusting spectacles, and touching everyday items such as handles and switches could transfer DNA.

Smith [3] suggests an eight point strategy for the investigation of a scene such as a home burglary. Gardner [1] and White [2] recommend similar strategies.

Attend the Scene and Make Contact with the Victim

When the CSI attends a scene, he should make contact with the victim, explain why he is there, and what is his role in the investigation. To assist in establishing a time frame, the CSI needs to ascertain if victims were on scene at the time of the offense and, if they were present, whether they saw or heard anything related to the offense.

If they were not present, it is important to establish when they departed and returned. This is important information that can impact on the intelligence that can be gained from a scene investigation, even if no forensic evidence is recovered.

Assess the Scene

Reassessment of the initial preservation is the immediate priority. Various factors must be considered, such as prevailing weather conditions and the possibility of further unintended interference with evidence, due to location.

By visual examination and questioning the victim, the CSI should review the extent of the scene and establish the scene boundaries. Careful observation allows the establishment of the points of entry and egresses and assesses the potential evidence, including objects left at the scene by the offenders.

Health and Safety Risks

Consideration should be given to any potential health risks present and the appropriate safety measures followed.

Carry out the forensic examination (process the scene).

It is important to adopt search and examination techniques appropriate to the scene and circumstances of the offense.

At burglary scenes, fencing, gates, and vegetation should be checked for fibers (*see* **Crime Scene Photography: US Perspective**; **Packaging and Transport**). The ground inside and outside the property line should be checked for footwear and tire marks (*see* **Evidence Collection and Preservation: Casting**; **Packaging and Transport**).

There may be window glass or items moved or abandoned by the perpetrators placed outside the premises. If so, as soon as the necessary photography and documentation is complete, those items should be examined for trace, biological, and fingerprint evidence, recovered and removed to a place of safety, to ensure the evidence is not damaged, degraded, contaminated, or lost and to prevent any injury to members of the public.

As every crime scene is individual, it is difficult to prescribe which items and indeed which examination precedes another. While Association of Chief Police Officers (ACPO) [4] recommend that DNA recovery should take precedence, this is not always possible. Where other evidence is located on the path to the possible DNA source, that evidence must first be recovered to prevent its loss.

Provide advice and guidance when examination is complete.

When the examination is complete, the victim should be advised as to what has been found and removed from the scene and given advice on what the best method is to clean up after concluding the examination.

The CSI also tries to ascertain which officers or other persons have entered the scene after discovery of the offense, and where they have walked. This permits determining whose fingerprints, DNA, or shoe impressions need to be acquired for elimination purposes.

Where elimination fingerprints, footwear marks, and DNA are required, an explanation of the need to obtain them and what will happen to those elimination samples, will be appreciated by the victim.

Complete the relevant documentation (see **Crime Scene Documentation***).*

Maintain continuity and integrity of samples (see **Crime Scene Documentation***;* **Packaging and Transport***).*

Disseminate the results of the examination (see **Crime Scene Documentation***).*

Burglary Scene – Potential Evidence to be Considered

By the careful questioning of the victim, it is possible to establish what has been touched, moved, or stolen. All of which allows the CSI to complete a detailed crime scene investigation report (*see* **Crime Scene Documentation** and Phys Ev as Intel).

The CSI has to consider the potential of all evidence types. Starting at the point where the offender(s) entered the property, the possibility of the following evidence types should be considered:-

Hairs and fibers snagged on fences, gates, bushes, doors, windows, and walls can help place a perpetrator, or at least their clothing, at a scene. Fibers can help to link scenes in a series of crimes, where an offender consistently wears the same clothing or gloves. They also provide an indication of where the property was entered (*see* **Crime Scene Documentation**).

Where necessary, botanical evidence can be utilized. In some cases, this can be in the form of a wooden weapon or safe ballast [2].

When a person walks across rough surfaces or debris such as broken glass, unique damage occurs to the tread of sole of the footwear. The human gait and various other factors produce different wear patterns on similar shoes worn by different individuals. Similarly, tires also receive unique damage. These impressions can be recorded and casts can be made (*see* **Evidence Collection and Preservation: Casting**).

Pioneered by Cornelius Van der Lugt from the Netherlands and by others, ear impression comparisons are accepted as evidences in some jurisdictions. Similarly, lip impressions are currently being assessed as a means of identification.

When an implement such as a screwdriver, prybar, or case opener is used to force entry, there are three evidential possibilities to consider. First, if door or window is painted or varnished, some of the paint is likely to be transferred to the implement. If the tool is painted, some of its paint will transfer to the surface of the door or window. The blade of a screwdriver can leave impressions on both the frame and the closing edge of a door. The grinding process used to shape the blade can produce unique striation marks which are visible under magnification. These transferred paints and impressions can be used both as evidence and intelligence (*see* Phys Ev as Intel and **Evidence Collection and Preservation: Casting**).

When breaking glass or forcing entry, an offender may have cut himself and leave vital DNA evidence, which assists in establishing his identity. In addition to blood, the possibility of discarded items, such as cigarettes, chewing gum, drink containers, and partly consumed food, having DNA on them may be recovered for analysis.

One should bear in mind not only the impressed footwear impressions in soil but also the possibility of their presence on floors, work surfaces, and paper strewn on floor. Even where impressions are indiscernible, the possibility of electrostatic recovery should be considered.

Where footwear indentations are visible on paper, it is likely to subject it to an ESDA examination as such impressions can sometimes be visualized or developed. When muddy footwear impressions are left on floors and work surfaces, developing them by the application of fingerprint powder can provide unique evidence or intelligence. While the more visible impressions may have been preserved by the FOA and the victim, it should be noted that they are often the least useful for evidential purposes. Further, the impressions in the crime scene having excess mud and debris removed by the simple act of walking are more likely to have detail useful to a footwear analyst.

The mainstay of crime scene investigation, finger and palm prints, can be left by even the most careful criminal (*see* **Evidence Collection and Preservation: Casting**).

Although a glove mark is not always useful evidence, it should never be discounted as an evidence type or intelligence tool. Damage to rubber, vinyl, or leather gloves may, just like footwear, turn out to be unique. Where a suspect is detained and his gloves are seized, they could provide evidence of his glove being used at a scene. Where a perpetrator has abandoned gloves, the chemical development of latent finger and palm impressions from the inside of suitable materials may be attempted wherever possible.

In the heat of the moment, many items such as implements, weapons, clothing, and possessions are lost or abandoned at the scene by perpetrators. Not only those items can bear forensic evidence, but also they can have other, possibly documentary, evidence that can lead to the identification of offenders.

A forenic scientist must have something against which the comparison can be made. Thus, where forced entry has been made, it is imperative that exemplars be taken. In the United Kingdom and other countries, these are referred to as control samples, e.g., glass, wood and paint, fibers from long pile carpets. If, for example, a suspect is arrested close to a crime scene, in possession of a screwdriver, the cast tool mark can place the screwdriver at the scene. This, however, does not positively establish that he was at the scene. If minute fragments of paint from the scene are found on his clothing, this can place him, at least close to, at the forced door. In this case, both pieces of forensic evidence, presented together, could be compelling.

On completion of the examination, the CSI must establish the persons with legitimate access that need to be eliminated by checking against fingerprints, biological, and physical evidence found. Wherever possible, the requisite elimination fingerprints and samples should be taken at this time by the CSI. Details of those who are no longer present at the scene and whose elimination evidence is needed should be obtained as soon as is practicable.

Vehicles – Potential Evidence to be Considered

Developed nations are wedded to motor vehicles to different degrees and in many criminal investigations vehicles are subject to crime scene investigation. At the lower end of the scale, the vehicle may have been forced open and items stolen, or it may have been used in the commission of a homicide or other crime. The extent of examination depends on agency policies and priorities.

As with all other scenes, one must remain aware of the contamination risks. It would be wise to follow the simple anticontamination procedures used at a burglary.

Where a vehicle is being examined as part of a serious crime investigation, full protective clothing should be worn.

It is important that where there is the possibility of a victim having been placed in the trunk, it should be established whether that area has been checked by officers attending the report of the vehicle being found. If this has not been done, examining and operating the release mechanism for opening the trunk should be undertaken.

Before processing the vehicle, the appropriate photographs should be taken and wherever visible potential evidence is found, additional close-up photographs should be taken.

The vehicle license plates and any corresponding state DMV indicators on the windshield should be checked and documented. When appropriate, the manufacturer's vehicle identification numbers should always be checked. They are located normally under the hood and on the floor pan next to the driver's seat, or, in some cases, are impressed on the dash of the car so as to be visible from the outside. It should always be remembered that if a vehicle bears a false identity, the engine serial number should also be checked.

If a window has been broken to gain entry, the frame should be examined for any fibers or hairs. If any are found, they should be recovered. Exemplars should be taken from all broken windows (*see* **Evidence Collection and Preservation: Casting**).

Throughout the examination, one should always be careful to recover blood evidence at a time and using a method that will not compromise the examination of other forensic evidences. Likewise, it is important to ensure that other evidence recovery does not compromise DNA analysis.

If the vehicle is believed to collide with a person, one should conduct a careful examination of the exterior, including windows, roof, and rear. Fibers hair and dried blood can be attached to the trim and damaged areas. Even the washing of the vehicle may not have destroyed this evidence.

Where the offenders sat in a vehicle, tape lifts should always be taken from the seat belts and seats (*see* **Packaging and Transport**). The material used in the manufacture of seat belts is particularly good at retaining extraneous hairs and fibers. The use of separate tape lifts for the seat back, seat, head restraint, and the rear of the front seats is recommended. It may be possible to determine the location within the vehicle occupied by the offenders.

Once this has been done, the investigation can focus on to the foot wells or floor pan. Any papers, food wrappings, partially consumed food, and used drinks containers found, should be recovered for possible fingerprint, footwear, and DNA analysis. Where loose mats are used on the floor, they should be removed carefully as there may be vital evidence, such as hairs, fibers, glass, paint etc, that could link the vehicle to a location, other vehicle, victim, or suspect (*see* **Packaging and Transport**). Where none are used, the fitted carpet area should be brushed carefully and, if necessary, the carpet is tape lifted (*see* **Packaging and Transport**). Only when the above evidence recovery processes have been undertaken, the search and examination can carry on.

At this point, if the vehicle is involved in a serious offense, the mileage and trip meters readings should be recorded, as well as the fuel level.

As with any scene, one must constantly assess both the potential evidence and hazards. A careful search of the glove box, door pockets, seatback pockets, and underside of seats should be made and any possible evidence should be recovered. It is important to be mindful of the possibility of encountering sharp objects that present a safety hazard to the investigators.

The mechanical fit of objects to items recovered elsewhere should also be considered. This is particularly important where the vehicle has possibly been in collision with another vehicle, object, or person. There may be broken parts, light lens plastic fragments, damage to bulbs, trim, and even panels with missing paint. Where a vehicle has been repaired using filler compound, this can also furnish valuable evidence.

Plastic bags from a roll of bags, cable or broken tools, or weapons are all possible sources of mechanical fit evidence. Items such as ropes and cords and pieces of tape such as packaging or duck tape are not just possible sources of a mechanical fit or fracture match. Rope may have other fibers, hair and epithelial cells caught in the plait, as well as possible microscopic pieces of dried blood. The mechanical fit of one section of tape to a roll of tape can often be matched. Fibers and hairs can attach not only to the

adhesive side but also to the edge of the roll. Fingerprints, DNA, and even bite marks are other evidential possibilities to consider.

Once you have recovered physical, trace, and visible DNA evidence, you should consider the use of alternate light sources as well as luminol.

Areas inside the vehicle covered by "orange peel" plastic surfaces, such as steering wheels, gear shift and parking brake, may not be suitable for latent print development but may be suitable for LCN DNA.

Where it is important to determine whether a vehicle has been at another location, one should consider foreign and exemplar paint samples, tire impressions, and recovering the debris from inside wheel arches and underside. When examining tires, their make, model, size, condition and position on the vehicle should be noted. This evidence could provide important information during the inquiry.

One should always consider the possibility of oil and grease leaking or being rubbed off. This, too, may provide important evidence that helps to place a vehicle at a scene. For example, if a vehicle has an oil leak and is stationary for a period of time, oil could be deposited on the ground. The oil sample should be taken from the sump area.

Outside Scenes – Potential Evidence

With the exception of possible livestock thefts in rural areas, most scenes in fields, woods, parks etc, will probably be limited to the investigation of serious offenses or related to vehicle involvement.

Where the scene is in or near water, samples of the water should be obtained.

The search and recovery process at a major outside scene would be decided by the Senior Investigator in consultation with the Lead CSI or crime scene manager (*see* **Crime Scene Management**). Crime scene investigation is the same for all offenses but serious offences prompt a greater response in terms of resources.

Crime Scene Management

Volume Crime Scene Management – First Report to Police

Crime scene management of these offenses begins with the first report to police. As it may be some time before a law enforcement officer attends the scene, the advice given by the personnel receiving the report can have important consequences on the final resolution of the case.

This advice should be to touch as little as possible and move about as little as possible. Once officers have been dispatched to the scene, subsequent questioning will allow dispatchers to evaluate the prevailing weather conditions and advise on retrieval

of items outside the premises to protect them from inclement weather.

First Officer Attending

The first officer attending should be aware of the potential that forensic science has to detect the crime. When approaching the scene, they should consider the following possibilities:

- Stolen property being hidden nearby with a view to later retrieval by the offenders.
- Fibers from offenders' clothing attached to any rough or broken surfaces with which an offender could have had contact.
- Footwear impressions:
  - In soil or mud where the offenders have breached the perimeter fencing of the scene.
  - In mud on smooth surfaces inside the premises. The best impressions for evidential purposes will be those further from the initial impression inside the point of entry. Any areas where illegal entry from outside has been gained should be entered with care.
  - In dust on smooth surfaces, as they could be recovered using an electrostatic lifting apparatus (ESLA) (see section on footwear recovery).
  - On papers scattered about during the commission of the offense. Papers should be left *in situ*, pending the attendance of a crime scene investigator (CSI). Footwear marks on papers can be developed using ESLA. Where footwear has left an indented impression on a piece of paper, its image may be enhanced at the crime laboratory by using an electrostatic development apparatus (ESDA), normally used for detecting indented handwriting or typescript on documents.
- Instrument marks, on doors and windows, that have been forced open by items such as a pry bar or screwdriver.
- Where doors and windows have been forced or the glass broken, officers should remember that, not only may offenders have snagged their clothing, but they may have cut themselves. Great care should be taken to ensure that this evidence is neither disturbed nor contaminated.

Major Crime Scenes – First Officer(s) Attending

When the first officer or officers arrive at a major scene, they have several, often conflicting, tasks to perform.

Their first priority is to preserve life but they must always consider the possibility of forensic evidence and, where offense details are apparent, take the route least likely to be used by the offender. This route is known as the common approach path (CAP) and should be used by all subsequent personnel entering the scene.

They must check for witnesses and ensure they are retained at scene and if possible kept apart from one another. It should also be considered that any witness might in fact be an offender.

They must also be aware of persons entering and leaving the immediate area of the scene. In addition to all the above, they need to ensure that the scene is secured and protected. This can be done by using police cordon tape or by improvization using garbage can lids, boxes, or even a car hubcap to protect fragile evidence. Always remember to "think big". Consider where the scene could end and keep people out. For example, if an incident occurs in a front yard or street, the whole length of the block should be cordoned off. This can always be modified and reduced later. Consider the impact on the case if CSI needs to extend a cordon and evidence is found in an area that anyone had access to.

Major Crime Scene Management in England and Wales

There is no legal definition in the United Kingdom of a major crime scene. It normally applies to scenes of murder or serious assaults that may prove fatal. A major scene ranges from a relatively simple domestic homicide where one partner has killed the other to serial killings, terrorist incidents, and mass disaster. However, large or small the scene, it is imperative it is managed in a professional structured way.

Prior to the 1990s there was an almost unprofessional approach to the management and examination of major crime scenes. The senior investigating officer (SIO), normally of superintendent rank, would decide on the sequence of examinations. Those officers often had little or no understanding of forensic science. Although by this time, police forces outside

London had from about 500 to 7000 officers, there was a lack of suitable expertise. In some forces the Scenes of Crime Unit, Photographic Unit, and Fingerprint Bureau were part of different divisions, reporting to different top-level management. Although the three departments interacted on a daily basis, there was no coordination of their activities. At a major scene, there was a reliance on the expertise of forensic science specialists but with no coordination at scenes some examinations were carried out at the expense of others and there was a real possibility that crucial evidence could be lost.

There was little incentive to change as confessions were much more common than they are today. Expert evidence was very rarely challenged and even the integrity of evidence, which was open to question in some cases, was almost always accepted.

The training available to an SIO and a CSI varied greatly and for those involved in what we now call "Scientific Support" there were very few career opportunities for personal development. Although there had been civilian staff in the departments for over 25 years in some cases, the management of the department was still the responsibility of a police officer. Police officers performing management roles in the Scenes of Crime, Photographic, and Fingerprint Units were sometimes in those posts for possibly only two to three years, as part of their career development. In some cases, this led to a lack of continuity and a very low status and esteem for those involved.

By the 1980s, several high profile appeals in criminal and especially terrorist cases demonstrated there was the possibility of unsafe convictions. This led to a lack of confidence in the police. This confidence is vital to the democratic principle of policing by consent.

From 1986 onwards, there were several reviews of the structure and use of forensic science by the police in England and Wales. However, those reviews only made recommendations and none of them actually placed any requirements on police forces. Successive recommendations were wide ranging and included training, organizational structures, roles, and equipment.

Forensic science laboratory provision in England and Wales has gone through radical changes over the last 15 years. The Home Office Forensic Science Service became an agency of the Home Office and later a Government owned company. As a result, forensic science moved from being a central service on behalf of the police to an effectively free market, where several competing organizations provide forensic services to police forces.

Recommendations for change with police forces were also made. They included the roles of scientific support manager (SSM), crime scene manager (CSM), and crime scene coordinator (CSC).

The Crime Scene Unit, Fingerprint Bureau, and Photographic Unit were all integrated into one Scientific Support Department (SSD) under the SSM with overall responsibility for all aspects of forensic science within the force. In what was then viewed as a radical policy, the SSM could be a police officer, a forensic scientist brought in from a laboratory or a civilian with the right skills and background. This move paved the way for a progressive career path for SSD staff and also to a more professional approach to forensic science within police forces.

With this professional approach, it quickly became evident that a far more scientific approach to managing forensic science at major scenes was required. The roles of CSM and CSC quickly evolved.

A CSM is normally a supervisory CSI. They have operational control of a major scene. They are appointed for individual major scenes and are part of the incident management team and forensic management team. The first CSM may well take a dual role as CSM and CSC in a relatively simple case.

In complex cases, a CSC is normally appointed to oversee and coordinate actions at all the scenes involved. In many cases as well as the primary scene there could be several secondary scenes. Any of the following could be a primary or secondary scene:

- scene of assault or killing;
- deposition site;
- vehicle(s) of victim and suspect(s); and
- residence(s) of victim or suspect(s).

It is imperative that there can be no suggestion of cross-contamination of those scenes by personnel going directly from one scene to another. It will not always be clear which scenes need to be connected to one another or to any of the subjects involved in the offense. Good practice is that as a CSC, you keep an anticontamination matrix (*see* **Crime Scene Documentation**).

Crime Scene Manager – Responsibilities

As a CSM, you would be a member of incident management team. This recognizes the vital nature of the forensic evidence available at a scene. As such you would have regular meetings with the senior investigator, exhibits officer, and others and would be involved in decisions as well as advising on forensic matters.

CSI Activities at Major Scenes

As either the first CSI or as a CSM arriving at a scene, you should always review and, if necessary, revise scene protection and cordons. It is worth repeating the advice to "think big". Consider where the scene could end and keep people out. For example, if an incident occurs in a front yard or street, the whole length of the block should be closed off. This can always be modified and reduced later and it allows you carry out a "flash search". Information gained about the exit route is always useful. No matter how careful the planning of a criminal enterprise, once the crime has been committed, caution can be thrown to the wind and perpetrators start to try and distance themselves from the offense. A point to point or "flash search" along this route may reveal garments, weapons, tools, or even documentary evidence. Consider the impact on the case if you need to extend a cordon and evidence is found in an area that anyone has access to.

You should also consider the need for inner and outer cordons at extensive scenes. All nonemergency service personnel are prevented from entering the outer cordon. This allows you to designate a rendezvous point and park essential vehicles between the two cordons. Only those personnel essential to forensic operations should be allowed inside the inner cordon.

Although it should already be in use, you should ensure that a scene entry log (*see* **Crime Scene Documentation**) is maintained. Always reinforce the need for exclusion and record keeping, especially where inexperienced officers are involved. In addition to any persons allowed access to a scene, all perimeter guards should be instructed to record details of all persons seeking entry. Where statutes permit, the identity of those persons enquiring what is happening should be obtained and what, if anything, those persons observed. This can possibly obtain useful information and where they later decide to give evidence for the defense, negate any perjury they may commit. Any vehicles that continuously drive past the scene should always have their details noted. The occupants may be purely inquisitive but they may have ulterior motives for their interest.

Many agencies operate a system that requires those entering a scene to sign in and out. This can eliminate any future doubts as to who entered a scene. A simple way to deter inquisitive officers of any rank is a large notice (*see* **Crime Scene Documentation**)

All CSIs should maintain a record of their actions. As a CSM you should also initiate a record of scene examination or CSM log. (*see* **Crime Scene Documentation**) Aide memoirs are useful but should not be treated as exclusive checklists. Always consider all options, possibilities, and the "I wonder if?" factor.

As the first CSI attending, you should always establish a CAP. This may require clearing a path from the perimeter to the deceased or center of the scene. This should always be the unlikeliest route the offender will have used. At external scenes, this may mean cutting a path through thick woodland to avoid any footpaths or tracks. You may also consider using planks laid on metal ladders to cross watercourses or any other means of access to a scene.

In an internal scene, best practice is the use of stepping plates. These allow investigators access to the scene without destroying any possible footwear evidence on the floor.

The CSM should undertake an initial assessment of scene. You should take time to get the full picture and consult with those who have information. Always remember to keep an open mind as your assessment must be an independent assessment of the scene and all hypotheses must be tested and no assumptions made. All observations, information received, and advice given must be recorded in the CSM log (*see* **Crime Scene Documentation**).

It is advisable to evaluate the extent and boundaries of your scene and plan accordingly.

When arriving at a strategy, a structured approach is critical. You must ensure that you have the correct resources and effective safety and welfare measures. Again, those decisions must be documented (*see* **Crime Scene Documentation**). At night, you should always consider securing the scene, pending daylight.

Before scene-processing activities commence, you must record the scene, using photographs and video.

A sketch plan or plans should be commenced and maintained as the processing progresses (*see* **Crime Scene Documentation**).

Secure fragile evidence to allow body removal, tape lifting, and fingerprint recovery from door frames, walls, etc. In many US jurisdictions, the deceased is the province of the medical examiner's or coroner's office and the body and its examination and recovery is their responsibility.

Where the police agency has sole responsibility for scene processing this can involve swabbing and recovery of fragile evidence from the body. You must always ensure that life has been pronounced extinct by a medical practitioner prior to any movement of the deceased. You should always ensure body recovery by CSIs to safeguard forensic evidence.

When all of the above has been completed, you should then begin the core process of crime scene investigation, the search for, identification, preservation, and recovery all types of contact trace evidence (*see* **Crime Scene Investigation**).

Throughout the scene processing, as a CSM must always ensure that techniques and decisions are within the areas of competence of personnel present and seek expert assistance where needed; serology, ballistics, blood spatter analysts, anthropology and cadaver, accelerant, and explosives dogs.

As a general rule, fingerprinting is the final process, as powder and chemical development could contaminate or destroy other evidence.

Search Strategies

Search strategies are dependent on various factors, including the operating environment. As part of your risk assessment (*see* **Crime Scene Investigation**; **Crime Scene Documentation**) you should consider any potential dangers, such as perpetrators returning to scene. The item may also be hazardous and you must consider how to preserve and recover it (see section Risk Assessment).

Methodologies. Most CSIs agree that there are five basic search patterns used for forensic purposes:

- **Circle or Spiral Search.** As described by many authors, it is a useful method where resources are limited or a specific item is being sought.

- **Strip and Line Search.** Strip search of a scene is a very effective method of searching a large area, such as fields or parking lots. The width of strip will be determined by the physical environment of the scene. Where necessary, string or tape such as those used to cordon a scene can be used to delineate the area a single person has to search. A strip search can be a useful method where human resources are limited.

  A line search is an ideal technique where there are sufficient personnel or the area concerned is on a slope. You must always remember to search downhill as any disturbed item will then still be within the area still to be searched.

- **Grid Search.** A variation of the strip search, it is a useful method to ensure small items are not overlooked. The scene is searched using the strip or line search technique, then re-searched at 90°. If on a slight slope, you should search across it first and then downhill. Start across at top of hill, then always down hill.

- **Zone Search.** This is a useful technique for searching areas such as cars, industrial areas, and multi-zone areas such as gardens. It is also an effective top tier division of extremely large scenes such as terrorist incidents.

- **Point-to-point Search.** This method is used to clear a path to the deceased, to enable the necessary processes to be undertaken, and to allow the body to be moved for autopsy. It is rarely used, except as a "flash" search, following the known or presumed route of suspects away from the scene. When fleeing a scene, offenders have been known to abandon, weapons, clothing, and even personal effects, in an effort to "distance" themselves from a crime.

Deciding on a Search Strategy. When deciding the type of search to undertake you have to consider the possible size of the object. If the size of the item is small or unknown, you need to consider a fingertip search. This is exactly what it says, hands and knees on the ground in a line. You may be searching for a spent cartridge case or spots of blood on leaves on a forest floor. This can be a very slow painstaking method, involving the careful movement or removal

of objects. No matter how time consuming, it can be essential to the evidence recovery process.

If the item is visible from head height, you have to consider if a line search would suffice, and if it could be above head height, the search of roofs gutters and down pipes needs consideration.

Where an item could be buried by soil movement, human, or animal activity, you should consider the use of ground penetrating radar.

A useful member of the team in this scenario would be a forensic archaeologist. If searching for human remains, the assistance of an anthropologist can be beneficial in determining if remains are human.

The physical environment of a scene inside premises such as stairwells, yards, elevators, and even fire and water damage can affect the processing of a scene.

The topography affects how a scene is processed and searched, as it may be difficult to traverse the terrain. If it is hilly, flat, marsh, pasture, thickly wooded, or brush you must be able to adapt your methods. If you are searching a wooded area, despite the obvious uncomfortable position, you should always search in a downhill direction as any item disturbed will move downhill and still be in the area to be searched. You may have to consider a double line approach in a wooded area. You would have two lines of personnel, one behind the other, the first line would search the ground and the second would scour the trees for obvious evidence.

Inclement weather can have a devastating effect on a crime scene. Rain can wash away evidence and light items can be blown away by high winds. You need to consider what measure if any you can take to prevent or lessen this. If necessary, you can the block drains to prevent some evidence loss but ultimately you will need to deviate from original plans and possibly recognized protocols. However, if you can justify these decisions and actions and document them in your CSM's log (see **Crime Scene Documentation**), any criticism will be removed or minimized.

Risk Assessment. In most developed countries, all work tasks must be carried out in a manner that is safe for any personnel and members of the public. In the United States, this is controlled by the Occupational Safety and Health Administration (OSHA).

In the United Kingdom, the Health and Safety Executive (HSE) has responsibility for ensuring compliance with the Health and Safety at Work Act 1972. Routine crime scenes can have generic risk assessments that cover low level risks that are normally encountered, such as broken glass, potential biohazards, and trip hazards (*see* **Crime Scene Documentation**). By their nature, any police operation is a fluid and major operations require dynamic risk assessments, continuously reviewed in the light of changing circumstances. Any CSM's log should include documentation to demonstrate the identified risks and the measures taken to eliminate or reduce them.

Threat Assessment. In the United States, it is normally recommended that at least one armed member of the agency remains at a major scene during the processing activity. Even in the United Kingdom, in rural areas, you should always consider that the offender may be living rough and that a search may reveal a camp or hide. Whatever the potential threat, a contingency plan, including an extraction plan should be decided upon and communicated to all personnel involved.

Resources. All of the above are affected by resource availability. The ideal equipment may not be available. Human resources are finite and the number required may not be immediately available. Both of these affect your strategy and mean that your strategies need to be flexible.

A very important consideration at any major scene is the welfare of personnel. Provision should always be made for an area where staff can relax for a short while and have some refreshment. Where a double cordon is in place the area between the inner and outer cordon should be used.

Exhibit Handling. To ensure integrity and security of recovered evidence, proper packaging is vital (*see* **Packaging and Transport**). As soon as an exhibit is recovered, it must be packaged, sealed, and the chain of custody documentation (*see* **Crime Scene Documentation**) completed. This should be double checked prior to removal from scene, handover to other agencies or exhibits officer. These simple steps ensure there is no possibility of contamination.

Quality Assurance Measures. To ensure that no potential evidence is missed, periodic reviews of

progress should be undertaken in consultation with the team(s) at scene and personnel involved in managing the investigation. Once the forensic examination of a scene is complete, where another trained CSM is available, a peer review walkthrough should be undertaken. This will minimize any possible oversights. This reflects good practice in homicide investigations as identified in the United Kingdom. Once this has been done, a walkthrough with the senior investigator highlighting activity is essential to confirm that all expected actions have been completed.

Once the examination has been confirmed as complete, a thorough search of the scene should be undertaken. Where possible, this should be carried out by a trained search unit, with a CSI present to photograph, recover, and document any additional evidence found. Where necessary an inventory of the scene should be completed. It should be noted that the examination and search are integral parts of a two-part operation and discovery of evidence during a search that includes dismantling or total removal of items does not mean it was missed by the CSI personnel.

Only when all activity completed can the scene be decommissioned and released. Where statutes permit, it is best to retain secure if possible, pending the completion of the investigation.

Crime Scene Photography: US Perspective

Introduction

The primary role of the crime scene technician is to document the context of the scene before it is altered or destroyed and to recover any physical evidence that may be present. These actions, if accomplished properly, ultimately assist the trier of fact in determining what occurred at the scene in question. In pursuing this goal, the crime scene technician accomplishes six basic activities. These include assessing the scene, making observations about the scene, documenting the scene, searching the scene for additional data or evidence, collecting all of the evidence located, and analyzing certain aspects of the scene (e.g., on-scene bloodstain pattern analysis or external ballistics).

Since every action taken by the technician has the potential to alter or destroy scene context, these six activities are accomplished in an order that places the least intrusive first, followed by the more intrusive actions. Assessing and observing the scene, in and of themselves, are not intrusive. They demand only that the crime scene technician move carefully in the scene, without disturbing physical evidence as they assess and make their initial observations. The subsequent steps of documenting, searching, collecting, and analyzing are quite intrusive; each demanding the crime scene technician interact directly with the scene. For this reason, scene documentation is always accomplished before any invasive search or collection activity.

The express purpose of crime scene documentation is to capture the scene context *in situ*, or as found. On-scene documentation involves several different elements including

- creating detailed notes on observations;
- capturing the scene context in photographs and video; and
- creating crime scene sketches.

Each of these elements of documentation is important to the overall investigation. No single element

stands alone, as each supports the other. Together they allow individuals who were not physically present at the scene to "see" and understand what the crime scene technician observed. From this documentation, theories of what happened are developed. When proper documentation exists, questions posed by the court about where an item of evidence was or in what condition it was found can be succinctly answered without hesitation. Without proper documentation anything goes. Counsel can make claims about items of evidence, with no functional means for the crime scene technician to refute or corroborate the claim. As important as crime scene notes and sketches are to this purpose, photographs of the scene are the most effective means of sharing what the crime scene technician observed there.

Basic Considerations for Crime Scene Photography

Photography of the scene is a critical element of crime scene documentation. The intent of the crime scene photographs is to lead the viewer from an overall perspective of the scene, to the details of specific items of evidence. Each photograph builds upon the next so the viewer is never lost or left wondering what they are viewing. The importance of capturing the scene context through the crime scene photographs cannot be overemphasized. A crime scene technician could spend an hour on the stand trying to explain some aspect of the scene; but using a single photograph, in a literal instant the court and jury are able to take in details such as relationships between items, color, and texture. Through photographs the crime scene technician allows the jury to see and experience the scene themselves.

To achieve this result, a standard photographic methodology is necessary. Such a methodology eliminates errors of omission and if applied appropriately produces functional and complete crime scene photographs. What is entailed in such a methodology? First and foremost it involves understanding and using three basic evidential photographs. These are the overall, evidence establishing and evidence close-up photo. Each photograph is discussed in detail later in the article, but the use of all three types of photographs allows the crime scene technician to capture scene context completely. Additionally, any practical methodology for crime scene photography should involve the following:

- The entire scene is photographed *in situ*, as soon as practical after arriving on-scene.
- Items of evidence considered to be fragile (e.g., footwear marks in dust, bloodstain patterns on the body) are documented completely before they can be damaged or altered.
- All observable items of evidence are photographed using the three basic scene photograph types before disturbing them in any manner.
- After completing a first series of photographs, photo/evidence placards are added and a second series of photographs are created. The placards allow the viewer to differentiate the various items of evidence from one another.
- If additional evidence is located in latter stages of the processing methodology (e.g., while collecting an item of evidence or when moving large items in the scene) the crime scene technician stops all activity and takes appropriate photographs of the new evidence. It is understood that these photographs may show the scene in an altered condition, but they are needed to functionally place the new evidence within the scene.
- For any on-scene analysis efforts, (e.g., a trajectory analysis of a bullet, defining the area of origin for a bloodstain pattern) the technician creates photographs that clearly demonstrate the result of that analysis. Once again, it is recognized that these photographs will show the scene in an altered state. Alteration of the surrounding scene is unimportant; the purpose of these photographs is to demonstrate the analysis result.
- A film roll reference card and photo log should be included in the documentation efforts. The film reference card is nothing more than a placard on which the technician writes where, when, and who produced the photos. The first photograph exposed on the media is of this card. The purpose of the photographic log is to keep track of the intended content of each photograph. **Crime Scene Documentation**

Composition of Crime Scene Photography, Understanding the Basic Types of Crime Scene Photographs

Composition is important in artistic photography, where the photograph is judged on its aesthetic value. Photographic composition is generally accomplished by organization of the space and items depicted

in the photo as well as consideration of how the various visual elements relate to one another. Artistic photographic composition involves various aspects including the following:

- **Contrast**

Contrast requires the photographer properly frame and light a subject in such a way that the background does not compete for attention.

- **Framing**

Framing requires simply that the subject of the photograph be captured completely in the field of view.

- **Simplicity**

A photograph should have one primary subject (e.g., a group of people, a landscape, or a butterfly). The value of a photograph with numerous visual centerpieces is often diminished by the resulting clutter and confusion it creates.

- **Rule of thirds**

The rule of thirds defines subject placement in the photograph. Applying the rule, the subject is always placed slightly off center rather than in the center of the viewfinder.

- **Viewpoint**

Viewpoint is a function of altering the camera position to create different perspectives. Lowering the camera height or aligning the camera's vanishing point with a skyscraper's lines are examples of altering viewpoint.

In artistic efforts, all of these composition elements are necessary to create aesthetically pleasing photographs. Crime scene photography is not the same. The purpose of the crime scene photograph is to accurately depict the scene without introducing distortion. For crime scene photography the concepts of simplicity, framing, and contrast are all applicable, but altering the viewpoint and the rule of thirds are not generally applied in crime scene work. For example, in terms of contrast, proper lighting of the subject of a photograph is always a challenge. The crime scene technician is limited in that they cannot alter the scene to change a background. Contrast and proper lighting are achieved through the use of fill-flash, off-camera flash, and bounce-flash. Simplicity is achieved by concentrating on the purpose of each photograph, asking "Why am I taking this photo and what do I want to show?" Simplicity requires a thorough understanding of the three basic types of crime scene photographs. Framing a subject is always important in the crime scene photograph, but as the technician is not concerned with aesthetic value, off center placement is rarely used.

To achieve composition simplicity and meet the underlying purpose of crime scene photography, each photograph must assist in leading a viewer through the crime scene and capturing the scene context. This is accomplished using three types of photographs. The three photographs are known as the following:

- *overall photographs;*
- *evidence establishing photographs; and*
- *evidence close-up photographs*

Overall Photographs

The purpose of the overall photograph is to capture the general condition and layout of an area. They are also effective in showing interrelationships between different areas of the scene. The crime scene technician seeks to show how the scene is oriented and capture major landmarks or focal points (e.g., doors, furniture items, bodies). Overall photographs are always the first photographs taken on-scene. Of all of the photographs created, overall photographs are the single best source to demonstrate that the scene was not intentionally altered by processing efforts. If someone questions some aspect of the scene (e.g., claims that the specific location of some item was altered by the investigators), overall photographs often show the location of the item when the initial processing began.

Overall photographs are generally exposed with a wide-to-normal angle lens and are taken from head height in a standing position (a normal human viewpoint). The use of a wide-to-normal angle lens (e.g., 28–50 mm) allows the photographer to capture a broad area in a single photograph, which is certainly helpful when one considers its purpose. The use of a 50–55 mm lens produces a photograph consistent with a human perspective and this lens is generally considered the standard for crime scene work. Nevertheless, wide angle lenses like the 28 mm lens can be used effectively in creating overall photographs without altering their value. The use of an extreme wide angled lens, such as a "fish-eye" lens is not recommended as it produces significant distortion. Although

a fish-eye lens allows a larger area to be captured in a single photograph, the level of distortion is so distinct that the photograph may not be allowed in court.

An effective method for creating overall photographs is to simply shoot the scene from various overlapping angles. In an interior scene the technician goes to a corner of the room or in an exterior scene to the perimeter and then takes a photograph across the area to an opposite corner or side (Figure 1). This process is repeated for each corner of the scene. The end result of the process is four or more photographs that provide overlapping coverage of the entire area. The photographs are shot at a distance, so small details may be lost (e.g., a shell casing may not be visible), but large items such as furniture, bodies, weapons, and other evidence items that are evident. Remember the purpose of the overall photograph is to capture the general condition of the scene as it was found. The four-corner method captures quite a bit of detail, but does not capture everything. If areas exist where specific evidence or initial conditions are not visible in the four-corner photographs, additional overall photographs of that area are required as well. As needed, the additional photographs are taken from whatever position is required for these odd areas; the sole purpose of which is to establish the initial condition and orientation of that area alone.

As the methodology described, overall photographs are typically taken in two series. During the first series, the crime scene technician does nothing to the scene. No scales or photo placards are introduced. This first series is taken as soon as possible after arriving on-scene and certainly before any significant action by the crime scene team. These overall photographs are used to demonstrate scene integrity and eliminate any claim that the scene, as shown in later photographs, was altered from its original condition. The initial series of overall photographs always depict the scene prior to any invasive processing activity.

A second series of overall photographs is exposed after an assessment of the scene. At that point various items of evidence are known to the technician. Photo placards are introduced into the scene adjacent these known items of evidence and the second series are shot in exactly the same way (e.g., corner to corner) (Figures 2–5). The introduction of the photo placards increases the value of the photograph. The placards allow the viewer to recognize that items that are not visible (e.g., the example of the shell casing) are, in fact, present in the same location.

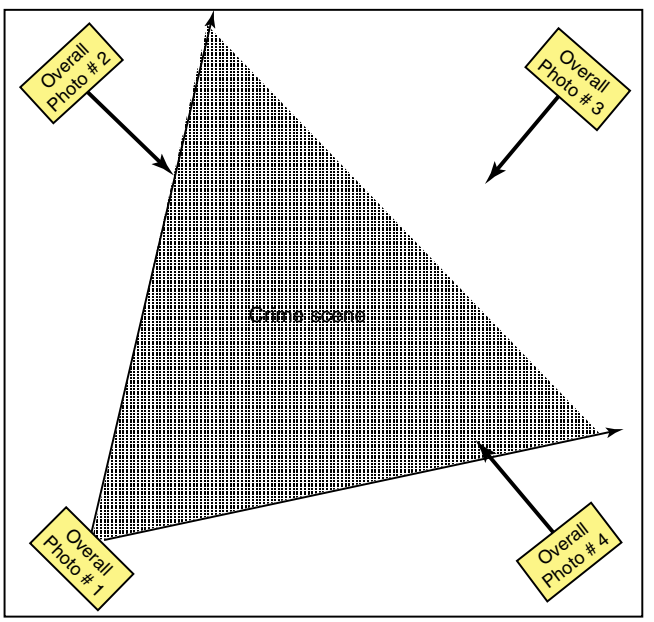

Figure 1 Overall photographs are most effective when they capture overlapping aspects of the scene. The easiest method to accomplish this is to take a photograph from each corner of the room or scene. The four resulting photographs will effectively capture the full scene context

Figure 2 Figures 2–5 demonstrate the concept of the overall photograph in an exterior scene. In this first photograph, the camera is oriented looking down the hill (SW-NE) into the scene. Note the trailer hitch in the foreground. Its inclusion is purposeful and will serve to orient other photographs back to this one

Figure 3 This overall photograph is taken looking NW to SE in the scene. The evidence flags are already in place to help illustrate where items of evidence are located

Another use of the overall photograph is to demonstrate the relationship between various areas in a scene. For scenes involving multiple rooms or dispersed areas outside, the use of a properly framed overall photograph allows the viewer to understand how one area relates to another (Figure 6).

Evidence Establishing Photographs

The purpose of the evidence establishing photograph is to frame an item of evidence in relationship with a known landmark in the scene. This is particularly important when we consider that many items of

Figure 4 This overall photograph is shot from the bottom of the hill looking NE–SW, back toward the position Figure 2 was taken from. Including the trailer hitch in Figure 3, allows the viewer to clearly orient this photo back to that photograph

Figure 5 This overall photograph is taken looking SE–NW across the scene. Beyond the presence of the evidence items, the pink fluorescent tape on the right side of the photograph was also visible in Figure 3. This is another landmark that allows us to orient the two photographs to some extent

evidence (e.g., bullet holes, bloodstains, and shell casings) as well as the surfaces on which they occur often look quite similar in close-up photographs. Without the evidence establishing photograph, the viewer is often confused by the close-up photograph, unable to understand what surface they are viewing (Figure 7). In combination with the evidence close-up photograph, the evidence establishing photograph allows the viewer to clearly orient themselves as to what item they are viewing and exactly where it is in the scene (Figure 8).

This particular photograph is often described as a mid-range photograph in which the crime scene technician is advised to shoot an overall or distant photo, followed by a midrange photograph and then finally a close-up photograph. Range or distance

Figure 6 Overall photographs can be used to orient separate areas of a scene as well. The wooded site offers little that allows us to know where it is. This photograph is taken at the top of the hill looking back at the adjacent residence. By framing the trailer in the photograph, when considered with Figure 5, the viewer has a clearer understanding of where the wooded site is in relation to the residence

Figure 7 Close-up photographs rarely assist the viewer in understanding where an item of evidence is. Items such as bloodstains, bullet casings, or bullet holes are often found on similar looking backgrounds; which only adds to the confusion. The function of an evidence establishing photograph is to remove this confusion. Consider Figure 8 in combination with this evidence close-up photograph

is not the issue and thus the term mid-range is misleading. The purpose of this photograph is to frame an item of evidence in relationship to a landmark in the scene. How that is accomplished is based on the context of the scene. Depending upon the context, an evidence establishing photo might be taken from 2 or 10 ft. That decision is based solely on the landmarks available. If the photograph

Figure 8 An evidence establishing photograph for Figure 7. This photograph captures the position of the various bloodstains including Stains #5 and #6. Together the two figures allow the viewer to see both the detail of the stains and understand where in the scene the stains are. Combined with an overall photograph of the scene that shows the door, one can quickly and easily understand the full context of where these stains were located

is approached arbitrarily from a distance aspect, then each establishing photograph would be shot from an arbitrary distance (e.g., halfway between the overall and close-up). No matter what term is used to describe this photograph, its purpose must be understood and met; it is taken singularly to identify where the item is in the scene. This photograph bridges the gap between the overall and evidence close-up photographs, allowing the close-up photographs to be understood in relation to the scene.

A 50–55 mm lens is usually adequate for shooting evidence establishing photographs. The viewpoint (camera position) used in the evidence establishing photographs can vary widely; however, avoid interjecting unnecessary angles that may distort the photograph or confuse the viewer. The importance is to frame the landmark and evidence item together in such a fashion that the viewer can identify each.

In small or uncluttered scenes, the second series of overall photographs with the placards in place often serve effectively as the evidence establishing photographs (Figure 9). If this is the case, additional evidence establishing photographs are unnecessary. In complex and larger scenes, the overall photos are not enough. Whatever the situation, the addition of the photo placards in the photograph enhances the viewers understanding. Photo placards are available from numerous sources and although commercial placards are relatively cheap, there is no requirement that the technician use a commercial product. Disposable placards are easily created from index cards and a bold marking pen. An additional technique for exterior scenes involves the use of grading flags and plastic lettering kits. Large adhesive plastic letters or numbers are attached to the grading flag and the grading flag is placed into the soil adjacent to the item of evidence (Figure 10).

Once the photo placards are in place, items should not be arbitrarily renumbered at some later point in the report, evidence voucher, or on the sketch.

Figure 9 In uncluttered scenes, the introduction of photo placards in the overall photograph may eliminate the need for a specific "evidence establishing" photograph. This overall photo effectively serves both purposes for items 1–5

During the initial placement, choose a numbering and lettering scheme that work throughout the entire crime scene processing and allow for the addition of as-yet discovered items. A simple method is to use a combination of alpha-numeric associations. Numbers are assigned to major items of evidence (e.g., item 1 and item 2) and if subassignment is necessary letters are used in conjunction with the number (e.g., 1a, b). Changing or using duplicate numbers or letters in subsequent documents or photographs create confusion for those viewing the documentation.

Evidence Close-up Photographs

The purpose of the evidence close-up photographs is to show detailed aspects of a particular item of evidence. As the name implies the photograph is taken from a distance that is as close as possible to the evidence. Far too often these photographs are taken from a distance of 3 or 4 ft away, when the subject of the photograph is the size of a coin (Figure 11). Such effort fails to capture any detail, yet they are still represented as "close-up" photos. The viewpoint for the evidence close-up photograph is very simple. Proper close-up photographs are achieved by placing the camera at a distance that allows the evidence to fill the frame of the viewfinder. Whenever possible position the camera, so the film plane is horizontal to the primary surface being photographed. After items are collected from the scene, additional close-up photos may be necessary as well (e.g., to show a fingerprint or small bloodstain on a murder weapon) (Figure 12). When creating these after-collection photographs, the technician should consider that recent advances in digital cameras now provide the means of photographing evidence that in the past was simply impossible to capture. Cameras like the Fuji S3 Pro UVIR allow the technician to document items like bloodstains on dark backgrounds, gunshot residues, bruises, and biological stains (Figure 13).

The best lens for creating a close-up photograph is either a 55-mm lens or a macrolens manufactured for that specific purpose. Macrolenses typically range from 50 to 105 mm, the latter often offering 1 : 1 aspect ratios. Proper lighting of the close-up photograph often requires effort. External strobes controlled in automatic mode by the camera function fine when taking overall and evidence establishing photographs. In close-up work, the camera body almost always ends up in close proximity to the surface being photographed. In this situation the automatic flash, more often than not, bleaches out surface details. Off-camera strobes held at an angle to the surface being photographed or adjustable beam strobes that allow the flash to be bounced off ceilings or adjacent surfaces are the primary way to properly light the

Figure 10 In an exterior scene grading flags can be used as an evidence placard. The grading flags are available from any hardware store and adhesive plastic lettering is found in any office supply store. The lettering is added as needed and the flag, which is on a metal rod, is inserted into the soil adjacent the evidence

close-up photograph. An additional method for lighting the close-up photograph is the use of a ring light.

Evidence close-up photographs without a scale of reference are not absolutely necessary in terms of investigative value; however, in the past, lawyers have argued that placing a placard in the photograph materially alters the essence of the scene. To prevent such attacks, close-up photographs can be shot along with the overall photographs without placards (Figure 14). Keep in mind that nothing is altered or manipulated in the process. For instance, it would be inappropriate to take close-up photographs of both sides of a revolver in the scene and then replace it and then take a second series with the photo placards. No matter how effectively the technician replaced the item, the second series would not be a true representation of the original condition of the revolver.

During the second series of photographs, placards are placed in close proximity to each item of evidence (Figure 15). To get both the detail of the item and include the placard number (the identity of the evidence), two approaches may be necessary when shooting photographs of small items of evidence. In some instances the placard itself may be repositioned to functionally place it as close as possible to the evidence. In other instances, particularly when shooting photographs of very small items, a smaller scale may have to be introduced to get as much detail as possible. In this instance, the small scale is annotated with the appropriate placard number. The

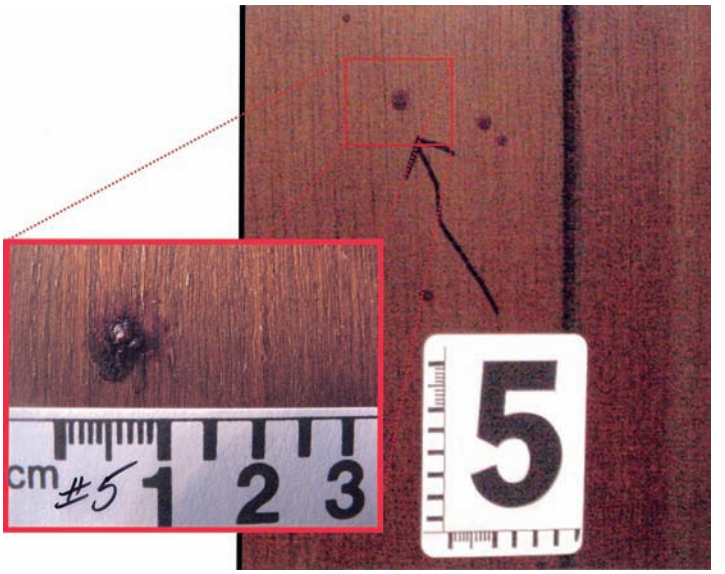

Figure 11 The purpose of an evidence close-up photograph is to show detail. The photograph on the right is typical of those represented as "close-up", but note that the detail of the stain in question cannot be seen. The inset photograph is framed much closer and now the small details (e.g., the bubbles in the stain) are evident. Close-up photographs should be framed as close as possible

scale of reference used for any given close-up photo may change, but a close-up photograph that fails to include some scale of reference is of limited value to the viewer. Placards, ABFO scales, or small rulers can all be used for this purpose.

Once the full context of the evidence is documented (e.g., observed in situ, detailed notes created, overall, evidence establishing, and close-up photos taken of the item as it lay in the scene, and the item's position is measured and sketched) the item can be collected and or manipulated without losing information. Additional close-up photographs are created when the item is collected. The item is carefully handled and photographed to capture all aspects and surfaces. Care is always in order when accomplishing this to prevent the loss or alteration of additional evidence (e.g., fingerprints and DNA). These additional photographs are often created after returning to the office, where it is easier to control lighting and the background environment. For this purpose, the technician should have an area at their office with a white nonglare background and off-camera lighting.

Using the three basic types of photographs, each item of evidence and all general aspects of the scene are captured in their unaltered condition. Once this is accomplished, the crime scene technician can move on to the remaining processing steps (e.g., sketching the scene, searching for additional evidence, and collecting all of the evidence). At any point in these efforts, if additional evidence is located or some aspect of the scene is discovered that has not been documented, the crime scene technician stops the ongoing activity and takes the necessary photographs. This is particularly true of on-scene fingerprinting efforts. Developed fingerprints should be documented *in situ* and then collected. This requires an evidence establishing and close-up photograph of each. If on-scene analysis is pursued in some fashion (e.g., bullet trajectory analysis, area of origin for bloodstains) the results of these efforts have to be photographed as well. These photographs are approached in much the same manner as any evidence photograph; however, these situations may require a little more composition effort to properly frame and demonstrate the analysis result.

Camera Control

There are two primary reasons why crime scene photography fails to achieve its intended purpose. The first reason is a failure to understand and apply the

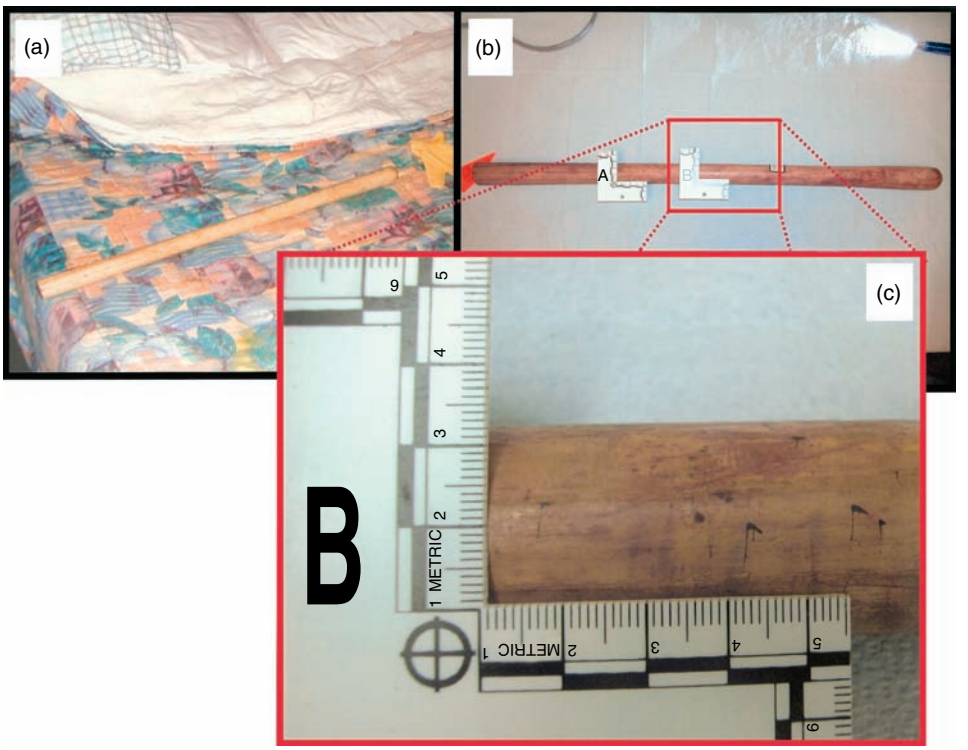

Figure 12 After collection at the scene, additional close-up photographs are often required. Note that in photo(a), the crime scene photograph, we can see the location of the wooden club, but its details are not evident. Photograph (b) was taken after collection, with the additional placards (a and b) added to show items of interest are on the club. Photograph (c) shows a close-up of the stains found at location (b)

composition aspects. The crime scene technician must understand the nature and purpose of each of the three basic crime scene photograph types (overall, evidence establishing, and evidence close-up). A second reason for poor crime scene photography is the inability to control the camera properly.

To create quality crime scene photographs that accurately depict the scene and have value to subsequent viewers, the technician must do the following:

- control camera stability;
- control light coming into the camera; and
- control camera focus and use depth of field effectively.

Camera Stability

Proper photography always begins with a stable camera. If the camera is in motion while the shutter is open, the result is blurring and loss of focus. Camera stability is accomplished by using a two hand grip or through the use of a tripod. A two-handed grip is more than adequate for a conventional camera using a 28–55-mm lens at any shutter speed of 1/60th or shorter. A shutter speed of 1/250th of a second is possible when operating with a lens of 100 mm or more in a handheld mode [1]. If the situation demands the technician to operate the camera with a longer shutter speed than those described, a tripod is necessary. With the advent of the digital single lens reflex (SLR) camera, the range of shutter speed for handheld operation is broader. Depending upon the camera, the technician may find they can functionally operate the digital camera in a handheld mode at much longer shutter speeds. In close-up work, no matter what the conditions or equipment, the use of a tripod enhances the quality of the resulting photos. The only downside to using a tripod for every close-up photograph is the increased time required to take

(a) (b)

Figure 13 Advances in digital photography allow the crime scene technician to capture details that in the past could not be captured. The red colored sweat pants in Photo (a) have bloodstains present on them. On the red background they can barely be visualized. Photograph (b) was taken using Fuji's S3 Pro UVIR. Using the cameras IR mode the stains are evident, but the conflicting background color is removed. This capability is particularly helpful when dealing with bloodstains on dark clothing. Photographs courtesy of Jason Guffey, Program Developer-General Forensics, Central Piedmont Community College, Charlotte NC

the photos; but the results are worth the trade-off of time spent on-scene.

Light Control

Proper composition in both artistic and evidential photographs requires proper lighting. Owing to the emphasis on close-up work in evidence photographs, improper lighting often leads to poor quality photographs. Use too little light and the picture is dark and details of the evidence can't be seen. Use too much light and the subject is bleached out with loss of detail as well. There are three techniques of lighting that aid the technician in creating properly exposed photographs.

The technique known as *fill-flash* is one approach. Without consideration for on-scene lighting conditions, all photographs are shot with the flash. What fill-flash achieves is consistent lighting of all surfaces in the photograph. In the past, manual flash systems required adjusting the flash settings for each exposure when using the fill-flash technique, which also increased the amount of time spent on-scene. Now most digital cameras have the ability to read the level of lighting and adjust the level of the flash accordingly. When shooting close-up photographs fill-flash is important as well, but the distances involved

Figure 14 Evidence close-up photographs are often taken both with and without a scale of reference or evidence placard. The only purpose of the close-up photo without a placard is to prove that the context of the scene was not altered by introducing the placard

Figure 15 An evidence close-up photograph for Figure 15, including a scale of reference. Many evidence placards come with a scale on them. This allows the viewer to identify it (e.g., item E) and understand its size. A close-up photograph without some form of scale of reference has limited investigative value

require the use of additional techniques to prevent overexposure.

One technique for preventing overexposure is the use of a flash diffuser. These devices generally snap over the flash facing and are made of an opaque white plastic. They diffuse the flash strobe creating a gentler more effective flash when the subject is close to the camera. An alternative technique is to use an

off-camera flash. The flash is connected to the camera by a sync cord. The camera lens is positioned as close as required for the subject matter, while the flash is held obliquely to the subject and at a greater distance (e.g., very often at arms length) (Figure 16). A final method for eliminating overexposure in photographs is to bounce the flash. Many flash systems have a flash facing that rotates from a normal 90° position up to a vertical position. By altering the angle of the flash facing, light is bounced off adjoining surfaces. At intermediate distances, bounce-flash effectively illuminates the subject and eliminates overexposure; however, for extreme close-up photographs, where the distance is less than 12 in., bounce lighting tends not to be effective.

Paint-with-Light

At night or in low light conditions, when shooting overall photographs a single strobe no matter how strong it is, may not be enough to achieve sufficient flash (Figure 17). In these instances, the technician should apply the technique known as "*paint with light*". Paint with light uses multiple flashes along with an extended exposure time to adequately light a scene and capture detail. The most typical circumstance requiring paint with light is when taking an overall photograph of an exterior scene at night, particularly when evidence is widely scattered across the scene. A single flash does not sufficiently light the scene from the camera position, resulting in poorly illuminated photographs. To paint with light, the camera is mounted on the tripod and once focus is set, the camera is placed on a bulb (B) or extended time setting. On this setting, as long as the shutter release is pushed, the aperture of the lens remains open. On a conventional film camera, a shutter release cable is used to keep the shutter open. On a digital SLR camera, there is an electronic shutter release cable or a menu option that allows the shutter to remain open. Whatever the particular mechanism, once the shutter is open the technician moves to positions on either side of the camera. There they manually initiate the flash toward the subject matter. The combination of the multiple flashes provides for a detailed photograph (Figure 18). If the area in question is in total darkness, the technician can walk into areas contained in the viewfinder, allowing them to initiate the flash from several angles but at a position closer to the evidence than the camera. To prevent any ghost image from appearing in this situation, the technician must keep the flash in front of them and always point it away from the camera. Paint with light works effectively during lowlight conditions as well, making efforts at dawn or dusk more effective. However, low light conditions demand the technician to remain outside of the area in the camera viewfinder when positioning the flash. If they fail to do this, the limited light present is usually enough to create a ghost image of the technician.

Figure 16 Particularly when taking evidence close-up photographs, it may be necessary to use an off-camera flash. The technician places the camera lens as close as required, while holding the flash at a greater distance

Focus and Depth of Field

Most digital SLR cameras in use today are automatic. The camera's computer determines the optimum focus, depth of field, shutter speed, and even adjusts the flash as needed. But understanding the effect of the depth of the field is still important. On occasion, the crime scene technician may have to use the camera in a manual mode. The subject matter of

Figure 17 Depending on the flash used and the size of the scene, when taking overall photographs at night the flash unit may not adequately illuminate the scene. In these instances, the technique known as *paint with light* is very effective. This photograph was taken on a tripod using an on-camera flash, compare it to Figure 18

Figure 18 This photograph was taken at the same time as Figure 17, but uses the technique known as *paint with light*. The camera was set on a tripod and the lens opened to the bulb (B) setting. The flash was manually initiated in three positions, first at the camera then forward of the camera to the right, and then once again to the left. The result is a well exposed photograph in which scene detail is evident

the photo is always the primary focal point of the picture, but there may be objects in front of or behind it, that are of interest as well. Depth of field is a description of how in focus objects in front of and beyond the subject are. This is a critical concern when creating the evidence establishing shot, where both the landmark and evidence item need to be in focus. Depth of field is controlled by changing the

f-stop setting of the camera. The f-stop defines how wide the lens aperture opens, which, in turn, controls how much light is used in the exposure. As the f-stop number increases the aperture becomes smaller, resulting in the introduction of less light. By limiting the amount of light for any given exposure (e.g., increasing the f-stop) there is a corresponding increase in the depth of field for the resulting photograph (Figures 19 and 20). For close-up photographs, a short depth of field is usually not an issue, so using a lower f-stop will not hurt the resulting photo. When shooting both overall and evidence establishing photographs the technician wants as much depth of field as possible. The more items and areas in focus in an overall or evidence establishing shot, the greater the value of the photograph to the viewer.

Focus is an obvious concern. Achieving focus for the most part is determined by the technician. Although many digital SLR cameras come with automatic focus systems, in many crime scene instances this function must be turned off. Too often the camera computer chooses the wrong item to focus on, or the focus may continually adjust when taking close-up photographs. Under these circumstances the only solution is to use a manual focus. Manual focus begins by understanding how the camera's focus system works. There are various manual focus systems available for SLR cameras. The most effective system for crime scene work is the split image. When the focus ring on the lens barrel is turned, the viewfinder "splits" the image into three parts. The top and bottom thirds in the focus circle remain aligned, but movement of the lens barrel causes the middle third to move in and out of alignment. By slowing and turning the lens barrel focus ring, the middle portion of the image is brought into alignment with the two outer areas. When the three sections are aligned the subject is in focus. Split image focus can be used effectively with photo placards and scales. The technician positions the camera at the distance they require, but instead of focusing on the evidence itself, they use the straight thin lines of the ruler to achieve an optimum focus. Once optimum focus is achieved, the evidence is centered back in the viewfinder and the photograph taken. This technique is effective when focusing on objects that lie close to or in the same plane as the ruler, but the technician must take depth of field into consideration. If the evidence itself extends any distance beyond the plane where the ruler is located and a low f-stop is in use, the entire item may not be in clear focus in the photograph.

Figure 19 A photograph taken to demonstrate the effect of f-stop. This photograph was taken at f3.5, with the focus set at the D placard. Note that the tree in the foreground and placard are in focus; however, the background items appear fuzzy

Figure 20 A photograph taken from the same position and with the same focus point as Figure 20. In this instance the f-stop was set at $f18$. Note that the background details are in focus as well. As we increase the f-stop (decreasing the amount of light entering the lens) we increase the area in the fore and background that appears in clear focus. Turning off the automatic mode of the camera and manually controlling f-stop can be helpful when taking overall or evidence establishing photographs

Video Photography

The use of the video camera at the crime scene can certainly supplement the crime scene documentation, but video footage does not replace standard crime scene photography. Video is an excellent tool for establishing scene integrity. After creating the initial series of crime scene photographs, the technician completes a nonintrusive walkthrough of the scene using the video camera. If at some later stage of the investigation, someone claims alteration of the scene by the crime scene team, the video footage along with the initial crime scene photographs should allow the team to establish nearly all of the initial conditions. The video camera can also be used in later stages of processing, documenting actions, and analysis efforts such as trajectory or bloodstain pattern analysis.

When using the video camera, a few added precautions are in order. The first concern is that the video camera does not function like the human eye. Humans can quickly avert their eyes from one area to the next, producing a seamless stream of images that remain in focus. If the video camera lens is moved in the same fashion from one focal point to the next, the resulting footage is jerky and difficult to watch. When panning with the video camera, eliminate any abrupt movements and keep the camera focused on areas of interest for more than just a few seconds. Any movement of the camera must be deliberate, panning slowly from one point to the next. Plan the panning effort in advance; don't pan back and forth from one side of a room to the other. Move in a methodical and logical fashion across the room or area in question. Once the camera is on an area of interest, obtain a good focus and keep the camera in place. An effective technique is to quietly count to 10, before moving the camera to a new point of interest. The use of the zoom lens should be limited and controlled as well. Treat the zoom function the same as panning with the camera; use a slow and deliberate effort when transitioning between one zoom angle to the next. Once the zoom position is achieved, maintain the camera in that position for at least 10 s. Just as lighting was important in still photography, lighting for the video camera is important as well. The human eye may be able to see effectively in low light, but video footage shot

under the same conditions without a strobe is often useless. Always use a strobe with the video camera unless outside and in daylight. A flashlight used as additional lighting for the video camera does not suffice.

A final precaution when using the video camera is to turn off the audio. There is rarely a reason to capture audio when shooting the crime scene. Far too often, comments that were unintended or inappropriate are caught on the audio track. The easiest method of turning the audio off is to insert a microphone jack (without the microphone attached) into the external microphone plug of the video camera. Beyond these considerations, video footage of the crime scene is approached in much the same fashion as still photography. Know what you're shooting and why you're shooting it. Then control the camera, the lighting and be sure to get a good focus.

Summary

Crime scene documentation consists of detailed notes, sketches, and photographs. Each of these three elements has a purpose but crime scene photographs are critical. Using the three basic photographs, the overall, evidence establishing and evidence close-up photograph, the crime scene technician leads the viewer through the scene from an overall perspective to the small details. Overall photographs provide overlapping coverage of the entire scene, showing major landmarks and items. Details of specific items of evidence are captured with the evidence close-up photograph, where the viewfinder is filled with the item of concern. Bridging the gap between the overall and close-up photograph is the evidence establishing photo. This photo is taken in such a manner that the evidence is framed with a recognizable landmark in the scene. The evidence establishing photograph prevents the viewer from becoming lost in the scene. Together these three basic photographs allow the technician to functionally prove to a jury or judge the actual conditions and context of the scene, as the technician viewed it. They are the heart of crime scene documentation and critical to establishing the integrity of both the scene and the evidence removed from it.

Crime Victims' Decision to Report Crime

The police rarely discover a crime on their own. In the vast majority of cases they learn of a crime via notification by the victim [1]. This has led researchers to conclude that crime victims are the "gatekeepers of the criminal justice system" [2]. Indeed, without notification by crime victims, few crimes would reach the attention of the police. The discretionary power accorded to victims is reflected by the consistent finding that fewer than half the nonlethal crimes (41%) that occur in a given year are reported to the police [3]. Of the estimated 18 million property crimes (e.g., burglary and theft) committed in 2005, just 40% were reported to the police [3]. In comparison, 47% of the estimated 5.2 million violent crimes (e.g., robbery, rape, and assault) committed in 2005 were reported to the police.

These figures derive from an ongoing telephone survey of 77 000 households involving 134 000 individuals conducted jointly by the Department of Justice and the Census Bureau since 1972. Known as the *National Crime Victimization Survey* (NCVS), the survey is considered to be the most reliable source of information about reported as well as unreported crime in the United States.

Findings from the NCVS reveal that, with few exceptions, features of the crime and its circumstances are better predictors of reporting than characteristics of the victim. Thus, with regard to violent crime, reporting of aggravated assaults (62%) is greater than reporting of robbery (52%) and rape/sexual assault (38%). With regard to property crime, motor vehicle theft (83%) is more likely to be reported than burglary (56%) or theft outside the home (32%). Further, the more severe the harm, the

higher the rate of reporting. Thus, higher reporting is associated with completed versus attempted crimes as well as crimes involving greater financial loss and injury [4]. Rapes and sexual assaults committed by strangers are more likely to be reported than similar crimes committed by nonstrangers.

However, the victim–offender relationship does not appear to affect the reporting of other types of crimes. With few exceptions, reporting does not appear to be a function of victim characteristics: the exceptions being that women and blacks are more likely to report violent victimizations to the police than men and whites [4].

Making Sense of the Data: Theoretical Approaches

The rational choice perspective is the dominant theoretical approach to explaining crime victim decision making [5, 6]. This approach assumes that when deciding whether or not to call the police, victims rationally calculate the potential benefits and costs of each option and then choose the one that appears most "profitable". Thus, victims who incur injury or large financial losses may conclude that they have more to be gain by notifying the police than by not doing so. Moreover, they may reason that the police will be more successful in apprehending the suspect because they will invest more effort in solving such crimes.

This perspective can also account for why rape and sexual assault victims who are acquainted with the perpetrator are less likely to report the crime than those who are attacked by a stranger. Victims who are acquainted with their attacker may feel that the costs of reporting outweigh the benefits. They might view it as a personal matter or not report out of fear reprisal from the perpetrator. In addition, they might reason that because of their prior acquaintanceship with the perpetrator, the police might question their credibility and therefore not vigorously pursue the case.

While the rational choice perspective has intuitive appeal and has proven useful in explaining some aspects of victim decision making, recent research suggests that modifications are necessary. First, researchers have come to recognize the importance of emotional factors in decision making [7, 8]. This may be particularly true for crime victims who, in the aftermath of their victimization, experience intense negative emotions of fear, anger, and sadness [9–11]. Such intense emotional experiences can impair the rationality of their decision making. Research suggests that emotional arousal can influence crime victims' attention, perceptions, interpretations, judgments, their ability to process information, and their processing strategies [12–14] (*see* **Posttraumatic Stress Disorder**; **Rape Trauma Syndrome**).

Second, interviews with crime victims reveal that they often do not make their decision in a social vacuum. A substantial number of crime victims consult with family, friends, and bystanders when deciding whether or not they should call the police and that such contacts are a key factor in their decision making [15–17].

Third, the decision process of victims is not a single "yes" "no" decision, but rather represents the culmination of a series of decisions or stages [16]. In the following paragraphs, a broad integrative rational choice model that incorporates these three qualifications is presented.

The Greenberg–Ruback Model of Crime Victim Decision Making

Greenberg and Ruback propose a three-stage model of victim decision making [16]. In order for victims to report a crime, they must first label a suspicious event a crime; second, they must decide that it is sufficiently serious; and third, they must decide that notifying the police is the best course of action. The model proposes that victims may not call the police because they fail to define the event as a crime, because they do not view it as sufficiently serious, or because they conclude that calling the police is not the best option. The model further proposes that the decisions at each stage are subject to influence by emotional and social factors. Let us examine the model more closely.

Stage 1: Defining the Event as a Crime

Whether or not a suspicious event is defined as a crime depends on how closely the event matches the victim's personal definition of a crime. For example, victims of attempted crimes may not view themselves as having been victimized despite the fact that such acts are legally defined as criminal. Similarly, victims

of date rape may not view the event as a rape since it does not match the classic definition of an attack by a stranger [18]. That an individual has a personal definition of a crime does not guarantee that the definition is psychologically accessible. Victims of crimes that occur in unexpected circumstances may be slow to label the event as a crime because noncriminal labels are more readily accessible [19]. Such unexpected circumstances could include crimes committed in broad daylight or by trusted others.

Alternatively, circumstances and emotions can enhance the accessibility of crime labels such as when one is alone at night on a dimly lit street and/or when one feels particularly fearful. Social influence can play a role in how an event is labeled. This is particularly true in discovery crimes, such as burglary or theft, where victims are not typically present during the commission of the crime. In these instances, victims engage in information-gathering activities, such as consulting with neighbors, friends, and coworkers, in order to help them define event. Such consultations are a major source of delay in police notification [20, 21].

Stage 2: Determining the Seriousness of the Crime

Research shows that one of the best predictors of victim reporting is the perceived seriousness of the crime [6, 16]. Across a wide variety of crimes, the more serious victims perceive their victimization to be, the more likely they are to call the police. According to the NCVS, one of the reasons most often cited by victims for *not* reporting the crime is that "the crime was not important enough" [22]. The model proposes that perceived seriousness is directly related to the magnitude of distress – the more serious the victimization, the greater the distress. Perceived seriousness depends on the combined effects of two sources: (i) victims' sense of being "wronged" by the attack and (ii) their feelings of vulnerability to subsequent victimization. The sense of being wronged involves beliefs of injustice and inequity with accompanying feelings of anger, resentment, and, sometimes, revenge.

Feelings of vulnerability are accompanied by the emotion of anxiety and fear. Consistent with this reasoning, research shows that anger and fear are the emotions most frequently reported by crime victims [16]. Studies show that beliefs about being wronged and vulnerable depend on three features of the crime: its perceived unexpectedness, the magnitude of subjective harm suffered by victims, and their perception of potential harm in the situation. The sense of being wronged is greatest when the crime is unexpected, subjective harm is severe, and the potential harm is low. Feelings of vulnerability are enhanced when the crime is unexpected, subjective harm is severe, and potential harm is great [16]. To the extent that victims judge the crime not to be serious, they will be less inclined to call the police. Victims' perception of being wronged and being vulnerable to future harm are subject to social influence. Thus, others in their interactions with victims can either amplify or decrease such feelings.

Stage 3: Deciding What to Do

Having labeled the incident a crime and evaluated its seriousness, victims next must decide what action to take. The model proposes that they can choose from among four broad options: (i) dealing with the matter privately, (ii) cognitively reevaluating the situation, (iii) notifying the police, or (iv) simply deciding to do nothing. From a rational choice perspective, victims will choose the option that from a costs/benefits analysis appears to yield the best outcome. Presumably, this involves selecting the option that they believe is most likely to reduce the distress deriving from their feelings of being wronged and vulnerable.

To the extent that a particular option successfully ameliorates their distress, victims will have less incentive to avail themselves of other options. This has clear implications for why many victims fail to call the police. If victims can reduce their distress via private solutions or by restructuring their perceptions of the situation, they will have less incentive to notify the police.

The emotional distress typically experienced by crime victims impacts their decision making in two ways: first, the stress is likely to make their decision fall short of a perfectly rational decision; and second, it increases the victims' susceptibility to social influence. With regard to the first impact, research shows that severe stress interferes with the decision makers' ability and patience to conduct a rationally exhaustive costs/benefits analysis of available options [12–14]. High stress has been found to narrow the focus of

attention, to impair the assimilation of information, and to restrict the range of considered options. Under such conditions, decision makers tend to opt for a less cognitively demanding strategy that meets some standard of *sufficiency* rather than employing a more cognitively demanding *maximizing strategy* [23]. The maximizing strategy involves a detailed examination of the costs and benefits of multiple options. One might say that under highly stressful conditions, victims' decision making may best be described as "semirational".

Second, research shows that under stress, victims are highly amenable to social influence. As Bard and Sangrey [24] noted, "A crime victim's entire structure of defenses becomes weakened under the stress of violation, leaving him or her unusually accessible to the influence of others" (pp. 37–38). Studies have demonstrated that immediately after the crime, a substantial percentage of victims turns to others for support, information, and advice, which has a decisive impact on their decision making [15–17]. This is true for victims of violent crime as well as property crime. Moreover, the data clearly indicate that victims tend to follow the advice offered them. It is noteworthy that social influence is not confined to the third stage of the model, deciding what to do, but, as previously stated, can apply to how victims label the event and how they evaluate its seriousness.

Option 1: Dealing with the Matter Privately. Rather than calling the police, victims can reduce their sense of being wronged by a variety of private means. In some cases where the perpetrator's identity is known, victims have sought private vengeance by individually retaliating, or by retaliating in concert with others (vigilantism) [25]. Property crime victims can threaten to harm the perpetrator in order to obtain compensation. They have also sought compensation from third parties (e.g., insurance companies) or have filed a civil suit against responsible third parties (e.g., a hotel for failing to maintain adequate security) [26]. Alternatively, some have obtained compensation by stealing from others [27].

Victims can also employ private solutions to deal with their sense of vulnerability. They can take actions to reduce potential perpetrators' *ability* to harm them. For example, burglary victims often "harden the target" by purchasing an alarm system, dead bolt locks, and window bars [28]. Other private options that have proven effective in reducing fear of crime include purchasing a weapon, participating in a self-defense course or a neighborhood watch program, and changing one's residence from a high- to a low-crime area [29–31]. Victims can also engage in actions designed to reduce harm-doers' *motivation* to harm them. Thus, victims of domestic abuse have attempted to avoid triggering subsequent attacks by pleasing the potential abuser and complying with his wishes [32]. Similarly, business owners pay "protection" money to avoid damage to their business.

These tactics share in common the belief that it is beneficial to provide potential perpetrators with benefits in order to avoid more serious harm. Finally, victims have retaliated against the perpetrator. By so doing, victims can reduce perpetrators' ability and motivation to victimize them in the future. Physical harm directed at perpetrators can serve to incapacitate them as well as cause them to think twice about repeating the attack. An example of an extreme case would be a battered woman who kills her abuser when he is asleep (*see* **Battered Spouse Syndrome**). In recent years, some courts have accepted a broader definition of imminent danger and therefore have shown more sympathy toward victims who kill their abusers [33].

Option 2: Cognitively Reevaluating the Situation. Victims have also been shown to attempt to reduce their distress by reassessing their earlier decision that a crime had been committed and/or by reevaluating the seriousness of the harm. Research has documented numerous such mechanisms employed by crime victims. Two of the most commonly documented mechanisms are self-blame and making downward comparisons. With regard to the first, victims commonly ask themselves "Why me?"

One consequence of such questioning is that victims blame themselves in part for the crime [34]. Such efforts at fault finding can reduce their sense of being wronged. And, if they can blame their behavior for contributing to the victimization, they can reassure themselves that they will not repeat the mistake in the future, which can reduce their vulnerability and fear [34]. Victims have been found to reduce the seriousness of their victimization by minimizing the magnitude of the harm. This can be achieved by making "downward comparisons", such as thinking "it could have been worse", or by comparing their

outcomes to those of others who have suffered worse fates [35].

Option 3: Notifying the Police. To the extent that the above options fail to reduce victims' stress, they will have more incentive to report the crime to the police. This point is supported by the finding that reporting is significantly correlated with victims' levels of anger and fear [16, 36]. It is not only the magnitude of victims' distress that motivates reporting, but in addition, the belief in the efficacy of the police (although some studies do not support this conclusion) [37]. However, results from the NCVS tend to support the importance of perceptions of police efficacy. Some of the most frequently cited reasons for not calling the police include "Nothing could be done" and "The police would not want to be bothered" [38].

What benefits do victims hope to obtain by calling the police? One motive for notifying the police is to reduce the sense of being wronged. In the case of property crime, if the police can apprehend the criminal, the stolen property might be returned or the criminal might be ordered to make restitution to the victim. Even if the police fail to apprehend the perpetrator, reporting the crime is necessary for receiving compensation from a third party, such one's insurance company. Victims' sense of injustice could also be reduced if the perpetrator is convicted and punished. Reporting to the police can reduce victims' sense of vulnerability, particularly when the offender is convicted and sent to prison. Victims might believe that the punishment will deter future crimes by the offender, as well as deterring other would-be offenders. Even when victims see little chance of the perpetrator being apprehended, they may feel less fearful because of the belief that reporting the crime will lead to more intensive police surveillance in their neighborhood.

Given these possible benefits of calling the police, why do victims report less than half of the crimes committed? The answer to this question lies in part in the anticipated costs of reporting. Studies document numerous costs for getting involved with the criminal justice system [16]. They include costs of transportation, parking, lost time from work or school, and child care. Questioning by the police and defense attorneys, particularly in cases of sexual assault, represent additional costs. Fear of retaliation represents yet another potential cost of reporting. When victims weigh the balance of benefits and costs, they may conclude that the costs outweigh the anticipated benefits of notifying the police. This weighing of benefits is reflected in the findings from the NCVS showing that one of the most frequently offered reasons for not reporting the crime is that "The crime was not important enough" [22].

Option 4: Doing Nothing about the Crime. This is the default option. Some victims may reason that any attempt to right the wrong or reduce their vulnerability will meet with failure. As Greenberg, Ruback, and Westcott [17] have stated, "Perceiving no visible solution to their distress, these victims have no recourse but to live with the injustice and wait in fear for the inevitable occurrence of the next victimization" (p. 98).

Criminalization of the Mentally Ill

Abramson coined the term *criminalization of the mentally ill* in 1972 to describe his observation that persons with mental illness were increasingly being arrested and prosecuted for minor offenses [1]. Since 1972, a number of researchers have addressed the criminalization hypothesis. This article reviews the definition of criminalization of persons with severe mental illness (SMI), discusses possible causes of criminalization of this population, and analyzes findings from empirical studies that examine the criminalization hypothesis.

The criminalization hypothesis has not been consistently defined in the literature [2]. The common underpinning of the various definitions used for the criminalization hypothesis is the process in which the care of a subgroup of persons with mental illness shifts from the mental health system to the criminal justice system. Most studies examine criminalization by focusing on one decision point in the criminal justice system, such as police–citizen encounters, arrest, or detention [3–23].

For this article, we define criminalization as persons with SMI being treated more punitively than persons without SMI for minor or nonviolent offenses at the point of arrest, prosecution, or detention, [2, 24]. The term *severe mental illness* refers to the following diagnostic categories: schizophrenia/psychotic disorders, major depressive disorder, or bipolar disorder [25].

Hypotheses on why Persons with SMI may be Criminalized

According to the hydraulic theory of social control, the criminal justice and mental health systems share responsibility for controlling deviant behaviors in a society [26]. As a result, changes in the capacity of one system may cause a shift in the other system [26, 27]. Three changes in the mental health system could result in the criminalization of persons with SMI: (i) deinstitutionalization, (ii) legal initiatives, and (iii) length of psychiatric hospitalization. Each has brought persons with SMI increasingly into the community.

Deinstitutionalization

State mental hospitals in the United States were systematically emptied of patients in the late 1960s and 1970s. Nearly 600 000 persons were in state mental hospitals in 1955 [28]. By 2000, approximately 55 000 persons were in state mental hospitals [29].

Deinstitutionalization and community care has benefited persons with mental illness. Mental health treatment is increasingly focused on psychosocial rehabilitation and addressing individualized needs [30]. However, deinstitutionalization has not benefited all persons with SMI. Many persons with SMI were released into communities that were inadequately prepared to provide needed services [28, 31, 32]. In addition, treating persons with SMI in community settings is itself a challenge. Many persons with SMI living in the community abuse substances [33, 34], do not comply with treatment protocols [33, 35, 36], and do not have adequate community support systems [28]. By living in the community without receiving adequate care, individuals with SMI may be more likely to come to the attention of law enforcement officials. Therefore, one unintended consequence of deinstitutionalization may be that persons with SMI have been shifted from the mental health system to the correctional system.

Legal Initiatives

Civil commitment (*see* **Civil Commitment**) laws are those which stipulate the criteria that must be met to commit persons with mental illness to mental health hospitals or treatment against their will. Increasingly strict civil commitment laws, were passed in the late 1960s and early 1970s, resulting in fewer and shorter involuntary mental health facility admissions of persons with SMI [28]. Persons with SMI who are both disruptive and refusing psychiatric treatment in the community no longer meet criteria for involuntary hospitalization [15]. In contrast, jails have a "no decline" policy [37]. Police officers may manage disruptive persons with SMI who refuse psychiatric treatment through arrest and/or detention in the absence of a better alternative in the community.

Length of Psychiatric Hospitalizations

In 1965, Medicaid and Medicare programs were introduced. These programs shifted the cost of most psychiatric care except residential psychiatric care from state governments to the federal government [38, 39]. The effect of this economic incentive is evident in the accelerated pace of deinstitutionalization after the introduction of Medicaid and Medicare. State psychiatric populations decreased 4% between 1955 and 1960 after the introduction of the antipsychotic drug chlorpromazine (also known as Largactil® and Thorazine®). In contrast, state psychiatric populations decreased 29% between 1965 and 1970 after the introduction of Medicaid and Medicare [39]. Moreover, the length of all (voluntary and involuntary) psychiatric inpatient hospital stays has decreased. In 1970, the median length of stay in psychiatric hospitals was 41 days [40]. In 1997, the median length of stay in psychiatric hospitals was less than 1 week (5.4 days) [41]. Because there are economic incentives to decrease hospital stays, persons with SMI may be released into the community prematurely [42]. Consequently, with few options for adequate treatment, housing, and social support, persons with SMI may be managed through arrest or detention by police officers in the community rather than being managed through the mental health system [36, 43].

Reviewing the Literature

Arrest of Persons with SMI and Police–Citizen Encounters

Many self-report and archival studies examine the criminalization hypothesis at the point of arrest in the criminal justice system [7–9, 11, 44–51]. Several of these studies compare arrest rates among persons in mental health treatment with general population arrest rates [9, 11, 46, 47, 50, 51]. Most studies found that arrest rates among persons in psychiatric treatment were greater than arrest rates among persons in the general population [9, 11, 46, 47, 50, 51].

Although studies on arrest provide important information on the elevated arrest rates of persons with SMI compared with the general population, using findings from these studies to evaluate the criminalization hypothesis is problematic. These studies do not measure how many persons with and without SMI come into contact with police officers, making it impossible to assess if having a SMI increases the probability of arrest.

The criminalization hypothesis is more effectively investigated by studying encounters between police and persons with SMI. Such studies can evaluate if having an SMI increases the likelihood of being arrested among all criminal suspects. Police officers use their discretion to determine the appropriate response to persons with mental illness [52]. Criminalization occurs if police officers respond differently to persons with versus without SMI, choosing to arrest those with SMI because of lack of a better alternative in the community. Criminalization may also occur because of an arresting officer's implicit beliefs that persons with SMI may be more violent or likely to persistently cause trouble.

Two common law principles guide police when responding to persons with mental illness in the community: a mandate to (i) "protect the safety and welfare of the community" and (ii) "protect disabled citizens" unable to care for themselves [52]. Within these broad guidelines, police officers respond to persons with mental illness informally or formally. Examples of informal dispositions between police officers and persons with mental illness that do not result in criminalization of persons with SMI include police helping a person with SMI find a homeless shelter and police attempting to calm a person with SMI through "counsel and release" [4]. More formal dispositions that do not result in criminalization of persons with SMI involve emergency apprehension; that is, bringing a citizen to the hospital for psychiatric evaluation. In contrast, criminalization occurs if police officers arrest persons with SMI because more suitable alternatives in the community are not available. Criminalization also occurs if police officers arrest persons with SMI who have been released prematurely from psychiatric facilities and who continue to be disruptive in the community [36, 43].

To evaluate the criminalization hypothesis via police encounters, two large-scale field studies compared arrest rates of criminal suspects with mental illness to those without mental illness [3, 53].[a] Teplin's study was designed to examine the criminalization hypothesis; Engel and Silver conducted secondary analyses of two general studies of police decision-making: (i) the Project on Policing Neighborhoods Study (data collected in 1996–1997) and

(ii) the Police Service Study (data collected in 1977). Both studies found that fewer than 6% of suspects were identified as having a mental illness, limiting ability to examine additional predictive variables.

The studies differ substantially in the measure used to assess mental disorder. Teplin used a measure of mental disorder based on the Diagnostic Statistical Manual of Mental Disorders-Version III (DSM-III); her measure was tested for reliability and validity. Trained observers used a symptom checklist to assess the presence of symptoms associated with SMI, e.g., "confusion/disorientation, withdrawal/unresponsiveness, paranoia, inappropriate or bizarre speech and/or behavior, self-destructive behavior", and a global rating scale to account for the environmental context of the behavior [53]. Significantly more persons with (46.7%) versus without (27.9%) SMI were arrested [53]. Qualitative analyses revealed that police arrested persons with SMI in three types of circumstances: (i) when hospitalization was the police officer's preference but the police officer did not think the suspect met civil commitment criteria; (ii) when persons with SMI publicly exceeded the community's tolerance of deviant behavior; and (iii) when the police "felt there was a high probability that the person would continue to 'cause a problem' (and thus result in a 'callback')" [54].

In contrast, Engel and Silver's definition of mental disorder relied on the definition developed for the original studies, the Project on Policing Neighborhoods Study and the Police Service Study. They relied solely on untrained officers' and observers' perception of mental disorder; it was not on the basis of *DSM* criteria or tested for validity and reliability. In contrast to the study by Teplin [53], Engel and Silver did not find higher arrest rates among persons with mental illness after controlling for a variety of situational, legal, and suspect characteristics [3]. However, the lack of replicable measures based on *DSM* criteria introduces a serious bias. Although police officers are adept street corner psychiatrists [54], police chronically underestimate the presence of SMI [55]. As many as one-half of persons with SMI are not detected by police [53]. Thus, the study by Engel and Silver is valuable because it shows that police do not knowingly arrest persons with mental illness. But, these findings are less relevant for the criminalization hypothesis.

In short, there is a paucity of recent methodologically sound studies of police decision-making. Future studies must investigate the extent to which prior findings pertain to today's milieu.

Court Processing of Persons with SMI

Many arrests do not result in criminal prosecution [56, 57]. Prosecutors exercise a great deal of discretion in how a criminal case is processed [2]. Persons with SMI may be criminalized by being treated more punitively at the point of criminal prosecution than defendants without SMI.

Only a few studies have examined the criminalization hypothesis at the point of court processing [2, 58, 59]. Hochstedler[58] found that during court processing, 85% of defendants identified as having a mental illness were charged with misdemeanor charges [58]. The court was as likely to sanction mental health treatment (61%) as it was to sanction punishment (59%) in these cases. Persons with mental illness were granted leniency in the criminal court system only if the offense did not reach "an unspoken threshold or seriousness" [2, 58].

Hochstedler [59] later compared the individual-level data from these defendants identified as having a mental illness to aggregate data on criminal sanctions. She concluded that defendants with mental illness may be "twice cursed". When traffic offenses were excluded, defendants with mental illness were less likely to be charged with felony crimes than individuals in the comparison group but were more likely to receive stricter criminal sanctions, with many sentenced to both mental health treatment and criminal punishment. However, because she compared individual-level data with aggregate data, the conclusions from this study are not decisive [59].

One study on court processing directly evaluated if misdemeanant defendants with mental illness were treated more punitively than misdemeanant defendants without mental illness [2]. After controlling for the seriousness of the charge, defendants with mental illness were given harsher sentences for all charges except for battery compared with those without mental illness. Misdemeanants with records of mental illness and who were recognized by the court as being mentally ill (with the exception of those found incompetent to stand trial) were treated the most punitively – more were "taken into custody, held in custody, and convicted" [2].

Findings from these studies suggest that misdemeanant defendants with mental illness are treated more punitively in the criminal court system than offenders without mental illness [2]. However, more research is needed to determine if these findings are robust.

SMI in US Jail Populations

US jail populations increased 97% per 100 000 US civilians between 1986 and 2000 [60, 61]. At the same time, 24 hour psychiatric residential treatment beds have decreased 30% per 100 000 US civilians, and the number of persons in state and county mental hospitals have decreased 57% per 100 000 US civilians [29, 61]. Consequently, the hydraulic theory of social control [27], which postulates shifting responsibility between the mental health and the criminal justice systems depending on the capacity of each, could account for some of the increase in US jail populations between 1986 and 2000.

Several empirical studies have been conducted to evaluate whether changes in mental health policy – including deinstitutionalization and changes in Medicaid and Medicare managed-care programs – have caused increases in the number of persons with mental illness processed in the correctional system. Studies have found that more persons with mental illness are processed through the correctional system after changes in mental health policy that restrict or reduce inpatient mental health care [9, 49, 62–65].

To the extent that persons with SMI are criminalized, we would expect prevalence rates of SMI to be higher in jails than in the general population. In the past 20 years, many epidemiological studies of jail populations have examined prevalence rates of SMI in US jails [15, 17–23]. However, only three studies compared the prevalence of SMI in jails with that in the general population. All three studies measured psychiatric disorder using the Diagnostic Interview Schedule (version III-R), a valid and reliable measure. Two of these studies found that in the Cook County Department of Corrections, a typical urban jail, the prevalence of SMI in male and female jail detainees was significantly higher than in the general population [18, 20]. In a rural state, Powell examined a random sample of 118 prison inmates from three small state prisons, and 95 jail inmates from three regional jails. The prevalence of SMI in the rural jails was only slightly higher than that in rural community settings [17]. These findings suggest that the process of criminalization may differ in rural and urban settings.

Conclusions

Studies have shown that persons with SMI have extensive contact with the criminal justice system at each point in the system – the police–citizen encounter, arrest, court processing, and jail detention. Studies of police decision-making underscore that many persons with SMI come into contact with police officers because they need assistance, not because they are criminal suspects [4, 66]. During court processing, 85% of defendants identified as having a mental illness were charged with misdemeanor charges, and misdemeanant defendants with mental illness are treated more punitively in the criminal court system than offenders without mental illness [2]. Several epidemiological studies found higher prevalence rates of SMI in jails than in the general population [18, 20]. Finally, findings from studies analyzing the overlap of jail and clinical populations demonstrate that persons with SMI have extensive contact with the criminal justice system. A substantial number of persons with SMI in outpatient (41%) [67] and inpatient (76%) [68] settings have been incarcerated in a jail at least once in their lifetime.

The net result of deinstitutionalization, legal initiatives making involuntary treatment more difficult, and shorter length of psychiatric hospitalizations has been an increase in the number of individuals with SMI, often untreated, who live within the community [6, 24]. Persons with SMI may become involved with the criminal justice system because they fall through the cracks of the mental health system [69]. Unfortunately, society's tolerance for these individuals and their behavior is limited, especially given the stereotype of the "dangerous" patient and the sometimes bizarre behavior that can accompany SMI [6]. As a result, many residents in the community frequently summon the police to deal with individuals with mental illness [52, 54, 55]. Furthermore, many persons with SMI also have cooccurring substance use disorders [69, 70], making placement and treatment in appropriate care facilities even more problematic. One study notes a finding from its qualitative data:

"police officers would often make the rounds of the various service agencies – from halfway house to hospital to 'detox' – before resorting to the disposition of arrest" [53]. Because of problems in securing a place in the treatment system, police may view arrest as the only alternative [54].

However, many studies of the criminalization of persons with SMI were conducted before special programs were developed to divert persons with SMI from the correctional system into the mental health system, e.g., special training programs for police, mental health crisis teams integrated into police departments, jail diversion programs, and mental health courts [52, 71–73]. Future studies should address the extent to which the recent programs designed to reduce criminalization of persons with SMI have been effective.

End Notes

[a.] One study [5] reanalyzed data from Teplin (1983). However, their analysis was flawed because they included nonsuspects who, by definition, cannot be arrested [3].

Cross-Examination: Impact on Testimony

Introduction

Cross-examination is the process by which evidence presented in court is scrutinized by the opposing counsel. It is one of the defining characteristics of the adversarial legal system. In theory, the primary purpose of cross-examination is to uncover errors and inconsistencies in a witness's testimony, thereby increasing the accuracy of the evidence that is presented in court. In practice, however, cross-examination is commonly used to discredit a witness's testimony, *regardless* of whether that testimony is correct or not [1].

Most legal textbooks describe a number of techniques that can be used to discredit a witness's testimony [2, 3]. For example, lawyers are taught how to lead witnesses to contradict themselves or to enlarge a story until it is improbable or unbelievable. Lawyers are also instructed to fire damaging facts at the witness during cross-examination, to attack the witness's credibility or credentials, and to ask questions in an illogical sequence in order to prevent the witness from becoming aware of the purpose of questioning [2]. In discrediting a witness's testimony, cross-examining lawyers frequently put forward an alternative version of events, the plausibility of which the witness is forced to acknowledge [4].

In light of these techniques, it is not difficult to see why cross-examination is traditionally viewed as a negative and aggressive procedure relative to the other components of the evidential process. Most witnesses, including police, find being cross-examined both intimidating and confusing. In fact, even experienced expert witnesses are typically given training designed to help them respond to cross-examination questions coherently and without undue anxiety [5, 6].

Cross-Examination of Children

Over the past three decades, researchers have firmly established the conditions under which forensic interviewers can obtain the most complete and accurate accounts from child witnesses and, conversely, the conditions that typically lead to errors (for reviews, see [7, 8]). In line with these findings, many countries have made changes to the way in which children's testimony is elicited [9] and presented in court (e.g., prerecorded videotape or closed-circuit television; [10, 11]).

Despite these advances, almost all of the recent recommendations and reforms have focused on the interviewers who solicit children's primary evidence. The effect of cross-examination on the accuracy of children's testimony has received very little attention.

In fact, the typical cross-examination of a child witness has been described as "a virtual *how not to* guide to investigative interviewing" [1, p. 279]. That is, the questioning style used during cross-examination directly contravenes almost every principle established for obtaining reliable and accurate reports from children. On the basis of prior empirical research, at least three aspects of cross-examination are likely to cause problems for children.

Leading and Closed Questioning. Although witnesses of all ages sometimes succumb to the effects of suggestive or leading questions, children are particularly susceptible (for reviews, see [7, 12]). For this reason, the use of suggestive or leading questions is strongly discouraged during direct examination whether it takes place in court or via prerecorded videotape. During cross-examination, however, lawyers can ask questions in which the desired answer is suggested or disputed facts are assumed. In fact, the right to use leading questions has been described as "one of the great advantages of cross-examination" [2, p. 105], and legal textbooks often encourage lawyers to suggest the desired answer wherever possible during cross-examination [2, 13]. Inspection of court transcripts of trials involving child witnesses has shown that leading and suggestive questions make up the bulk of the questions that are asked during cross-examination [14, 15].

Linguistic Complexity. Research with children has repeatedly shown that they will attempt to provide an answer, even if they do not understand the question [16, 17], or if the question does not make any sense (e.g., "Is milk bigger than water?") [18, 19].

Given this, most current standards of best practice for interviewing children recommend that the questions that are posed to children are developmentally appropriate for the child's cognitive skill and linguistic competence.

Despite these recommendations regarding direct examination, lawyers typically use a large number of linguistically complex questions during cross-examination [14, 15, 20–23]. In practice, complex questions are much more common during cross-examination than during other aspects of evidential questioning [14, 15, 23].

There are a number of linguistically complex features inherent in cross-examination. First, cross-examination questions often include a vocabulary of words that children do not understand, including a large number of legal terms, and children often overestimate their understanding of these words. For example, both Flin *et al.* [24] and Saywitz *et al.* [25] have shown that although children may claim to know the meaning of a legal term, when they are required to give a definition, they often provide an erroneous answer (e.g., confusing "jury" with "jewelry").

Second, cross-examination questions often require children to use complex concepts such as height, weight, age, time, and distance. Again, research has shown that children's understanding of these concepts has a very long developmental trajectory [26].

Finally, cross-examination questions often include complex syntactic features. For example, the questions posed to children during cross-examination are frequently multifaceted (e.g., "So he picked you up and then the two of you went to the movies and then he dropped you at the bus stop – is that correct?"), ambiguous (e.g., "When you and your father picked up your brother from school, did he seem happy?"), or may contain embedded clauses (e.g., "Did you talk to the lady that your father told you about?"), or inappropriate negatives (e.g., "Did you not leave the house at three o'clock?"). During cross-examination, lawyers also change topics abruptly, a tactic that they are advised to avoid when questioning their own witnesses because it is extremely confusing.

Credibility Challenges. By definition, cross-examination is highly confrontational because it involves the lawyer openly disagreeing with the witness's testimony. While lawyers sometimes allege that children are mistaken or confused about the event they are recalling, most cross-examinations of sexual abuse complainants involve the child being directly or indirectly accused of fabricating the allegation [4, 27]. For example, during cross-examination, children may be accused of lying because their disclosure was delayed, because the seriousness of their allegations have increased over time, or because, from the outside, it appears as if the complainant and the alleged perpetrator have a harmonious relationship [4].

Children's vulnerability to leading questions is higher under intimidating conditions [28] and when the child believes the interviewer to be authoritative [29], but it is important to note that challenges to a child's credibility during cross-examination are not always outwardly aggressive. Over 70% of defense lawyers surveyed by Davies *et al.* [4] indicated that the best manner in which to cross-examine a child was to be nonthreatening and gentle, at least initially. In fact, some experts have argued that children's evidence can be discredited even *more* readily by interviewing them in a friendly, charming manner and engaging trust before confronting the child [5].

Delay. Many countries have acknowledged the potential negative effects of delay on children's testimony by allowing child witnesses to present their direct evidence via prerecorded videotape [11]. Cross-examination, however, does not take place until the time of the trial. Although trial delays vary widely across countries, jurisdictions, and individual cases, children often wait several months between making an allegation and being cross-examined in court [23, 30–32], and delays of several years are not uncommon [30]. Given that the accuracy of children's recall declines over time [33], and declines more quickly than that of adults [34], delays leading up to cross-examination may be especially problematic for children.

Cross-Examination and Accuracy. Although the rules for direct and cross-examination differ markedly, and many of the questions that are asked of children during cross-examination appear to be developmentally inappropriate, the real question is whether there is any evidence that cross-examination has a negative impact on the accuracy of children's testimony. In one of the first studies designed to address this question, Brennan and Brennan [20] tested 6- to 14-year olds' understanding of cross-examination-style questions obtained from court

transcripts. They reviewed court transcripts for commonly asked questions and then asked same-aged children in the laboratory to repeat these questions back to the experimenters. Brennan and Brennan then measured the extent to which the child's response accurately captured the question's meaning. They found that many common courtroom questions were misunderstood by children.

In another study, Zajac *et al.* [15] compared child witnesses' responses to lawyers' questions during direct and cross-examination. Despite the fact that cross-examining lawyers asked a high proportion of complex and grammatically unsound questions, children rarely requested clarification, and the nature of their answers indicated that they often misunderstood lawyers' questions. Children also exhibited a high degree of compliance with the leading questions that they were asked during cross-examination. Most notably, Zajac *et al.* found that 75% of the children made at least one change to their earlier testimony under cross-examination. Almost all of these changes (95%) were preceded by a leading question that challenged the child's credibility (e.g., "But that's not really what you told her, is it?"). The changes that children made during cross-examination were not restricted to peripheral details of the alleged events. In fact, some children retracted their abuse allegations altogether.

Are the changes that children make to their testimony during cross-examination directed toward or away from the truth? For obvious reasons, the use of court transcript data does not allow researchers to evaluate the effect of cross-examination on children's accuracy. In principle, the changes that children made during cross-examination in Zajac *et al.*'s study could have increased their overall accuracy. Given the complex and challenging nature of the cross-examination process, however, it is equally likely that these changes may have made children *less* accurate.

In order to explore and empirically evaluate the effect of cross-examination on the accuracy of children's testimony, Zajac and Hayne [35] developed a laboratory analog of cross-examination. Zajac and Hayne's methodology was unique in that they examined the effect of an ecologically valid, yet standardized, cross-examination interview on children's reports of a personally experienced event. Because the researchers were knowledgeable about the target event, they could evaluate the accuracy of the changes children made to their reports during cross-examination.

In Zajac and Hayne's [35] study, 5- and 6-year-old children visited the local police station, where they participated in four unique activities (e.g., getting their "mugshots" taken). Six weeks after the visit, children participated in a simulated direct-examination interview. During this interview, they were asked general (e.g., "Tell me everything that you can remember") and yes/no (e.g., "Did you see the police car?") questions about the visit to the police station. Eight months later, children were shown their direct-examination interview on videotape and were then interviewed with a standardized laboratory analog of cross-examination. These procedures are analogous to those currently used in both New Zealand and the United Kingdom.

During the cross-examination phase of the Zajac and Hayne [35] study, the specific questions that children were asked were modeled after the kinds of questions that had been asked by defense lawyers in Zajac *et al.* [15] (e.g., "Maybe you *did* get to try on handcuffs, but you just can't remember. That's what *really* happened, isn't it?"). In response to cross-examination, 85% of the children changed at least one of the answers that they had provided during their direct-examination interview. In fact, one-third of the children changed *all* of their previous responses. Overall, cross-examination-style questioning significantly decreased the accuracy of children's reports to a point where following cross-examination their accuracy levels were not significantly different from chance. Similar findings have since been obtained with older children [36], and using forensically relevant events (e.g., bodily touch by a male authority figure) [37].

More recent empirical research on cross-examination in children has set out to examine some of the other factors that might impact the degree to which their accuracy is compromised.

Delay. In an attempt to model the conditions in actual forensic settings, Zajac and Hayne's [35] cross-examination interview occurred after an 8-month delay. In light of research showing that suggestibility increases with delay [38], Righarts *et al.* [37] hypothesized that children might perform better if the delay between direct examination and cross-examination was eliminated. To test this hypothesis,

Righarts *et al.* cross-examined 5- to 6-year-old children either 1–3 days or 8 months after their initial, direct-examination interview. Despite highly accurate initial reports, children's performance during cross-examination was very poor, even when they were cross-examined shortly after the target event. In fact, children's cross-examination accuracy scores did not differ as a function of delay. Thus, it appears that the cross-examination questions *per se* pose a difficulty for children, and reducing the delay between the allegation and the trial or conducting pretrial cross-examination may do little to facilitate children's performance.

Individual differences. It is widely acknowledged that the accuracy of children's eyewitness reports hinges largely on the way in which they are questioned, but even when external factors are held constant, children do not respond uniformly to forensic questioning. For example, under direct examination, individual differences in children's social, emotional, biological, and cognitive functioning can influence the content and accuracy of their reports [39]. What about the role of individual differences in children's response to cross-examination?

Preliminary research on this question has been conducted by Zajac *et al.* [40]. They examined the role of several psychosocial variables on children's performance under cross-examination questioning.

Although all children in that study made mistakes during cross-examination, children's level of self-esteem, self-confidence, and assertiveness exerted a small but significant contribution to cross-examination performance. That is, the same factors that may make children targets for abuse, or may be the consequences of abuse, could also make children particularly susceptible to the cross-examination process.

Preparation for cross-examination. Many jurisdictions have implemented formal preparation programs for children who are required to testify in court. These programs generally involve reducing the stress associated with testifying by familiarizing children with their role as a witness and with courtroom personnel and procedures. Although these programs are not directly designed to facilitate accuracy, are there ways of preparing children for cross-examination that might help them to provide accurate testimony?

A growing body of research has examined the use of preparation techniques aimed specifically at helping to reduce children's suggestibility. Many of these interventions involve simple verbal warnings, for example, telling children that the interviewer does not know what happened, that the questions might be tricky, and that it is okay to correct the interviewer. Many of these interventions have met with at least some success [41]. These types of warnings, however, appear insufficient to buffer children from the negative effects of cross-examination on accuracy [42].

Recently, Righarts and Zajac [42] developed a comprehensive method of preparing children for cross-examination questioning. As in earlier research, children participated in a unique staged event and were then interviewed with an analog of direct examination. Prior to the cross-examination interview, the researchers showed half of the children a short film about a girl who gets lost, and then gave children both practice and feedback on the types of questions that they were to be asked in the cross-examination interview. The entire preparation session took approximately 20 min, and was conducted 1–2 days before the cross-examination interview.

Relative to control children, those children who received preparation made fewer changes to their earlier responses, and changed a smaller proportion of their correct responses during the subsequent cross-examination interview. Furthermore, overall accuracy levels during the cross-examination interview were significantly higher in the intervention group than in the control group. In short, the intervention was successful.

The preparation intervention developed by Righarts and Zajac [42] has several distinct advantages. First, during the preparation session, children were asked questions that were entirely unrelated to their "testimony", making allegations of coaching less feasible. Second, the intervention increased children's accuracy even though it was delivered by an unfamiliar interviewer, which would be the case in real-life situations, where court preparation would be conducted by an independent third party. Third, the intervention did not reduce the number of prior mistakes that children *corrected* during cross-examination. Finally, for the 9- and 10-year-olds, the success of the intervention was unrelated to children's performance during the preparation session. That is, for these older children, mere

exposure to the preparation session was sufficient to increase accuracy during cross-examination.

Cross-Examination of Adults

The negative effects of cross-examination on children's accuracy are of concern, but they also raise questions about how adults respond to this particular questioning style. Although many aspects of cross-examination are more likely to affect children than adults (e.g., complex language, intimidation, and long delays), this does not mean that older witnesses will be buffered from the negative effects. Like children, adults are susceptible to leading questions and suggestion [43], linguistic complexity [44], social pressure or intimidation [45], and interviewers of high status [46]. Furthermore, there are several categories of witness who may be particularly susceptible to being discredited during cross-examination (e.g., witnesses who recount traumatic events, elderly witnesses, or witnesses with communication or learning difficulties).

The cross-examination of adult witnesses is likely to be qualitatively and quantitatively different from that of child witnesses. For example, we know that adult witnesses, on average, are cross-examined for a longer period of time than are children [47]. We also know that cross-examining lawyers ask adults a higher proportion of complex and credibility-challenging questions than they ask children [47]. Furthermore, when cross-examining adults, lawyers may use different reasons for challenging a witness's story. In cases of sexual assault, for example, adult witnesses are likely to be challenged on issues of consent, whereas this issue is not valid when cross-examining children.

Preliminary research conducted by Zajac and Cannan [47] on the cross-examination of adult sexual abuse complainants has shown that adults are not immune to the negative effects of cross-examination on their testimony. While the adult complainants in the Zajac and Cannan study were less likely than child complainants to comply with leading questions and more likely to give clarification in response to closed and leading questions, their responses did provide reason for concern. For example, like children, adults showed very low levels of clarification-seeking and expression of uncertainty, even when questions were ambiguous, complex, or nonsensical. Most concerning, adult complainants were just as likely as child complainants to change their earlier testimony under cross-examination. Many of these changes were made in response to credibility-challenging and leading questions. It is now imperative that laboratory research examines the effect of cross-examination-style questioning on adults' accuracy, in an attempt to determine how this process might affect witnesses' ability to provide accurate details of their past experiences.

Conclusion

Although the ultimate goal of any legal investigation should be to ascertain the truth, a number of recent studies have cast doubt on whether cross-examination is an effective means of obtaining accurate eyewitness reports. Findings from a number of studies have shown that the cross-examination process may pose particular problems for child witnesses. It is particularly concerning that the types of questions typically employed during cross-examination have been shown to exert a negative effect on the accuracy of children's reports. While recognizing that cross-examination is a mainstay of adversarial trial procedure, further research is required to identify the factors that may reduce or exacerbate the negative effects of cross-examination on the testimony provided by both children and adults.

Cross-Examination of Experts

Nature, Purpose, and Scope

When a witness, whether lay or expert, has been called by a party to a law suit to give sworn testimony in a court or court-related procedure, and that witness has been subjected to questions by the party who called him on direct examination (*see* **Direct Examination of Experts**), the opposing party has thereafter an opportunity to ask questions of that same witness. This stage of the trial process is called the *cross-examination*. During the direct examination, the cross-examiner would have listened very carefully to the answers given by the expert, who must be prepared to be challenged on all the answers that he or she had given. The properly prepared witness would also have discussed, with the direct examiner, any areas in his testimony that are open for possible challenge.

Cross-examination is permitted so that the veracity and accuracy of the witness' testimony can be questioned and challenged where appropriate. In the context of testimony by experts, the litigant may seek to explore potential weaknesses in the expert's qualifications, question the appropriateness and accuracy of the methods of examination used, explore potential insufficiency and inaccuracy of the data obtained, and throw doubt on the credibility of the conclusions drawn from the data. In this article, only issues relating to the above are discussed.

Additionally, witnesses may be cross-examined on issues unrelated to job performance but relating only to credibility or honesty of the experts. These issues are typically referred to as *matters impeaching the credibility of the expert* and are discussed separately.

Not all possible avenues are explored on cross-examination in each case. Prior to commencing the cross-examination, a litigant will typically evaluate which approach is most likely to result in information useful to him, and forgo other possible avenues of exploration. Some cross-examiners are extremely skilled and conduct searching cross-examinations that, in important cases, may take many hours, even days, to complete. Others may, for whatever reason, be more perfunctory. Effective cross-examination

skills are believed to be an art and are highly individual to each trial attorney.

The form, duration, and manner of cross-examination of experts may differ from jurisdiction to jurisdiction. Local procedure dictates, to a large extent, how cross-examination is to be conducted.

In the adversary system, the person against whom a witness has testified has an absolute right to subject the witness to cross-examination. In criminal cases, if the right of cross-examination is abridged, the direct testimony of the witness cannot stand and must be stricken from the record.

The right of cross-examination is not without limits. Local statutes, court rules, custom, or common law may dictate the extent, duration, and scope of such questioning.

It must be noted that the right of cross-examination extends to court-related procedures only. This includes not only actual trials but also such pretrial proceedings of a judicial nature as are depositions, pretrial hearings, and even some posttrial hearings.

The style of advocates conducting a cross-examination differs also according to the personal attributes of the advocates, the credentials of the witness, and even the locale where the trial occurs. In the United Kingdom, Canada, and other adversary system jurisdictions, the tone tends to be less adversarial and strident as may be seen in many American courtrooms. When called to give testimony as a court-appointed expert – a process that while widely permitted by law is invoked seldom – both sides to the dispute are permitted to cross-examine the witness.

In civil law systems, the right of cross-examination serves a more limited function. When the examining magistrate questions witnesses while compiling the file that would make up the *dossier* upon which the decision to prosecute would be made, such questioning of witnesses by the magistrate may not allow for cross-examining the witnesses by an attorney for an accused, assuming that a potential accused has already been identified. Local practices may vary in this regard.

Cross-Examination – Some Additional Concepts

Preliminarily, a litigant who has the right to cross-examine an expert witness must decide whether it is strategically wise to do so. Secondarily, recognizing that answers given by an opposing party's witness cannot always be anticipated with confidence, the structuring of an effective cross-examination requires skillful preparation on the part of the interrogator. If a cross-examination is not carefully prepared, the questioning may well have the undesired result of strengthening, rather than weakening, an opponent's case. Along with books about brilliant cross-examinations resulting in true reversals of fortune, there are also many examples to be found, where inept cross-examinations simply permitted the expert to repeat answers that were already given on direct examination.

Thus, as a matter of tactics and in recognition of the imponderables of asking questions to which the attorney may not know the answer, lawyers are ordinarily taught that if an opposing witness has not damaged the client's case on direct, little is to be gained by cross-examining the witness at all, unless an opportunity exists to elicit evidence from the witness that has not yet been brought out and may be helpful in clarifying or supporting the opponent's position.

Generally, all testimony must be relevant to the disputed issues before the court. During cross-examination, that means the questions posed are limited to matters discussed during direct examination. Most courts, however, do not impose strict limitations on the scope of cross-examination and will permit questioning on any issues that are raised, either expressly or implicitly, by the direct examiner or by the issues before the court. In addition, impeachment regarding matters that pertain to the witness' honesty and credibility are always appropriate within the limits of the law.

Cross-Examining the Qualifications of the Witness

In adversary system jurisdictions, after a witness has been found qualified to give opinion evidence as an expert following direct examination, it is still permissible to cross-examine an opponent's expert as to his qualifications, because the extent of the expert's education and experience as a witness affects the weight and credibility of his opinion.

Litigants have many opportunities to explore the extent of an expert's knowledge-base and experience. There are professional societies who maintain

the curriculum vitae of their members or have, at the least, registers that show whether a person is a member, has obtained certain certifications and distinctions, or has been subject to ethics complaints and/or sanctions. In addition, much information about the extent of an expert's knowledge is currently available on the Internet from a great variety of sources. This includes not only professional sources but also contact information about attorneys who have opposed the same expert in other cases. These lawyers may be willing to furnish transcripts of earlier testimony that appear to contradict what an expert is stating in the current case.

It becomes important for the meticulous expert to constantly review the standard texts, protocols, and tenets of his profession, so as to be properly prepared to answer challenges on every aspect of his professional experience. It is often said among forensic scientists that they can never stop learning and must not only "keep up" with the latest advances in their field but they must also constantly review what the accepted wisdom of the past was. Nothing in the expert's professional field is immune from challenge on cross-examination.

Attempts seeking to exclude an expert witness's testimony can be made prior to trial by the filing of a motion *in limine* (*see* ***In Limine*** **Motions and Hearings**). Such a motion may be based on the lack of appropriate qualifications of the proffered witness, weaknesses in the training of the witness, or other factors that may disqualify the expert from giving opinion evidence about a specific issue – such as professed unreliability of a technique espoused. Even if the pretrial motion to exclude the expert's testimony is unsuccessful and the witness is allowed to testify, the same questions posed to the expert prior to trial in support of exclusion may again be made on cross-examination during the trial. These questions remain relevant to the credibility of the expert – an issue the jury must evaluate.

Any expert witness who (i) possesses appropriate qualifications for a profession, (ii) has the needed experience, (iii) has performed a professional examination following approved protocols, (iv) has accurately obtained certain results, (v) has drawn conclusions from these observations that are readily recognized as valid in the profession, and (vi) has properly reviewed all data before taking the witness stand has little to fear from cross-examination. The important admonition to the expert is to always state the truth, not deceive expressly or by omission, and to follow standards of the profession.

Cross-Examining with Contrary Opinions Expressed in the Expert's Professional Literature

In most jurisdictions, challenging an expert's testimony on cross-examination on the basis of professional literature or textbooks in the expert's discipline is subject to evidentiary limitations. This is true particularly in adversary system jurisdictions where stringent rules against the use of hearsay evidence may remain. Views expressed by authors of published materials who are not present in court are often believed to be hearsay because they represent assertions of persons who are not subject for cross-examination.

However, when such views by acknowledged authorities in the field are brought in only for the purpose of contradicting the testifying expert's views, the questions may be appropriate because they are offered, not for the truth of the published views, but to reflect on whether the witness on the stand is believable. The cross-examiner simply attempts to show, by this method, that there are distinguished authorities in the profession who hold views differing from those of the testifying expert.

Despite such evidence not being "hearsay", the use of treatises and professional literature is subject to some limitations. They can be used to impeach an expert only if the text or treatise is first recognized as "authoritative" through the testimony of an expert. In limited situations, such treatises or publications may indeed themselves become positive proof of the truth of their content (*see* **Learned Treatises as Evidence**).

There are two different rules concerning the use of written authorities on cross-examination to impeach or discredit an expert. The first rule allows cross-examining an expert on a published statement only if the expert has relied on the written authority. A less restrictive rule also permits cross-examination on the basis of published professional literature if the expert admits that the particular publication is a recognized authority, even though the expert did not rely on it in reaching an opinion. If an expert being cross-examined refuses to recognize a

particular publication as authoritative, such fact may be established by another expert, or even by judicial notice (*see* **Judicial Notice of Scientific Principles and Facts**).

In most jurisdictions that permit the admission in evidence of a published treatise or periodical, the publication itself is not admissible as substantive evidence if its excerpts are used solely for impeachment purposes. Excerpts that call in doubt the expert's conclusions may be read to the jury, but the publication itself is not received in evidence. The rationale for that limitation on evidentiary use is that while the reading of the author's text may be justified as an exception to the rule against hearsay, it should not be permitted to assume additional dignity by being taken to the jury room during deliberations because there was no cross-examination of its author.

Redirect and Re-Cross-Examination

In most jurisdictions, after an expert has been cross-examined, the litigant who called the witness has an opportunity to conduct a redirect examination. This process is often referred to as *rehabilitating the witness*. It consists of asking explanations about answers given during cross-examination that appear to have damaged the witness's credibility. Redirect is limited only to matters raised during cross-examination.

When the process of redirect examination has been concluded, the challenging litigant may have a further opportunity, subject only to limitations imposed by court rules or the judge's discretion, to further cross-examine the expert on answers given during redirect examination. In some jurisdictions, i.e. Canada, re-cross-examination is either prohibited entirely, or subject to stringent limitations.

Dangerousness: Risk of

An Introduction to Dangerousness

The question of an individual's dangerousness is raised often within both civil and criminal law systems (e.g., parole decisions, civil commitment, child custody cases; [1, 2]). Frequently when this issue arises, mental health professionals are asked to provide an assessment of the individual's "dangerousness", a broad concept that indicates an individual's propensity to commit a dangerous act [3]. Historically, it was assumed that dangerousness resided primarily within the individual, and external factors were minimized. Psychologists and psychiatrists, whether in practice or research, therefore tended to sort people into two groups – dangerous and not dangerous. From such assessments, dichotomous clinical predictions were then tendered as to whether individuals were likely to commit dangerous acts in the future. However, research during the late 1960s through the 1980s suggested that mental health professionals were quite inaccurate prognosticators, and they faced severe criticism for participating in these assessments. In response to the strong criticism, spurred on by legal decisions within the United States, substantial research effort was focused on methods for improving these predictions.

In addition, the very task was reconceptualized throughout the 1980s to the present day. Rather than construing individuals to be "dangerous", locating the vast majority of cause within the individual, and tending to make one-time dichotomous predictions of violence, the field has moved toward the concept of "risk assessment", an ongoing process of evaluating a person's risk factors for specific behavior(s), with the acknowledgment that many risk factors may be external to the individual [4]. Despite the movement away from the term *dangerousness* by mental health professionals, this term continues to have important meaning within a legal context, and in fact it is still used within some mental health settings as well (primarily psychiatric).

Jurisdictions across the United States, Canada, and the United Kingdom include the criterion of dangerousness in various civil and criminal laws. This article provides a brief review of the concept of

dangerousness from a legal stance. In addition, the methods for assessing dangerousness and how risk assessment has evolved over the years into its current form are discussed.

Dangerousness

It is difficult to provide a single definition of dangerousness. The definition of the term varies between jurisdictions and has changed over time. For instance, in the early part of the twentieth century, property offenses were considered "harmful acts" and property offenders could be considered dangerous and incarcerated indeterminately [5]. However, over the years, the definition of dangerousness tightened considerably and by the 1960s, the term reflected a risk of harm, particularly violence, to others, typically borne of individual or constitutional factors. That is, dangerousness was assumed to reside within the individual. It was at this time that "dangerousness to others" became a widely accepted criterion for civil commitment in most jurisdictions throughout the United States [6], Canada [1], and the United Kingdom [7].

Dangerousness in Civil Law

Risk assessments of dangerousness occur in many contexts within civil law, such as child protection and custody disputes, immigration cases, and labor regulations [1]. Civil psychiatric commitment is another area where assessments of dangerousness are often relied upon. As mentioned, most jurisdictions now have "dangerousness to others", in some form or another, as a criterion for civil commitment. Up until the 1970s, the main criterion for involuntary hospitalization in the United States was the "need for treatment" [8]. During the 1970s, most states revised their civil commitment statutes to require an individual to be both mentally ill and dangerous to self or others for involuntary hospitalization to occur [9]. Although many states have since revised their commitment laws to allow the commitment of persons assessed as "gravely disabled", the criterion of dangerous to self or others remains prominent in all state civil commitment statutes [10]. A similar legal standard has been established across Canadian jurisdictions. Following the civil commitment legislation in the United States, Canada moved to include the dangerous criterion to its commitment laws. Currently, every provincial Mental Health Act includes dangerousness to self or others criteria, although the wording and the specificity of the definition of dangerousness may vary across provinces [1].

More recently and controversially, there is also specific legislation for the *civil* commitment of *criminal* offenders, particularly sex offenders, who are deemed to pose an ongoing threat to society. Historically, in the United States, the first "sexually dangerous person" law was enacted in 1937 in Michigan [8], and other states soon adopted similar provisions. At this time, the purpose of the sexually dangerous person laws was to help society deal in a nonpenal manner with sexual offenders who were too ill to deserve punishment [11]. During the 1970s, many of the statutes were repealed owing to the increasing criticism over the lack of scientific validity of the categories used by these laws (e.g., sexual psychopathy), ineffective treatment, and inaccurate prediction methods [11].

However, since 1990 a second generation of commitment laws, generally referred to as *sexually violent predator* laws (SVP laws), have been passed in 20 states as of the time of writing this article [12]. As opposed to the purpose of the first set of sexual predator laws, the new SVP laws were established as a public safety measure and allow the precautionary, indeterminate detention of sex offenders who have completed their criminal sentences [13]. "Patients" are able to be released back into the community once treatment has reduced their risk to manageable levels. In practice, however, given the general ineffectiveness of sex offender treatment, very few people have been released back into the community during the tenure of these laws [11]. This state of affairs has drawn criticism based on civil rights grounds.

The first of the new SVP legislation was established in the State of Washington [14] in response to public outcry for greater society protection following the abduction, rape, and sexual mutilation of a young boy by a sex offender who had admitted his intent to torture children upon release from prison [15]. The Washington SVP statute defines an SVP as "a person who has been convicted of or charged with a crime of sexual violence and who suffers from a mental abnormality or personality disorder which makes the person likely to engage in predatory acts of sexual violence" [13]. The Washington statute served as a model for other state SVP legislation, and although the exact wording may vary from one state to another, all legislation requires similar criteria:

1. The individual must have a history of criminal sexual behavior.
2. The individual must have a mental abnormality or personality disorder predisposing the individual to sexual violence.
3. There must be a likelihood of future sexually violent behavior.
4. There must be a connection between the mental abnormality and the potential sexual harm [13].

Although the final decision as to whether the person will be designated an SVP is left to the court, mental health professionals play an integral role in the process. In order to determine whether the individual meets the above criteria, each potential SVP must undergo an evaluation by a mental health professional. Mental health professionals provide their opinion during the trial phase of the SVP proceedings, which occurs only if there is probable cause that an individual is an SVP [16]. If the offender is determined to be an SVP, the individual is committed indefinitely, until the person is judged to no longer pose a threat to society.

The constitutionality of SVP laws has been challenged before the courts, with *Kansas v. Hendricks* [17] being one of the most well-known cases. In this case, Mr Hendricks, a diagnosed pedophile who admitted being unable to control his urge to molest children, challenged his commitment on the basis of double jeopardy, *ex post facto* law making, and substantive due process grounds [18].

In response to the arguments presented by Mr Hendricks, the court ruled that the proceedings in the Kansas statute were civil in nature, not criminal, and therefore deemed it unnecessary to address his claims of double jeopardy and *ex post facto* law making. With respect to Hendrick's third claim, the court ruled that the Act's definition of mental abnormality satisfied substantive due process requirements. As a result, the constitutionality of the act and Mr Hendrick's commitment were upheld [18]. Since this time, the constitutionality has been challenged again (e.g., *Kansas v. Crane* [19]); however, the US Supreme Court has continued to uphold the SVP laws.

The United Kingdom has civil commitment laws that are similar to those found in Canada and the United States. According to the *Mental Health Act* [20], an individual can be involuntarily committed if "it is necessary for the health or safety of the patient or for the protection of other persons" [20]. In addition, the person being committed must be treatable [21]. However, recently an amendment to the *Mental Health Act* has been made that removes the treatability criterion, at least under certain conditions, for the purpose of managing the problematic behaviors presented by people with personality disorders [22, 23]. The policy is referred to as the *dangerous severe personality disorder* (*DSPD*) program. Under the DSPD policy, there are three admission criteria:

1. more likely than not to commit an offense that might be expected to lead to serious physical or psychological harm from which the victim would find it difficult or impossible to recover;
2. the presence of a severe personality disorder; and
3. an established link between the personality disorder and the risk of offending [24].

The reform to the Mental Health Act was prompted by two cases in the 1990s in which persons with personality disorders committed horrible crimes upon their release from prison [25]. This new policy allows for the detention of people with a severe personality disorder, regardless of whether they have previously committed a crime. This latter point is incredibly contentious, and, on its face, is inconsistent with the principles of fundamental justice that persons can only have their rights abrogated (i.e., sentenced to imprisonment) if they have engaged in officially proscribed behaviors, such as criminal behavior. It indicates that the concept of "dangerousness" is still well-entrenched in UK law.

The United Kingdom has established a number of beds for patients who are admitted under this legislation, half of which are in high security prisons and half in high security hospitals. Similar to the SVP statutes in the United States, an individual who is assessed to have a dangerous and severe personality disorder is detained indefinitely, until a comprehensive risk assessment is completed, which demonstrates that risk has been reduced [23]. Additionally, patients may be subject to a period of compulsory care and treatment in the community following discharge. The community care and treatment order would include specific requirements for the patient, and specify the actions that the clinical supervisor is empowered to take if the patient fails to comply with the order, including a provision to recall the patient to hospital. Similarly, a recall to hospital may occur

where the care and treatment could no longer be given effectively or safely in the community, or where the patient is posing a risk of serious harm to others [23].

One final area in civil law in which the issue of dangerousness, and the ability to predict violence, is important is with respect to a mental health professionals' duty to protect third parties (*see* **Duty to Warn**). In both the United States and Canada (depending on jurisdiction), judicial decisions have clearly demonstrated that mental health professionals can be held liable for failing to take reasonable steps to protect third parties from the violence of their patients or clients [1]. This was most famously illustrated in the case of Tarasoff v. The Regents of the University of California [26].

In Canada, this issue was raised in the case of *Wenden v. Trikha* [26]. In this case, Mr Trikha was admitted to hospital and was under the care of a psychiatrist. Soon after his admission, Mr Trikha left the hospital without permission and was involved in a car accident in which Ms Wenden was seriously injured. In the lawsuit brought against the hospital, the court held that when a psychiatrist becomes aware that a patient presents a serious danger to the physical well-being of a third party or parties, there arises a duty to take reasonable steps to protect such a person or persons provided they can be identified. In this case, the question of identifiability of the victim was difficult; therefore, the court ruled that the psychiatrist had not acted negligently as no specific victim could be identified.

The role of mental health professionals' duty to protect third parties also arose in the Supreme Court of Canada case of *Smith v. Jones* [27]. In this case, the defense counsel hired a psychiatrist to assess the accused and told the accused that the interview was legally privileged. During the assessment interview, the accused revealed in substantial detail his plan to kidnap, rape, and kill prostitutes. The psychiatrist reported to defense counsel that the accused was dangerous and likely to commit future offenses unless he received adequate treatment. The accused later pled guilty to the charge (aggravated assault against a prostitute). The psychiatrist contacted the defense counsel to inquire about the proceedings and learned that his concerns regarding the defendant would not be presented to the court. Upon learning this, the psychiatrist commenced action to disclose the information he had in the interest of public safety. The psychiatrist filed an affidavit describing his interview with the accused and his opinion based upon the interview. The trial judge ruled that the public safety exception to the doctor–patient confidentiality and solicitor–client privilege released the psychiatrist from his duties of confidentiality and concluded that the psychiatrist was under a duty to disclose the information to the police and Crown counsel. The accused appealed the trial judge's decision; however the ruling was upheld by the Supreme Court of Canada and the psychiatrist was permitted to reveal the statements made by the accused and his opinion based upon the interview. *Smith v. Jones* specified the conditions under which legal privilege can be violated for public safety reasons. The court identified three factors that should be taken into consideration in determining whether public safety outweighs solicitor–client privilege: (i) Is there a clear risk to an identifiable person or group of persons? (ii) Is there a risk of serious bodily harm or death? and (iii) Is the danger imminent? These three factors must be defined within each separate context and different weights will be allocated to each factor, as well as the various aspects of each, in any particular case. The court also indicated that, since legal privilege is the strictest of all types of privilege or confidentiality, the exception would apply to other forms of confidentiality, such as that between mental health professional and patient or client. These cases suggest that the judiciary believes that mental health professionals have the ability to recognize the risk individuals pose and to intervene effectively [28].

Dangerousness in Criminal Law

Canada has also established legislation to incarcerate offenders indeterminately if they are deemed to pose undue risk to society. However, as opposed to the civil SVP laws found in the United States, the Canadian Dangerous Offender (DO) and Long-Term Offender (LTO) legislation falls within the criminal law system. Additionally, whereas the SVP laws in the Unites States vary from one state to another, the Canadian Criminal Code, and therefore DO/LTO legislation, applies across the country. In the 1940s, Canada paralleled the movement in the United States for handling sexual offenders and enacted the first DO provisions with the *Habitual Offender Act* (1947) and the *Criminal Sexual Psychopath Act* (1948) [29]. Both of these acts survived until 1977, when the

DO provisions were passed, which remain in place today [30].

To designate an offender as a DO, the Crown must present an application to the court after a conviction but prior to the sentencing. In order for an offender to be designated a DO, the index offense must be a serious personal offense other than homicide (punishable by imprisonment of at least 10 years) and the offender must have been assessed as a "threat to the life, safety and physical or mental well-being of other persons" [31].[a] If an offender is found to be a DO, the court imposes an indefinite sentence and the offender can only be released upon a judgment that the person no longer poses a threat to society.

In addition to the DO statute, Canada more recently enacted LTO provisions. The purpose of the LTO provision, enacted in 1997, is to ensure that sexual offenders are provided with long-term supervision once they are released into the community [30]. Similar to the DO application process, an LTO application is made by Crown Counsel following a conviction but prior to sentencing. To be designated an LTO, the offender must have committed an offense that is punishable by a sentence of two years or more, there must be a substantial risk that the offender will reoffend and there must be a reasonable possibility of eventual control of risk in the community [30]. Unlike a DO or an SVP, an LTO is not given an indefinite sentence. In fact, no additional custody time is added to an offender who is designated an LTO. Instead, the LTO designation allows for community supervision of the offender for up to 10 years after release.

The question of dangerousness can be raised in multiple other criminal law contexts. The dangerousness of an offender may be considered in decisions to release an individual on bail, transfers of juveniles to adult court, parole decisions, and institutional classification decisions, to name a few [1, 2]. In the United States, dangerousness can also be raised when deciding whether to impose the death penalty. Many states in the United States continue to use capital punishment as a sentencing option for offenders who commit serious crimes. Within this process, mental health professionals can be asked to assess whether an individual is likely to commit a dangerous act in the future. If the individual is deemed likely to pose a threat to the community in the future, which in some jurisdictions includes fellow prisoners, the death penalty could be imposed.

Similar to the SVP civil commitment cases, the constitutionality of psychiatrists providing assessments of future violent behavior was challenged in the United States death penalty case of *Barefoot v. Estelle* [32]. In this case, the offender was convicted of capital murder in Texas and the question of whether the death penalty should be imposed was deliberated at sentencing. As required by Texas statute, the question of whether there was a probability that the offender would commit further criminal acts of violence in the future and would constitute a continuing threat to society was submitted to the jury. One element of the evidence presented by the State was the testimony of two psychiatrists who testified that the defendant would probably commit future acts of violence and represent a continuing threat to society.

On the basis of the evidence presented, the jury answered affirmatively to the above questions and imposed the death penalty. The offender appealed his sentence, arguing that the psychiatrists' testimony was unconstitutional because psychiatrists are not competent to predict future dangerousness and their predictions are so likely to produce erroneous sentences that their use violated the Eighth and Fourteenth Amendments of the United States Constitution. However, the Texas Court of Criminal Appeals rejected this argument and the death sentence was upheld.

Risk Assessment

Clearly, mental health professionals are relied upon often and within many different legal contexts to assess dangerousness, or predict violence. Unfortunately, mental health professionals have not always demonstrated a clear ability to perform this task. During the 1960s, 1970s, and early 1980s, mental health professionals were seriously challenged regarding their ability to predict violence. At this time, the prevailing view was that dangerousness was a stable disposition and that only a one-time dichotomous yes/no prediction of future dangerousness was required [4]. Following important legal decisions in the United States (e.g., *Baxstrom v. Herold* [33]; *Dixon v. Attorney General of the Commonwealth of Pennsylvania* [34]), researchers were provided with a unique opportunity to assess the predictive ability of mental health professionals. As a result of these court cases, a number of presumed "dangerous" patients

were released from involuntary hospitalization under court orders and returned to the community or less secure institutions [35]. After following up with these patients, it was found that very few of the patients were involved in a violent incident after release [35, 36]. In a four-year follow-up period, only 7 of 98 *Baxstrom* patients released to the community committed new violent offenses, despite the fact that all had been predicted to be violent [35]. The incidence of violence was slightly higher, though still low given that all patients had been predicted to be violent, for the *Dixon* patients, with 14.5% of patients released involved in a violent incident in a three-year follow-up [36]. The results from the *Baxstrom* and *Dixon* studies illustrated two important points: (i) violence was overpredicted and (ii) there was a low base rate of violence during the follow-up periods [28]. Monahan [37] reviewed the accuracy of clinical prediction in these and several other early studies, which he referred to as *first-generation studies*, and concluded that

> *psychiatrists and psychologists are accurate in no more than one out of three predictions of violent behavior over a several-year period among institutionalized populations that had both committed violence in the past (and thus had a high base rate for it) and who were diagnosed as mentally ill* (p. 77, emphasis in original).

Monahan was not the only person who criticized the ability of mental health professionals. Ennis and Litwack [38] concluded from the first-generation research studies that mental health professionals had no ability to assess risk and suggested that mental health professionals should be barred from offering testimony because their judgments were not valid. Professional organizations also voiced their opinions regarding the poor ability of mental health professionals. The American Psychiatric Association [39] concluded that psychiatrists had not demonstrated any ability to predict future violence or dangerousness and that no special psychiatric expertise in the area of violence prediction had been established.

Despite the poor outlook on mental health professionals' ability to predict future behavior, the legal system continued to demand violence predictions by mental health professionals [40, 41]. Attempts to challenge the use of violence predictions as evidence in both the United States (e.g., *Barefoot v. Estelle* [32]) and Canada (*Re Moore and the Queen* [42]) were rejected by the courts [1]. It appeared that the role of mental health professionals as predictors of violent behavior within the legal context was solidified.

Considering the important role that mental health professionals were continuing to play in the legal world, it was imperative that mental health professionals and researchers worked toward improving predictions of violence. At the conclusion of his review of clinical prediction, Monahan [37] urged researchers to move toward a "second generation" of studies and provided numerous suggestions for improving research. As a result of the criticism and the suggestions provided, researchers moved into the second generation of research studies and began to use more sophisticated methodology. Following the suggestions provided by Monahan [37] and others [3], researchers began to conduct studies that used shorter follow-up times [43–45], focused on risk factors in greater detail [44, 45], measured violence from multiple sources [43, 46] and began to examine the role that situational/environmental factors might play [46].

Monahan [37] also argued for a more actuarial, or statistical, approach to violence prediction. In line with this suggestion, numerous actuarial measures, such as the Violence Risk Appraisal Guide (VRAG) [47] and the Static-99 [48], were developed. The actuarial method is based on empirically established correlations between a set of risk factors, on the one hand, and violent outcome on the other [49]. On the basis of foundational work of Paul Meehl [50], the actuarial method uses set rules (i.e., algorithms, equations) to combine risk factors in order to derive estimates of the risk of future behavior for any given individual [51].

To develop the actuarial measures, researchers attempted to identify the characteristics that could be used to distinguish those individuals who are likely to behave violently in the future from those who were not likely to behave violently [1]. Through this research, a number of potential risk factors were explored and certain risk factors associated with violent behavior were identified. Actuarial measures focused mostly on static, or historical, risk factors and there was a growing consensus that this type of factor was the most strongly predictive of violence [28]. Static factors that demonstrated an association with violence included previous violent behavior [52, 53], psychopathy [54], a history of substance use [55], and young age [56] (for review of risk factors, see [1, 28]).

The results of the second-generation research demonstrated that mental health professionals have some ability to assess risk and make predictions [9]. Contrary to the results from the first-generation research that suggested that mental health professionals successfully predicted future violence in only one of three cases, the results from the second-generation studies suggested that the ability to predict future violence improved to one of every two cases [9]. Further, the new research often demonstrated large statistical effect sizes for the prediction of violence (for reviews, see [28] [57]).

Perhaps, one of the most important developments that occurred with the increased focus on improving dangerousness predictions was the shift in the conceptualization of the task itself [28]. The change in the conceptualization saw the terms *prediction* and *dangerousness* replaced with "risk" and "assessment". Steadman and colleagues [4] explained that the reconceptualization was a result of the emerging public health perspective that viewed violence as a threat to the health of society, rather than merely as a discrete event. The public health perspective, it was argued, would be better able to balance the rights of mentally ill persons not to be unfairly detained, while at the same time protecting the rights of society to not be victims of violence [4].

A number of conceptual differences between predicting dangerousness and risk assessment have been described. First, the term *dangerousness* itself was criticized as being vague and not able to delineate what the danger is or for whom the danger exists [58]. In contrast, the terms *risk* and *risk assessment* are viewed as terms that acknowledge the multifaceted nature of violence by giving consideration to the type of violence, the population at risk, possible contextual inhibitors or disinhibitors, and the type of harm [1]. Further, risk is not viewed as a stable disposition as dangerousness was. Instead, risk should be seen as a continuous probability statement that can fluctuate over time [4]. It is a state of potential, and an assessment of risk is an estimate of how likely that state of potential is to materialize.

A prediction of dangerousness or violence, on the other hand, was a definitive statement about the future. As such, estimates of risk should take the form of ongoing assessments of a potentially changing state of potential, as opposed to the one-time predictions of dangerousness of the past. Finally, the purpose of a risk assessment is not violence *prediction*. Mental health professionals are asked to conduct risk assessments for the purpose of managing risk and violence *prevention* [58], even if it means that prevention takes the form of incarceration as opposed to treatment. With this goal in mind, risk assessment research has now moved into the third generation.

Although there is general agreement that an actuarial approach improves consistency and validity of group-based predictions beyond that of unstructured clinical prediction, commentators have noted several shortcomings of a purely actuarial approach [58–60]. First, actuarial prediction approaches tend to overoptimize predictive accuracy. Many, though not all, actuarial devices were developed in single samples, and not subjected to cross-validation. Upon cross-validation, there is often attenuation in observed accuracy. Second, and relatedly, actuarial devices that were developed within specific settings cannot be assumed to generalize to novel settings, in that their predictive properties depend to some extent on the nature of the development sample. Third, many actuarial instruments focus upon static risk factors that are less sensitive to change than dynamic risk factors [61]. As such, they have limited utility to the fundamental task of risk reduction and management.

Finally, it is not clear that an actuarial prediction, which is derived from the behavior of groups of individuals, necessarily applies at the individual level. That is, if 60% of a group of offenders in Category *X* of Risk Measure *Y* are violent, this does not mean that any subsequent individual who scores in Category *X* has a 60% chance of future violence. As Hart *et al.* [60] have argued and illustrated, such attempts at precise numerical prediction at the individual, as opposed to group, level are highly prone to error.

In response to these problems, another structured risk assessment model was developed, termed *Structured Professional Judgment* (*SPJ*) [58, 59, 62]. Like actuarial approaches, it includes risk factors with empirical support, but SPJ instruments select risk factors based on a thorough review of the literature, rather than performance in single studies, with the goal of enhancing generalizability across samples and applications. Similarly, SPJ instruments have a set of operationally defined risk factors in order to enhance reliability. Unlike actuarial approaches, SPJ instruments strive for comprehensive domain coverage in terms of risk factors, rather than relying solely upon

the set of risk factors that emerge from a single development study.

A major difference between SPJ and actuarial approaches is that SPJ approaches do not involve strict algorithmic decision making. That is, there are no numeric cutoffs, or risk categories based on a person's score on an instrument, that determine decisions about risk. Although, as its name suggests, SPJ measures provide structure to the decision-making process, they do not adopt algorithms for several reasons: (i) as mentioned, algorithms derived in a given sample often degrade in predictive accuracy when applied to new samples; (ii) though algorithms promote consistency, they may diminish individual relevance, in that the assumption is that the algorithm applies in the same manner to all persons (i.e., assumes that all risk factors are of equal relevance for all people); (iii) algorithmic procedures presume a fixed future – they cannot take ebbs and flows in future circumstances into account; and (iv) cases in which only a few risk factors are present, but those risk factors are highly salient for a given individual, tend to result in "low risk" classifications, even if individual risk is high.

SPJ approaches rely both on nomothetic data and individual relevance. Concerning the former, they include operationally defined risk factors with support in the scientific literature. Concerning the latter, their clinical assessment protocols encourage evaluators to give due attention to how these nomothetically supported risk factors apply in the given case. That is, rather than simply noting that a person has substance abuse problems, SPJ approaches then require evaluators to consider (i) the way in which substance use has manifested for the given individual and (ii) the extent to which substance use appears critically tied to the violent behavior of an individual.

Critics of the SPJ approach [63] have argued that it lowers reliability and validity through the allowance of discretion at the variable integration phase of decision making. Though this is a controversial aspect of SPJ, research to date suggests that the reliability and predictive validity of the SPJ approach are at least comparable to that of the actuarial approach, and in some studies, exceed it [64–66]. There are two main types of validity analysis that are important within the SPJ context: (i) do the risk factors, as defined within the given SPJ instrument, relate to violence? and (ii) do the judgments of low, moderate, and high risk – based on a consideration of the presence and relevance of risk factors present in a given case, and the anticipated intensity of risk management strategies necessary to reduce risk – relate to violence?

In an illustrative example of whether SPJ-defined risk factors relate to violence, Douglas, Ogloff, Nicholls, and Grant [67] followed 193 civil psychiatric patients after release from psychiatric hospitalization. In an average two-year follow-up, risk factor scores on the SPJ instrument under investigation (the HCR-20, [62]) were strongly related to violence, with an area under the curve (AUC) of 0.80 for violence leading to criminal conviction. Similarly, those who scored above the median of the HCR-20 were 13 times more likely to record a criminal conviction for a violent offense than those who scored below the median score of the HCR-20. Concerning the issue of whether judgments of low, moderate, or high risk, predict violence, de Vogel and de Ruiter [68] reported that even with the numeric (actuarial) HCR-20 scores in a predictive model, the ratings of low, moderate, and high risk improved upon their predictive accuracy. Although there are exceptions, these studies are typical of findings on SPJ risk assessment instrument (i.e., that their risk factors predict violence, and that judgments of low, moderate, and high risk predict violence as well or better than numeric prediction (see Douglas, Guy, & Weir [69], for an annotated bibliography).

In conclusion, the concept of "dangerousness" has evolved substantially over the past 40 years, when it first occupied a central stage in forensic mental health. Credible studies no longer lump all persons with mental disorder into a single gross category. Meaningful predictions are not offered in simple "yes" or "no" terms. Contemporary research on "dangerousness" – now known as risk assessment and management – attempts to fuse the vast literature on what is known about violence risk factors with principled and structured decision making. Most recently, risk assessment approaches attempt to integrate the concept of violence risk management, with the goal of reducing violence. Future research should continue in this tradition and incorporate even more attention to the concept of risk reduction, since there is little point in predicting violence if we do not attempt to prevent it (see Hart [58]).

End Notes

[a.] It should be noted that the designation "dangerous offender" is not strictly for sexual offenders. Violent offenders can be designated as DOs as well [30]. However, most people who are designated DOs are in fact sexual offenders.

Databases

Introduction

Typically forensic DNA databases consist of two separate collections of profiles: a database of the profiles of individuals who have either volunteered or been compelled to submit samples, and a database of profiles obtained from samples from crime scenes or from exhibits associated with an alleged offense (Figure 1). The administrator of a database typically has capacity to compare profiles from

1. individuals to individuals;
2. crime samples to individuals; and
3. crime samples to other crime samples.

The overall database comprises (at least) two separate indices. One contains the DNA profiles from individuals, whereas the other stores DNA profiles from crimes. These separate databases can be matched internally (as depicted by arrows (a) and (c) in Figure 1). These matches seek to locate duplicate entries on the "offender database" or crimes with a common DNA profile, respectively. The databases are also matched against each other (as depicted by arrow (b) in Figure 1). This is often regarded as the most informative match process, as it links individuals on the "offender database" with profiles associated with crimes.

In a relatively short period, the growth of DNA databases internationally has been rapid with tens of millions of short tandem repeat (STR) profiles now held from convicted offenders, suspects, and unsolved crimes. Links provided through DNA database searches have contributed valuable intelligence to literally millions of criminal investigations. Often links are provided for crimes which are notoriously difficult to resolve, such as property crime (such as burglary and vehicle theft) and historic unsolved crimes (commonly referred to as "cold cases"). The global scale of DNA database use, its relative infancy, the complexity of addressing requisite socio-legal concerns, and the expanding capability of forensic DNA profiling combine to create a challenging law enforcement tool that demands careful assessment and management. This section introduces the emergence of forensic DNA databases in more detail and isolates aspects of their development for more detailed consideration.

A Brief Summary of National DNA Database Programs

Over the past decade, the establishment of a forensic DNA database has been a focal point of development for police and forensic agencies. There has been wide acceptance of the concept, and large-scale DNA

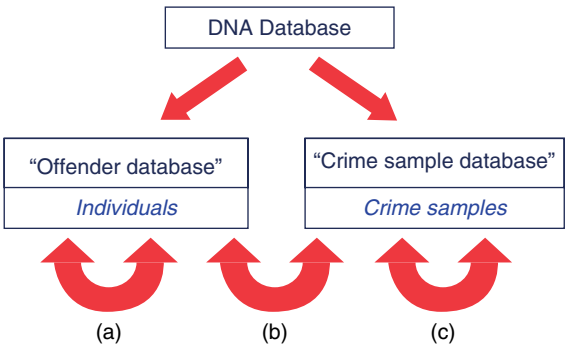

Figure 1 Summary of functionality of a standard DNA database system

database operations now exist in most developed countries.

As the initial National DNA Database, the United Kingdom has benefited from a broad legislative regime and consistent funding and has grown remarkably since 1995. The UK National DNA Database (NDNAD) now contains over 4 400 000 person profiles (as at October 2008) and over 350 000 crime profiles, and has contributed investigative links in over 750 000 cases. National DNA databases also exist in 27 European Union countries: Austria, Belgium, Croatia, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Hungary, The Netherlands, Norway, Portugal, Slovenia, Spain, Sweden, Switzerland, and Ukraine (data provided by European Network of Forensic Science Institutes (ENFSI), see http://www.enfsi.eu/). By late 2007, there were over 1 500 000 million person profiles and 350 000 crime profiles on European databases. These had led to over 200 000 links involving previously unsolved crimes.

In 1989 the Federal Bureau of Investigation (FBI) launched the Combined Offender DNA Index System (CODIS) as a pilot program. This was fortified in 1994 with the creation of the *DNA Identification Act*. The technology was standardized to a panel of 13 STR loci (known colloquially as the CODIS loci). All 50 states have enacted legislation to establish a State Index, and once uploaded at the State level, the data are combined at the National level through CODIS. In August 2008, there were over 6 200 000 individual profiles and 233 000 crime profiles on CODIS. There have been more than 74 000 investigations aided through CODIS over its 10-year history. The information management system that operates CODIS is made freely available by the FBI and has been adopted in at least 27 countries.

The Canadian Government committed to DNA databasing by introducing the *DNA Identification Act in 1998*, and implementing the national database in June 2000. The National DNA Database of Canada has shown consistent growth over its eight-year history. Currently (August 2008) the National DNA Database holds over 143 000 person profiles and 43 000 crime profiles and has contributed links to over 11 500 previously unsolved crimes.

China recently established a National DNA Database program that grew from 28 000 in 2005 to over 1 500 000 by 2008. Profiles are contributed by over 200 laboratories including Hong Kong, which itself has over 20 000 profiles on a database that was established in 2001. Japan began DNA database operations in December 2004 and each province is equipped for standardized DNA analysis. Singapore has over 10 000 profiles on a successful National system. Smaller, more restrictive national database programs exists in Korea and Taiwan but other major Asian countries such as Malaysia, Thailand, and Indonesia currently have no National DNA database system. There is no National DNA database in India, although mechanisms to develop one are underway. A draft Bill was released in February 2006 advocating the sharing of State data at the national level.

Australia is a federation of six States and two Territories. Each has implemented a DNA database, with the first (Victoria) beginning in 1997. Because of difficulties, harmonizing laws data was only combined onto a National system in 2007. The National Criminal identification DNA Database (NCIDD) is managed by the Federal agency CrimTrac and now

holds over 315 000 person profiles and 110 000 crime profiles. Since linking the databases, there have been over 9000 interstate links. The New Zealand National DNA database began in 1995 as the second national database in the world. In global terms, it remains small with over 75 000 person samples and 18 000 crime profiles but it contains profiles from 2.1% of the New Zealand population which is a higher proportion than countries such as the United States (1.7%) and Canada (0.5%) but lower than the United Kingdom (7.0%). The New Zealand DNA database has a high crime-to-person hit rate (almost 60% of crimes loaded) and has contributed over 10 500 links to unsolved investigations.

There are major initiatives to develop the capacity for DNA profiling and database use in Africa. Botswana established a DNA database in 2002. A DNA Project underway in the Republic of South Africa has seen over 80 000 profiles loaded on the Republic of South Africa database. A Bill was proposed in 2004 to allow the construction of a DNA database in Israel, although operations are yet to commence. Moves are also underway to unify database operations across the United Arab Emirates.

An appealing aspect of forensic DNA technology has always been the potential for the standardized STR outputs to be shared widely by police and/or forensic agencies. While this widespread international exchange has yet to be reached, the recent heightened awareness around the threat of transnational crime and terrorism has precipitated significant early steps toward the formation of international DNA database capabilities. In Europe, the Council of the European Union released the first resolution covering the exchange of DNA analysis results in 1997. The resolution called on Member States to consider establishing their own national DNA databases and to agree common standards for DNA profiling to facilitate the exchange of data. This approach was acknowledged as an important tool for investigating and combating cross-border crime. Work on agreeing common standards for DNA profiling was being advanced under the umbrella of the ENFSI. The Prüm Treaty, signed by Belgium, Germany, France, Luxembourg, the Netherlands, Austria, and Spain in March 2006, provides for enhanced cross-border cooperation of the police and judicial authorities. The signatories agreed to give one another access to their DNA and fingerprint files using a *hit/no hit* system. This approach creates a necessary distinction between databasing and speculative searching of DNA profiles between states and the preferred process of exchanging specific profiles during serious international investigations.

An example of bona fide international databasing is the Interpol DNA Database, set up by the Interpol General Secretariat in 2003. The database (or Gateway) provides a resource through which Interpol's member countries can exchange and compare DNA profile data. Access to the Interpol database (by what are termed "beneficiaries" or "users") is allowable only following a written undertaking. Existing users can also object to any new beneficiary being granted access. The submitting countries retain ownership of the profiles and have direct control of submission, access, and deletion, in accordance with (their own) national legislation. Once a match occurs and the submitting country has been notified, then that country can communicate or request additional material to or from another country, subject to restrictions imposed by that country. This framework is aimed at meeting understandable concerns about privacy of, and control of, profiles once they leave national borders.

To date, wholesale contributions to the Interpol Database have been limited to a few countries. Presumably, this is due to the realization that for most crime types there is limited intelligence value in exporting large quantities of DNA profiles for international searching. By September 2006 Interpol's DNA database held just over 60 000 profiles from 39 countries and had produced 95 hits. Several of the successes have involved multiple crimes, some of them most serious, over multiple countries. Given that in all cases the act of searching involved only adding a profile already collected and analyzed, each of these instances of success must be seen as adding quite significant value toward achieving an otherwise improbable identification.

From the selected countries mentioned in the above summary alone, there are now over 15 000 000 profiles held on National DNA database systems around the world. Collectively they have contributed links to over 1.1 million unsolved crimes. This represents the product of considerable investment from national governments and the police and forensic agencies responsible for law enforcement in these territories. Although, while this progress is impressive, DNA database operations are still relatively recent

additions to the criminal justice system and the principal focus to date has been on their establishment and growth. It is important that we also examine the operational and socio-legal impact the databases have had on the criminal justice system and how we can learn from experiences to date and ensure that continued positive outcomes will flow from their future use.

Operational Impact of Forensic DNA Databases

As the technology that forms the basis for DNA intelligence databases is specialized, the operational components have remained the responsibility of forensic biology laboratories. In general, the database and its products are the property of law enforcement agencies with the analytical and matching processes administered on their behalf by forensic institutions. All aspects of the process, whether handled by police or scientists, are subject to governing legislation. Often this legislation contains clauses that facilitate external review of operations by delegated parliamentary authorities. From a forensic scientist's perspective, the legal basis for the administration of DNA databases represents an additional level of governance over their work. DNA laws typically contain sections that prescribe the appropriate conditions under which a DNA sample can be collected, analyzed, and stored, and the criminal sanctions that are enforceable for individuals in breach of these requirements. Although not possible to itemize all the various offense categories here, they generally include intentionally or recklessly supplying forensic material for analysis, improperly accessing or disseminating information stored on the DNA database, and matching profiles on the database unlawfully. Penalties can include fines and/or prison sentences.

In a practical context, the impact of the operational management of forensic DNA databases has had a much more profound effect on forensic organizations than the need to adjust processes to adhere to the governing legislation. The snapshot of global database models provided above illustrates that a unifying trend in major jurisdictions has been a steady increase in the scale of database operations. While this has occurred in concert with increasingly broad legislative regimes, it is more likely to have been a critical impetus for iterative legislative expansion.

The workload generated through DNA database operations has compelled forensic laboratories to find efficiency gains in the analytical process. The workload generated through DNA database operations has been a major burden on forensic DNA providers. Many have simply not coped with the volume of submissions and have experienced considerable backlogs and case processing delays. In the United States, in 2003, there were over 540 000 unsolved homicide, rape, and property crime cases in the hands of police or forensic agencies awaiting DNA testing [1]. Considerable resources have been directed toward this issue by the US Government (USDoJ, 2003) [2], the National Institute of Justice, and the American Society of Crime Laboratory Directors (ASCLD) [3], but the issue remains an intractable one and one that commonly effects major forensic organizations.

This circumstance has compelled forensic laboratories to find efficiency gains in the analytical process and has resulted in a vastly different model of case management. Historically, police and forensic scientists have had a focus on clearing one crime at a time. Cases were submitted to the forensic laboratory after considerable investigation had occurred and, in most cases, a suspect had been identified. The role of the scientist was to process these cases and determine whether there was evidence that could assist either the prosecution or defense of that specific crime. Occasionally, there were cases where the forensic analysis contributed vital investigative information that assisted the location and arrest of a suspect. The broad utilization of DNA technology and, in particular, the advent of DNA databasing has seen this paradigm change. Essentially, the analysis of evidence items occurs earlier in the investigative process with the hope that the scientist can produce intelligence information (such as a database link) in crimes for which no suspect has been identified through other means. The increased volume of submissions has also seen a trend away from individual case management and toward batch processing. It has also led to a greater prevalence of automated laboratory techniques that seek to achieve high-throughput analysis without extensive human involvement at all.

The combination of high analytical demand and the considerable funding associated with forensic DNA analysis has created an opportunity for commercial genetic testing providers to enter the forensic *market*. This is a common feature of the US and UK landscapes. "Forensic" samples (exhibits relating to the alleged offense) typically remain the responsibility of the *crime lab*, but private companies are

contracted to analyze *offender samples* on behalf of the State.

Another trend associated with the emergence of DNA database operations has been the broadening range of crimes submitted to forensic biology laboratories for analysis. In the 1980s, DNA profiling was primarily used to solve serious crimes. It now contributes to the investigation of a broad spectrum of crimes, including property offenses such as burglary. The variation in jurisdictional, legislative, and operational frameworks can impact the case submission profile; for example, certain countries in Europe initially focused on the investigation of serious violent and sexual offenses [4]. In general, there has been a clear pattern of decrease in the proportion of cases from serious crime categories and an increase in the proportion of cases submitted from volume crime categories [5]. Data from the New South Wales state laboratory in Australia demonstrates a significant decrease in proportional levels of sexual assault (53.0–8.0%), murder and manslaughter (8.7–1.0%), malicious wounding (8.9–2.9%), and attempt to murder (3.6–0.3%) submissions between 1998 and 2005 (database operations began in 2001). The case categories where there was a significant increase in proportional submissions include break, enter, and steal (2.7–37.8%); stolen vehicle (0.0–15.6%); robbery (6.3–12.8%); stolen from vehicle (0.0–4.9%); and malicious damage (0.0–3.3%) [5]. In all categories the most significant change in the case submission profile occurred after 2001, indicating that the profile of casework received by the laboratory has changed since the beginning of DNA database operations.

The changing nature of case submissions, represented above, has also been accompanied by an associated change in the type of exhibit located, and hence the type of sample(s) presented for DNA analysis. For example, serious, violent crimes would be expected to result in injuries and bleeding from those associated and therefore a higher likelihood of receiving blood as the principal evidence type. Likewise, crimes of a sexual nature predominantly involve a male offender and hence will typically be associated with semen evidence. Property crimes and drug crimes are less simple to classify in this way and are not thought to be strongly associated with a characteristic evidence (or sample) type. A general trend, however, is that these types of incidents often result in the submission of more discrete evidence types, such as cigarette butts, drinking containers, food remnants, tools or swabs from surfaces, or objects that the offenders are believed to have touched or handled (commonly referred to as "trace DNA") [6].

Investigative and Intelligence Use of Forensic DNA Databases

As mentioned earlier, the establishment of forensic DNA databases has been a contributor to a change in thinking within forensic science. Historically, each case was processed as a unit or perhaps as a small series. The analyst adopted a *cradle-to-grave* approach and usually sought to refute or corroborate the version(s) of events suggested during either the investigation or trial. Typically, a suspect had been identified through other means and the forensic analysis was comparative rather than suggestive.

This model has changed significantly. Forensic DNA databases have catalyzed profound changes in the volume and profile of forensic case submissions, meaning that with the exception of certain serious crimes, the focus has shifted to a batch-processing model within which the DNA database is an embedded component and where all cases and individual samples are viewed as potentially linked. At an organizational level, the critical objective is efficiency: maximizing the processing capacity in the minimal time and with the minimal associated expense. These objectives have typically been set and driven by police users as they align best with their investigative priorities.

The ability to link cases and identify a crime series has been an effective strategy in law enforcement for some time [7]. Incorporating DNA outcomes into the existing array of investigative data provides an additional mechanism to link cases committed by the same individual or organization, adding also a highly discriminating mechanism for identification. Through the ability to provide technical information capable of directing police investigations (such as by identifying a suspect or a crime-to-crime link), DNA databases are able to operate as an intelligence tool. Another important investigative feature of DNA databases is their ability to transcend jurisdictional boundaries, which may have hampered abilities of law enforcement agencies to link crimes and offenders which transcend such boundaries. This is particularly true in large countries, for example, the United States,

Canada, and Australia, where states or provinces have the responsibility for law enforcement within particular physical and legislative boundaries. This more proactive use of forensic DNA outcomes also presents opportunities for more integrated and intuitive use of the technology. Achieving this relies upon a complete understanding of the nature and scope of the investigative contribution that forensic DNA profiling can make, presently and in the future.

The amalgamation of DNA profile data from numerous crimes also provides a means to examine forensic outcomes holistically for tactical or operational intelligence. The cases and crime information residing on forensic DNA databases (and indeed other forensic holdings) contain vast records of links made through scientific analyses, covering an amalgamation of crime types and localities that often remain separate in police investigative and intelligence structures. Analyzed collectively, database outcomes also offer significant value to fields such as criminology. A future step in the use of forensic DNA databases could be to extend the operational success of DNA databases to allow greater analysis of trends in criminal behavior. This could lead to proactive policing strategies that are based on a contemporary understanding of criminality.

Familial Searching

Recently, DNA databases have been utilized to assess profiles that are returned after a search with a high level of allele sharing. This is due to the increased likelihood that such a result would be returned from a person related to the donor of the comparison profile, than from an unrelated, random individual. This application of the use of forensic DNA databases is known as *familial searching* and was pioneered by the UK Forensic Science Service (FSS) as a legitimate investigative use of the UK NDNAD. These searches produce leads that are refined through combination with other investigative information such as geography, age of the donor, Y-chromosome testing, and so on.

Familial searching was first applied by the FSS in 2002 in the case of serial murder of three women in South Wales, which had occurred in 1973. A DNA profile taken from crime scene evidence was used for comparison and provided investigators with a familial match to Paul Kappen. Police investigation then led them to his father, Joseph Kappen, who was identified as the rapist and murderer of the three women.

While there have been celebrated examples of success from cases of familial searching, a degree of challenge and adverse commentary has begun to surface. For example, concerns have been raised that minority groups will be unfairly targeted when from a sweep of partial matches, as these groups are overrepresented in convicted offender databanks. Other opponents to this technique claim that law enforcement will waste time and resources following up on a variety of leads, many of which may be false and have no bearing on the case. However, when investigating a crime, a variety of leads must be considered and pursued; some will have merit and others will not. Through this technique forensic science has the potential to generate leads for investigative consideration, some of which return results of great significance.

Cold Case Review and Postconviction Testing

Forensic DNA testing and state and national databases have been used retrospectively to reexamine evidence from historic, unsolved offenses originating as far back as the 1970s. In some circumstances, this analysis has not only identified a suspect for the crime in question but has proven the innocence of an already incarcerated person. In America, through the New York Innocence Project (http://www.innocenceproject.org/) based at the Cardozo School of Law, New York, 217 persons have been exonerated (as on June 1, 2008) following DNA testing of exhibits related to their original convictions. Collectively, these men have served over 2500 years in prison for crimes that they never committed, with the average jail term being in excess of 12 years. In 16 cases, the death penalty had been imposed before an individual's innocence was proved. About 70% of those exonerated were members of minority groups. Additionally, in over 35% of cases involving postconviction DNA exoneration, the true perpetrator was also correctly identified through the use of DNA testing.

As of July 2007, 42 states of the United States had some form of law permitting inmates' access to DNA testing. The remaining eight states had no law granting such access (National Conference of State Legislatures). The legislative models vary in

the extent of provisions they afford to inmates seeking DNA retesting. In some states, all incarcerated felons are granted access to postconviction DNA testing with the associated costs borne by state authorities. In others, there are restrictions on the eligibility of certain inmates: for example, those who pleaded guilty or whose lawyers failed to request DNA testing at trial. In some models there are time limits on when an application can be made, and the petitioning inmate must meet the cost of reanalysis. As with all laws, there is a need to strike a balance, in this case between the rights of incarcerated felons to have their convictions reviewed, and the potential for misuse of state resources and the protracted continuation of criminal matters.

The revelations of programs such as the innocence project provide an example of the potential for DNA testing to uncover the truth – whether it does so on the "side" of the victim or their wrongly convicted attacker. However, it is important that we also remember that DNA is simply another example of forensic evidence. While it allows a high level of certainty regarding its conclusions, it is not infallible and does not have the same effect when used in a stand-alone capacity, in the absence of support from investigative outcomes or other forensic evidence. Also, obtaining meaningful DNA evidence relies on the accurate localization of biological material at the crime scene and the demonstration of appropriate chain of custody and procedural handling of the subsequent analysis. Operating in this way is commonplace in contemporary investigations; however; it is less assured in historic investigations, and in some cases the lower level of rigor applied through outdated practices can jeopardize the usefulness or admissibility of forensic evidence recovered later using contemporary techniques.

For postconviction testing to be of future use, it is incumbent that all relevant evidence be collected and stored appropriately so as to allow for subsequent reanalysis. Again, it is necessary to strike a balance between collecting and storing everything indefinitely and destroying vital items of evidence too hurriedly. This is another area to be considered in postconviction legislative models and in best-practice policies and procedures for police and forensic agencies.

The realization of the ability of a "new" technology such as DNA analysis to provide greater clarity and certainty in historic investigations tells us something else about our field of science. That is, that we should continue to strive to adapt and develop our technical capability. The impressive outcomes of postconviction use of DNA testing provide a stark reminder of how the technologies of tomorrow may well provide the ability to reflect with more clarity and certainty on cases occurring today.

Socio-Legal Issues Associated with Forensic DNA Databases

It is important to remember that although DNA profiling is arguably the most powerful and rapidly developing forensic investigative tool, its use is not without controversy. This is due largely to its enormous potential to implicate individuals in a crime and the risk of its deliberate or accidental misuse. The present and future uses of forensic DNA profiling are a worrying prospect for some members of the international criminal justice community and for members of the public as well.

Almost ubiquitously, the establishment of DNA databases on a state or national level has required substantial changes in legislation. There is considerable variation in the legislative models applied in different jurisdictions. Initially, offenders convicted of serious violent or sexual crimes were seen as the most suitable candidates for DNA database inclusion. Over time, the gambit of offenses for which a compulsory DNA sample can be obtained has increased to include property crimes and, in some places, summary offenses. In addition, the need for an individual to be convicted is no longer mandatory in many jurisdictions, and individuals can be sampled upon suspicion or arrest. In all cases, the legislation seeks to strike a balance between the desire for the state to develop and utilize a significant forensic resource for the purpose of more effective crime resolution and reduction, and the rights of individuals exposed to the criminal justice system.

Legislative amendments of the type that lead to the establishment of forensic DNA databases nature are destined to be controversial. In some cases, observers feel that these new laws have been enacted too hastily, have lacked suitable public and legal scrutiny, and have been justified under misleading, populist "law and order" politicking. Others worry that extending police powers to allow the collection of DNA samples represents an encroachment into the previously sacred territory of criminal law and

a diminution of basic individual rights, in particular the right to silence and the right against self-incrimination. Other observers are concerned by the storage of human genetic information and its potential for future misuse.

Forensic scientists utilizing forensic DNA databases have an increased need for awareness of relevant socio-legal issues. In a practical context, DNA-based legislation represents an additional level of governance for forensic professionals and one of the first pieces of law that places direct requirements on the manner in which they undertake their professional work. In addition, it prescribes sanctions for individuals or institutions who contravene the administrative processes detailed in these laws. The debate that has continued on many of the issues associated with the use of forensic DNA profiling in the criminal justice system has expanded to encompass applications of the scientific process that are primarily the responsibility of the forensic community. Forensic professionals (and particularly the administrators of forensic institutions) must acquaint themselves with these issues and enter the existing debate. Failure to do so could mean that the direction for the application of our scientific tools will become the responsibility of people from outside the forensic community itself.

Summary

Despite the rather spectacular results that have emerged from the use of forensic DNA databases, the technology remains a relatively recent development and one that will continue to develop over time. It is important to remember that as databases grow and age, they will become more challenging to manage, as much of the information stored on them will become increasingly redundant. It is important that forensic practitioners and administrators continue to research and refine DNA database applications to ensure they continue to have an effective, positive impact.

Dating: Document

Introduction

In questioned document examinations, the age of a document is often an important criterion to determine authenticity or highlight fraud. The following questions are therefore frequently asked to the expert: Was a receipt actually produced at the mentioned date? Was a contract signed at the same time by the involved stakeholders? Was a paragraph added several years after the establishment of a testament? To answer these questions, it is necessary to determine the date at which a document was written or printed.

The time frame may be a few months or several years. As a result, many forensic scientists investigated the issue of dating documents. Every book about document analysis has a chapter or paragraph about dating methods [1–8]. The dating can focus on different aspects of questioned documents. Whereas dating through paper, toner, or handwriting examinations is less considered in the literature, the potential of inks has been more particularly studied and many methods have been proposed so far [9–35]. Several reviews have been published on the topic over the last 30 years [36–45]. Although a number of laboratories apply ink dating in caseworks, the method raises a large amount of controversy and debates among the scientific community [39, 45–61].

The objective of this contribution is to give a comprehensive overview on the dating of questioned documents, and more particularly their ink. In the first part, three fundamental approaches to dating are presented with examples of dating methods. This article also introduces the problematic of method validation and interpretation of dating evidence.

Dating Principles

Three fundamental approaches can be defined and formalized [62] (Figure 1). The first, often called the "*static approach*" [41], focuses on the production date of documents raw constituents and their introduction on the market. The second, addressed as the "dynamic approach" [42], is based on aging processes of documents. The third approach aims at reconstructing the chronology among documents or ink entries by ordering them in sequence. Differentiation between "absolute" and "relative" age of documents is usually made in the literature [15, 16, 18, 46, 50,

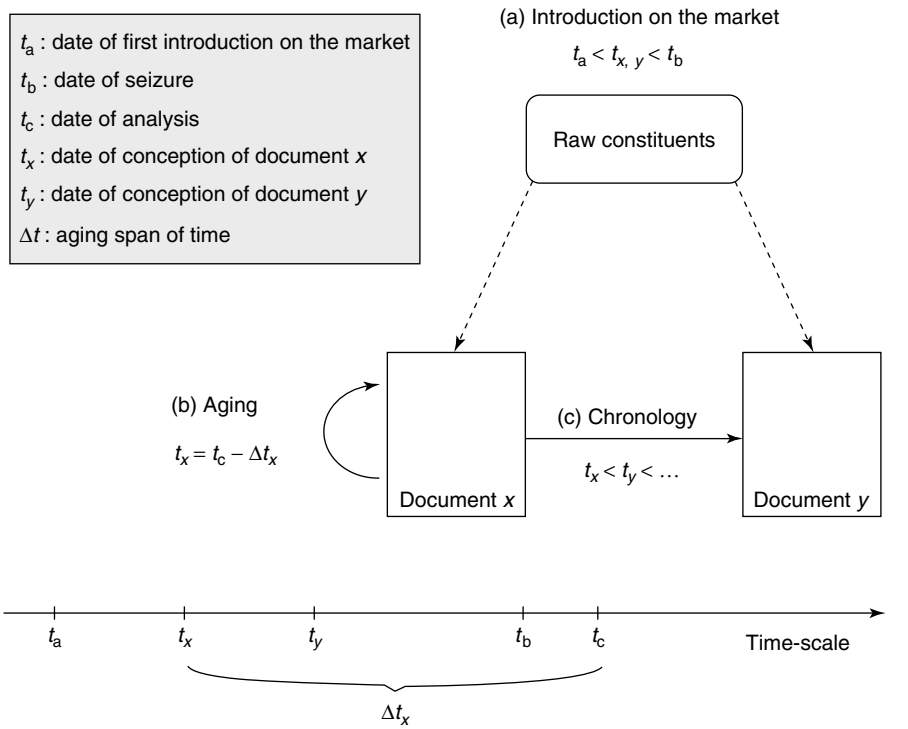

Figure 1 Age determination of questioned documents relies on (a) the date of introduction of raw constituents on the market, (b) aging of ink since document conception, and (c) reconstruction of the chronology of document conceptions. The date of first introduction of the market (t_a), the date of seizure (t_b), the date or analysis (t_c) and the aging time span (Δt) are known and/or yielded by the investigation. These pieces of information then help answer the question about the conception time of the documents (t_x and t_y)

52]. Determining the relative age of a document compared to others is equivalent to reconstructing their chronology.

Introduction on the Market

An estimation of the age of documents can be based on the analysis of stable compounds, found in the paper, ink, or toner, that are specific to a certain period in time. Fabrication properties change and evolve with time as a function of new industrial developments and progress. For example, ballpoint pens appeared on the market in 1944 and were characterized by oil-based inks up to 1951, when glycols solvents were introduced in their ink composition [63, 64]. Fluorescent brighteners have been introduced in paper composition in the 1950s [65]. Copper phthalocyanine dyes and pigments were introduced in 1954 in blue ink for their good light stability. Gel pens were first found in Japan in 1986 [66]. This approach is generally called "*static*" in the literature because the measured parameters are invariable in time. It allows the determination of the first possible date of existence for a given composition of ink, paper, or toner found on a questioned document. Incoherencies and anachronisms can be highlighted, as was the case for the paper analysis of Hitler's diaries [65].

The developments mentioned above are quite important and relatively easy to measure, but they occur quite infrequently. Most evolutions in the composition of paper, ink, and toner are less easily detected and are closely guarded industrial secrets. To highlight the date of introduction on the market of minor characteristics, two conditions must be respected:

1. First the determination of the composition must be based on validated and reproducible analytical methods **Ink Analysis** in order to insure that the selected set of parameters does not alter as a function of time (i.e., their aging is negligible).
2. Secondly, it is essential to have access to a comprehensive database containing the selected parameters of all inks, toners, and paper introduced on the market. Ideally this should cover a broad spatial and temporal range.

An alternative method is to introduce chosen markers in the composition that point at the time of introduction on the market. For example, the Bureau of Alcohol, Tobacco, and Firearms (ATF) started a yearly ink tagging program in collaboration with ink manufacturers in the mid-1970s [8, 41, 67]. The objective was to introduce a different tag each year that was easily analyzable. This required close collaboration with ink manufacturers and a constant monitoring of the introduced tags (which should never repeat) and can generate a nonnegligible increase of the ink costs. Some special papers also enclose their date of production in the form of microimpressions or indirectly through specific watermarks [68].

Aging

The second approach is based on measurements of the questioned documents parameters that change as a function of time. Some older methods such as chloride and sulfate ions migration from the ink into the paper [9–12] can no longer be used, as most inks are now free of these ions. Earlier gallotannic inks were also acidic, and caused paper deterioration. Moreover, they contained iron that oxidized, provoking a change of color [1, 2, 13]. The introduction of new composition along the years also meant changes in the aging processes and dating methods.

Paper was studied to a lesser extent than ink [69, **Paper Analysis**], because it starts aging directly after manufacture (or earlier when the tree was felled), and that can be well before the document conception. On the contrary, it is expected that ink does not age in the cartridge [70], but only after it is apposed on paper: dyes fade [13, 15, 16, 19, 22, 71–75], solvents diffuse and evaporate [24–28, 67, 76], and resins polymerize [76–79]. Aging processes of ink follow complex pathways that are considerably influenced by a number of factors other than time, inducing acceleration or quenching of the aging. The influencing factors can be ordered in three main classes [45, 74, 76]: (i) initial composition of the ink (in the cartridge), (ii) physical and chemical properties of the substrate (paper porosity and coatings, etc.), and (iii) storage conditions (temperature, light, air flux, humidity, etc.). In practice, no information on these factors is generally available. This is why the determination of the absolute age of an ink entry remains truly difficult and in most cases impossible. The more important objective is therefore the determination of a time range rather than a precise date. The

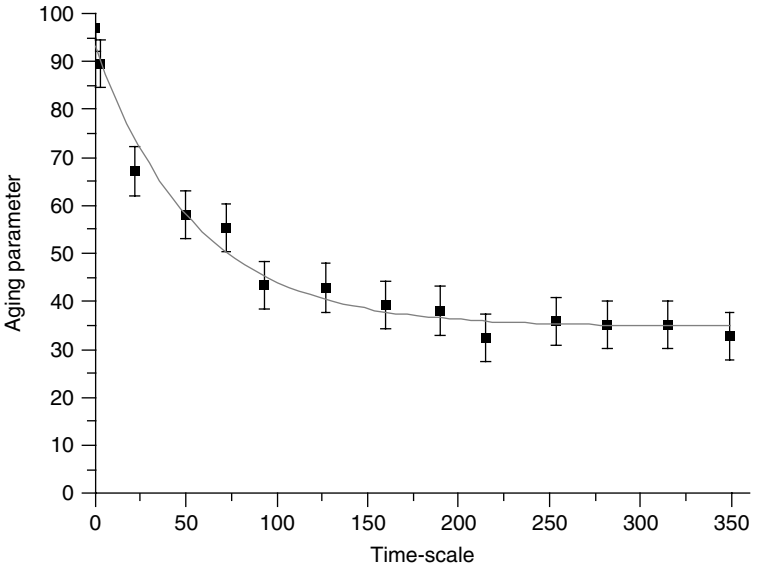

Figure 2 Typical aging curve (exponential decrease of first order): an aging parameter of the ink is plotted as a function of time (for example in seconds, hours, days, or years) [Reproduced with permission from Polymedia Meichtry SA.]

considered scale can significantly vary depending on the measured parameters. Thus, while solvents disappear very quickly from the ink, dyes degradation occurs more slowly over several years. Measured changes are reported as a function of time in order to establish an aging curve (Figure 2).

As fading of dyes is visible to the naked eye, many dating methods based on the aging approach were developed to measure color degradation with time [13, 20, 22, 71, 73]. Unfortunately for forensic scientists, dyes that are unstable in the presence of light do not degrade in the dark, or do so only very slowly [72, 75]. Therefore, dating relying on dye degradation usually is carried out only by comparing ink entries from the same pen that were stored in the same conditions. Unlike reported in [35], the absence of difference in the degradation states of two ink entries does not necessarily mean that they are contemporaneous. In fact, the inks could also have been stored for a significantly different number of years in the absence of light [45].

Lately, interest was revived into a method first proposed in 1985 by Stewart [24], in which evaporation of the volatile components of ink is measured using gas chromatography mass spectrometry (GC/MS) [26–28]. However, after a few months their quantity is generally too low to be reproducible and pertinent, as evaporation and diffusion of solvents happen promptly after ink apposition on the paper [27, 57, 76].

When ink dries, resins polymerize inducing fastening of the ink on paper. Resins are high-molecular-weight molecules, which are present in low quantity in the ink entries. They are therefore very difficult to analyze [77–79]. An indirect way to evaluate their hardening derives from the measurements of ink extractability over time. Observations have shown that generally as ink ages it becomes more difficult to extract. Earlier, changes in the extractability of ink have been investigated by measuring the dissolution rates in acids [4]. Later, sequential extraction of the ink was proposed, in order to eliminate the dependence of the extracted mass (i.e., difference in ink thickness provoked difference in the mass obtained). Thus, two extractions were carried out consecutively, first in the "weak" solvent, then in a "strong" solvent. Then extractions are analyzed to quantify either dyes [15, 16, 21, 23] or solvents [25, 51, 52] in order to calculate an extraction percentage (P). The extracted quantity in the "weak" solvent (M_1) is divided by the total amount extracted in the two solvents ($M_1 + M_2$) in order to obtain the following ratio:

$$P(\%) = \frac{100 \cdot (M_1)}{(M_1 + M_2)} \quad (1)$$

These methods are based on the following hypothesis: a "weak" solvent extracts only the fraction of the ink that is still fresh, while a "strong" solvent extracts the totality of dyes of solvents in the ink entry. Thus, a large P means that the ink is still fresh, while a low P indicates an old ink.

Since then, many authors showed that the measurements based on dyes extraction were not reproducible [39, 47, 48, 51–53, 58]. This is due to the fact that the quantity of dye extracted is dependent not on the capacity of the solvents to extract them, but also on their initial quantity in the ink and their subsequent degradation. It was observed that every ink did require different extraction solvents and their aging curves were significantly divergent. Some inks even showed an inversion of the tendency as a function of their age: their P value increased with time instead of decreasing as was expected [23, 55].

New methods based on sequential extraction of solvents were recently developed [27]. Earlier, Aginsky [25] proposed a method that made use of artificial aging in order to calculate a portion of the aging curve. However, the relevance of artificial aging was also questioned [45, 46, 50].

Chronology

This approach aims to determine the relative age of a document in comparison to others (i.e., to order them in chronological sequence). Different methodologies can be applied, such as the study of latent writings by oblique lighting or electrostatic detection apparatus (ESDA). If latent writings from a document are found on a second document, then the latter was physically placed under the first one during writing. This information may be useful in sequencing the order of writings.

The determination of the sequence of crossing lines proved to be very useful in certain cases [29–33, 45, **Intersecting Lines: Documents**]. It is, however, not always easy to determine optically which line is above the other. Therefore, chemical [45] and spatial techniques [30–33, 79, 80] were developed and proved useful in some cases.

Finally, the comparison of ink aging states may help to reconstruct the sequence of apposition of ink entries on documents [15, 16, 18, 46, 50, 52]. This can only be applied for inks stored in the same conditions on the same type of paper (i.e., diaries). The general evolution of the aging curve must be known (Figure 3). If a diminution is expected, it is imperative to insure the aging parameters never increase whatever the conditions.

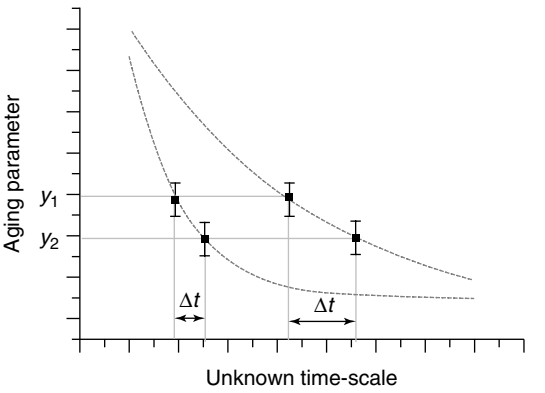

Figure 3 If the aging curve is unknown (dots), the values obtained from two ink entries can be ordered in chronological order at the imperative condition that the general evolution of the curve is known (increase or decrease). Storage conditions, paper type, and ink composition must be the same. Measurement error must be taken into account [Reproduced with permission from Polymedia Meichtry SA.]

Validation

The analytical development of dating methods (Table 1) requires a considerable amount of time and resources. It is therefore important not to underestimate the task of ensuring their scientific validity before implementing them in practice. Some important aspects of analytical reliability were enounced by Horwitz [82]: reproducibility (between laboratories precision), repeatability (within laboratory precision), systematic error or bias (accuracy), selectivity, and limit of reliability. The robustness of the method is also an important factor.

It is of concern that errors are very rarely mentioned in literature and are generally not represented in the figures. It is, however, essential to make certain that predicted differences provoked by aging are in fact higher than measurement errors. Further, the available ink in practical cases is generally not sufficient to repeat analysis several times in order to obtain a mean and a standard deviation [61]. Developments of dating methods are carried out with known

Table 1 Summary of document dating possibilities: relevant application time frame and main limitations of dating methods. All methods must be validated before their implementation

Approach	Time variable	Time frame	Main limitations
(1) Introduction on the market	Tags	1970s – end of project	Limited number of inks with tags
	New developments	Not defined	Secret of fabrication
(2) Aging	Dyes	Months	Unreliable
	Solvents	Weeks	Possible only for a limited number of inks
	Resins	Years	No data
	Paper	Years	Limited to historical document
(3) Chronology			
	Dyes	Months	Same ink and support (e.g., diary)
	Solvents	Weeks	Same ink and support (e.g., diary)
	Line crossings	Years	Aging of the crossings
	Latent writings	Years	Their absence gives no information

ink samples prepared and stored in controlled conditions, and blind testing on realistic samples is therefore imperative. When low quantities are analyzed, such as solvents in ink entries, the detection and quantification limits play an important role to determine a threshold at which the method is not applicable anymore. The most demanding aspect is the interlaboratory validation. In fact, till date most dating methods are used only by one single laboratory. In order to apply dating in casework, the forensic experts should deploy their efforts most particularly in adequate validation of their method [49, 51, 54, 61].

Interpretation

Interpretation of evidence, like in other forensic fields, plays an essential role in the dating of ink and should already be included in method developments. In fact, the question about the age of an ink entry lies perhaps more on the inference of sources rather than on the technological or analytical aspects. Thus, it is important to consider all the possible sources (alternative hypotheses) to allow for a balanced interpretation of the evidence [61].

A Bayesian statistical framework can be applied to assist in reaching an opinion regarding the date of a document. In this case, when one has to look at the probability of the evidence (E) given the ink entry has been made at a time t_1 (hypothesis of the plaintiff, H_p) compared to the probability of this same evidence given the ink entry has been written at a different time t_2 (hypothesis of defense, H_d). Then the prior odds of the hypotheses of the plaintiff H_p and the defense H_d existing before observation of the evidence E are multiplied by a factor called *likelihood ratio* (LR) to obtain the posterior odds that account for the new evidence E. The LR is an indication on the strength of the evidence in supporting one of the hypotheses in Bayesian logic [61, 83]. It is defined by the probability of E given H_p is true divided by the probability of E given H_d is true:

$$LR = \frac{P(E/H_p)}{P(E/H_d)} \tag{2}$$

For example, when comparing two ink entries to determine their relative age, one has to evaluate the probability of obtaining the observed results, if the entries have the same age, and the probability of obtaining these results, if the entries do not have the same age. If the dye compositions of the two ink entries were determined and found to be nondifferentiable, at least three explanations should be taken into account. In fact, the analysis of two ink entries having the same age, the same initial composition, paper, and storage conditions would logically lead to nondifferentiable results. However two inks having different ages, but the same initial composition, on the same paper and stored in the dark, would also lead to nondifferentiable results, because dye fading occurs very slowly in the absence of light [75]. Finally, two inks having different compositions and/or stored in different conditions did sometimes also yield nondifferentiable results [45].

Conclusion

From its beginning, the field of questioned documents has been concerned with dating. Proposed methods usually lean upon complex processes and controversy among the scientific community is still high. Every document dating method, whose objective is to be applied in forensic caseworks, must fulfill validation requirements. Moreover, source inference must also be taken into account in the interpretation of the dating evidence. Till date, most methods still fail to be adequately validated and should be applied with extreme caution. The limitations of the methods used must be adequately disclosed and documented.

Acknowledgments

The author would like to thank all the people who helped to achieve this work, and especially Prof. Bernahrd Spengler of the University of Giessen, Dr. Dieter Kirsch of the Bundeskriminalamt in Wiesbaden and Prof. Pierre Margot of the University of Lausanne.

Daubert v. Merrell Dow Pharmaceuticals

Facts and Issues Summarized

Two infants, one with a surname Daubert, were born with limb-reduction birth defects. Their parents and the infants sued Dow Pharmaceutical Company, the manufacturer of Bendectin, the drug that the plaintiff

mothers took during pregnancy to alleviate morning sickness. The suit claimed that the drug caused the limb reduction. The drug company provided the trial court with 30 studies involving more than 130 000 patients who had used Bendectin. None of the studies had found a statistically significant correlation between use of the drug and birth defects in offspring. The plaintiffs' experts sought to counter with a reanalysis of these studies, in which reanalysis showed a possible link, but the trial court refused to admit this evidence and granted a summary judgment for the pharmaceutical company.

An intermediate appellate court – the Ninth Circuit Court of Appeals – affirmed the trial court's decision to exclude plaintiffs' expert evidence, reasoning that their testimony did not satisfy the *Frye* standard. The *Frye* standard, which had become widely accepted by American state and federal courts, mandated that for novel scientific evidence to be admissible in court, the specialized subject matter had to be generally accepted as reliable in the field to which it belongs (*see* ***Frye v. United States***).[b]

In the *Daubert* case, the relevant science was epidemiology and the appeal's court found that the plaintiffs' expert testimony was not based on published, accepted, and peer-reviewed scientific knowledge in that the plaintiffs' experts' recalculations had indeed been created for the sole purpose of the litigation, and had not been published in peer-reviewed journals (*see* **Federal Rule of Evidence 702**).

On review of this decision, the US Supreme Court had to decide whether the 1923 *Frye* rule of general acceptance had survived the passage of the Federal Rules of Evidence (FRE) (*see* **Federal Rule of Evidence 702**). The Court held that it did not, deciding that proof of reliability of the expert's methodology was to be the sole criterion for its admissibility. The case was remanded for reconsideration by the lower court in light of the Supreme Court's mandate.

Upon remand, the Ninth Circuit Court applied the "reliability" criterion and again granted summary judgment for the defendant, finding that the plaintiffs' expert testimony that had failed to satisfy *Frye* had also failed to meet the *Daubert* standard.[c]

Discussion of the *Daubert* Opinion

The Court's primary holding in *Daubert* was that the 1975-promulgated FRE superseded *Frye*'s requirements of general acceptance in federal civil and criminal trials.

The decision also explained how Rule 702 was to be interpreted. *Daubert* held that the trial court's gatekeeping function requires proof of reliability of the methodology used by experts in arriving at their opinions. *Frye* had cast the function of determining whether an expert's testimony was "demonstrable" on the scientific community by requiring proof of its general acceptance by the field in which it belonged.

Daubert, by contrast, assigned the role of determining reliability of the testimony, as well as its relevance to the issues, to be decided to the trial judge. Although Rule 702 is applicable to a broad range of expert testimony other than that presented by scientists (*see* **Federal Rule of Evidence 702**), the *Daubert* decision dealt only with scientific expert testimony because that was the nature of the case at hand[d] (*see* ***Kumho Tire v. Carmichael***).

The Court stated that the trial judge must determine at the outset whether a qualified expert is proposing to testify to (i) scientific knowledge that (ii) will assist the trier of fact to understand or determine a fact in issue.

In determining reliability, by which the Court must have meant "reproducibility", *Daubert* cautioned that the trial courts must evaluate whether the expert's methodology was likely to lead to replicable (reproducible) results. The inquiry was to focus on the methodology used, and not on whether the conclusion reached by the expert in the particular case was accurate.

To guide the courts in this effort, the Supreme Court suggested several factors for courts to use in assessing the reliability of proffered scientific evidence, though the Court was at pains to stress that these factors were not to be considered litmus tests. Indeed, trial judges were recognized to have a wide range of discretion in the admissibility decision and were to use a "flexible" approach for determining whether a results of a particular technique were reproducible and trustworthy.[e]

The Daubert Factors Explained

The four suggested *Daubert* factors are as follows:

1. Whether the relevant science can be and has been tested by a scientific method

This was said to mean that the theory on which the science relies has been empirically tested. A

hypothesis is conjectured upon scientific principles, investigated with observed data, and determined to be false or true. The Court cited Karl Popper's criterion for the scientific status of a theory or methodology to be its *falsifiability, refutability*, or *testability* (*see* **Falsifiability Theory**) [4].

2. Whether the underlying theory, technique, or methodology has been subjected to peer review or has been published in the professional literature

The term *peer review literature* generally refers to professional journals or periodicals, wherein inclusion of an article has preliminarily been screened by other scientists who deem it worthy to be submitted for comment and scrutiny to the relevant scientific community. Published works, which the Court considered to be one aspect of "peer review", receive even more analysis and critical comment, but the Court recognized that some propositions may be too new or too limited in scope to have been widely published.

3. Whether the results of the chosen methodology have been subjected to an error-rate determination

To what extent the theory or conjecture is likely to be wrong is a relevant issue in determining its reliability or reproducibility and, hence, its trustworthiness. Error rates, when they exist, are meaningful in that they help confirm the degree of confidence with which scientific conclusions reached in a particular area are regarded by professionals.

Finally, in an almost complete reversal of its rejection of the *Frye* rule as a standard for admissibility, the Court added that

4. Whether a theory had received general acceptance in the relevant scientific community may also be a meaningful consideration

Using the *Frye* terminology at (4), the Court admitted that general acceptance could remain as a factor in determining the reliability of a technique, but its significance was no longer primary or determinative of the outcome. The Court found that *Frye* aspired to an austere standard that was incompatible with the more lenient approach to admissibility of the FRE. Use of these four criteria would allow newer and likely more sophisticated scientific methodology to be admitted as testimony if other criteria safeguarding its reliability were met.

Other Considerations Expressed by the Court

FRE 402 further guided the Supreme Court's reasoning. Rule 402 mandates that all evidence be relevant to the case and defines "relevant" evidence in Rule 401 as that which has "any tendency to make the existence of any fact that is on consequence to the determination of the action more probable or less probable than it would be without the evidence."

The Court also dealt with two other concerns noted by the litigants in *Daubert*. First, that abandoning *Frye* would lead to a "free-for-all" causing potential juror confusion by "absurd and irrational pseudoscientific assertions". The adversary system properly conducted, the Court countered, would sort shaky from firm evidence in the crucible of vigorous cross-examination and the presentation of contrary evidence by the opposing parties.[f]

Another concern that had been expressed suggested that the judge's screening role may preclude an adequate consideration of insights and innovations that may well eventually prove to be valid.[f] The Court stressed that there are "important differences between the quest for truth in the courtroom and the quest for truth in the laboratory". The need to arrive at a final and binding result in legal controversies requires that such decisions be made on admissibility of evidence. The Court suggested that judges are competent to apply its rules and strike a balance between these competing interests.

Impact of the Decision

Daubert was sweeping in its influence, if not always a champion of clarity, logic, or realistic in the assumption that the trial court judges would be able to display sufficient scientific acumen in determining the reliability of sophisticated methodologies. Indeed, it is said that to cast judges in the role of amateur scientists was ill conceived. Although it is true that the misuse of scientific evidence has always been seen as a fundamental assault on justice, the Court obviously believed that its *Daubert* discussion and standard would provide adequate safeguards against the use of unreliable or untested scientific evidence in court.

Because the decision was directed at federal courts, the individual states were free to adopt or

reject it at their discretion. Many states have since decided to follow the federal model, but a sizable number of American states' judicial systems still use the *Frye* standard in its original form or as modified locally. It is also recognized, however, that even in states that have not adopted the *Daubert* formulation of admissibility of expert opinion evidence, court decisions since 1993 have, nevertheless, been greatly influenced by the Supreme Court's *Daubert* opinion and holding.

A curious consequence of *Daubert* has been that while the decision clearly stated the *Frye* test to be too rigid a requirement for admissibility, trial courts interpreting it have found the *Daubert* mandate to be, instead, more demanding in its need for proof of reliability than the *Frye* test of general acceptance in a professional field had been. In addition, surveys of judges have shown that most of them continue to attach the greatest weight to the general acceptance of a technique [5].

Several studies have been conducted to measure the effect of *Daubert* on trial court decisions subsequently. Most show that the courts scrutinize more closely the reliability of expert opinion evidence today than they did before the *Daubert* decision date [13].

Daubert standards have also been useful for analyzing evaluations in disciplines somewhat removed from *Daubert's* model of scientific methodology. For example, the Millon Clinical Multiaxial Inventory (MCMI) and its later versions have been used by mental health professionals to assist with psychiatric screening and clinical diagnoses. In an article by Richard Rogers, Randall Salekin and Kenneth Sewell, the MCMI-III was found to have fundamental problems with its scientific validity and error rates precluding its admissibility under *Daubert*. Reconstructing validity through a "meta-analysis" did render portions of MCMI-II acceptable in *Daubert* measures [6].

The *Daubert* decision and its US Supreme Court progeny (*see* ***General Electric v. Joiner***; ***Kumho Tire v. Carmichael***) [4, 5] continue to have a major impact on the development of proof by forensic scientists presenting opinion testimony in courts, even in courts beyond the United States.[a] Where it is applied as a criterion for admissibility, the public as well as judicial acceptance of forensic evidence as valid and credible continues to grow.

End Notes

[a.] The decision is also followed as the law of a number of American states. But even beyond USA borders, it is quoted by courts in other adversary system jurisdictions as well as in civil law countries. E.g., making reference to *Frye* and *Daubert:* In R. V. Dallagher, [2003] 1 Cr. App. R. 12; 2002 WL 1446192 (CA. Crim. Div. 2002), the U.K. Court of Appeal (Criminal Division) cited the United States *Frye* decision as being in accord with the English approach when it quashed a conviction obtained on a crime scene ear mark identified as having been made by defendant as "unsafe". The Court also cited *Daubert* as being a more lenient standard of admissibility than *Frye*. It should also be noted that civil law countries quote from reports by local researchers on reliability of forensic techniques in which the researchers' opinions are based on *Frye* and/or *Daubert* criteria, which the courts then adopt in deciding specific cases. See, e.g., http://www.forensic-evidence.com/site/ID/IDearNews.html mentioning reports of the Netherlands Forensic Institute at the Netherlands Ministry of Justice and by university professors from Holland and Belgium, which in turn were relied on by the Netherlands' "Gerechtshof te Amsterdam" in the Netherlands (Dutch court of appeal at Amsterdam) in reversing a conviction based on methods that find "insufficient support in accepted evidentiary principles"

[b.] See *Frye v. United States* and General Acceptance Test for Novel Expert Testimony. See also, *Daubert v. Merrell Dow Pharmaceuticals* about the FRE incompatibility with *Frye*: "Nothing in the text of this Rule (702) establishes "general acceptance" as an absolute prerequisite to admissibility. Nor does respondent present any clear indication that Rule 702 or the Rules as a whole were intended to incorporate a 'general acceptance' standard. The drafting history makes no mention of Frye, and a rigid general acceptance requirement would be at odds with the 'liberal thrust' of the Federal Rules and their general approach of relaxing the traditional barriers to opinion testimony". (1923).

[c.] See *Daubert v. Merrell Dow Pharmaceuticals*, 43 F.3d 1311 (Ninth Circuit, 1995), on remand from the Supreme Court. This subsequent decision is often referred to as *Daubert II*. The author of the *Daubert II* opinion, Judge Alex Kozinski, wrote about *Daubert*'s "Brave New World" in which judges who must apply the *Daubert* mandates will henceforth live.

[d] Whether *Daubert* also applied to nonscientifically based expert opinions and skill-based testimony was left an open question. The Court addressed this issue in 1999 in the *Kumho Tire* case. See, *Kumho Tire v Carmichael*.

[e] The Court stated: "... [I]t would be unreasonable to conclude that the subject of scientific testimony must be 'known' to a certainty; arguably, there are no certainties in science... ." Daubert, 509 U.S. at 590, 113 S.Ct. at 1295 (1993).

[f] See, *Daubert* opinion, 509 U.S. at 596, 113 S.Ct at 2798 (1993).

Death: Time of

Introduction

Death and dying are processes that are characterized by loss of the function of the great organ systems (cardiovascular system, respiratory system, and nervous system) and their coordination. The loss of the coordination of the great organ systems reveals a dissociation of the function of the different organs [1]. The agonal period may be initiated by either disease or trauma; the final crisis leads over a vita minima in which no vital signs may be apparent to the death of the individual characterized by irreversible cessation of circulation or respiratory arrest (Figure 1). Under special clinical conditions, brain death may replace the classical signs of death (irreversible circulatory or respiratory arrest and their consequences postmortem lividity and rigor mortis). The duration of the agonal period may differ largely:

- Ultrarapid agonal periods may be found in explosions with a total dismemberment of the body in milliseconds.
- Short agonal periods of some minutes' duration are found in many violent deaths and acute natural deaths.
- Long terminal episodes lasting hours to days are seen as terminal episodes of longlasting diseases, e.g., cancer.

In the final crisis of an agonal period, vital signs may not be apparent and persons still alive may falsely be pronounced dead (Figure 2). In most cases where death was certified for persons still alive an intoxication with central depressants in combination with hypothermia was the reason for the lifeless condition. Therefore, especially in cases of hypothermia, the old proverb of emergency physicians that no one is dead until he is warm and dead should be kept in mind [2].

Supravitality

The irreversible circulatory – or respiratory – arrest is, in most cases, the main criterion for death [1]. Metabolism of tissue, however, does not cease immediately after death but runs on for some hours. The main energy-producing metabolic processes are in the early postmortem period: the creatine-kinase

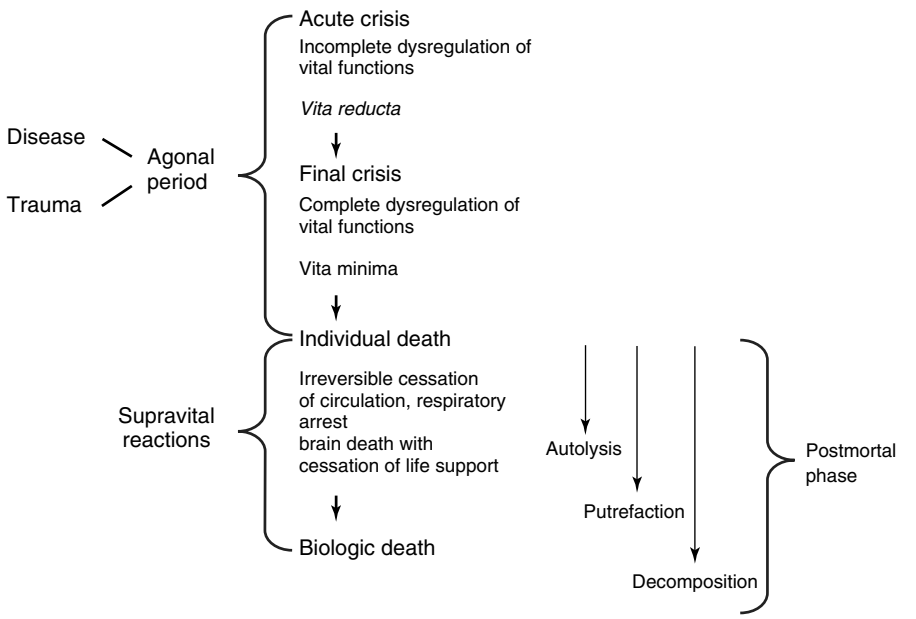

Figure 1 Scheme and terms of the agonal period. The agonal period is initiated by either disease or trauma

Figure 2 An old lady lying dressed on the bank of a river. Vital signs were missing. Although postmortem changes (lividity, rigor mortis) were missing, she was pronounced dead by an emergency physician. Probably cold stiffening was mistaken for rigor mortis. Cause of death was intoxication with central depressants

reaction and then anaerobic glycolysis [3–6]. During this period of intermediary life, supravital reactions can be examined, which are defined as reactions of tissues on excitation postmortem [6]. The duration of the supravital period is much longer than that of the resuscitation period, known from physiology and experimental surgery (Figure 3). Resuscitation period is the time of global ischemia after which the ability to recover expires; the supravital period covers also the period after, which is characterized by an increasing irreversible damage of structure and function. The resuscitation period of skeletal muscle under normothermia lasts, e.g., 2–3 h; supravital electrical excitability of skeletal muscle may be preserved up to 20-h postmortem. Some supravital reactions are of great practical importance in forensic medicine since they can easily be examined at the scene of crime and give an immediate result on the time elapsed since death: these are the mechanical and electrical excitability of skeletal muscle and the pharmacological excitability of the iris.

Mechanical Excitability of the Muscle

The mechanical excitability of skeletal muscle is examined by rigorously hitting a muscle with the back of a knife or a chisel, e.g., the biceps brachii muscle at right angles to the arm axis. Of course other muscles can be examined as well, but reference values for estimating the time since death are available only for the biceps brachii muscle [5, 7]. There are three reaction patterns of the muscle depending on the postmortem interval (Figure 4):

- In the first phase, mechanical excitation of the muscle reveals a contraction of the whole muscle (propagated excitation). This first phase of idiomuscular contraction is identical to Zsako's muscle phenomenon. The first degree of idiomuscular contraction, a propagated excitation, can be observed up to 1.5–2.5 hpm.
- In the second phase, a strong and typically reversible idiomuscular pad develops. This phase may be seen as long as 4–5 hpm (Figure 5).
- In the last phase, a weak idiomuscular pad develops, which may persist over a longer period (up to 24 h). This weak idiomuscular pad can be seen in the time interval up to 8–12 hpm. If the idiomuscular pad is not visible it should be palpated for; otherwise, skin incisions may be necessary to demonstrate the presence of an idiomuscular pad.

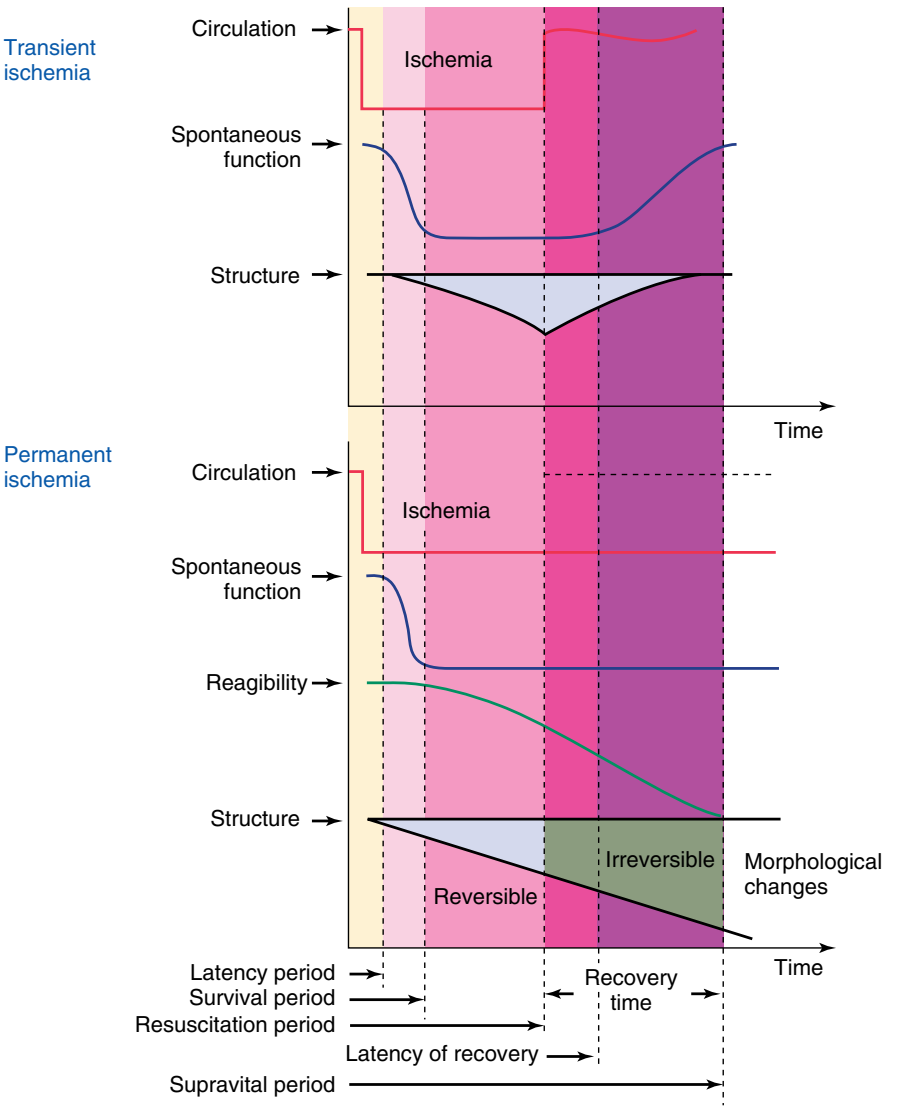

Figure 3 Diagram of the duration of the supravital period (bottom) compared to the resuscitation period (top). The supravital period after irreversible circulatory arrest exceeds the duration of the resuscitation period after transient ischemia by far

Electrical Excitability of Skeletal Muscle. The earliest investigations on electrical excitability of skeletal muscle were carried out at the end of the eighteenth century and beginning of the nineteenth century and electrical excitability was recommended as a method for estimating the time since death [8]. Subsequently, extensive investigations have been carried out using techniques to objectify muscular contraction [9–12]. However, for practical purposes, most investigations on postmortem electrical excitability of skeletal muscle are based on a verbal description and subjective grading of the muscular response to excitation – the muscular contraction – according to

- the strength of contraction and
- the spread of movement to areas distant from the electrodes.

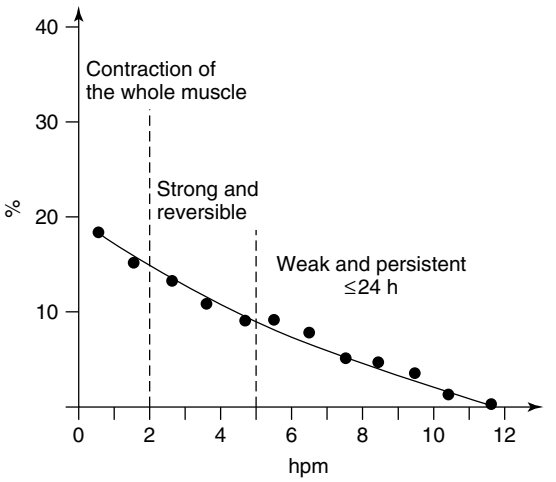

Figure 4 Three phases of idiomuscular contraction after mechanical excitation of the muscle; frequency of a positive reaction (y axis) over the postmortem interval (x axis)

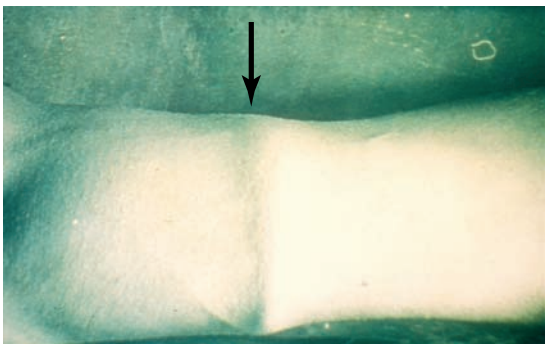

Figure 5 Typical idiomuscular pad of the biceps brachii muscle

In the early postmortem interval, excitation leads to a strong contraction of muscles and the excitation spreads to muscles distant from the electrodes, while with increasing postmortem interval, the contraction becomes weaker and the muscular response is confined to the place of excitation. This reaction pattern can be seen more or less in all muscles. Lastly, only a fascicular twitching or movement of the electrodes is visible. The most extensive investigations have been carried out for the orbicularis oculi muscle since movements of this muscle are easily visible [5, 13–16]. For the orbicularis oculi muscle puncture, electrodes are inserted in a distance

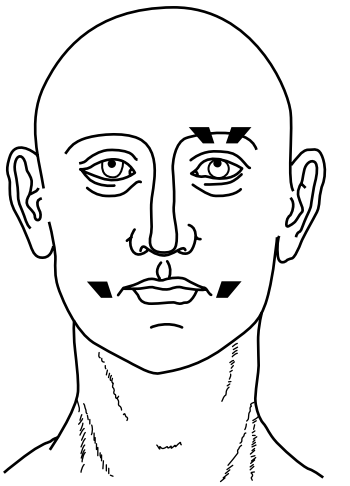

Figure 6 Position of electrodes for examining electrical excitability of mimic muscles

of 15–20 mm in the nasal part of the upper eyelid 5–7-mm deep (Figure 6). The muscular response is graded into six stages. In the very early postmortem interval (degree VI), the whole ipsilateral muscle contracts, in degree V only the upper and lower eyelids and forehead contract, and with increasing postmortem interval the reaction is confined to the place of excitation (Figure 7, Table 1).

For stimulation, a small square wave generator producing constant current rectangular impulses of 300 mA, 10 ms duration in a repetition rate of 50 ms is used (Figure 8). The grading mean values and 95% limits of confidence for the stages are presented in Figure 7.

The 95% limits of confidence for the six stages of electrical excitability of the orbicularis oculi muscle have been proved to be reliable on independent case material [15] and in field studies [17–19]. However, in cases with hematoma or emphysema of the eyelid, electrical excitability may last much longer than corresponding to the upper 95% limits of confidence for the special stage (Table 1, last column). The same is true for cases of hypothermia [15]. On the other hand, in cases of longlasting diseases with a long terminal episode, the duration of electrical excitability is shorter than in cases of sudden death due to the fact that glycogen, which is responsible for the resynthesis of ATP, may be already depleted during life.

Other muscles can be examined as well and reliable reference data are available, e.g., for the

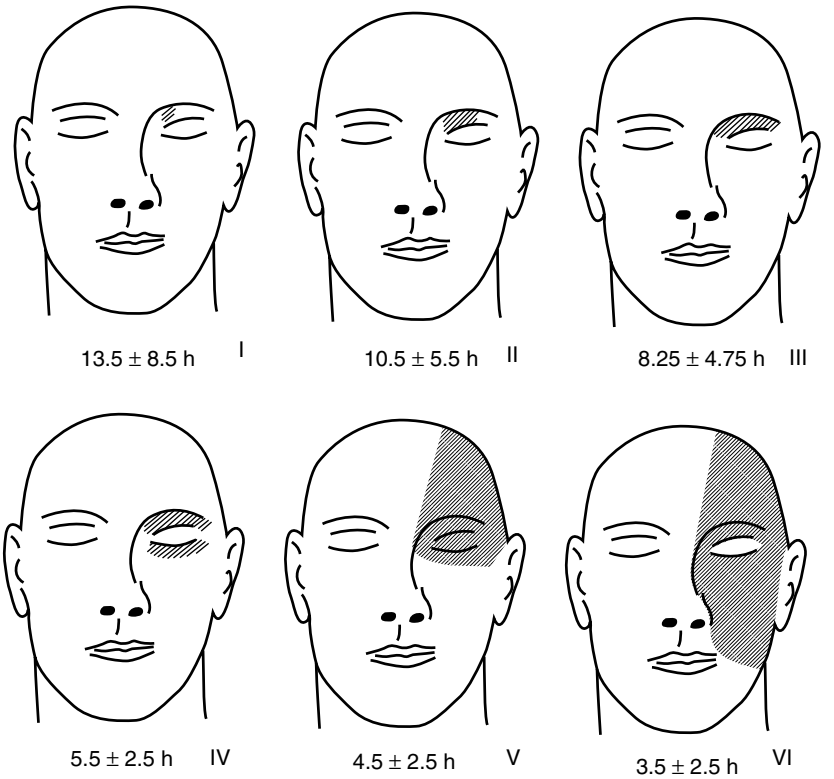

Figure 7 Six stages of positive reaction after stimulation of the orbicularis oculi muscle (see also Table 1)

Table 1 Upper and lower confidence limits for the six levels of electrical excitability in hours in different random samples: forensic pathology with a short terminal episode; clinical pathology with a longer terminal episode; and cases with emphysema and hematoma of the eyelid. In cases of clinical pathology, the duration of electrical excitability is shorter than in cases of forensic pathology

Stage		Forensic pathology	Clinical pathology	Hematoma/emphysema of the eyelid
I	Local upper eyelid	5–22	3–16	–29 traumatic emphysema 27.3–52 postmortem emphysema –32 traumatic hematoma
II	1/3–2/3 upper eyelid	5–16	0–16	
III	Whole upper eyelid	3.5–13	1.5–9	
IV	Upper and lower eyelid	3–8	1–7	
V	Upper and lower eyelid + forehead	2–7	1–7	
VI	Upper and lower eyelid + forehead + cheek	1–6	1–6	

orbicularis oris muscle (Figure 9). The muscles of the thenar or hypothenar may react on stimulation up to about 11-h postmortem [9–11].

Pharmacological Excitability of the Iris. Compared to skeletal muscle, the smooth iris muscle is excitable by electrical and pharmacological

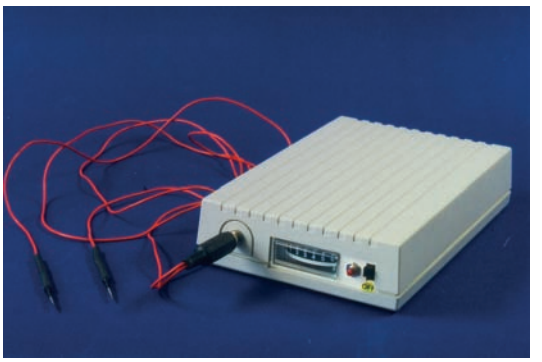

Figure 8 Square wave generator for defined stimulation of, e.g., facial muscles enabling the procurement of the data in Table 1 and Figure 7. Producer and supplier: Peschke J, http://home.t-online.de/home/j-peschke/rztg1.htm

stimulation for a much longer period [13, 14, 20]. In some cases, excitability on subconjunctival injection of noradrenalin or acetylcholine may be preserved up to 46 hpm (Table 2). For practical purposes, the pharmacological excitability of the iris after subconjunctival injection of drugs can be recommended, whereas the drugs should not be injected into the anterior chamber. Of course, the starting diameter of the pupil should be stated before injection using a transparent, multidiameter pattern. About 0.5 ml solution of noradrenalin, tropicamide, atropine, or acetylcholine should be injected. A positive reaction can be seen within 5–30 min, with the diameter becoming greater (atropine, tropicamide, and noradrenaline) or smaller (acetylcholine). The duration of reaction lasts at least 1 h. When no change is visible after this time, the reaction is negative (Table 2). It is sufficient to examine the pharmacological excitability of the iris just with one drug since examining a double reaction after injection of a mydriatricum first, then a mioticum, gives no further information on the time since death.

Table 2 Postmortem excitability of the iris after injection of different drugs

Drug		Postmortem excitability (h)
Mydriatics		
Norepinephrine/epinephrine	1%	14–46
Tropicamide	0.25%	5–30
Atropine/cyclopentolate	1%/0.5%	3–10
Miotics		
Acetylcholine	5%	14–46

Further supravital reactions are the reagibility of sweat glands on the injection of drugs, sperm motility, vitality of leukocytes, DNA incorporation, and postmortem blood clotting. However, these

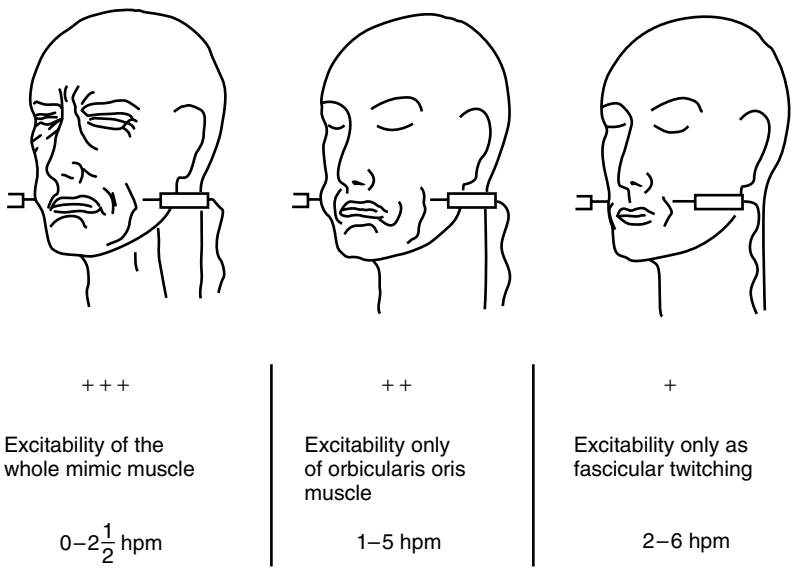

Figure 9 Three stages of positive reaction after stimulation of the orbicularis oris muscle

Table 3 Lividity: causes, consequences, and phenomena checked on the body

Causes		Consequences		Phenomenon
Decrease of force of myocardial contraction	⟶	Stasis	⟶	"Kirchhofrosen", local stasis with patchy discoloration during agonal period due to centralization of circulation
Cardiac arrest, hydrostatic pressure	⟶	Hypostasis	⟶	Livores with a "shifting" quality and "disappearance on pressure"
Vascular permeability	⟶	Hemoconcentration	⟶ ↘	Decrease of shifting and disappearance on pressure
Autolysis, putrefaction	⟶	Diffusion of hemoglobin	⟶	No shifting, no disappearance on pressure

supravital reactions have not gained any practical relevance in forensic medicine.

Postmortem Lividity

After irreversible circulatory arrest, postmortem lividity develops as the earliest postmortem change [1, 16, 21]. After the circulatory arrest, the hydrostatic pressure becomes the leading force within the parallelogram of forces consisting of blood pressure, structural barriers, tissue turgor, and pressure of underlying surfaces [13]. Hypostasis means the movement of body fluids under the influence of gravity. All fluid compartments are involved in hypostasis; that is, not only the intravascular but the transcellular fluids as well. Influenced by gravity, blood is moved into the lowest parts within the vascular system of the body; in a supine position the blood moves into the back, the buttocks, thighs, calves, and back of the neck. Irregular pink patches on the face, especially the cheeks, in the agonal period are caused by local stasis and are called *Kirchhofrosen* (Table 3). Postmortem lividity visible in the skin is a consequence of the movement of blood into the capillaries of the corium. Postmortem lividity may be visible after 20–30 min postmortem, in the early stages as still pink patches, which gradually coalesce with increasing postmortem interval. Owing to the consumption of oxygen, the pink color changes to dark pink or blue (Figure 10).

In the area of deep hypostasis, cutaneous petechial hemorrhages due to capillary rupture may develop and are called *vibices* (Figure 10b). Of diagnostic and criminalistic relevance is not only the development of lividity but also the color, the distribution on the body, the phenomena of fixation (disappearance after turning the body), and disappearance (blanching) on thumb pressure.

In carbon monoxide intoxication and cyanide intoxication, the color of hypostasis is cherry pink, and in methemoglobin intoxication it is brownish (Table 4, Figure 10d). Owing to the lack of dissociation of oxygen from hemoglobin, a bright pink color may be seen in hypothermia as well. In a body brought from cold environment into normal room temperature, a typical zonal segmentation of hypostasis may be seen with a dark blue color in the rewarmed areas (Figure 10c).

Of predominant criminalistic significance are the phenomena of *disappearance on pressure and disappearance after turning the body*. In the early stages, lividity will completely disappear on soft thumb pressure, with increasing postmortem interval the pressure will increase as well, later the lividity will disappear only incompletely on pressure, and lastly it will not disappear at all.

If the body is turned in the early postmortem interval, some or all of the hypostasis may move down to new areas. In a comparatively later postmortem interval, only some of the hypostasis will slip down to the new area and only a slight blanching will be noted in the original area (Figure 11, Table 5).

With increasing postmortem interval, the disappearance of lividity on thumb pressure and relocation after shifting decreases, and then completely ceases. This is caused by an increasing hemoconcentration of intravascular erythrocytes due to transcapillary plasma extravasation (i.e., the fluid moves from the blood leaving the red cells behind, which cannot move without the liquid). The intravascular hemoconcentration is the main reason for the gradually decreasing disappearance on thumb pressure and after

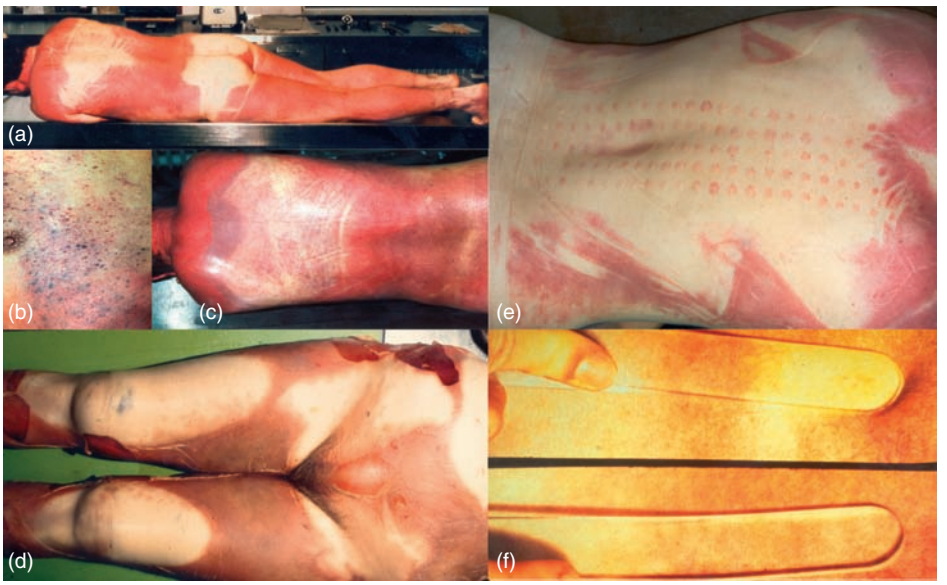

Figure 10 Postmortem lividity. (a) Postmortem lividity in a supine position, the pink color being due to storage in a refrigerator. (b) Petechial-like hemorrhages due to capillary rupture in areas of deep hypostasis (vibices). (c) Zonal segmentation of hypostasis: partly dark blue, partly red. (d) Brownish color of hypostasis in methemoglobin intoxication. (e) Patterned hypostasis of the back due to the underground. (f) Complete disappearance of lividity on light pressure

Table 4 Postmortem lividity discoloration[(a)]

Etiology	Color	Mechanism
Normal	Blue–purplish	Venous blood
Carbon monoxide	Pink, cherry red	Carboxy hemoglobin
Cyanide	Pink, cherry red	Excessively oxygenated blood due to inhibition of cytochrome oxidase
Fluoroacetate	Pink, cherry red	Same as above
Refrigeration/ hypothermia	Pink, cherry red	Oxygen retention in cutaneous blood by cold air Left shifting of Hb O_2 dissociation curve
Sodium chloride/nitrite, nitrate	Brown	Methemoglobin
Hydrogen sulfide	Green	Sulfhemoglobin

[(a)] Modified according to Spitz and Fischer [22]

shifting. In a comparatively later postmortem interval, hemolysis and hemoglobin diffusion into the perivasal tissue starts. However, this is only a secondary mechanism contributing to the fixation of hypostasis [6, 13].

Phases of hypostasis are, therefore, beginning, confluence, maximum, disappearance on thumb pressure, complete or incomplete disappearance after shifting, and are changing with time.

Longitudinal studies on these criteria on large random samples are missing. Other studies are of limited value. The best statistical data available were summarized by Mallach [16, 25], who calculated mean values, standard deviations, and 95% limits of confidence based on textbook reports (Table 6). Since better data are missing, these data are still undisputed. However, it should be kept in mind that these data do not represent absolute limit values. Investigations with a quantitative measurement of livor mortis [26] have not yet gained practical importance.

Beginning is evidenced if mottled patches at lower parts of the body (for instance, neck in supine position) are observed.

Confluence is identified if separate areas of discoloration of moderate intensity are observed.

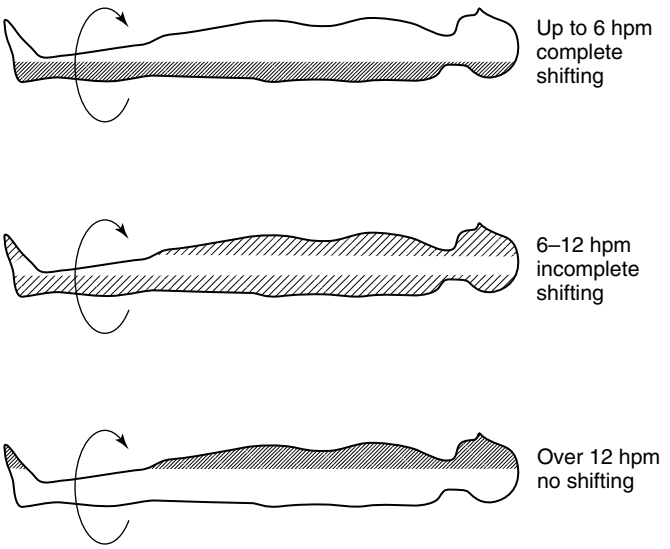

Figure 11 Shifting of lividity after turning the body (modified according to [23]

Table 5 Time course of different criteria of lividity according to W. Naeve [24]

Lividity	Time postmortem
Beginning	15–20 min
Confluence	0.5–2 h
Maximum confluence	4–10 h
Complete disappearance on pressure	10–20 h
Incomplete disappearance	10–30 h
Complete shifting	2–6 h
Incomplete shifting	4–24 h
Only slight pallor after shifting	20–30 h

Maximum can be identified if, during crime scene investigation and autopsy, hypostasis did not increase.

The criterion *thumb pressure* is positive if lividity disappears completely on light thumb pressure.

Complete relocation is when all hypostasis shifts down to the new dependent areas. This may be observed at the scene when a body is turned from a facedown to a supine position.

In *incomplete shifting*, hypostasis not only remains in the former dependent areas but shifts as well, to a more or lesser extent, to the new dependent areas.

Rigor Mortis

The second postmortem change and sign of death, developing in normal ambient temperature about 3–4 hpm (hours postmortem) after primary flaccidity, is rigor mortis. Rigor mortis was misjudged as a sign of death up to the nineteenth century, although Shakespeare (Romeo and Juliet, Act. IV, Scene 1) described all elements of rigor mortis very well:

> Each part, deprived of supple government, shall, stiff and stark and cold, appear like death.

With irreversible circulatory arrest, all muscles of the body will become completely flaccid due to the loss of tone. In the early postmortem interval, adenosine triphosphate (ATP, the chemical source of energy) can be resynthesized due to the creatin-kinase reaction and anaerobic glycolysis. Once the ATP level has fallen under 85% of the initial value, actin and myosin filaments will contract and the subjective impression of stiffening of the muscle can be noticed (Table 7) [1, 3, 13, 27, 28]. In practice, development and state of rigor mortis are proved subjectively by flexing a joint: either the muscles are flaccid or during development of rigor mortis resistance may be felt (Figure 12). If rigor develops completely, even a strong investigator cannot flex or stretch a joint. Biochemical, physiological, and

Table 6 Time course of different criteria of lividity[a]

Table 7 Overview of biochemical, mechanical, morphological, and physiological basis of rigor mortis

	Delay period	Establishment of rigor	Rigor phase	Postrigor phase, secondary flaccidity
Biochemistry	ATP level: $0.435 \pm 0.555\,mg\,g^{-1}$ muscle	ATP level decreased to less than 85% of the original value	–	NH_3 ↑
Mechanics	–	Stiffness ↑, plasticity first increased, then decreased. Contraction of loaded muscle	–	Spontaneous elongation of loaded muscle; plasticity ↑
Morphology	–	Appearance of fine transverse striations (bridging between A and I filaments) with a periodicity of 400 Å	Swelling and destruction of mitochondria and the sarcoplasmic reticulum	Irreversible elongation of muscle; decoupling of myofilaments, disintegration of structure
Physiology	Exponential decrease of membrane potential: above −55 mV propagated excitation possible; below this level up to −30 mV only local concentration on excitation	–	–	–

Figure 12 Owing to rigor mortis, the lower leg is fixed against gravity (a). Objects in the hands must not be mixed up with instantaneous rigor mortis or cadaveric spasm (b)

mechanical properties of the rigor (pre- and postrigor) phases are summarized in Table 7.

Rigor must not be mixed up with cold stiffening. When rigor is present, hypostasis must be present as well; in cases of cold stiffening (body core temperature 30–33 °C), hypostasis is absent.

The development and state of rigor should be examined not only in one but also in several joints (mandibular joint, finger, knee, and elbow joint) to get an impression if it is still in progression or has already reached its maximum.

Rigor mortis does not start in all muscles simultaneously. Nysten's rule (1881) that rigor starts in the mandibular joint, muscles of the trunk, then in the lower extremities, and lastly in the upper extremities is true for most cases who die in a supine position [8]. However, in cases with glycogen depletion during agony in the lower extremities, rigor will start here.

Resolution of rigor mortis is due to protein degradation (increase of ammonia – NH_3)

In different fibers of a muscle, rigor does not start simultaneously but successively. This phenomenon can be used for a rough estimation of the time since death as well. If some fibers have already become stiff, this stiffness can be broken by flexing a joint; rigor may now develop in other, not yet stiffened fibers. Depending on the time when stiffness has been broken, rigor may develop again on a higher or lower level unless it was already fully developed (Figure 13). This phenomenon of reestablishment of rigor mortis may be seen up to 6–8 hpm, in very low ambient temperatures up to 12 hpm.

Secondary flaccidity may become apparent in normal ambient temperature after two days. In deep ambient temperatures (winter <10 °C), fully

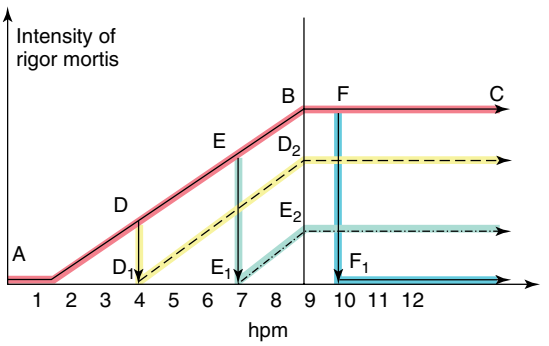

Figure 13 Re-establishment of rigor mortis after breaking. The later during development of rigor mortis rigor is broken, the lower will be the level after re-establishment. If rigor is broken after it has already been fully developed (F) it will not be re-established at all

developed rigor mortis may be preserved two weeks or longer.

Cadaveric rigidity, cataleptic spasm, or instantaneous rigor is a phenomenon always mentioned in textbooks but nonexistent in practice. No case reported in the literature stands up to criticism.

Rigor mortis is established not only in skeletal muscle but also in smooth muscle, e.g., of the skin, as well. Rigidity of the smooth musculi arrectores pilorum can be seen as gooseflesh (cutis anserina) (Figure 14).

Development, duration, and resolution of rigor mortis are dependent on the amount of glycogen in the muscle at the moment of death, ambient temperatures, and so on.

Therefore, rigor may develop very fast in persons who die during or soon after physical exertion

Figure 14 Gooseflesh of the right forearm due to rigidity of the smooth musculi arrectores pilorum

Table 8 Time course of different criteria of rigor mortis according to calculations by Mallach on textbook reports

Rigor state	Average in hpm and standard deviation	Range of scatter in hours (2 s)		Number of quotations
		Lower limit	Upper limit	
Beginning	3 ± 2	–	7	26
Maximum	8 ± 1	6	10	28
Duration	57 ± 14	29	85	27
Complete resolution	76 ± 32	12	140	27

or exhaustion or from electrocution. All above-mentioned criteria of rigor mortis (development, reestablishment, fully developed, duration, and resolution) are time dependent. This becomes already evident from one of the rare studies of the nineteenth century on rigor mortis. Niderkorn, who determined the time necessary for the completion of rigor mortis in 113 bodies, found it fully established after 4–7 h in 76 corpses (67%), in 2 cases rigidity was complete within 2 hpm, and in 2 others it was complete within 13 hpm.

However, the interindividual variability due to endogenous and exogenous factors is great. Longitudinal studies on a great random sample are missing; however, animal experiments, taking into account various factors influencing the time course of rigor mortis, have been published [29–35]. Devices for an objective measurement of rigor mortis have been developed [36] but have not yet gained practical importance.

The best available data in spite of all justified criticism are again from Mallach [16, 25], based on a literature compilation (1811–1969) with statistical analysis (Table 8). These values again cannot claim to be absolute limit values. As lividity, rigor mortis can give only a rough estimation and no accuracy can be expected. It never should be examined alone.

Rigor is examined by flexing or stretching joints. Beginning can be stated to have occurred if a slight rigor can be observed in some joints.

Complete development or maximum means that it has strongly developed in all joints.

Reestablishment can be stated to have occurred if rigor is found again in a joint (mostly elbow) some time (hours) after breaking it. Mostly rigor is broken during crime scene investigation and examined again at autopsy.

Algor Mortis

The fall of body temperature at postmortem is due to four factors: convection, conduction, radiation, and evaporation, the first two being the leading causes.

The rate of cooling depends on various conditions and varies with several factors:

- ambient conditions (temperature, wind, rain, and humidity);
- weight of the body, mass/surface area ratio;
- posture of the body (extended or thighs flexed on the abdomen); and
- clothing/covering.

Different temperature probe sites were used (surface skin temperature, axilla, liver, rectum, and brain temperature); for practical purposes, only central core temperatures (rectum, brain) are of value today [13, 37, 38]. Body cooling does not follow Newton's law of cooling. The early authors in the nineteenth century using rectal temperature described a lag time, the postmortem temperature plateau, before an exponential body cooling according to Newton's law starts (Figure 15) [8, 13].

The temperature plateau is due to the fact that central axial temperatures cannot begin to decrease until a heat gradient is set up between the core of the body and the surface. This delay is variable and may last for some hours.

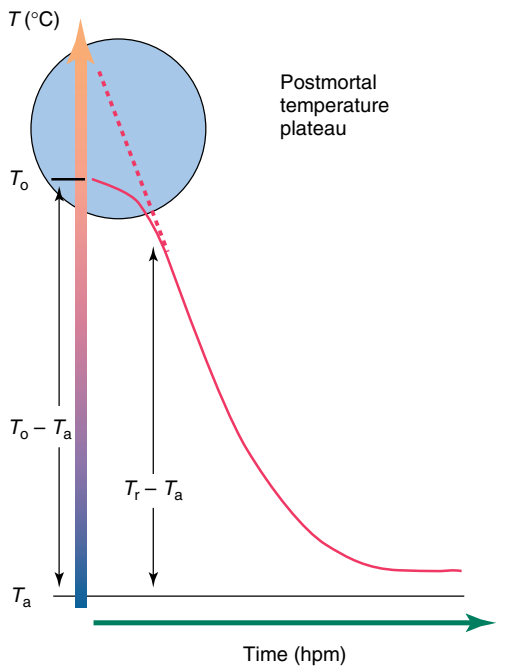

Figure 15 Sigmoidal shape of the cooling curve, which is best described by Marshall and Hoare's two-exponential term. The quotient $\frac{T_r - T_a}{T_o - T_a}$ is a good measure of the progress of cooling. If this quotient Q is < 0.3, only a minimum interval of the time since death should be given. T_o, rectal temperature at death ($T = 0$); T_r, rectal temperature at any time; and T_a, ambient temperature

A mathematical expression of the rectal cooling after death was published by Marshall and Hoare [39], taking into account the whole sigmoidal shape of the cooling curve. Marshall and Hoare performed body cooling experiments under "standard conditions of cooling", which are defined as "naked body with dry surfaces, lying extended on a thermically indifferent base, in still air." Their mathematical model of body cooling was expressed in a two-exponential term:

$$Q = \frac{T_r - T_a}{T_o - T_a} \quad A \times \exp[(B \times t) + (1 - A)] \times \exp\left(\frac{(A \times B)}{A - 1}\right) \times t \qquad (1)$$

where Q, standardized temperature; T_r, rectal temperature at any time t; T_o, rectal temperature at death ($t = 0$); T_a, ambient temperature; A, constant; B, constant; t, and time of death.

The second exponential term is subtracted from Newton's exponential term taking into account that temperature plateau is a from null increasing temperature decrease.

This mathematical expression is valid for all central axial temperatures and is the ultimate success in modeling body cooling for purposes of estimating the time since death [39, 40].

The exponential form with the constant B expresses the exponential drop of temperature after the plateau, according to Newton's law of cooling; the term with the constant A as part of the exponent describes the postmortem temperature plateau.

The experimental work that led to an identification of these constants is outlined in several original papers [41–45] and two monographs [13, 37], which are referred to here.

Empirically, it was found that the individual value of B can be computed under chosen standard conditions of cooling by

$$B = -1.2815(bw^{-0.625}) + 0.0284 \qquad (2)$$

where bw is body weight (kilograms).

This reflects that the body cooling after the temperature plateau is mainly influenced by the body weight.

Values for the constant A could be empirically identified on the material studied under standard conditions and the material of De Saram and Webster [46], reevaluated by Henssge:

A is 1.25 for ambient temperatures up to 23 °C and 1.11 for ambient temperatures above 23 °C.

The temperature at the time of death, T_o, is the third constant of Marshall and Hoare's formula. For this constant, the value of 37.2 °C is used.

With this empirical solution of Marshall and Hoare's formula, the time since death can either be computed according to

$$Q = \frac{T_r - T_a}{37.2 - T_a} = 1.25 \times \exp(B \times t) - 0.25 \times \exp(5 \times B \times t) \qquad (3)$$

(for ambient temperatures up to 23 °C) or

$$Q = \frac{T_r - T_a}{37.2 - T_a} = 1.11 \times \exp(B \times t) - 0.11 \times \exp(10 \times B \times t) \qquad (4)$$

(for ambient temperatures over 23 °C)

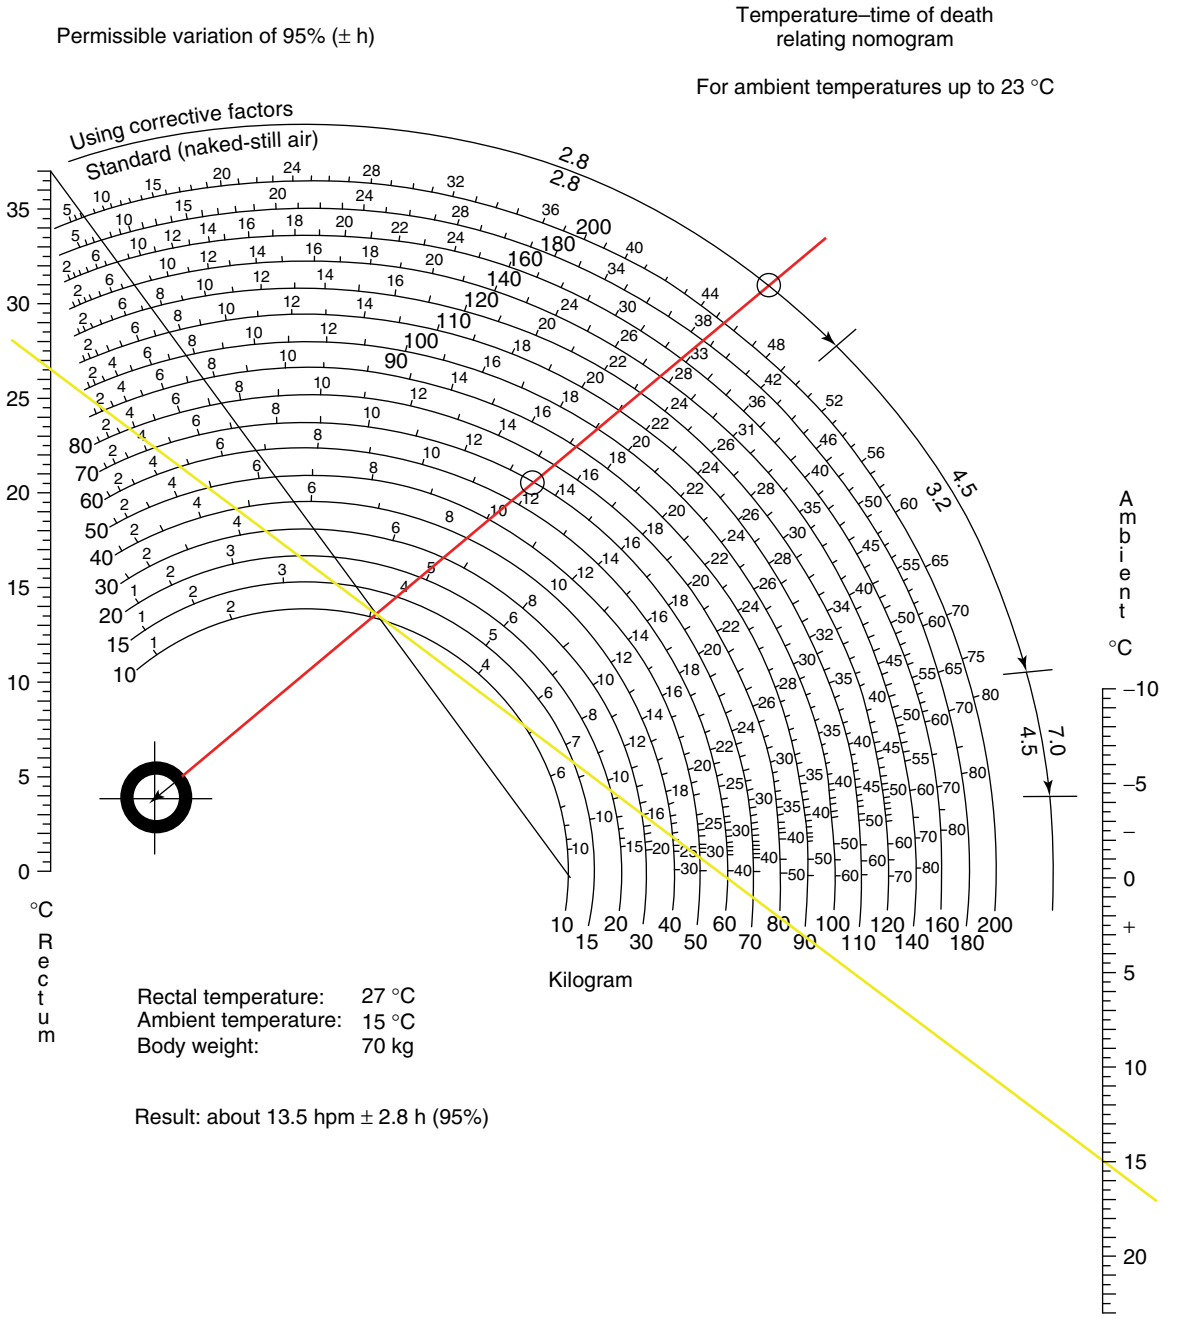

Figure 16 Temperature–time-of-death nomogram for ambient temperatures up to 23 °C. At the scene of crime, for instance, a rectal temperature of 27 °C at an ambient temperature of 15 °C was measured. At first, the point of the scale of the measured rectal temperature and ambient temperature has to be joined by a straight line (yellow), which crosses the diagonal of the nomogram at a specific point. For the second step, a second straight line has to be drawn passing through the center of the circle (below left of the nomogram) and the intersection of the first line and the diagonal (red line). The second line crosses the semicircles for different body weights. The time since death (in this case, for 70 kg body weight) can be read off at the intersection of the semicircle of the given body weight. The intersection gives the mean time since death, and the intersection with the outer circle the 95% limits of confidence, which may be higher if corrective factors have to be used

using computer programs developed by Henssge or using a nomogram (Figure 16).

The nomogram is valid for the chosen standard conditions of cooling (naked body with dry surfaces, lying extended on a thermally indifferent base, in still air). Conditions that improve or delay body cooling compared to standard conditions (lying in water and wind on one hand, clothing and covering on the other hand) reduce or increase the real body weight. Extensive cooling experiments under varying cooling conditions led to empirically found corrective factors for the body weight (Table 9). With these corrective factors, the nomogram can be used for nonstandard cases. These corrective factors themselves are dependent on the body weight (Table 10) in cases of a low and high body weight under higher thermic insulation conditions. Higher body weights need lower factors and, vice versa, lower weights need higher factors [37]. The nomogram can also be used in cases of sudden change of ambient temperature [47].

Application of the Nomogram Method in Casework

1. Inspection of the scene of crime, body posture, clothing, covering, sunshine on the body, windows (closed, opened: when?), radiators, and floor (thermally indifferent?).
2. Measurement of ambient temperature (air) close to the body and at the same level (10–20 cm above the base); measuring the temperature of

Table 9 Empiric corrective factors (CF) for body weight[(a)]

Dry clothing/ covering	Air	Corrective factor	Wet through clothing/ covering wet body surface	In air	In water
		0.35	Naked		Flowing
		0.5	Naked		Still
		0.7	Naked	Moving	
		0.7	1–2 thin layers	Moving	
Naked	Moving	0.75			
1–2 thin layers	Moving	0.9	2 or more thicker layers	Moving	
Naked	Still	1.0			
1–2 thin layers	Still	1.1	2 thicker layers	Still	
2–3 thin layers		1.2	More than 2 thicker layers	Still	
1–2 thicker layers	Moving or still	1.2			
3–4 thin layers		1.3			
More thin/thicker layers	Without influence	1.4			
Thick blanket		1.8			
and		2.4			
Clothing combined		2.8			

[(a)] – The listed values of CF apply to bodies of average weight (reference: 70 kg) (see Table 10) in an extended position on a thermally indifferent supporting base.
– "Thermally indifferent" supporting bases are, e.g., usual floor of rooms, dry soil, lawn, or asphalt. In comparison, bases that appear more thermically insulating or heat conducting should additionally be taken into account.
– Excessively thick upholstered bases require CF of 1.3 for naked bodies. In cases of clothed bodies, CF should be increased by 0.1 units (thickly clothed) to 0.3 units (very thickly clothed).
– Insulating but not excessively thick upholstered bases such as a mattress (bed) or thick carpet require CF of 1.1–1.2 for naked bodies.
– Bases that accelerate cooling, e.g., concrete, stony or tiled bases on ground require CF up to 0.75 for naked bodies.
– In cases of clothed bodies lying on bases, CF should be reduced by 0.1 unit (thicker clothes) or by 0.2 units (very thin clothes)

the underlying surface as well. Have any changes of thermic conditions been made since the body was found?

3. Single measurement of deep rectal temperature at the scene using an officially calibrated electronic thermometer with probes for measuring air, surface, and rectal temperature. The deep rectal temperature must be at least measured 8 cm within the anal sphincter.
4. At autopsy control, whether the estimation of the body weight was correct by weighing the body.
5. Evaluation of the corrective factor. Are there any conditions that accelerate or delay cooling compared to standard conditions? For rectal temperature, only the thermical conditions of the lower trunk are relevant:
   (a) clothing/covering;
   (b) resting or moving air;
   (c) kind of supporting base.
   In cases of strong insulation conditions and very high or low body weight, the corrective factor must be adapted to the body weight.
6. Using the nomogram.

Connect the points on the scales for rectal and ambient temperature by a straight line. This line crosses the diagonal at a particular point. Draw a second straight line going through the center of the circle, below the left of the nomogram and the intersection of the first line and the diagonal. The second line crosses the semicircles that represent the body weights. At the intersection of the semicircle with the body weight, the time of death can be read. The second line touches a segment of the outermost semicircle. Here the permissible variation of 95% can be seen for standard cases or cases using corrective factors. If ambient temperature or corrective factors are in question, repeat the procedure with other appropriate values. If the chosen ranges of ambient temperature and corrective factors are rather wide, it is recommended to give two values of time: the shortest time resulting from the combined lower limits of the evaluated ranges of body weight, ambient temperature, and corrective factor and the longest time resulting from the upper limits of body weight, ambient temperature, and corrective factor.

The range of time of death can be seen in this way.

If the rectal temperature has nearly reached the ambient temperature ($Q < 0.3$), only a minimum interval of the time since death should be given (mean value minus appropriate 95% limit of confidence).

For temperatures above 23 °C, another nomogram developed on the data of De Saram must be used (Figure17). The difference between this nomogram and that for temperatures up to 23 °C is only due to the relative lengths of the postmortem temperature plateau; it is shorter in higher ambient temperatures.

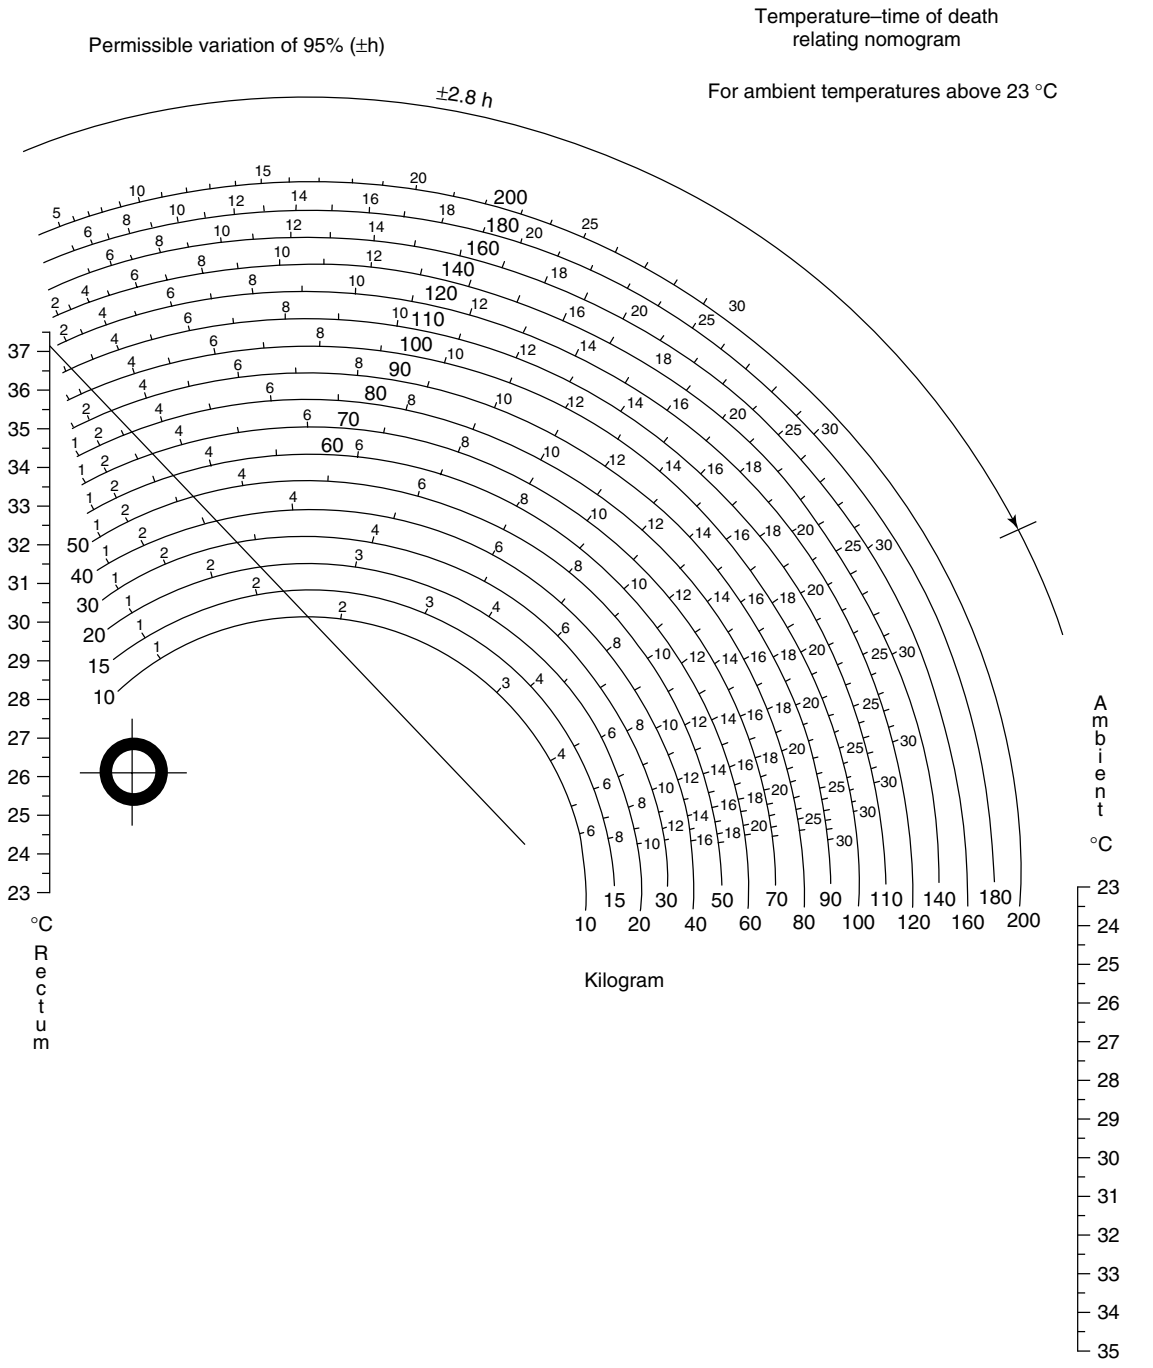

Figure 17 Temperature–time-of-death nomogram for ambient temperatures above 23 °C

Requirements for use:

- no strong radiation (for example, sun, heater, cooling system);
- no strong fever or general hypothermia;
- place of death must be the scene where the body was found;
- no uncertain severe changes of the cooling conditions in the period between death and examination;
- no high thermal conductivity of the surface beneath the body; and
- no longer terminal period after fatal injury (time since death may be inconsistent with time of assault).

Meanwhile, a multicenter [48] and a single center [18] study on the accuracy of the nomogram method compared to the investigations of the police comprising 76 and 72 cases, respectively, were carried out. These are two of the very rare field studies on the accuracy of proposed methods. Both studies covered a wide range of ambient temperatures, body weights, and corrective factors. The estimated period did not contradict the investigated period in any of the cases. Especially in the earlier stages, investigations of the police can be supported effectively by the method.

Cooling conditions can be simulated using cooling dummies. For further information, see References [37, 49, 50].

From all methods developed to estimate the time since death, the nomogram method based on the two-exponential term by Marshall and Hoare is by far the most successful and reliable one since

- actual cooling conditions can be taken into consideration quantitatively;
- data on the precision of the method are available; and
- field studies have confirmed the accuracy and reliability of the method.

Further Postmortem Changes

Autolytic changes, especially in vitreous humor [51–57] and putrefactive changes [58, 59], to the extent they are of importance for determining the time since death [60, 61], are addressed in the chapter (*see* **Time of Death Determinations**; **Chain of Possession of Tangible Evidence**), time of death determinations. There are also suggestions on how the postmortem changes discussed here can be used for estimating the time since death.

Death Penalty and Age

At the end of 2005, 36 states within the United States of America and the federal prison system held 3254 prisoners under sentence of death [1]. The youngest inmate under sentence of death was 20 and the oldest was 90. Those executed in 2005 had been under sentence of death an average of 12 years and three months.

Lifespan developmental perspectives emphasize continuity and change from birth to death, with notable changes observed in both cognitive capacity and physical status. It has been noted that the period between infancy and adulthood is a time of tremendous growth and change in which an individual's cognitive abilities broaden and intensify, and their physical capabilities are fully developed. In contrast, the period between early adulthood and late adulthood is one of relative quiescence in which both cognitive and physical abilities remain relatively stable while gains in emotion regulation, motivation, and concepts of self predominate. This period is then followed by yet another period of tremendous change that is typified by cognitive and physical decline that ultimately results in death.

In two recent landmark decisions, the United States Supreme Court (USSC) recognized that cognitive capacity was relevant in deciding what class of individuals should be subject to the death penalty. In the 2002 decision in *Atkins v. Virginia* [2], and the 2005 decision in *Roper v. Simmons* [3] the USSC made it unconstitutional to execute individuals with mental retardation and individuals who were under the age of 18 years at the time they committed a capital offense (*see also* **Juvenile Justice: Adolescent Development**). To date, the USSC has been silent to the issue of cognitive decline and its relevance to the stated goals of the death penalty.

The End of an Era: The United States Supreme Court Abolishes the Death Penalty for Juveniles

As previously noted, over the years the legal system has recognized the importance of age. The importance was recognized as far back as 1899 when the American juvenile justice system decided that adolescents who violate certain laws should be provided with treatment, rather than be punished for their actions [4]. In cases such as *Belotti v. Baird* [5] and *Eddings v. Oklahoma* [6] the USSC recognized that the period of adolescence was distinct from adulthood and that during this period, individuals were vulnerable to the influence of others and did not possess the level of experience, perspective taking, or maturity required to make critical decisions in an informed manner.

Despite the recognition that the period of adolescence was different from that of adulthood, the USSC did not intervene on behalf of juveniles until 1988 in the case of *Thompson v. Oklahoma* [7]. In *Thompson*, the USSC stated that the execution of a person who was 15 years of age or younger at the time of the crime violated the Eighth Amendment against cruel and unusual punishment. The Court was guided by "evolving standards of decency" [8] that rendered such punishment unconstitutional. By 1988, 18 states had restricted the death penalty to defendants aged 16 years or above at the time of the crime, and there had not been an execution of someone under the age of 16 years for 39 years. In addition to noting the evolving standards of decency, the Court in *Thompson* directed attention to the importance of inexperience, limited education, and limited intellectual functioning in making sentencing decisions. Quite simply, the Court believed that the goals of retribution and deterrence could not be met with the execution of youthful defendants. Lastly, the Court commented that their decision was supported by the fact that professional organizations and leading members of the "Western European Community" believed that executing a defendant who was under the age of 16 years at the time of the crime offended civilized standards of decency. Of note, one year later, the application of the death penalty for youth who were between the ages of 15 and 18 years at the time of the crime was upheld in *Stanford v. Kentucky* [9].

It took 17 years for the USSC to take a major step in changing the laws regarding capital punishment in the United States. In the case of *Roper v. Simmons*

[2], the Court decided that the death penalty was not appropriate for defendants who were under the age of 18 years at the time of the crime. The decision came on the heels of the Court's decision to abolish the death penalty for individuals who have mental retardation [2]. In their 6-3 opinion, the Court stated that the execution of a mentally retarded individual violates the Eighth Amendment right against cruel and unusual punishment. Writing for the majority, Justice Stevens stated that due to disabilities in areas of reasoning, judgment, and control of their impulses, individuals with mental retardation do not act with the level of moral culpability that characterizes the most serious adult criminal conduct. It was further noted that the presence of these impairments can put into question the reliability and fairness of capital proceedings. Citing *Atkins* as a backdrop, Simmons filed an appeal of his death sentence with the Missouri Supreme Court stating that the same reasoning used in *Atkins* should apply to juvenile offenders. The Missouri Supreme Court agreed and resentenced Simmons to life without the possibility of parole. In 2004 the USSC granted *certiorari* to determine if imposition of the death penalty for an individual under the age of 18 years violated the Eighth Amendment against cruel and unusual punishment. In a 5-4 decision, the USSC banned the execution of individuals that were under the age of 18 years at the time of the offense [3].

As would be expected, the decision in *Roper* was not met with universal acceptance. In their 5-4 decision, the dissenting justices were unified in their opinion that the Missouri court should be admonished for not adhering to precedent as set forth in *Stanford* and that the difference in maturity between adults and juveniles was not substantial, nor was it universal. Justices Scalia, Rehnquist, and Thomas further stated that by including nondeath penalty states in the purported national consensus, the Court artificially elevated their position, and that the use of international law has no place in the opinions that arise from the USSC.

The Emergence of an Era: Aging Criminals and the Death Penalty

Older inmates are the fastest-growing segment of the population in federal, and state prisons in the United States [10]. Aday [11] reported that the number of prisoners 50 years and older in state and federal correctional facilities in 2001 was 113 358, three times as many as the number in 1990. This growth was thought to have resulted from three primary forces: (i) the overall aging of the population, (ii) tougher sentencing laws (e.g., mandatory minimums, and "three strikes" laws), and (iii) the elimination of parole [12]. Although age 50 is not considered old in community settings, research has found that incarcerated individuals of age 50 and older physiologically resemble community-dwelling individuals approximately 10 years older than their chronological age [13]. In other words, a 60-year-old inmate under sentence of death is likely to resemble a community-dwelling person who is 70 years of age. Though the exact cause of this rapid aging process is not known, it may be due to an inmate's history of excessive drug and alcohol use, poor nutrition, stressful life experiences, personal neglect, and lower socioeconomic status in comparison with nonoffenders. As of December 2005, 672 death row inmates were over the age of 50 years, which accounted for approximately 21% of the United States death row population [1].

Although little attention has been given to the enactment of the death penalty among older offenders, questions about the constitutional justification for executing these individuals can be raised due to potential disabilities in reasoning, judgment, and control of their impulses. Such deficits are associated with cognitive incapacity secondary to dementias such as Alzheimer's disease. Alzheimer's disease is the most common form of dementia in the United States, 5.1 million Americans had Alzheimer's disease in 2007, and it is estimated that 11–16 million older Americans will suffer from the disease by the year 2050 [14]. In brief, dementia is a clinical term that describes a variety of illnesses with hallmark symptoms of cognitive decline from previous levels of functioning. These cognitive declines primarily involve memory or executive functioning deficits (e.g., the ability to sustain attention, to plan, to make informed decisions, and to solve problem). Additionally, cognitive decline associated with dementia is accompanied by deficits in adaptive functioning, particularly in the personal care and community functioning domains [15]. With the gradual progression of the disease comes an increasing level of impairment in adaptive functioning. Ultimately, an adult with dementia will forget to carry out day-to-day activities (e.g., they may forget to

take their medication or to pay bills) and over time will forget personal historical events. Older inmates with dementia may not remember the circumstances surrounding the crime for which they are incarcerated or the rationale behind their death sentence.

Numerous case studies have suggested the important role of dementia as a factor in late life criminal activity [11]. Rosner and colleagues [16] examined the cognitive abilities of 52 defendants between the ages of 62 and 88 who were referred for assessment of competence to stand trial. Eighty-three percent of the defendants were facing charges related to violent crimes. Rosner and colleagues found that a substantial number of these older defendants suffered from dementia.

To date, the USSC has not addressed the issue of the execution of elderly inmates under sentence of death or the need to assess their competence for execution. The issue, however, has been cited as a serious concern by death penalty experts in the United States and by experts internationally [17]. According to USA Today February 10, 2005 as cited in the death penalty information site [17], two unidentified elderly inmates have asked federal judges to rule on the constitutionality of executing inmates with Alzheimer's disease, dementia, or other age-related illnesses. As stated by Jonathan Turley of George Washington School of Law, "Dead man walking is one thing ... dead man being pushed along to the execution chamber in a wheelchair is another thing."

By way of case example, in 2004, J.B. Hubbard, a 74-year-old man, was put to death in Alabama for the murder of a woman in 1977. At the time of his execution he had been under sentence of death for 27 years and was the oldest inmate put to death since the reinstatement of the death penalty in 1976. His attorneys argued that executing Mr. Hubbard would be a violation of the Eighth Amendment due to his age and mental incompetence. Specifically, at the time of his execution J.B. Hubbard exhibited multiple symptoms of dementia including the inability to remember names of significant individuals in his life, inability to remember significant events in his life, and deficits in self care [17]. Additionally, he suffered from colon and prostate cancer and was so weak that other inmates helped him walk to the shower and to comb his hair.

Setting the Example: The USSC Prohibits the Execution of Inmates Who Have a Mental Illness and do not Understand or Rationally Appreciate the Reason behind Their Execution

In 2007 the USSC took the position that, to be executed, an individual must understand and appreciate the application of the death penalty in their individual case [18]. Specifically, the Court determined that conducting an execution in the absence of rational thought and understanding violated the Eighth Amendment of the United States Constitution. Thus, in order to execute a mentally ill offender, the offender would need to evince: (i) the ability to understand the purpose of punishment and (ii) the ability to appreciate the personal consequences of previous actions necessitating punishment. As noted in the majority opinion, an offender is incompetent for execution if he does not "have a rational understanding of the penalty about to be imposed". Such understanding and appreciation are necessary to fulfill the purpose of retribution and establish the offender's competence to be executed. It can readily be seen that the cognitive deficits associated with dementia, mimic almost exactly the concerns put forth in *Panetti*.

It is important to note that the decision in *Panetti* was consistent with the constitutional protections established in *Ford v. Wainwright* [19]. In *Ford,* the Court established that "the Eighth Amendment forbids the execution only of those who are unaware of the punishment they are about to suffer and when they are to suffer it". Like *Ford,* the decision in *Panetti* supports the notion that to be executed a person must be aware of the reason for this punishment; however, *Panetti* extends the protections by including the need for a rational, as well as factual, understanding of the basis for the decision. The Court noted that mental health experts can assist the Court in determining competence, and specifically stated that "there is precedent to guide a court in conducting Eighth Amendment analysis". Not surprisingly, the cases cited in *Panetti* were *Atkins v. Virginia* and *Roper v. Simmons.*

Deception: Detection of

Introduction

Deception detection is a useful and critical ability for humans in variety of settings. Growing concerns about terrorism have highlighted the need for accurate detection of deception. All the 19 of the September 11, 2001 terrorists lied to the officials on at least three occasions (when applying for an entry visa, when crossing the border, and before boarding their airplanes) and none were detected in their deception. This is perhaps not surprising given the substantial body of research showing that human beings are not innately skilled in detecting deception [1, 2].

Moreover, even those whose professions appear to require deception detection are not good at deception detection. Recognizing this weakness in human ability; police, national security experts, and scientist have explored other strategies to detect deception. One alternative approach to deception detection is to use technology to examine various physiological responses that may provide cues for deception detection. To date, only one of those approaches, the polygraph, has received widespread application

around the world [3], although other approaches have been attempted (*see* **Deception: Detection of and Brain Imaging**).

Psychophysiological Detection of Deception (Polygraph)

Psychophysiological detection of deception (PDD), commonly referred to as *polygraph testing*, involves the use of autonomic physiological measures to make inferences about a subject's credibility. Typically, modern PDD instruments take measures of respiratory activity, relative blood pressure, skin conductance (palmar sweating), and vasomotor activity (blood flow at the surface of the skin, usually at the thumb) [4]. Movement can also be monitored in an attempt to detect artifacts and deliberate distortion. There are two major approaches to PDD, information-based tests and deception-based tests. Information-based tests attempt to determine whether the suspect has specific information that only a guilty person should have. Deception-based tests take a more direct approach and ask direct accusatory questions. These two approaches and their variations are described below.

Information-Based Psychophysiological Detection of Deception. In taking the information-based approach [5], often called the *guilty knowledge test*, or more correctly the *concealed information test* (CIT), if a murder occurred, and the weapon was a 38-caliber revolver, and if that information was not made public, then a suspect could be asked: If you committed the murder you would know the murder weapon. Was the murder weapon: a 45-caliber automatic, a 38-caliber revolver, a 9-mm automatic, a 44-caliber revolver, a 25-caliber automatic, a 22-caliber revolver? The critical item is never placed in first position as the first in such series almost always evokes a physiological response. Several critical items developed from the investigation would be used in a complete information-based examination. The expectation would be that a naïve individual would respond to items at random, whereas the guilty would show a nonrandom pattern with consistent physiological arousal associated with the items identified by the investigation. One advantage of this approach is that the false-positive rate (that is, the rate at which the innocent fail the test) can be predicted based on statistical models of chance.

Laboratory research using the CIT in a variety of mock crime scenarios consistently produced results for CIT that support the statistical models for false-positive rates and suggest a true positive (correct identification of the guilty) rate of around 80% [6]. Unfortunately, the field studies of the CIT have failed to produce equivalent true positive rates. Data from the field suggest that true positive rates for the CIT in the field are about 50% [7, 8]. The difference between the laboratory and the field is perhaps not surprising. The general tact in laboratory studies of the CIT is to choose items for the CIT that have been pilot tested to assure that they are remembered by persons committing the mock crime. Such pilot testing is not possible in field situations and there are no predictive theories of eyewitness memory to use to confidently determine what may be remembered from a crime scene by a highly aroused perpetrator. This inability to assess the memorability of potential CIT items would seem to be a serious problem for the application of the CIT in real cases [8]. Moreover, at least in American forensic cases, the opportunity to apply the CIT seems to be severely limited. Podlesny and his colleagues studied Federal Bureau of Investigation case files and found that only about 10% of their cases were amenable to CIT assessment, even under ideal conditions [9, 10]. To date, Japan is the only country to report widespread application of the CIT [11]. Unfortunately, the supporting evidence for the use of the CIT in Japan is still primarily anecdotal.

Deception-Based Physiological Detection of Deception. The deception-based approaches to PDD use direct accusatory questions, known as *relevant questions*, that address the issue under investigation. For example, in a murder investigation where the victim died from a gunshot, a relevant questions would be, "Did you shoot John Doe?" The earliest deception-based approach was known as the *relevant–irrelevant test*. The relevant–irrelevant test contained only relevant questions and simple irrelevant questions to which the subject was assumed to be answering truthfully, "Are the lights on in this room?" The working theory of the relevant–irrelevant test was that only guilty individuals would show dramatic and consistent responses to the relevant questions. Virtually all contemporary scientists who study PDD state a belief that the working theory of the relevant–irrelevant test is naïve and incorrect. The current belief is that

innocent subjects will easily recognize that the relevant questions are much more important than the irrelevant questions. This recognition is likely to result in a substantial number of false-positive outcomes [4]. Research has supported that belief with the relevant–irrelevant test consistently producing large number of false-positive outcomes [4]. As a result the relevant–irrelevant test currently has little application in forensic testing, although it continues to have application in employment screening [4].

Reid [12] recognized the problems with the relevant–irrelevant test and developed an alternative that replaced the earlier test and is now the test of choice worldwide for forensic PDD tests [3]. Reid's innovation was the introduction of a question that was presented to the subjects in such a manner that it would probably elicit a response that was a lie, "Before the year 2007, did you ever lie to a person in a position of authority?" This question was referred to as a *comparison question*, and the new technique was referred to as a *comparison question test* (CQT). The comparison question is left deliberately vague and covers a long time period. Subjects are told that deception to the comparison questions will make the subject look like the kind of person who could have committed the crime under investigation.

The rationale and the various variations of the CQT have been described in detail elsewhere [4, 8]. The working rationale of the CQT is that guilty individuals will produce strong physiological responses to the relevant questions because they know they are lying to those questions, they have memory of committing the crime, and they are afraid to be caught in their deception. Guilty subjects are not expected to respond strongly to the comparison questions because they address relatively unimportant matters as compared to the relevant questions concerning the crime under investigation. Innocent subjects are expected to produce strong physiological responses to the comparison questions to which they are deceptive and because they have been told that deception to the comparison questions is indicative of criminal involvement. Innocent subjects are not expected to respond strongly to the relevant questions because they are answering them truthfully. The intentional focus of the relevant questions is expected to be on the comparison questions. Overall, the expectation is for an interaction of responding between the question types and guilt. That is, guilty subjects are expected to respond with relevant question responses greater than comparison question responses. Innocent subjects are expected to respond with the opposite pattern, that is, comparison question responses greater than relevant question responses. Currently, there are a number of versions of the CQT in use, in practice, but all of them rely on the same basic idea of comparing the responses to relevant and comparison questions.

During the last 35 years, a large number of studies were conducted on the validity of CQTs. That research was conducted in both the laboratory and field settings. Although those studies have produced a range of validity estimates, it now seems that those studies converge on an estimate of validity around 90%, with some tendency for more false-positive errors, when only the polygraph charts are used for decisions [3, 4, 8]. The tendency toward false-positive errors disappears if only the original examiner's final decisions are evaluated [8].

The CQT has found widespread application in the United States and elsewhere. In the State of New Mexico, the results of polygraph tests are generally admitted as evidence at trial [13]. Across the other states polygraph are sometimes admitted, sometimes used in special proceedings (e.g., sentencing), are frequently used in charging decisions, and they have nearly universal use as an investigative tool. The CQT also has international use currently being used by police in many countries worldwide [8].

There is, however, controversy around the CQT. Some scientists think the working rationale of the CQT is naïve and cannot work. Some have persisted in that belief even in the face of overwhelming data indicating that their position is wrong [14, 15]. Moreover, survey research clearly shows that the majority of the informed scientific community does not support their position [8]. Other scientists criticize the CQT because a complete scientific theory to explain all aspects of the phenomenon is lacking [14]. This position ignores the mass of published research showing high validity for the CQT in application. This is an odd position for scientists to take and it is roughly the equivalent of saying because we lack a complete understanding of gravity, we must therefore not rely on things accelerating toward large masses like a planet. By such reasoning, the pharmaceutical industry and the medical profession should abandon the use of most prescription medicines! In reality, polygraph decision making has been shown to be as accurate as or more accurate than many medical and psychological diagnostic procedures in common use [16].

There are, however, some valid concerns about the application of the polygraph in practice, particularly in the United States. The polygraph profession is poorly regulated and at this time there are no binding standards of practice beyond those provided by those states that license polygraph examiners. The American Society of Testing and Materials International has promulgated a set of nonbinding standards of practice [17] that would seem to be a step toward greater standardization and professionalism in the practice.

There is also a concern about the use of countermeasures to defeat the polygraph. A contemporary review of the scientific research on countermeasures [18] has reached the following conclusions. General state countermeasures that affect the subject throughout the examination (e.g., drugs) are ineffective against the CQT. Specific point countermeasures that can be applied during the test (e.g., muscle tension or mental arithmetic) can be effective for some subjects, if and only if they follow specific training. Spontaneously attempted countermeasures are ineffective. Reading accurate information about the structure of the CQT and possible countermeasures has no effect on the validity of the CQT [19]. Statistical decision models may be more resistant to countermeasure attacks than human-based analysis methods [18].

The use of the polygraph in other than forensic settings is considerably more controversial. A recent review by the National Research Council of The National Academies [20] concluded that there was insufficient data to support the use of polygraph as a screening tool for national security.

Voice Stress Analysis

Over the last 35 years a variety of machines have been marketed claiming to detect deception through the detection of a microtremor in the voice. If such a device worked, it would offer many advantages to those with a need to detect deception. Proponents of these devices, known as a *voice stress analyzers* (VSA) note that their use requires much less training than for PDD, their use is much quicker, and they can be clandestinely. Following their initial introduction. Horvath, in a 1982 review concluded, "Without exception, however, the scientific evidence reported to date shows that voice stress analyzers are not effective in detecting deception; none of these devices has yet been shown to yield detection rates above chance levels in controlled situations." [[21], p. 340]. Although a number of additional studies have been reported since 1982, many of them examining the new computerized version of the VSA, there is no reason to update Horvath's 1982 conclusion. To our knowledge, no controlled study of the VSA has ever produced better than chance results in detecting deception. Given the unanimity of the scientific research, the continued use of the VSA by the police is simply quixotic.

Deception: Detection of and Brain Imaging

Introduction

In this article we summarize the field of deception detection by means of brain activity measures. In the following, we use the terms *deception* and *lying* as synonyms, although some scholars have distinguished between the two (but cf. [1]).

Over the last century, the field of deception detection has gone through three phases. In the first phase, deception detection methods were based on behavioral cues, such as blinking rate and voice pitch, brought about by increases in arousal generated by the act of deceiving. However, no behavioral cues have proven reliably to signal deception [2, 3].

In a second phase, aided by technological advances, the field focused on the detection of subtler changes associated with shifts in the level of arousal that are not visible to the naked eye; that is, researchers focused on changes in peripheral psychophysiological variables, such as heart rate and skin conductance. This phase led to the development of the polygraph that is still the instrument most widely used for deception detection (*see* **Deception: Detection of**). However, despite their widespread application, these measures also proved to be unreliable [4].

During the third phase, in order to find variables that were more diagnostic of deception, researchers began to look at measures of processes that index more directly activity in the brain, the system that produces the lies. That is, rather than rely on the downstream results of brain processing, be they overt behaviors or psychophysiological changes, researchers have turned to the source – the brain – and tried to discover whether deception is signaled by distinctive patterns of neural activation.

Brain Measures and the Detection of Deception

Although there are emerging technologies that may be useful in the field (e.g., optical imaging), the primary technologies used to detect deception with brain-based measures have been event-related potentials (ERPs) and neuroimaging, primarily functional magnetic resonance imaging (fMRI).

ERPs and Detection of Deception

ERPs are derived from the electroencephalogram (EEG), a noninvasive measure of electrical brain activity obtained from electrodes placed on the scalp of an individual. Given the portability and low cost of the technology, it is not surprising that there has been considerable interest in using ERPs in efforts to detect deception – with the hope of eventual

field applications. The EEG is the summation of a myriad of neural processes occurring in the brain at the same time. Thus, to extract measures of brain responses specific to an event of interest, such as the presentation of a word or a picture, one needs to average the EEG data over tens or hundreds of repetitions of the same type of event. ERPs are obtained by time-locking the averages to the onset of the event of interest, which decreases the influence of processes that are not related to the event of interest while at the same time increases the influence of processes that are in fact related to it. The resulting average shows a characteristic sequence of positive and negative deflections that unfold over time, referred to as *ERP components*.

One of the most reliable ERP components is the P300, a positive peak that occurs about 300 ms after a rare and meaningful stimulus is perceived. The P300 is the ERP component that has been most commonly used in deception research, almost exclusively in *concealed information tests* (CITs), also known as *guilty knowledge tests* (GKTs). Note that, technically, these tests do not detect deception *per se*, because the neural signatures of stimulus recognition are present regardless of whether or not the person is being deceptive. However, researchers hope that these tests will enable one to infer the presence of deceptive behavior.

These tests involve presenting three types of stimuli: (i) *probes*, that is, stimuli related to the information that is concealed and that are known to the guilty individual but not to innocent individuals; (ii) *irrelevants*, that is, stimuli that are unrelated to the concealed information and unknown to both the perpetrator of a crime and innocent individuals; and (iii) *targets*, that is, stimuli included to ensure that participants pay attention to the task. The proportion of probe stimuli is very low, compared to that of irrelevant stimuli and the probe stimuli, ideally, are recognized only by the guilty individuals. Thus, probe stimuli generate larger P300s than irrelevant stimuli in guilty but not in innocent individuals. This is the core logic of the ERP approach for detection of deception. Variants of these paradigms differ primarily in the details of the analyses.

Rosenfeld and his collaborators reported the first peer-reviewed ERP studies that used the P300 as an index of concealed knowledge in an effort to detect deception [5, 6]. In these studies, the researchers found that the P300 could be used as an index of knowledge that the participant possesses, even if the participant denied possessing it. Thus, the P300 could be employed to determine what the participants know and also to determine whether they may be lying about what they know.

Numerous methods based on the P300 have been proposed by different laboratories. However, the efficacy of these methods is still controversial, and different laboratories have reported different accuracy results. For example, Farwell and Donchin [7] reported accuracy of 87.5% (accuracy is usually defined as the average of the guilty individuals judged to be guilty and innocent individuals judged to be innocent by the method at hand). Farwell is also associated with the most controversial P300-based method, referred to as *Brain Fingerprinting*. This term relies on a false analogy with actual fingerprinting, implying that the brain stores an immutable replica of an external event. The assumption is that such replica can be accessed via brain fingerprinting. Farwell has claimed 100% accuracy with an improved method, the "Memory and Encoding Related Multifaceted Electroencephalographic Response" (MERMER) but, to date, no peer-reviewed evidence of the accuracy of the method has been published in psychophysiology or neuroscience journals [8].

In numerous publications on the topic, Peter Rosenfeld and collaborators have reported accuracy rates between 80 and 95%, depending on the paradigm and analyses employed. Similarly, John Allen and collaborators reported detection rates of over 90% with overlearned information [9], but less than 50% with mock crime scenarios [10]. The only independent field study using these methods reported accuracy rates of only 48% [11]. Finally, a recent comparison of methods for ERP assessment in the P300-based CIT paradigms reported that accuracy rates varied within the 74–80% range [12].

fMRI and Detection of Deception

fMRI, unlike ERPs, has very good spatial resolution, and so it can localize brain processes with great precision. However, the current temporal resolution of the technique is rather poor, compared to the speed of processing in the human brain; fMRI is based on detecting relatively slow changes in regional cerebral blood flow produced by neural activity. Furthermore, the lack of portability and cost of

the technology (fMRI scanners weigh several tons and require complex infrastructure to be maintained) raises critical issues regarding its application in the field.

Since 2001, there have been numerous fMRI studies of deception using various paradigms [13–27]. Most studies have employed versions of the CIT, although some have used more ecologically valid paradigms. These studies have generally shown statistically significant differences in group analyses in the brain activation that underlies deceptive versus truthful responses. Although there is variability from study to study, the brain regions that are most diagnostic of deception are usually found in lateral and medial portions of the frontal cortex.

Most studies have only examined group data, leaving open the critical issue of how accurate this technology is in single individuals. However, a few of these fMRI studies have estimated the accuracy of the methods in single individuals, using CIT paradigms. For example, Davatzikos and collaborators [15] used high-dimensional nonlinear pattern classification methods (Support Vector Machines) in a group of 22 individuals to discriminate patterns of brain activation associated with producing deceptive and truthful responses in a simple CIT paradigm. The results indicated that predictive accuracy, as measured by determining the proportion of individuals correctly classified in a group not used to train the classifier, was about 88%. Kozel and collaborators [17] used a mock crime scenario involving stealing a ring or a watch. Participants were then scanned with fMRI while they were telling the truth or lying. A group of participants was used to define brain regions that distinguished truthful from deceptive responses and these brain regions were then used to determine whether participants in new group were lying or telling the truth. Results indicated accuracy rates of about 90% in this second group. However, these findings have not yet been replicated by other laboratories, and their generalization to situations relevant to national security and forensic science is unknown.

Countermeasures

Countermeasures are methods used to confound deception detection procedures. For instance, a classic countermeasure is to increase arousal intentionally, and thereby confuse the polygraph – such as by biting one's tongue right after comparison questions (*see* **Deception: Detection of**). Although these kinds of physical countermeasures are not likely to work with brain-based techniques, cognitive countermeasures that rely on inducing specific changes in brain activation are highly problematic. It has been shown that simple countermeasures in which participants generate covert responses to some irrelevant stimuli in CIT paradigms (effectively transforming these stimuli into targets) result in a large P300 being produced by these stimuli [28]. This finding invalidates the logic on which P300 methods are based, and drastically reduces their accuracy [28].

There have been no studies on the effects of countermeasures on fMRI deception detection accuracy rates, but it is very likely that fMRI methods would be affected in similar ways as ERPs by these types of cognitive countermeasures: the brain regions usually found active during deception are also engaged during many other cognitive tasks.

Other Technologies

Some emerging neuroimaging technologies may be used for detecting deception in future applications. One such technology is noninvasive optical imaging [29]. The potential advantages of this technology are its low cost, its portability, and its sensitivity to some of the same signals measured by the most common form of fMRI. Although noninvasive optical imaging has produced reliable results in numerous cognitive tasks [30], there have been no peer-reviewed publications using this technique in deception tasks.

Conclusions

Although brain-based methods for detecting deception are relatively young and show considerable promise, the published accuracy rates so far are not clearly better than those obtained with conventional techniques based on peripheral psychophysiological measures, such as the polygraph. Many researchers are working intensely on different approaches to using brain-based methods; this research focuses on improving paradigms, developing more sensitive brain measures, and devising more sophisticated data analyses. Practical issues also pose important, although not insurmountable, questions about the applicability of brain-based techniques such as fMRI in the field.

GIORGIO GANIS AND STEPHEN M. KOSSLYN

Deception: Truth Serum

"Truth serum" is the popular generic term for drugs and other substances used for the purposes of obtaining information from an unwilling subject; typically by a police, intelligence, or military organization seeking information from a prisoner or potential informant. Sometimes also known as *truth drugs*, these substances have also been used in conjunction with psychotherapy, and promoted as tools for determining the "truth" from persons not simply unwilling to cooperate but also ostensibly unable to reveal information on topics for which they have no conscious knowledge.

Origins of Belief in "Truth Serums"

Throughout recorded history, intentionally or by accident, human beings have been using many substances, in addition to alcohol, that affect mental functioning. For example, ergot, a fungus that can grow on rye and other grasses, was used in rituals in ancient Greece. In modern times, psychoactive substances related to lysergic acid diethylamide (LSD) have been isolated from ergot [1]. The long-term evolution of mind-altering experiences has been accompanied by many beliefs about the properties of psychoactive substances including attributions of their effectiveness as aphrodisiacs, potions for altering the behavior of others, and even beliefs about the ability of various substances to compel truthful responses.

Over time, science has given us a better understanding of the actual properties of these substances, provided drugs derived from basic psychoactive materials, and more recently synthesized new psychotropic drugs in the laboratory. Nevertheless, although significant advances in biochemistry have led to understandings of biochemical dynamics, full understanding of the relationship between biochemistry, behavior, and memory has presented formidable challenges [2] – in no small part because insights into behavior are always influenced by human dreams, fears, and vested interests.

Alcohol use has been traced back to the Stone Age [3], and the time of the early Roman Empire was recognized as having truth-inducing properties (*in vino veritas* or "in wine there is truth"). It took until the 1920s, however, for a Texas obstetrician named *Robert House* to give truth induction an *imprimatur* of science. House had been experimenting with the use of scopolamine in childbirth and concluded that when properly administered, it was "impossible to lie" when under its influence. Dr House promoted his discovery as a "humane third degree" that would protect the innocent from being "convicted upon circumstantial evidence" while eliminating "any excuse for . . . brutal third-degree methods" [4].

Law enforcement officials had long been aware of the effects of alcohol, and that withholding drugs from an addict could facilitate confessions, but the idea of an effective scientific truth drug had great appeal not only for the police but the general public. Soon the Chicago police, in particular, were using scopolamine with reported success [5, 6]. Although scientific research on the nature of memory had been making steady progress into the first decades of the twentieth century, the concept of a truth drug required that emerging concepts of memory be supplanted by a belief that memory was actually akin to a vast video recording, storing every detail of a person's life, permanently and without distortion, even if the

individual had no conscious knowledge of the thus-recorded facts [7].

Misconceptions about the nature of memory would surround the "truth" technologies until finally challenged at the end of the twentieth century. Erroneous beliefs persisted, however, and fostered the discovery of many successor drugs, including barbiturates, that were advanced as "truth" drugs by Horsley in the 1940s [8].

Drugs Promoted as "Truth Serums"

Alcohol

Not only is there a long-standing belief that alcohol can act as a truth drug but also its use for this purpose has persisted to the present day. The Russians, in particular, have an extensive history of using grain alcohol (ethanol) in large doses during interrogations, including interrogations of their own agents to determine loyalty [9] (*see* **Alcohol: Behavioral and Medical Effects**).

Scopolamine

Scopolamine is a botanical alkaloid of the Solanaceae, or nightshade family [10]. The use of scopolamine as a mind-altering substance (producing feeling of flying, hallucinations, and other behaviors that occasionally caused users to be identified as witches) has been traced back to 3000 BC [11]. It was the refinement of the drug in Germany in the 1890s that led the German doctor Von Steinbuchtel of Graz to develop a procedure for the use of intravenous scopolamine to induce "twilight sleep" (*Daemmerschlaf*) in women going into labor. While it was believed that the procedure would prevent pain, it was later discovered that the drug simply induced an amnesia that eliminated memory of the pain and the birth itself.

Moreover, scopolamine stimulated graphic erotic outcries and statements that physicians often assumed to be truthful, contributing to the belief that scopolamine was a "truth" drug (nurses often objected to the use of the drug for what they considered to be a source of amusement for male physicians). In addition, the procedure often led to subsequent psychotic-like symptoms and posttraumatic stresslike memories in the mothers. However, it was the discovery that the drug could cause depressed respiration, could be introduced to the neonate through breast milk; and, in rare instances, could cause death of the mother, the child, or both, that led to the eventual discontinuation of the procedure.

Scopolamine is an antimuscarinic agent, which is a competitive inhibitor of acetylcholine at some synapses, like those in the ciliary body, the iris, and secretory (salivary, bronchial, and sweat) glands. The mechanism of action for its extensive use in the prevention and treatment of motion sickness is unclear, but presumably involves direct anticholinergic action on the vomiting center. The Nazi doctor Josef Mengele reportedly experimented with scopolamine as an interrogation drug. Scopolamine's effectiveness as "truth serum" was investigated by various intelligence agencies in the 1950s, including the CIA as part of project MK ULTRA [12]. It continued to be used in this way into the 1970s.

Barbiturates

Barbiturates are sedatives and hypnotics derived from barbituric acid; they are controlled substances due to their high potential for abuse. Barbituric acid was first discovered by the German chemist Adolf von Baeyer in 1864, who combined urea (an animal waste product) with malonic acid (derived from the acid of apples). Barbiturates probably obtained their name from the fact that they were discovered on Saint Barbara Day. The generic names of barbiturates generally end in *al*. It is the class of barbiturate derivatives known as *thiobarbiturates*, which contain a sulfur molecule in place of one of the oxygen, that were found to have properties that led to their use as truth drugs.

The principal mechanism of action of barbiturates is believed to be their affinity for the gamma-aminobutyric acid $(GABA)_A$ receptor, the principal inhibitory neurotransmitter in the human central nervous system (CNS). In addition to this, GABA-ergic effect, barbiturates also block a subtype of glutamate: the principal excitatory neurotransmitter.

Sodium pentothal (thiopental sodium for injection) [13] is an ultrashort acting barbiturate, meaning that sedation lasts only for a few minutes. Sodium pentothal slows the heart rate, lowers blood pressure, and reduces CNS activity. Sedation occurs in < 1 min after injection. Sodium pentothal is also used as a general anesthetic for procedures of short duration, for induction of anesthesia given before other anesthetic drugs, as a supplement to regional anesthesia (such as a spinal block), and as an anticonvulsive.

Sodium amytal (amobarbital) [14] is an intermediate-acting barbiturate. Sedation occurs in 1 h or longer and lasts for 10–12 h. Sodium amytal depresses the central nervous system. It has been used as a sedative, hypnotic, an anticonvulsive, and has been used as a "truth" drug in what were termed *amytal interviews*.

Benzodiazepines

Benzodiazepines, often abbreviated to "benzos", are a class of psychoactive drugs with varying hypnotic, sedative, anxiolytic, anticonvulsant, muscle relaxant and amnesic properties, which are mediated by reducing CNS activity. Benzodiazepines are useful in treating anxiety, insomnia, agitation, seizures, muscle spasms, and alcohol withdrawal. The generic names of drugs in this class typically end with *pam*.

The use of barbiturates has largely been supplanted by benzodiazepines because of the increased safety of the latter. Barbiturates, benzodiazepines, and alcohol all bind to the $GABA_A$ receptor, but the barbiturates bind with the highest affinity with longer receptor binding half-lives. Barbiturates can activate GABA receptors in the absence of the GABA molecule, whereas benzodiazepines require the presence of GABA to have an effect. This explains why an overdose of barbiturates may be lethal, but overdoses of benzodiazepines alone are typically not lethal.

Temazepam (Restoril) [15] is very fast acting, and the benzodiazepine most frequently used as a "new generation truth serum".

Barbiturates, benzodiazepines, and scopolamine must be administered intravenously and with very careful titration, in order to maintain the dose at a sufficient level to induce the trancelike state required for interview, yet avoid death or other serious side effects. Ethanol must also be administered in very large quantities, and excessive amounts can cause death. Contrary to accounts in popular fiction, it is virtually impossible to follow a truth drug protocol surreptitiously or for a person to be under the influence of a "truth" drug without being aware that such a drug is being employed. Moreover, each of the above substances interferes significantly with judgment and higher cognitive function, with a corresponding impact on the potential for recovering verifiably accurate information.

Other Substances

A number of other substances have been touted as "truth" drugs but no reliable documentation exists to support claims of their effectiveness. The Soviets have boasted of various secret substances, including one codenamed SP-17, but there is no proof that this is anything other than vodka.

Although there is no documentation of oxytocin (sold as an injectable drug under the brand names *Pitocin* and *Syntocinon*) [16] ever being used in an attempt to elicit truthful answers to questions, this nonapeptide found in pituitary extracts from mammals has generated discussion in intelligence circles. From the Greek "quick birth", oxytocin acts as a neurotransmitter in the brain, and in women, it is released in large quantities after distension of the cervix and vagina during labor, and after stimulation of the nipples, facilitating birth and breast-feeding. In humans, oxytocin is thought to be released during hugging, touching, and orgasm in both sexes. In the brain, oxytocin is involved in social recognition and bonding, and may be involved in the formation of trust between humans [17] and in generosity [18]. Moreover, oxytocin increases social behaviors in autistic adults [19]. Although an interrogation setting would likely offset any psychodynamic of this drug, the biochemistry suggests possibilities for interview effectiveness and a rethinking of the use of drugs in intelligence operations.

The Nature of Truth and Memory

Even as the notion of "truth serum" was capturing the fancy of police and the public in the 1920s and 1930s, scientists were publishing research findings on the nature of memory that contradicted the assumptions in the foundation of truth technologies (*see* **Memory: Reconstructive**). Memories are actually edited and consolidated compilations of what may have even initially been flawed or only partial fragments of experience. Memory is not a vast video recording that stores every detail of a person's life. Perceptions are often very short term and fleeting, such as one's images of the terrain as one glances down when he or she is running over uneven ground – these serve a purpose and are then discarded. Typically, memories of the day may be detailed but are eventually sorted out and summarized. The images of what is seen on a commute to work in the morning are processed,

probably during sleep the same night, into simply a recollection that one went to work the previous day. Over time, "memories" of commuting to a previous job will be summarized into recognition of only the fact that one took a particular route to work on most days.

Subsequent additions to these compilations may be selected because they fit well with earlier impressions that were, in turn, shaded by subtle distortions and defenses. The brain's management of memory can be compared with management of a filing system – things that seem redundant are eventually discarded, recurrent information is summarized, and occasionally things are simply misfiled. Digging back into memory to reconstruct a reliable account of historical truth resembles the task faced by a reporter when preparing a story of a train accident from multiple fragments of conflicting eyewitness accounts.

Courtroom witnesses can be compared to people who have been involved in such a train accident. Even if they are fortunate enough to avoid the influences of personal bias and motive, they can find themselves attempting to reconcile perceptions of events they did not anticipate, having viewed the most critical aspects of the event from unique and often distorted vantage points, observed with less than fully focused attention. Like the task of the reporter, memory reconstruction requires weighing sources and credibility, and learning to live with irreconcilable inconsistencies.

Forensic experts therefore find it helpful to distinguish human memories, even when highly credible and consistent, as narrative truth rather than historical truth [20]. Such memories may be very vivid and real to the people experiencing them, and are often the closest available approximation to what the parties obviously accept as "truth", but they can never be the same as historical truth, any more than a movie about a train accident can be the same as the actual original accident.

Eyewitness observations are obviously of great interest to the criminal justice system when a potential witness is thought to have information that may relate to an open case (*see* **Eyewitness Testimony**). Witnesses who have seen perpetrators, getaway cars, or details relating to a crime are often interviewed yet remain unable to recall key details. Occasionally, such witnesses were asked to submit to hypnosis (*see* **Hypnosis and Memory**) or take a "truth serum" to better facilitate recall. Popular topics of movies and crime novels, these processes are often glamorized and easily misunderstood.

Both hypnosis and drug interviews lower inhibitions and minimize conscious editing of beliefs, but neither can facilitate recovery of information that the subject never possessed nor can they conclusively distinguish a conviction that the subject believes to be true from actual historical truth. There are, however, instances in which these techniques can be useful, and one way to think about how they do work is through a computer analogy. When you delete a file from the disk on your personal computer, the file is seldom immediately erased, but is instead deleted from the indexing capability that allows the computer to access and retrieve the data. The computer may eventually run out of storage space and write over some or all of the actual deleted information, but in the meantime, the original data simply sits, inaccessibly, on the disk itself.

This process is similar to what the brain does as it reviews and processes daily perceptions; it selects what it considers to be important and releases the rest to simplify processing and maximize the use of storage capacity. If something is "misfiled" it may be retained, but is "forgotten" unless or until there is a reason to recall the information with which it was actually stored.

However, while this compilation process is taking place, unprocessed details remain in the brain, just as "deleted" files can remain on a computer disk. Most people who have inadvertently erased an important file have had occasion to learn about computer utilities that allow you to "recover" data. These utilities do not work like application programs; they instead allow direct access to files no longer indexed for logical access, "forgotten" but as-yet-unerased data files. Hypnosis and drugs can serve a similar function with the human mind, allowing the bypass of normal mental processing logic, and possibly the recovery of images that have been misfiled or are awaiting deletion.

Suppose an investigator is seeking, for example, the license plate of a getaway car. This information could have been noticed in passing by someone on the street, but ignored and subsequently set aside by the mind as unimportant to that person. No longer accessible, the number sequence of the license plate may, nonetheless, sit in memory awaiting final processing and deletion. Hypnosis or medication may

provide a way to search through fragments of images and find what could be the elusive plate number.

Using hypnosis or medication does *not*, however, provide any indication of the historical truth of the information. The human mind is filled with vague perceptions, questionable beliefs, fantasies, images from favorite old movies, snatches of tales told around childhood campfires, and countless other vivid information of dubious authenticity. It is the job of the mind's central indexing system to keep track of all of this information and remember what is real and what is not. When this critical *source monitoring* is suspended, as it is in hypnosis or by "truth" drugs, it becomes impossible when attempting recollection to distinguish truth from fiction. This may not be a problem for an investigator who can check plate numbers against possible suspects and gather additional sources of physical evidence to verify and build a case, but to think of such interview results as "truth" is without scientific basis.

An even greater danger, however, lies in the potential for altering human memory once the mental safeguards designed to distinguish information by source and reliability – source monitoring – have been lowered. The application programs on a computer, for example a word processor, keep track of when and why files were created. Recovery utilities bypass this electronic form of source monitoring. Just as a computer user can then accidentally misuse a file recovery utility to misinterpret or corrupt files on a hard drive, an investigator can use hypnosis or drugs to interpret or suggest images and beliefs that never originated in actual human experience.

This "editing" of perceived reality does not even require special procedures or prescription drugs. Many over-the-counter and illicit drugs, including alcohol, have, among their properties, an ability to weaken that portion of the brain that monitors the origin and credibility of images and beliefs. Moreover, this reduction in source-monitoring efficacy, which increases susceptibility to influence, need not require drugs or external intervention of any type.

Alterations in belief and memory are influenced by both the nature and context of the messages to which people are subjected, as well as by individual characteristics and motivations. The former, which includes what may be also termed *propaganda and coercion*, can be understood collectively as forms of persuasion.

Persuasion

The experiences of American prisoners during the Korean War generated international attention to what had become popularly known as *brainwashing*. Following that War, extensive studies were conducted with former prisoners. The results, published in *Psychiatry* in 1956 [21], helped to shape the direction of research on social influence, and lay the foundation for what has since been confirmed in what we now know about the operation of the human brain.

The approach used by the Communists was, according to the report, "to gain complete control over those parts of the physical and social environment which sustain attitudes, beliefs, and values, breaking down interactions and emotional bonds which support the old beliefs and values and building up new interactions which will increase the probability of the adoption of new beliefs and values. If the only contacts a person is permitted are with persons who *unanimously* have beliefs different from his own, it is very likely that he will find at least some of them with whom, because of growing emotional bonds, he will identify and whose beliefs he will subsequently adopt". (p. 333–334).

"Taken singly," the study concluded, "there is nothing new or terrifying about these techniques... [some even]...have their counterparts in education and in psychiatry...[or are widely used]...by the *police* [emphasis added], by newspaper reporters, and by others interested in aggressively eliciting information... Forced confessions and self-criticism have been widely used techniques in religious movements as a basis for conversion...the only novelty... [here]... was the attempt *to use a combination of all these techniques and to apply them simultaneously* in order to gain complete control over significant portions of the physical and social environment..." (p. 334).

The role of persuasion or coercion in any given human decision is in part a matter of perspective, and we must always carefully weigh questions of free choice and duress [22]. Nevertheless, the impacts of persuasion and duress are real [23], and the concerns that they raise are reflected in the structure of our legal systems and the holdings of the courts [24] (*see* **Confessions: Evidentiary Reliability of**; **Interrogation**; **Interrogative Suggestibility**; **Capacity to Waive Miranda Rights**).

Suggestibility

Suggestibility is a function of both individual characteristics and personal hopes and fears (*see* **Eyewitness: Suggestibility of**; **Children: Suggestibility of**; **Children: as Witnesses**).

In June 1962, employees of a Southern textile mill were stricken with a mysterious illness. Investigators attributed the illness to the bite of insects that were brought into the factory in a shipment of cloth that had arrived from England. The insect attacked the skin, the bite leaving a wound similar to the bite of a gnat. In about 20 min, the victim was stricken with severe nausea and a rash that covered much of the body. Within a matter of days the resulting epidemic forced the closing of the factory.

Yet despite the consistent and specific symptomatology, so impressive that a vast array of professional talent was mobilized to cope with the problem, and the strength of the victim's belief in the reality of the "June bug", no acceptable medical explanation could be found. Given the demands of a peak production season, the personal needs of employees, and the fact that no other complaints could be found to lodge against a relatively new and progressive factory, the existence of an "epidemic" at that time and place was the ideal answer to the wishes of its victims [25]. If the wish can be the father of the dream, that dream is but a step away from belief. And belief, even in a factitious illness as seen in Munchausen syndrome and induced in children by their parents in Munchausen by proxy [26–30], can be powerful enough to produce the required physical symptoms. Powerful enough in the case of Voodoo, for example, to result even in death [31, 32].

The phenomenon is hardly new, nor is it confined to our culture. George Rosen, in his classic *Madness in Society* [33], traces similar examples back to ancient times. Madness is, moreover, the correct term. While such behavior is hardly productive – wiping out people's savings, threatening their health and even their lives, and often leading those caught up in its frenzy to neglect responsibilities and violate the law – it is neither the product of mental disease nor within any definition of legal insanity. It is simply people acting as though their fantasies were reality. And nothing fans the flames of madness like having the people around you, those to whom you usually turn to test reality, share your belief in the reality of your own dreams and delusions.

The ability to keep track of the source of perceptions and beliefs – source monitoring – like most individual traits, varies widely throughout the human population. In the early 1970s, Herbert Spiegel confirmed the variability of response to hypnotic suggestion, and identified a high level of susceptibility that occurs naturally in 1 out of every 10–20 people [34, 35].

Individuals in this grade 5 group frequently demonstrate spontaneous trance logic, the capacity to act as if unaware of the most extreme logical inconsistencies, and to suspend normal levels of critical judgment. Such individuals are particularly sensitive to the views and preferences of those around them, and outstanding in their ability to comply with the wishes and beliefs common to their environment. People with this characteristic can act as if hypnotized even when every effort is made to avoid hypnotizing them, and when in their own spontaneous trance states they are highly susceptible to enduring distortions of memory and the confusion of fantasy with reality.

Implanted Memories

It was not until the 1990s that events forced a reexamination of the assumptions implicit in the belief that "truth" drugs and procedures could yield scientifically reliable results. For most women, the 1980s had been a time of fruition in a decades-long campaign for expanding opportunities. At its root, however, many activists saw the women's movement as similar to the civil rights struggle. A faction of its constituency even came to envy the privilege, attention, and status accorded the dependent and the oppressed with whom they identified.

Throughout any culture, there are unhappy people searching for an explanation for their unhappiness [36]. There is no seemingly safer refuge than fantasy, and early in his career Freud was struck by the number of grown women who recounted childhood sexual encounters with parents and other adults [37, 38]. Freud eventually concluded that these stories had to be factually untrue, if only on the weight of the evidence and their internal inconsistency [39], but the accounts were understandable by their ability to interweave themes of sexual desire, seduction, dependency, and exploitation into a warm blend of desirability and justification for special dispensation.

As the women's movement progressed, the desire to satisfy this combination of fantasies found expression in the vast popularity of fictional works that were increasingly presented as true accounts; for example, *The Exorcist* [40], *Sybil* [41] *Michelle Remembers* [42], and *Communion* [43]. All of this may have come to nothing more than harmless diversion had it not been for the convergence of three larger social forces. The first was the women's movement that made it increasingly difficult to dismiss women's concerns as delusional nonsense. The second was the shocking discovery that all forms of sexual abuse *really were* much more common and destructive than previously believed. Finally, in the 1960s, psychotherapy itself had undergone a dramatic transformation that had brought in significant numbers of "alternative" clinicians – many of whom dedicated their practices to meeting the felt needs of special client populations.

Much of this new professional faction worked very hard to appear independent of previous "male" biases. Cloaking their activities with the respectability of sympathetic, well-credentialed psychiatrists [44], and evoking images of the Nazi war crime cover-ups, popular writers with few if any clinical credentials began to pour out mass-marketed books like *The Courage to Heal* [45] and *Breaking the Circle of Satanic Ritual Abuse* [46].

These books, and the individual and group "therapy" sessions, which they spawned, swept the country. Feminist and New Age bookstores could not keep the wave of materials on their shelves, and the "abuse therapy" business boomed – funded in large part by insurance dollars [47]. But once the movement ignited, it took on a life of its own. Before long, psychologist/lawyer teams sprang up to avenge the "victims", and the most popular adjunct treatment for the abused patient became litigation. Kits catering to those thirsty to sue and thus have the forum, which they were told would offer their essential therapeutic opportunity for confrontation and justice, joined the pop psychology books that packed bookstore shelves [48].

Starting with a trickle in the mid-1980s, the courts were soon inundated by a torrent of suits that by the 1990s would grow in number to over 800, with at least 17 000 threatened or in various stages of preparation [49]. From the beginning, it was the courts that stemmed the tide, using the statute of limitations under the discovery rule to prevent cases alleging old harms that no one can adequately defend against [50]. Rarely if ever did any plaintiff assert any corroborating evidence, and all of the cases seemed to boil down to the word of one family member against another. Nevertheless, the mass media quickly took up the quintessential feminist cause – how could the law presume that a woman was wrong when she accuses a man of the most unspeakable of exploitive crimes. In rapid succession, more than half of the states in the nation revised their statutes of limitation to facilitate suits alleging recovered memories of sexual abuse [51, 52].

Many of the allegations were outrageous, involving complex cults and accomplices from outer space [53, 54]. Although the accusers ranged across all genders and backgrounds, the vast majority were not stereotypical victims but white women in their 20s to mid-40s from American Gothic families who had been well educated and had found moderate success in middle-level professions. Most had few signs of serious disturbance until they entered therapy. In fact, this influx of persons seeking help required dusting off the previously discredited diagnosis of "multiple personality disorder" [55], transforming it into a condition characterized as "extreme and dramatic, involving significant amnesia ... [with] ... sudden loss of memory, change from a sad, dependent, and helpless personality state to an angry, demanding hostile one in seconds ... involving alterations in identity, memory, consciousness, and somatic function ... [that] ... occurs as a defense during and after trauma, a means of maintaining mental control just as physical control is lost" (for source of quotations *see* **Dissociative Disorders**).

"Dissociation may especially occur when role conflict with important family figures on whom one depends is involved, a condition that has been described as 'betrayal trauma' ... Keeping conflicting views of the same person in mind creates considerable tension and confusion, and complicates memory storage and retrieval." The mental health professions were divided by the controversy that resulted, clinicians on the one hand contended childhood sexual abuse opened up a vast new population in need of care, and researchers on the other hand pointing to a century of science that refuted the basic assumptions underlying the clinicians' assertions [56, 57, 58] (*see* **Memory: Repressed**).

Childhood sexual abuse therapists were convinced that the symptoms seen in their new patients were

proof of early sexual trauma, the memories of which had been repressed. If they could simply "recover" those memories, they would have the smoking gun needed to initiate the litigation that would "cure" the psychiatric condition [59, 60]. Amytal and hypnosis were employed, and, not surprisingly, the desired repressed memories were "recovered" [61]. These therapists solution reached back to Dr House and the "truth serum" that had captured the fancy of the public early in the century.

Concerned behavioral and forensic scientists came together to document the truth [62]. Vilified by the opposition as a refuge for sex perverts [63], their organization went to work taking on what had become a worldwide problem. Working with the accused, they lobbied to make their voice heard in the legislatures and turn back the popular tide of statute changes that had effectively targeted accused offenders in a way normally not used against any other class of defendants. Secondly, they learned to use the litigation process and in doing so, revolutionized third party standing by opening the door to suits by falsely accused family members against their accuser's psychotherapists – this despite a history of legal tradition that held that only patients or those paying for a patient's care could sue for malpractice [64–66]. As the opposition began to crumble, some 300 accusers recanted with 60–70% of these also lining up to sue their own former therapists [67–72]. Finally, the scientists attacked the credibility of the expert testimony used to support "recovered memory" litigation against family members in a systematic effort by experts to protect the integrity of behavioral science expert testimony [73–78].

Faced by objective data from respected scientists, a new perspective came to dominate the media. In 1993, Lawrence Wright published his account of the Paul Ingram case in the *New Yorker* [79], and in April 1995 *Frontline* ran a two-part special that brought to an end any momentum that may have remained in the recovered memory movement [80]. The tide of accuser suits crested in 1994 [81, 82], and turned to recede in the wake of the landmark case of *Ramona v. Ramona* [84].

What Kind of "Truth" Can "Truth Serums" Elicit

"Truth serums", of course, are neither serums nor scientific tools capable of reliably eliciting historical truth. Hypnosis and the various drugs touted as truth serums do generally lower inhibitions and inhibit the cognitive functioning needed to distinguish stored recollections from implanted beliefs, but this can also be said of the persuasive techniques that do not rely upon drugs or traditional hypnosis.

Interrogation employing any of these techniques, or simply providing an alcoholic drink, is likely to make the subject more talkative. If such actions result in any information, the accuracy of that information is likely to be greater if it involves recent events still in short-term memory. However, even under the best of circumstances, recall is always limited by the accuracy of the information stored, the quality of the storage, and the precision of the retrieval.

Lowering inhibition and reducing cognitive control encourage a person to be more talkative, but loss of inhibitions is not the same as loss of self-control. Subjects can still lie, fantasize, and even provide deliberately misleading information, although they can also be more easily manipulated by an interviewer's suggestions and cues into telling falsehoods. Although it may be possible to troll for miscellaneous facts such as a license plate number, such information would be of dubious value unless it could be independently verified. In short, the procedures used for most of the twentieth century to obtain secrets and information ostensibly beyond the conscious awareness of human subjects are inconsistent with established scientific findings and unsuitable for the purposes for which they have been used [84].

Legal Issues and Admissibility

Four major considerations govern the admissibility of all of the "truth technologies", and, in turn, any decision to employ the procedures in the first place.

Finder of Fact

Just who is or is not telling the truth in a legal situation in which the facts at issue are material to the outcome of the case is a question of fact usually left to the trier of fact – the jury or in some instances a judge. The judiciary is very reluctant to take such decisions away from the trier of fact, and therefore does not permit expert testimony to substitute for a party taking the stand for direct assessment by a jury. Similarly, although science has clearly demonstrated that eyewitnesses may provide the most unreliable

forms of evidence, we leave their evaluation to the jury and even make it difficult (depending upon jurisdiction) to provide expert testimony on the reliability of eyewitness testimony.

For the same reason, the courts generally do not allow admission of the results of lie-detector tests or other new high-technology deception technologies [85]. Not only are they of questionable scientific accuracy but they are also limited by the same human memory constraints as hypnosis and truth serums (*see* **Deception: Detection of**; **Deception: Detection of and Brain Imaging**).

"Truth serum" and hypnosis evidence also impinge upon the prerogatives of the finder of fact, and for this reason alone have been held inadmissible as legal evidence.

Self-Incrimination

Although the courts have never addressed the issue directly, "truth serum", as well as hypnotic evidence, is presumed to be coercive and therefore its results, as they relate to a criminal defendant, are inadmissible against that defendant [86].

Torture

Recently, the scope and intent of Miranda have been strengthened through the legal argument that the use of "truth serum" is torture, and therefore even if its results were not precluded under Miranda itself, it would be precluded as torture [87].

Court Holdings on Admissibility

Although the U S Supreme Court has never addressed the admissibility of "truth serum" evidence directly, the 1963 Chicago *Townsend* case [88] is frequently cited as binding precedent. In that case, the State did not dispute petitioner's assertion that the use of a "truth serum" to obtain his confession was unconstitutional. State courts have also consistently held that "truth serum" evidence is inadmissible, typically because it fails to meet scientific evidence standards [89]. Moreover, even if a suspect did not confess under the influence of a drug but simply provided a single scrap of information that ultimately led to evidence sufficient to convict, that entire chain of evidence could be excluded as "fruit of a poisonous tree".

Tradecraft and Clinical Practice

Obviously, substances that have been used as "truth serums" can have other legitimate medical applications, and nothing in the science of memory or truth precludes their use for those additional purposes. However, some gray areas that touch upon truth warrant mention. For example, one of the authors of this article was treating a patient who had suspected hysterical paralysis. Because this condition involves higher cognitive processes that may nevertheless be unconsciously preventing a physical act otherwise unimpeded by a physical anomaly, an intravenous barbiturate was administered to bypass higher cognition; whereupon the patient no longer suffered paralysis. In a sense, this was a test of truth, but here the truth was a function of altered behavior rather than reported memory [90].

The use of "truth" technologies, although attempted in the past by virtually all major intelligence agencies, is currently disavowed worldwide. The United Nations considers the use of "truth" drugs to be physical abuse and, therefore, a form of torture [91, 92]. Moreover, intelligence and interrogative tradecraft has generally come to a consensus that traditional interview techniques, without drug or high-technology supplementation, are the most effective way to gain information. As one operative observed, when one person acts as the "good cop" and creates a bond with the prisoner, the process probably makes use of the brain's own oxytocin. As the interrogator observed, recent science has just taught us "the neurophysiology . . ." [93].

The issue was revisited in 2002, when some authorities, including former Central Intelligence Agency and FBI chief William Webster, became frustrated by the lack of forthcoming information from suspected al-Qaeda and Taliban members held at the U.S. prison in Guantanamo Bay. Some, including Webster, advocated administering "narcoanalysis" drugs to uncooperative captives [94]. Because terrorists are known for their preoccupation with secrecy and loyalty, this suggestion alone may have served a propaganda objective. Nevertheless, considerable thought has been devoted to the "ticking bomb" scenario [95].

This is the situation in which a country's authorities know that terrorists have set in motion a weapon of mass destruction. One of the terrorists in custody will not talk. There is no real concern about

the conviction of this one terrorist or about the admissibility of any evidence that he may provide – only finding and defusing the bomb. Though the authorities know that statements made under the influence of any "truth" substance may not be true, they consider any information to be better than nothing and are prepared to follow any lead. Should they use the drug?

Conclusions

"Truth" substances are one member of a class of techniques and technologies that maximize suggestibility and facilitate persuasion. Although these all may make a subject or suspect more talkative or tractable, there is no scientific basis for the belief that statements made under their influence are necessarily true. Truth and memory are complex topics, and involve fragile mental processes. There is also no basis for believing that memories of distant events reflect historical truth or can be "recovered" from the subconscious. Although "truth" drugs can lower inhibition and reduce cognitive control, these effects are not the same as loss of self-control. Subjects can still lie, fantasize, and even provide deliberately misleading information, although they can also be more easily manipulated into telling falsehoods by an interviewer's suggestions and cues. The use of these substances is considered torture under international law, and evidence obtained through or as a result of their use is legally inadmissible in virtually all courts of law.

Delusions

In the current diagnostic nomenclature of the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR), delusions are defined as false beliefs based on incorrect inference about external reality that is firmly sustained despite what constitutes incontrovertible and obvious proof or evidence to the contrary. Delusions are beliefs that are not ordinarily accepted by the affected person's social or cultural milieu [1, pp. 821–822]. A delusion needs to be distinguished from an overvalued idea in which an individual harbors an unreasonable belief or idea, but does not hold it as firmly as is the case with a delusion [1, pp. 821–822].

The aforementioned description of a delusion entails two important defining characteristics. First, it tends to view the nature of delusion as a seemingly unitary process. Second, delusional thinking tends to be viewed as a mutually exclusive binary process, i.e., delusions are fixed cognitions but not vice versa. More recently, delusions have been increasingly viewed as a multidimensional process in which some delusional characteristics are robustly representative of delusions, while others present with a more variable nature [2]. In this entry, we follow the latter view, because it provides a clearer and more systematic explanation of delusional experience. For example, a high degree of conviction continues to be an important characteristic of delusional thinking that frequently results in fixed delusions that constantly preoccupy the affected individual. Nonetheless the intensity of delusional conviction can fluctuate considerably, depending on factors such as social isolation and exposure to environmental stressors.

Delusions are amongst the most significant of psychiatric symptoms as they figure prominently in serious mental disorders such as schizophrenia, schizoaffective disorder, psychotic disorder due to general medical condition, substance-induced psychotic disorder with delusions, and of course, delusional disorders. A delusion has the distinction of being the only psychotic symptom for which separate category of psychotic disorders derives from the symptom itself.

Delusions may be divided into primary and secondary types. Primary delusions are explained by a psychological process that is essentially irreducible such as a religious delusion. Secondary delusions can be explained by other psychological processes such as hallucinatory experiences or affective factors. Differentiating primary versus secondary components may be of forensic relevance. For example, command hallucinations urging a person to kill others may increase a paranoid delusional conviction and the risk for violence toward others. This example also highlights the need to differentiate delusions from other psychotic symptoms as potential contributors to violent behavior.

Delusions may have varying degrees of organization. Some delusions are relatively simple, with a tendency to fragment, whereas others may present with very complex and highly stable plots involving many people, organizations, and conflicting concerns. Some delusions display a stable time course and may last for many years, while other delusions are relatively short-lived, though recent research suggests that certain factors such as never having married, older age, diagnosis of schizophrenia, delusions of body/mind control and thought broadcasting, having acted on a delusion, and higher levels of psychopathology and functional impairment are associated with persistence of delusional thinking [3].

Delusions are often classified according to content [4]. In "persecutory" delusions, the affected person believes he or she has become the object of mockery, harassment, persecution, or conspiracy. These delusions form the core feature of paranoid schizophrenia and delusional disorders. The central theme of "grandiose" delusions involves a grossly

exaggerated belief in the worth, importance, or power of the affected person. They are especially common in the manic states of bipolar disorder and mood disorder due to a general medical condition as well as occurring in schizoaffective disorder, schizophrenia or delusional disorder due to a general medical condition or induced by an exogenous substance. "Somatic" delusions encompass the belief that physical events in a person's body are occurring despite much evidence to the contrary. An example of a somatic delusion is a man who believes that he is pregnant and is about ready to deliver his own baby. A "nihilistic" delusion is characterized by the nonexistence of the self, part of the self, others, or the world. An example of this is a person who believes that he or she lost all his organs and is empty inside. Nihilistic delusions may be synonymous with somatic delusions if the emphasis of the delusional content involves nonexistence of the body or body part. "Jealousy" delusions involve the false belief that one's marital or sexual partner is being unfaithful. "Erotomanic" delusions involve the theme that the patient is the object of amorous pursuit by another. In "misidentification" delusions the affected person believes that the self or another presents with new physical or psychological attributes resulting in a new identity. A man who believes that his mother has been replaced by a physical double of his mother would be an example. Delusions have also been divided into a binary system of bizarre versus nonbizarre delusions. Bizarre delusions involve ideas that are not plausible such as, for example, if someone delusionally believes that most human beings are mechanical robots. An example of a nonbizarre delusion has an element of plausibility, as exemplified by the delusion that a spouse is sexually involved with a close friend of the man who harbors delusional jealousy.

Most cases of delusional thinking involve only one individual. However, on rare occasions, a delusional system may involve multiple individuals. For example, in the condition of folie-á-deux (currently subsumed under the diagnostic category of shared psychotic disorder), a second previously unaffected person develops the same delusion(s) as the primary or inducing person who already harbored an established delusion(s). The central feature of the induced or shared delusion(s) is its development in the context of a close relationship between the primary and secondary persons [4].

The Origin of Delusions

Although psychiatrists and other mental health professionals have in many cases constructed a psychodynamic explanation of the psychological and ecological factors that led to the development of an individual's delusional thinking, in recent times research has focused on the biological origin of delusions. Delusions are thought to be caused by abnormalities in cerebral physiology [5]. Although discrete physical causes are often not found, many delusions have been associated with an extensive array of biological factors. A large list of brain diseases can lead to the development of delusions. Delusional thinking can be found among many common neurological or medical conditions, including Parkinson's disease, Huntington's disease, syphilis, Alzheimer's disease, epilepsy, brain tumors, and traumatic brain injury. Medical conditions outside of the brain and central nervous system can also give rise to delusional thinking, including various endocrine disorders, vitamin deficiencies, and autoimmune disorders that would be recognizable to everyone [6]. Using various neuroimaging techniques [such as single proton emission computed tomography (SPECT), magnetic resonance spectroscopy (MRS), and positron emission tomography (PET)], researchers have been able to demonstrate brain changes on the cellular and neurotransmitter level in the development of delusions and other psychotic symptoms in individual who have used various psychoactive substances, including alcohol, amphetamines (primarily methamphetamine), cannabis (marijuana), cocaine, methylenedioxymeethamphetamine (MDMA, also known as Ecstasy), phencyclidine (PCP), ketamine, and inhaled hydrocarbons (such as gasoline, glue, paint, and related compounds) [7–12].

Treatment of Delusions

When there is an identified biologic causation to the delusions, such as a vitamin deficiency or endrocrine disorder, the treatment of the medical condition with the appropriate vitamin or hormone replacement/blocking agent would be the first step. Similarly, when treating a substance-induced psychotic disorder with delusions, abstinence from the offending drug should, but not always, ablate or attenuate the delusion(s) and other associated symptoms. Treatment of delusions accompanying a degenerative brain

disease such as Alzheimer's disease or Parkinson's disease has a lower success rate in view of the limitations of the therapeutic interventions for these medical illnesses.

In treating delusions in cases of schizophrenia, mood disorders with psychotic features, or other psychoses, use of antipsychotic medications has generally resulted in reduction of auditory hallucinations, delusions, and/or other manifestations of psychosis in most individuals. Interestingly, the clinical response in individuals with delusional disorders appears to be less successful [13]. Nonetheless, a significant proportion of individuals harbor delusions that appear to be refractory to clinical intervention.

Malingering of Delusions

The central feature of malingering involves the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives [1, pp. 739–740]. The frequency of feigned psychosis is unknown [14]. Research has not yet arrived at a foolproof method to determine the presence of genuine verses manufactured psychosis.

From reviewing the literature and his clinical experience, forensic psychiatric Philip Resnick has found that recognition of a malingered delusion requires clinical knowledge of the phenomenology of genuine delusions. Rensick has identified four particular signs that raise the suspicion of feigned delusions. These four signs include: abrupt onset or termination of the delusion; an individual's eagerness to call attention to the delusions; conduct markedly inconsistent with delusions; and bizarre content without disordered thinking [14].

However, on closer inspection of Resnick's inquiry, Resnick's method involves comparing the individual's description of the delusions with characteristics of delusions described by actual patients. Although the survey of the literature on the presentation of delusions shows likely characteristics as to what constitutes a genuine delusion, there remains some degree of uncertainty in some cases. Of course, during the course of ordinary and routine clinical practice of inpatient psychiatry, individuals may misrepresent the presence or extent of delusions to resist or gain admission, remain in the hospital, or seek release from the hospital.

At this point, keeping abreast of the clinical and research psychiatric literature may be best strategy for psychiatrists and other clinicians to know the typical characteristics of various delusions. The determination of the genuineness versus the manufacture of a reported delusion often does not present as a simple dichotomous choice. Individuals who have had previously experienced delusions, whether from a mental disorder, medical illness, and/or recreational or prescribed drug use, have first hand knowledge of the characteristics of a delusion, thereby complicating the task.

Probably the most frequent occurrence of manufacture or exaggeration of delusions involves requests for admission to psychiatric facilities, whether by individuals with no history of mental illness or by individuals who have previously harbored delusions. Also the most frequent manifestation of denial of actual delusions takes place when individuals seek to avoid psychiatric hospitalization, or if already hospitalized, to obtain release.

Delusions in Forensic Settings

Outside of the civil commitment setting, delusions arise in a variety of legal contexts. In a nutshell, forensic evaluators attempt to determine the presence of delusions in regard to the legal issue involved and if present, the effect(s) of delusion(s) on the legal matter at issue. Outside of the treatment-related civil commitment realm, common forensic evaluations in which delusions may be especially germane involve disability, competency to stand trial, mental state at the time of the offense, and dangerousness.

The so-called content-specific delusions, particularly those involving specific objects or targets of the delusion, may have increased forensic relevance. In particular, misidentification delusions, erotomanic delusions, and jealous delusions have been associated with cases of violence directed at the object of the delusion [15–17] though the relative risk of these delusions compared to delusions in general remains unclear.

Functional Capability Versus Disability

Delusions can be a significant factor in determining a person's work ability or degree of compensable disability. Individuals harboring paranoid or persecutory delusions may seek to avoid perceived persecutors, thereby precluding employment in positions that require interpersonal interaction. Certain

jobs may draw delusional individuals such as security guard work [18]. Delusions not involving specific paranoid or persecutory fears may be of such intensity that an individual becomes preoccupied to the extent that the person would not be able to focus on the tasks of the job. Delusions thus may form the central reason in evaluations for disability income, fitness for duty, or disability retirement.

Certain delusions, for example, nihilistic delusions may led to individuals refusing to eat because they harbor the delusion that they are already dead. When individuals reach the point that they lack the ability to provide for their basic survival needs, appointment of a guardian or conservator may be necessary.

Although not a disability issue, in the occupational context, workers who raise false allegations of harassment or discrimination based on sex, race, or gender that arise from delusional thinking may be especially problematic.

Competence to Stand Trial

Pretrial defendants who harbor delusions may have significant impairment in the capacities to meaningfully communicate with defense counsel to prepare a defense or to participate in the courtroom proceedings. Such impairment could jeopardize the defendant's competence to stand trial if the jurisdiction's criteria for incompetence are satisfied. The presence of delusions does not automatically confer incompetence as some individuals can proceed with their case if the delusions do not dominate their thinking or whose specific content is peripheral to the trial process. Defendants who harbor specific delusions revolving around defense counsel, for example, may preclude these individuals from even meeting with defense counsel.

Mental State at the Time of the Offense

Delusions often form part or all of the basis for a clinical-legal opinion supporting the insanity defense or diminished capacity. In regard to the insanity defense, delusions play a crucial role. An adjudication of not guilty by reason of insanity can be made if the trier of fact finds that the delusions negated the defendant's cognitive or volitional capacities as outlined by the jurisdictional insanity statute.

For example, a worker who develops the delusion that her boss is a nonhuman extraterrestrial creature who intends to kill her and then kills her boss in front of coworkers may qualify for the insanity defense, based on an incapacity to know right from wrong (or appreciate the criminality of her act) at the time of the killing.

Dangerousness

When assessing individuals for risk of harm to others, whether for initiation of civil commitment, or prior to releasing an insanity acquittee into the community, the presence of psychotic symptoms, particularly delusions, often merits close consideration. Delusions almost always are not a solitary factor in risk assessment, but need to be considered along with a host of other symptoms and factors [19]. Because of different study designs and different samples, there are varying findings as to effect of delusions in contributing to violent behavior [20–23].

Demonstrative Evidence

Demonstrative Evidence Is a Broad Label

Demonstrative evidence is a term used to describe a particular form of physical or documentary proof under the technical admissibility rules used primarily in the United States, the United Kingdom, Canada, and other countries, whose system is based on the adversary system of justice (*see* **Expert Opinion in Court: a Comparison of Approaches**; **Expert Opinion: United States**; **Expert Opinion: United Kingdom, Canada, and Australia**). Demonstrative evidence is not used as substantive proof of a fact but, instead, to explain the oral factual or opinion testimony of a witness.

Demonstrative evidence can be in the form of casts, models, drawings, photographs, motion pictures, videotapes, computer animation (*see* **Computer Animation and Simulation Evidence**), physical objects, and other types of an inanimate nature such as skeletons, toys, dolls, etc., [1–7]. The scope of what can be offered as demonstrative evidence is only limited by the imagination of either the witness or the litigator.

In the forensic sciences, demonstrative evidence is widely used by a great variety of skilled professionals. A representative list includes the following:

- plaster casts of impressions made by trace evidence analysts or other crime-scene investigators;

- scale models of places, buildings, or objects that are related to the place where the incident that is the subject of litigation occurred;
- skeletons or anatomical models to illustrate wounds or injuries;
- anatomically correct dolls to aid a victim of a sexual abuse and rape case;
- maps, plans, and sketches that relate to a crime or an accident scene, whether made free-hand, to scale, by an investigator, witness, or licensed surveyor;
- artist drawings of suspects, Identi-Kit likenesses, computer-generated composite sketches, and other representations of unknown persons from visual descriptions furnished by eyewitnesses or victims;
- charts and drawings produced photographically that illustrate an identification expert's conclusions, such as those used by fingerprint experts to draw attention to matching characteristics in latent marks and known exemplars, or by firearm and toolmark examiners on photomicrographs matching marks impressed on crime scene and exemplar bullets or cartridge cases;
- other photographs produced by film and paper as well as digital cameras, whether in black and white or in color or even when produced by specialized photographic techniques such as X rays or by other medical instrumentation, representing buildings, locations, persons, objects, or findings that are relevant to issues in civil as well as criminal incidents;
- motion pictures and videotapes of places or persons involved in litigation-related incidents, including but not limited to driver-arrest circumstances, day-in-the-life-of-a-person moving images, and similar occurrences;
- computer animations and simulations of events supporting accident reconstruction findings and other incidents of relevance to civil and criminal cases; and
- charts and summaries, compiled under a great variety of circumstances.

Weighing the Probative Effect against Potential Prejudicial Impact

The admission of such evidence is ordinarily within the discretion of the court. The judge will typically weigh the probative value of the evidence against the prejudicial effect that the evidence might have on the jury. It is always required that the proposed evidence illustrates or explains a relevant issue in the case.

As the admission of demonstrative evidence requires that there be a testimonial sponsor of the proof who has personal knowledge of its connection to the litigation, the sponsor–witness must lay a foundation before the demonstrative proof can be admitted. Depending on the nature of the item, such proof may include testimony of a substantial connection with the event or occurrence litigated, or a substantial similarity to it.

Thus, a witness proposing to testify with the aid of a photograph may be asked whether the photograph of a locality involved in an incident depicts the location substantially as it existed at the time of the event in issue. As part of "laying the foundation" for admission, the witness may further be asked to explain how his involvement in the events began that ultimately let to its recovery or production. The witness may also be asked to give an explanation of the mechanism or technique by which the photograph was produced.

In the case of the admission of movies or videotapes, a court suggested that necessary foundation testimony includes, first, a showing by someone having personal knowledge of the filmed object that the film is an accurate portrayal of what it purports to show and, second, that the evidence is needed to an understanding of what happened [8]. This will permit a court to decide whether the probative value of the demonstrative evidence outweighs the danger of unfair prejudice to the opposing party [9].

"Mugshots": Earliest Form of Photographic Evidence

Identification pictures (mugshots) are perhaps the earliest form of photographic demonstrative evidence known to legal jurisprudence. Such evidence has been admitted in courts worldwide since the very origin of photography. Thus, perhaps the first known example of "mugshots" produced by the early photographic processes called *tin-types* and *daguerreotypes* of arrested suspects were used in Belgium in 1843 [10]. The French police official Alphonse Bertillon, the inventor and originator of the anthropometric system of identifying individuals by bodily measurements [11], is credited with adding a profile view to the collection of identification photographs

recorded in the Paris *Préfecture de Police*, beginning in 1873 [10].

In the admission of handwriting comparison evidence, courts were almost as early in recognizing the use of photographic evidence as they were in admitting mugshot evidence. Thus, in an 1859 case, an American court approved of the admission of photographs in aid of testimony challenging the authenticity of the signature of Governor Pico of California on a land-grant document [12].

Today, because of the widespread, nay universal, use in all media of visual stimuli, courts are likely to admit demonstrative evidence of the widest variety, as long as the proper foundation testimony is presented.

Diatoms

Introduction

What are Diatoms?

Diatoms are unicellular microscopic algae belonging to kingdom Protista and class Bacillariophyceae. More than 200 genera and approximately 100 000 species of diatoms have been reported in the literature so far. Some of the commonly occurring diatom genera are listed in Table 1. Diatoms are found in fresh water, salt water, and in moist soil. Diatoms usually have yellowish or brownish tint, which is due to the presence of photosynthetic plastids. There is large variation not only in the size (which varies from few micrometers to more than 100 μm) but also in their shape, from box-shaped to cylindrical and symmetrical to asymmetrical (photomicrographs of some of the common genera of diatoms have been shown in Table 2).

The growth of diatom takes place by mitotic cell division as well as by the formation of an auxospore by sexual reproduction. Living diatoms often have specific salinity, temperature, and other

environmental tolerances; therefore, growth of diatoms is directly related to the temperature, light intensity, and physiochemical characteristics of the water, i.e., pH, salinity, concentration of silicon, the presence of organic matter, etc. Their population increases during spring and autumn (because of the favorable climatic conditions), while it decreases during summer and winter [1].

Classification of Diatoms

On the basis of their symmetry, diatoms can be divided into two orders as follows:

- Centrales (*Biddulphiales*) – which have valve striae arranged basically in relation to a point and appear radially symmetrical; and
- Pennales (*Bacillariales*) – which have valve striae arranged in relation to a line and appear bilaterally symmetrical.

The most acceptable classification system was developed by Round *et al.* [2]. Centric diatoms (plankton) commonly found in the marine water can be divided as follows:

- *Coscinodiscineae* – having a marginal ring of processes and nonpolarity symmetry;
- *Rhizosoleniineae* – with no marginal ring of processes and have unipolar symmetry; and
- *Biddulphiineae* – with no marginal ring of processes and have bipolar symmetry.

The pennate diatoms can be divided into two suborders as follows:

- *Fragilariineae* – which is araphid and
- *Bacillariineae* – which posses a raphe.

Structure of Diatom

All the diatoms are covered by a "frustule", which is made up of two valves of different size. The larger valve is called *epitheca*, which connects the smaller valve or "hypotheca" with the help of a "cingulum", also called *set of girdle bands* (Figure 1).

The valves are composed of silica (SiO_2), which is a characteristic feature of their silica shells and can be used for their identification. The face side of the valve is decorated with various identifying features like pores (areolae), processes, spines, hyaline areas, etc. Another important characteristic feature of the diatoms is "raphe", which is found mostly in pennate diatoms and it divides the valve into two (Figure 2).

Forensic Diatomology

Historical Perspective

In some earlier attempts, ideas about the presence of aquatic debris in a drowned body were framed by Guy [3]. He stated that whenever drowning takes place, water, along with some mud and other debris, channels to the various organs. First, diatoms were discovered in the lungs by Hofmann in 1896. Revenstorf [4] used this evidence to help solve a drowning mystery in 1904. This test was improved by Kasparck [5], who digested lung tissue in acid medium to extract diatoms. Incze [6] successfully tested blood and parenchymatous organs for the presence of diatoms. Later Tamasaka [7] used bone marrow as a source material for the recovery of diatoms in drowned bodies. His studies helped to reach a conclusion that the presence of diatoms in bone marrow can indicate that the death is due to drowning. Timpermann [8] reported that the presence of even a single diatom in the bone marrow can establish that the cause of the death is due to drowning but later on in 1979, he suggested that it might not be a solid basis for such a diagnosis. Geissler and Gerloff [9] and Hendey [10] were the pioneer diatomologists, who first brought the specialized knowledge about this study in the forensic field. In 1977, Peabody further evaluated the results obtained from diatom tests and recommended this test for the diagnosis of the drowning cases. His work was a pioneering contribution in the field of "forensic diatomology". Pollanen [11–13] and his colleagues contributed significantly by conducting various experiments for utility and

validity of diatom test and proposed various factors that could interfere in the proper application of this test.

Ludes *et al.* [14–16] also conducted some experiments in order to locate the most probable site of drowning on the basis of diatom test and performed "Continuous River monitoring of diatoms". Recently, Rohn and Frade [17] published an article on diatom test and its significance. They mentioned the significance of diatoms in medicolegal investigations along with its history.

The origin of nondrowned diatoms has always remained a controversial issue because few workers have found diatoms even in the nondrowned bodies. Geissler and Gerloff [9] were of the opinion that this test should not be used on drowned infants. Mueller [18] also reported that diatoms can pass from the air to other organs. Spitz [19] conducted some experiments on rats and concluded that the presence of diatoms in the organs might be due to contamination by water and airborne diatoms. Apart from this, another possible cause was due to the contamination from laboratory glassware and reagents.

Why is Diatom Evidence So Good for the Diagnosis of Drowning Case?

Water contains a variety of other planktons but the reasons why only diatoms are used as criteria in these cases are as follows:

- These microorganisms have acid resistant frustules, which makes them easier to extract from postmortem tissues. Otherwise, any attempt made to extract any other fragile microorganisms from the tissue may end in failure.
- They are numerous and more importantly smaller in size to penetrate into the various distant organs.
- They can be easily identified and classified.
- In case of failure of chemical testing of blood for the diagnosis of drowning, this test can be administered.
- In case of skeletonized drowned body, the only alternative left is the diatom test.

Forensic Significance of Diatom Test

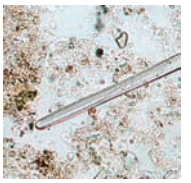
Diatoms can act as very sensitive and significant evidence in drowning cases. The test conducted to identify diatoms helps in distinguishing between antemortem and postmortem drowning, i.e., whether person was living or dead at the time of submersion. In other words, this test explains

- whether the cause of death was drowning or not and
- whether the person was alive at the time of immersion or not.

This test can also play an important role in searching the most likely drowning site [15, 16, 20], particularly in the cases

- when the body is found on land and no reference water body is available and
- when the body is found in the same water body away from the actual site of drowning, due to the body floating or dragging with the flow of water or other reason.

Fate of Diatoms Inside the Body



When a person breathes underwater (only in antemortem drowning), some water enters the lung cavity with force and exerts pressure on the lung walls. Owing to this pressure, lung alveoli get ruptured and water reaches the blood stream. Till the last heart beat, water keeps on mixing with the blood and during this course some diatoms (if at all present in the water) particularly the smaller ones are also pushed into various vital organs like liver, spleen, kidneys, brain, and even bone marrow. So it is only the respiratory pressure which helps diatoms to reach these distant organs.

On the other hand, the chance of diatoms entering in distant vital organs remains negligible if the person is already dead (postmortem immersion) and is thrown into the water. In certain instances, however, the diatoms can be detected in the lungs even in the case of postmortem drowning when, due to the passive absorption of water, diatoms can reach the lung cavity and their journey ends there.

Validity of Diatom Test

The validity of diatom test can be checked by applying the guidelines of "Criterion of Concordance" given by Pollanen in 1998. According to this criterion, the significant number of diatoms should be

Table 3 A few small sized diatoms

Some other diatom		
Gomphoneis	*Hantzschia*	*Diatoma*
		
Amphipleura	*Surirella*	*Synedra*
		

present inside the distant vital organs and they should match with the diatom species found in the water body from where the body has been recovered. This criterion can also be useful in providing solution to the controversial aspect of diatom test (diatoms are always present in human tissues) by stating that the diatoms species found in the blood must match with the species found in distant vital organs of the victim (such as the bone marrow). This refutes the doubt of many pathologists, who claim that diatoms are always present in human tissues. Therefore, application of the "Criterion of Concordance" is thought to be satisfactory enough to convince most critics in a court of law [13]. Similarly, Ludes *et al.* [14] studied the required number of diatoms in different vital organs of a drowned person. They concluded that diatom analysis should be considered positive only when a minimum established number of diatoms was present in the different vital organs, i.e., 20 diatoms per 100 µl of pellet (obtained from 10 g of lung samples) and 5 diatoms from other organs.

What are the Drowning-Associated Diatoms (DAD)?

For any forensic expert, the knowledge about drowning-associated diatoms (DAD) becomes necessary while dealing with drowning cases. Specific features of the diatoms like their type, size, and density can be crucial to get their entry into the different vital organs. No doubt smaller diatoms like *Achhnanthes, Hannae, Diatoma and Cyclotella*, etc. (Table 4) have more chances of entering into distant body organs, but fairly large diatoms like *Synedra* (Table 3) can also be found in these organs owing to their delicate nature. *Navicula, Nitzschia, Achnanthidium*, and *Cyclotella* are the most common types of diatoms found in the peripheral organs of drowned persons because they are widely distributed and have optimum size.

As the diameter of lung alveoli is very small, it is not possible for all the diatoms to penetrate into the organs through the lung cavity. Diatoms that can penetrate through this capillary network are called *drowning-associated diatoms*.

Large diatoms in the bone marrow can be indicative of laboratory contamination, as mostly small pinnate diatoms are found in the bone marrow [11]. After extracting some diatoms from the bone marrow, Pollanen concluded that strictly restricted

Table 4 Photomicrographs of some commonly occurring diatoms

Achhnanthes	*Cyclotella*	*Hannae*
		

sizes of diatoms are usually associated with drowning. This becomes a very useful guide in determining the type of diatoms that can be found in the bone marrow. Similarly, Hurlimann *et al.* [21] also stressed that penetration of a diatom in the lung capillaries depends on its size and density; therefore, it is required to emphasize on the morphological and morphometric studies of diatoms to diagnose death by drowning. In 1998, Lunetta *et al.* discovered the penetration of diatoms into the alveoli-capillary barrier by using transmission electron microscope (TEM) and scanning electron microscope (SEM). During this research, they observed various diatom species like *Diatoma moniliformis* ("penetrating" through the wall of a distal airway); *Navicula specula* (penetrating through Kohn's pore); *Tabularia fasciculat* (partially penetrating into a laceration of epithelial and endothelial lining of a distended alveolar septum); *Nitzschia paleacea* (partially penetrating through a laceration of alveolar wall); and *Mastogloia smithii* (penetrating the alveolar wall through a clearly visible laceration).

Forensic Analysis of Diatoms

Postmortem Samples

Usually postmortem samples sent for diatom examinations are of two types:

- hard bones like sternum and femur or
- soft tissues like lungs and liver.

Femur and sternum bones have been considered the most useful and least contaminated samples for this test [11]. These samples either can be cut open for the collection of marrow or they are directly dissolved by acid digestion method to extract diatoms. Even dissolution of these samples is not very difficult but complete extraction of diatoms frustules from these samples needs great care and skill.

Reference Water Samples

About 500 ml of water samples should be collected from the suspected site of drowning and stored in the refrigerator as a reference sample.

Extraction of Diatoms from Postmortem Samples

Chemical digestion method (by cooking the organs with acid) and enzymatic digestion method are most commonly for the extraction of diatoms from postmortem samples.

Various methods used for the extraction of diatoms are as follows:

- acid digestion method (nitric acid);
- ultrasonic radiation to solubilize tissue;
- enzymatic digestion with proteases such as proteinase-K;
- strong anionic detergents such as sodium dodecyl sulfate (SDS) and hydrogen peroxide; and
- membrane filtering method (blood samples)-not in use.

Acid Digestion Method

This is the most commonly used method for the dissolution of rigid postmortem samples like bones.

Method. About (50 g) of marrow is removed from the bone sample and put in a boiling flask. Approximately, 50 ml of concentrated nitric acid is added to it and marrow-acid suspension is simmered on a hot plate for approximately 48 h in a fume hood. After cooling the suspension at room temperature it is centrifuged (200–300 rpm/30 min). The distilled water is added to the obtained residue and is again centrifuged. The final supernatant is discarded and the pellet containing nitric acid-resistant material is aspirated using a Pasteur pipette and put on a clean microscopic slide for examination [12].

Enzymatic Method

The enzymatic method was considered more convenient in terms of rapidity, safety, and environmental protection than the chemical test.

Method. About 10 g each of the organs (peripheral lung tissue, kidney, liver, brain, and femur bone marrow) is minced with scissors. The sample is rinsed and mixed with 500 ml of 10 mg ml^{-1} proteinase-K and 100 ml of 0.01 M Tris–HCl buffer (pH 7.5) containing 2% SDS. The mixture is incubated at 50°C for overnight. In total, 500 ml proteinase-K is added and the solution is diluted with 100 ml of distilled water. It is then centrifuged at 3000 rpm for

15 min and the upper layer is discarded. The sediment (100 ml per slide) is transferred to a cover glass, mounted in Naphrax and examined under the light microscope Ludes *et al.* [15].

Extraction of Diatoms from Reference Water Samples

Modified Acid Digestion Method

This sample is mixed thoroughly and transferred to a sterilized beaker. Then 40–45 ml of concentrated nitric acid (HNO_3) is added to digest the unwanted material from the sample and then the sample is kept undisturbed for about 2 h. The whole sample is then centrifuged at 5000 rpm for 10 min. The supernatant is removed leaving behind only a pellet containing diatom frustules at the bottom of the tube. This pellet is suspended in distilled water and again centrifuged in the same way. This process is repeated twice to ensure all traces of the acid are removed Singh *et al.* [24].

Enzymatic Method

Method. Water samples are treated with hydrogen peroxide (130 vol%) at 80°C for 12 h. The solution is then cooled at room temperature and the second centrifugation is set at 2500 rpm for 15 min. After discarding the supernatant, residue is finally centrifuged with distilled water (3000 rpm for 10 min), which produces a pellet containing diatoms. After removing the supernatant, the sediment is air dried and mounted in Naphrax [15].

Acid Digestion Method for Sea Water

Water sample is incubated with fuming nitric acid for 30 min in a boiling water bath. Then the sample is washed with pure ethanol twice. This washing is made by simple centrifugation at 3200 rpm for 10 min. The residue is heated and dried on a glass slide and diatoms are examined with an optical microscope at higher magnification [23].

The "acid digestion" method is used in majority of the cases because it is easy and a better means to remove the organic materials. Besides having many merits, this method also has some demerits like

- substantial amounts of acids are required to digest 100 g of the tissue sample;
- a high-speed centrifugation is required to remove traces of acids that make this method lengthy;
- chemical digestion of fatty materials may not be completely removable;
- chances are there that diatoms may be lost in repeated washings and centrifugations;
- as Kjeldahl flasks and reflux apparatus are costly, therefore, they are reused after washing, so acid digestion is prone to contamination from the reagents as well as the glassware.

No doubt, the acid digestion method is effective for detecting diatoms, but necessarily not very safe. Despite having many limitations, acid digestion method is still better and is very frequently used for the extraction of diatoms from water and tissue samples.

The "enzymatic digestion" method is simple, safe, and effective for detection of both phytoplankton, including diatoms and zooplanktons, which is not possible with the acid digestion method. Therefore, this method is more advantageous than the acid digestion method in diagnosing drowning cases. Using subtilisin, this is an effective and rapid method of destroying tissue materials and Tris buffer can be easily cleaned by centrifugation. However, this method is bit costly compared to the traditional methods [24].

Preparation of Slides

Extracted diatoms need to be properly preserved for their noticeable visibility through microscope. For preservation, diatoms are permanently mounted on the microscopic slide.

Method

Residual material obtained after centrifugation is put on a microscopic slide and is allowed to fix. Then a drop of DPX mountant is poured on the center of a clean prelabeled slide, covered with a cover slip, and then examined under the microscope for possible diatoms.

Diatom Identification

Slides are examined using a binocular compound light microscope on 1000× (oil immersion) to maximize resolution.

Standards and Controls

- In diatom examination, the control water samples must be used for comparison purpose invariably.
- Standard diatom samples can be preserved on slides and can be used as standards for comparison purpose.

Role of Diatomological Maps in the Forensic Investigation of Drowning Site

Another important aspect of "forensic diatomology" is its use in search of most putative drowning site. Sometimes under suspicious circumstances

- the drowned body is recovered from a different location in the same water body, but away from the actual site of downing, i.e., the body has been dragged with the flow of water or has been done manually by somebody or
- the presumed drowning site may not be there at all, i.e., body is found on the land away from any water body.

The qualitative and quantitative analysis of diatom species can be performed to ascertain not only the cause of death but also the most probable site of drowning. Distribution of diatom species in any particular water body and their correlation with the diatoms recovered from the drowned body can be a method of choice to resolve the questions related to drowning site. After generating the profile of diatom flora of any water body, a diatomological map can be designed. These diatomological maps can be of great help in the characterization of the selected water bodies and are of immense help in diagnosing the suspected drowning cases occurring in any particular area [15, 20, 23, 24].

Authors have conducted studies dealing with the algological analysis from three different water bodies (Galta ji, Jal Mahal, and Mavath) of Jaipur city of Rajasthan [24]. Significant qualitative and quantitative differences in the distribution of some diatom species were observed. Certain site indicator diatom species were also found in the selected water bodies. On the basis of this database, diatomological maps of the selected sites were designed. Some characteristic diatom like *Rhoicosphenia* and *Cyclotella* were observed in Galta ji (a small waterfall). This water body was full of diatom blooms. Other large types of diatoms like *Synedra and Melosira* were also found here. However, in Jall Mahal (a pond) where water was stagnant and highly polluted fewer types and number of diatoms could be found. Except *Navicula*, which is the most commonly found diatom, *Cyclotella* was the only other dominating diatom species found. Mavath is a seasonal water pond, where elephants are brought to take bath. A great diversity of diatoms, i.e., *Synedra, Nitzschia, Diatoma, Navicula, Geissleria*, and *Achcanthidium*, was observed. *Geissleria* was found to be restricted to this particular water body, whereas *Navicula* and *Cyclotella* were found in all the three sites.

Conclusions

Diatoms are not found in all the drowning cases but if present in distant vital organs in sufficient numbers they provide positive evidence that death is due to antemortem drowning. A few authors still have some doubts about the authenticity of this test. According to them, the diatoms are not only inhaled through water but also through air. However, this position is difficult to sustain when the diatoms are found inside the peripheral organs.

Diatom analysis, like many forensic processes, requires proper care to avoid any sort of contamination while performing this test and necessary conditions like "Criterion of Concordance" should be followed. Application of this test would be a great assistance in the investigation of drowning cases.

Another aspect related to diatom test is the determination of the actual drowning site. Site-specific diatom species can also play a crucial role in the search for possible drowning site. But in order to minimize errors, results pertaining to such studies should be accurately interpreted. To achieve this, the studies related to monitoring of water body for diatoms need to be extended by conducting a comparative study to investigate the seasonal distribution of diatom species. These comparative studies can help to resolve many discrepancies or changes in diatomological database that can take place with the passage of time.

Scope of Biomolecular Studies in Forensic Diatomology

The methods related to molecular biology, especially DNA, occupy a secure and very significant place in various fields of the study. These methods may prove

to be beneficial for the future development of diatom tests for drowning [11]. This aspect has never been given much importance, but the use of polymerase chain reaction (PCR)-based methods for the detection of diatoms in human tissues would be an achievement in the field of "forensic diatomology". Sensitive methods seem to be an advantageous alternative over the average microscopic examination of diatoms, particularly in tissue. A high degree of uncertainty could be removed if diatom comparison is made on the bases of their genomes.

Differential Extraction

As an initial step in the investigation of a sexual assault complaint, the complainant undergoes a medical examination to assess for medical trauma and to sample physical or biological evidence resulting from the attack. Commonly seminal staining is located on swabs taken from the complainants clothing, genital area, or body. In addition, the crime scene examination may yield other items of evidence such as bedsheets, condoms, tissues, and scene swabs. The common challenge with these samples is to separate epithelial cells from the spermatozoa. The epithelial cells typically arise from the complainant (such as from the lining of the vagina or mouth, or from the skin surface), whereas the spermatozoa typically arises from the seminal fluid of the perpetrator (assuming they ejaculated). Separation is achieved by exploiting the different biological constitution of the cells present. Spermatozoa have an extremely durable cell membrane containing thiol-rich proteins that are resistant to cell lysis in the absence of a reducing agent. By controlling the introduction of this reducing agent, it is possible to preferentially regulate the lysis of sperm cells and nonsperm (epithelial) cells. This is known as differential lysis, as it is a two-step cell lysis procedure.

Nonsperm cells are lysed first by a conventional lysis buffer (with the assistance of heat and proteinase K). The postlysis supernatant is removed for DNA analysis of the nonsperm fraction. The remaining fraction contains the sperm cells. These are lysed by the use of a reducing agent that breaks the disulphide bonds that form the extracellular membrane of spermatozoa. Dithiothreitol, or DTT, is a commonly used reducing agent [1]. For samples from sexual assaults that do not contain spermatozoa, it is not possible to separate the cellular content via differential lysis and alternative techniques such as Y-chromosome DNA profiling may be required. It is also important to note that the separation process is not 100% efficient and it is possible for epithelial cell DNA to appear in the sperm fraction, and vice versa. Nonetheless, the method has a satisfactory specificity for the typical samples encountered in forensic analysis.

Direct Examination of Experts

Nature, Purpose, and Scope

When an expert witness is summoned to give testimony at a judicial proceeding, he is normally not permitted to get on the witness stand and simply tell the court what he knows. Instead, testimony is elicited in the form of questions posed by the litigant, to which inquiries the witness gives answers. This process is called *direct examination*. The prohibition against testifying in the narrative is to allow the opposing side to interpose objections to certain questions if they call for inappropriate or inadmissible answers under the rules of evidence. As with all trial proceedings, rules may vary from jurisdiction to jurisdiction. We discuss those that are most prevalently used in the adversary system.

Questions asked on direct examination must tend to assist the fact finder in understanding the fact and the issues of the case. Information that is irrelevant, incompetent, or immaterial to the issues in the case, cannot be elicited. There may also be countervailing policies that restrict potentially helpful information from being introduced. Thus, information about certain privileged matters may be restricted, as would information that tends to inflame the jury and has been determined to be more prejudicial than probative. The purpose of these restrictions on use of information is to protect the fairness of the judicial process and prevent decisions from being based on conjecture or on evidence of doubtful or limited probative worth.

In addition to restrictions on the content of information sought to be elicited, there are also evidentiary restrictions on the manner in which a question is phrased. These are called *objections* to the form of the question. Eliciting information may not be done on direct examination by asking leading questions. A leading question is one which suggests what the answer ought to be, for example, the question, "and then you identified the defendant as the perpetrator"?

There are, however, a number of exceptions to the prohibition against the use of leading questions. Leading questions can be used in the beginning of a direct examination to orient the witness to the subject matter about which questions are about to be posed. That information is only deemed to be preliminary and therefore not crucial. In many jurisdictions, questions about the qualifications of an expert may also be posed in a leading form. Lawyers are also permitted to ask leading questions when the witness has trouble understanding what is happening: witnesses who are old, feeble, young, or forgetful. Further, the rule against using leading questions is always relaxed or overlooked when questioning is addressed to a hostile witness, or to the adversary person in a civil dispute, or to someone who is closely associated with the adverse party. These witnesses may not freely supply the information that is sought to be elicited.

It also is always appropriate to use leading questions on cross-examination. Indeed, most cross-examiners will ask leading questions because it is the only way they retain some measure of control in seeking to avoid nonresponsive or volunteered statements.

There is one form of a leading question that is always improper, even when asked on cross-examination. It is the asking of questions that are misleading, argumentative, or compound – meaning two questions in one. A typical example of such a compound, argumentative, and improper question of a witness who has been confronted with a prior inconsistent statement would be: were you lying then or are you lying now?

In jurisdictions where rules of evidence still closely approximate the common law, there may be other rules that affect the form of questioning experts. Examples involve when a witness who is testifying orally may use a writing to assist in remembering information. Lawyers who call the expert, typically explain the manner in which present recollection may be refreshed by use of a writing that is not in evidence, or when and how past recollection recorded can be proved.

Expert Witnesses and Opinion Evidence

Some lay witnesses may offer opinion evidence about facts which the witness has observed. Thus a lay witness may be permitted to testify, for example, "I saw the defendant cross the street and, in my opinion, he was drunk." Lay witnesses are hardly ever permitted to offer an opinion that goes to the ultimate issue to be decided. This would be whether negligence existed in a tort case, or an opinion on the guilt of innocence of an accused in a criminal case.

Even if such an opinion were to be rationale based on perception, it is deemed not to be helpful to the fact finder.

What sets experts apart from ordinary fact witnesses is that an expert can not only testify to facts personally known or observed, or to data collected and examined, but will also be allowed a far greater latitude in expressing opinions based on the data collected, as long as the opinions are likely to be helpful to the fact finder. In jurisdictions, where a common law prohibition against "ultimate issue testimony" still exists, expert witnesses are most frequently exempted from that restriction. Thus, under Federal Rules of Evidence in the United States, and in those jurisdictions that have similar provisions, expert opinion evidence is not inadmissible, except for a few narrow exceptions, merely because the opinions embrace the ultimate issue to be decided.

Eliciting the Testimony of the Expert on Direct Examination

The law considers a witness to be an expert if he is shown to be qualified by knowledge, skill, experience, training, or education in a particular profession or occupation. While formal education is not required of experts, and a person can become an expert merely by having gained experience and skill in a particular task, there may be additional qualifications that courts exact for some professionals. Medical doctors, and other highly credentialed researchers and specialists, will be normally permitted to qualify only when they have obtained the required official certification or licensure that may be needed for practicing in their fields or the formal education required by the rules of their professions.

Thus, before a witness is permitted to offer opinion testimony as an expert, it must be shown that the witness is qualified in the discipline in which he proposes to offer testimony. It is the judge who initially makes the decision whether a witness has the necessary qualifications to be an expert. That process follows five distinct but fairly routine steps, consisting of (i) showing that the witness qualifies according to law to give opinion testimony; (ii) how the witness became involved in the case; (iii) how the witness conducted an examination or collected data; (iv) what conclusions were drawn from the findings; and (v) the probative meaning of the conclusions.

1. Qualifying process

The initial process of qualifying the witness is designed to enable the judge to rule that the proffered witness is permitted to give opinion evidence during the direct examination. This process elicits the following information:

(a) personal information about the witness, his employment history, and current position;
(b) formal education, training, and possession of current licensure or certification, if required;
(c) additional continuing education activities and attendance at professional symposia;
(d) membership in professional societies, and participation in society activities or leadership functions (officers, committees, etc.);
(e) specialized training beyond that which is obtained in colleges and universities;
(f) writings, publications, lecturing, and teaching;
(g) extent of the witness's experience in dealing with the specific tasks or examinations that are particularly applicable to the case before the court;
(h) how examinations of the type relevant to the case are conducted and what results may be expected; and
(i) prior testimony in similar cases.

After this information has been elicited, in some jurisdictions, the direct examiner moves that the witness be permitted to qualify as an expert. At this point, the opposing attorney may request permission to *voir dire* the witness. Such questioning, if permitted, will be limited to a cross-examination on the witness's qualifications. After the *voir dire*, the court will decide whether the witness is qualified to offer opinion testimony.

2. The witness's involvement in the case

In a fairly perfunctory manner, questions will next elicit when and how the expert became involved with the case at bar, and through what process evidence was obtained for examination. This stage is important in maintaining an unbroken chain of custody of any physical evidence that may be available.

3. The expert's examination

Questioning next focuses on the actual examination, wherein the witness will not only be asked to explain what was done but also to establish that each and every step of the recommended or required

examination protocol was followed. This is true also of a description of the analysis, comparison, evaluation, and verification process. In discussing the methods used in the analysis, the expert must also be mindful of other methods that were not performed, and the reasons why a certain process was preferred or selected. The witness may likely be cross-examined on any methods that were available but not utilized.

4. The results of the examination

An expert's appearance in court would be meaningless unless he had arrived at a conclusion. This is the part of the direct examination where the ultimate opinion of the expert will be elicited. Most courts require that the opinion be provided to the court with a reasonable degree of professional certainty. Opinions that are merely guesses, or cannot be substantiated with the data, are normally not admissible since they are deemed to be based on conjecture and speculation.

For that reason, it is important for the expert to be able to justify the basis for his opinion in a cogent, understandable manner.

5. The importance of the opinion in the context of the disputed issues

The direct examination testimony will conclude with an assessment of the value of the opinion in relation to the issues, which the fact finder must decide. This varies greatly depending not only on the discipline involved but also on the quantum of evidence that was available for examination. Some forensic disciplines engaged in impression comparisons, profess to express their findings as "matches" or "individualizations." Others merely state that a certain conclusion is likely, possible, improbable, or similar characterizations of the probative impact of the evidence.

Modern courts dealing with highly sophisticated crime laboratory techniques may want to know whether the methodology used is accepted as a standard of the profession. Of equal importance may be whether it has been widely publicized in the literature and subjected to peer review, and whether error rates have been established.

All of these facets of the examination will also be extremely important for the cross-examination of the evidence, which is ready to commence when the direct examiner hands over the witness for questioning by the opposing attorney.

Disaster Mental Health

Disaster Mental Health

People have always given aid and comfort to each other during times of disaster. However, attempts to structure and professionalize this assistance are fairly recent developments. Disaster mental health, as an evolving field of practice and study, is a collection of interventions and practices that are designed to address incident-specific stress reactions, rather than ongoing or developmental mental health needs. Traditional mental health practice is based on a medical model, with a clinician seeing a patient in an office setting. Disaster mental health introduces a paradigm shift, requiring that practitioners (clinicians and indigenous helpers) work with individuals and whole communities in the field rather than in an office.

This is similar to the clinical conceptualization of community psychology. Disaster mental health practitioners, like community psychologists, are likely to view emotional distress through a sociological lens that focuses on normal experiences rather than on pathological responses following disaster.

Different mental health disciplines (e.g., social work, psychology, and psychiatry) have varying levels of exposure to systemic interventions used in community psychology models and practices. The difference in how disaster mental health practice is viewed is critical to the development of organized systems of intervention that address individual and collective mental health needs after a disaster. If disaster mental health is viewed from the sociological standpoint, intervention systems are more likely to reflect the kinds of supports that people rely upon in day-to-day living. If disaster mental health is approached using a medical model, intervention systems are designed to

identify and treat maladaptive or pathological reactions to disaster. Disaster mental health interventions have evolved from both of these traditions.

Disaster Mental Health Interventions

Disaster mental health interventions typically include screening for symptoms of major disorders, outreach, and public education activities. The goal of these activities is to normalize stress reactions while both identifying those who may be at risk for developing more severe symptoms and avoiding any actions that may induce adverse outcomes [1]. This set of interventions is often called *psychological first aid* (PFA) and is gaining popularity as a skill set that can be taught to anyone and applied in a variety of situations.

The use of the phrase psychological first aid appeared infrequently in journal articles of the 1980s, and was typically described as a clinical intervention. In the 1990s, the American Red Cross began deploying licensed mental health personnel to carry out disaster mental health activities as part of their array of volunteer services offered after a disaster. More recently, the social science literature has begun to reflect discussion about PFA as both a tool for triage used by clinicians and as a set of skills that can be taught to other disaster responders to mitigate or normalize the psychological effects of disaster or a critical incident.

The international community (e.g., World Health Organization; United Nations) refers to the set of activities that make up PFA as psychological support, mental health, or psychosocial programming. The international view seems to predate, yet parallel the emerging United States movement toward dividing PFA into skills that can be carried out by indigenous helpers as well as trained clinicians [2].

Most disaster mental health interventions include the practice of encouraging survivors of disaster-related trauma or grief to talk about their experience. The effectiveness of this practice has been tested and debated in the literature, but is still considered central to all disaster mental health work. The PFA approach encourages people to talk with someone they trust, like a friend or family member. Medical models of intervention that rely on the special expertise of a clinician also encourage people to talk, though in a more guided format such as in the context of a cognitive behavioral approach. Disaster mental health practitioners in the field generally do not provide treatment for disorders; instead they provide triage or screening for problematic symptoms and refer to other clinicians, preferably based in the local community, who can then provide ongoing treatment services.

Research has not shown an undisputable link between most of the interventions presently used in disaster mental health and the prevention of major problems like posttraumatic stress disorder (PTSD) (*see also* **Posttraumatic Stress Disorder**). There have been efforts to gain expert consensus regarding potential best practices, but to date there are no universally accepted standards of care in disaster mental health. The field of disaster mental health has yet to standardize nomenclature and identify specific competencies that workers must have to function effectively as disaster mental health practitioners across jurisdictions. The lack of specific competencies has led to the development of a number of training curriculums, philosophies, and systems across voluntary and nongovernmental organizations that prepare workers to respond to the psychological, social, emotional, and spiritual needs of people after disasters or humanitarian emergencies. The American Red Cross and the US Department of Veterans Affairs National Center for Posttraumatic Stress Disorder both have PFA curricula and guides that are widely used in the United States [3].

The international disaster response community, unlike the United States, has focused less on competencies of clinical responders and more on widespread preparation of indigenous populations to provide psychological support to one another. Clinicians often serve as trainers or supervisors to indigenous helpers in mixed workforce models of service provision.

A broader evolving clinical role in disaster mental health is related to risk communication. This is assisting public officials to construct concise messages that can be relayed to the public via media about the disaster, its risks and potential consequences. Risk communication in the context of disaster response is a mechanism for communicating vital information that may increase compliance with directives, inform the public about common reactions to the event and help people gain some control over their lives after a disaster.

Who Provides Disaster Mental Health?

The division of labor between mental health clinicians and indigenous workers in a disaster mental health response varies according to the availability of clinicians, type and duration of disaster response, culture in which the disaster occurred, and level of involvement of outside entities (e.g., voluntary or nongovernmental organizations). The current lack of accepted standards for preparation of a disaster mental health workforce, both clinical and indigenous, is a glaring gap in the development of organized disaster mental health response. This is compounded by the lack of rigorous research on the effectiveness of interventions commonly used in disaster mental health.

Until there is hard science to support the field, a division of labor between clinical and indigenous personnel will be guided by history, culture, and context. The practice of disaster mental health within an ecological framework recognizes that one part of a system cannot be fully understood in isolation; and that each individual, family, and community's level of distress or resilience is influenced by a complex interplay of systems and events. The use of natural helpers within the local communities to augment the disaster mental health response creates community resilience that may ultimately mitigate negative psychological or social effects of some disasters. The role of indigenous helpers in an organized disaster mental health workforce is typically as culture brokers. They are often peers to those affected by the event (disaster or humanitarian emergency) and are therefore trusted sources of information. In organized systems of intervention, clinicians provide some supervision for indigenous workers.

Legal Issues and Disaster Mental Health Practice

Many disaster mental health practitioners are volunteers. Some are associated with specific aid or relief organizations and enjoy legal protections offered by the organization. Others volunteer their services more spontaneously after a disaster [4]. In the United States, state emergency response statutes typically immunize volunteers from civil suits arising from actions that may even be seen as negligent, so long as their conduct is provided gratuitously in the context of an emergency response. In the case of volunteers, it is likely that clinicians would be more vulnerable to any legal action than indigenous workers. Clinicians who provide supervision to indigenous workers have the additional concern that they may be held responsible for the actions of those they supervise. Clinical supervision under disaster response or relief conditions can be challenging, given the inherent chaos of the situation. Most clinicians prefer not to supervise more than 10 disaster workers at a time so that they can adequately track and manage the type of service being offered in the field.

Disaster mental health practitioners, like traditional purveyors of clinical service, are concerned about potential legal problems related to liability and malpractice. Historically, establishing legal liability for harms caused by mental health practitioners has been difficult. Demonstrating a causal link between a patient's psychological injury and a practitioner's act or omission can be a major obstacle. A central problem is distinguishing between the harm caused to a disaster survivor by virtue of experiencing the disaster *versus* that potentially caused by a practitioner. Additionally, without practices that are widely accepted to guide disaster mental health intervention choices, it is difficult to establish a legally recognized standard of care.

In the United States, Establishing negligence is the dominant legal theory employed to assert liability against mental health practitioners (*see also* **Medical Malpractice**). Negligence is behavior which falls below a legally recognized standard of care employed by a reasonable person in similar circumstances. Negligent conduct is not as culpable as gross negligence or intentional wrong doing, but it can serve as the basis for a successful malpractice lawsuit in many jurisdictions. Establishing negligence, and potentially malpractice, generally involves three factors: a treatment relationship must have existed between a practitioner and patient; the patient must have suffered an actual harm; and the cause of that harm was the practitioner's negligent behavior [5].

Establishing that a treatment relationship exists between disaster mental health practitioners and those they serve is difficult since practice is generally centered on the philosophy of normalizing symptoms rather than treating pathology. In disaster mental health there is also a noticeable absence of billing, medical records, or other formal indicia of such a relationship. The treatment relationship is probably most pertinent for clinicians who serve as the agent accepting referrals from disaster mental health practitioners in the field. Upon creation of such a treatment relationship, the mental health practitioner's

conduct toward the patient – whether that be an act or omission – must fall under the recognized reasonable standard of care for treatment of like conditions [6]. Generally speaking, the more experimental or unproven a treatment is, the less likely it will be considered an acceptable exercise of a professionally recognized standard of care [7].

In addition, in establishing that a treatment relationship existed, a case of malpractice could not proceed unless the plaintiff could prove that they experienced injury or harm [8]. This may take the form of a deteriorating mental or physical health condition, excessive alcohol or drug abuse, job loss or decline in job performance, and divorce or strained familial relationships. All these things could also be considered reactions to the stress of experiencing the disaster event [9]. Connecting such harm to negligent acts or omissions of a disaster mental health clinician instead of to the disaster experience would be difficult. This is known as the *proximate cause* – the cause that directly produced the harm and without which it would not have happened. The etiology of many mental illnesses is still unknown to the medical community. A plaintiff's poor mental health or emotional well-being could be the cause of a practitioner's substandard conduct, the natural development of his condition, or the influence of other factors.

Disaster mental health practitioners enjoy a number of protections from civil liability. These immunities are driven by policy concerns to encourage responders to provide help to people in need without fear of lawsuits. In the United States, Canada, Japan, and some European nations, there are "Good Samaritan" statutes which encourage medical professionals to come to the aid of injured persons. Generally, they shield practitioners from negligence liability if they render care that is free, in good faith, as part of a direct response to emergencies, and does not amount to reckless behavior [10].

In the United States, additional protections from liability exist in state emergency management statutes. Such laws are usually triggered by an official declaration by a state executive. These laws anticipate that some degree of disorder will characterize the immediate aftermath of a disaster and its response. They usually waive professional licensure and regulation requirements for a temporary amount of time in order to facilitate rapid response to an emergency situation. Importantly, they also typically bar civil suits against responders and their organizations that acted in good faith as part of a response effort, so long as their acts or omissions did not constitute reckless behavior or intentional wrong doings.

Determining whether behavior is protected under Good Samaritan laws and immunities in emergency management statutes is a matter of reasonableness. If a responder's actions were consistent with a good faith effort to provide assistance in an emergency context, courts will generally shield such behavior from liability. If, however, a person departs from a good faith and reasonable effort to assist in response activities, or engages in objectively reckless behavior, then liability protection ends.

Legal exposure for disaster mental health clinicians and indigenous workers has not been tested to date. Although the application of disaster mental health interventions is widespread, evaluation of the long-term effectiveness of their various forms of implementation will benefit from ongoing empirical documentation.

Disaster Victim Identification

Introduction

The right to possess an identity is not automatically recognized by national or international law. The "Convention on the Rights of the Child" is the only international convention that addresses the subject of identity as a fundamental human right by proclaiming that childhood is entitled to special care and assistance [1].

Article 7 of the Convention establishes that, from birth, every child has the right to a name and to have that individuality recognized. Article 8 emphasizes the preservation of that identity and the fundamental importance of preserving that name, nationality, and family belonging.

The Geneva conventions [2], consisting of four treaties, set the standards for international law in relation to humanitarian issues. They chiefly concern the treatment of noncombatants and prisoners of war and, therefore, do not provide a legal framework for matters pertaining to the identification of the deceased if the mass fatality event is outwith a combat scenario.

The only formal resolution pertaining to identity in a nonwar situation was ratified by Interpol Standing Committee on DVI (Resolution AGN/65/Res/13 – 1996) [3]. This "recognizes that for legal, religious, cultural, and other reasons, humans have the right not to lose identities after death and that the identification of disaster victims may be of vital importance to police investigations".

Therefore, the identifications that were undertaken in the Former Republic of Yugoslavia as a result of the Balkan conflicts throughout the 1980s and 1990s are governed by the Geneva Conventions [2] and those who lost their lives in the Asian Tsunami have had their identities returned via observance of the Interpol resolution [3]. If the country involved is not an Interpol member, then there is no impediment to the deceased being interred in a mass grave without attempts to establish their identity [4]. Indeed, there is no legal requirement for any country to establish identity of its deceased unless it is written into their own national constitution as the Interpol resolution is not an international law, merely recognition of propriety i.e., a written motion adopted by a body without law making powers.

Legality notwithstanding, there are two important reasons why identification of the deceased is important and should be addressed wherever possible following a mass fatality event. In 1871, William Gladstone reminded us *''Show me the manner in which a nation cares for its dead and I will measure with mathematical exactness, the tender mercies of its people, their respect for the law of the land and their loyalty to high ideals."* Identifying the dead is a core aspect of the humanitarian response to a fatality. The grief of a family, a community, or indeed a nation can rarely be assuaged if the names of the deceased remain unknown. Suspicion, conspiracies, and abandonment of faith result and when these occur they can be of sufficient magnitude to unseat a government. Therefore, disaster victim identification (DVI) is extremely important in the aftermath of

a mass fatality event. Standards and commonality of approach are vital ingredients.

The second important reason for establishing identity is related to legal requirements. This is equally true whether the event is a natural disaster (e.g., hurricane), man made (e.g., nuclear reactor explosion), or terrorist (London bombings). Each will have a specific drive for the rationale of establishing identity as it may be related to an issue of probate, culpability and, therefore, prosecution or perhaps national and international security.

In the United Kingdom, the Civil Contingencies Act [5] recognizes the police service in a "first responder" role. More specifically, the police service is identified as being primarily responsible for the recovery and identification of the deceased. Assistance to undertake these tasks comes from outwith the police service and may include specialist search teams and specialists including pathologists, odontologists, anthropologists, archaeologists, anatomical pathology technologists, radiographers, biologists, etc. An ineffective recovery and identification procedure will most likely lead to a formal enquiry and while it may not be primarily driven by the need to blame, this often becomes a significant media focus. However, an enquiry can have beneficial effects for the discipline of DVI as it serves to assess objectively the operation and can make recommendations to ensure that any mistakes made are not repeated. The enquiry undertaken by Lord Justice Clark [6] into the events of the Marchioness disaster (the sinking of a pleasure boat on the River Thames, London, United Kingdom) have had long reaching beneficial effects on the way in which DVI is approached in the United Kingdom and led to the development of one of the most important roles in a mass fatality event – that of the senior identification manager (SIM). The SIM will always be a serving police officer who will work alongside the senior investigating officer (SIO), their prime role being to address all the issues pertaining to the identification of victims. This ensures that this important role is under the command and direction of one single point of contact.

A series of national and international events between 2004 and 2006 caused The Home Office and the Foreign and Commonwealth Offices of the UK Government to recognize that a national response capability was required to mass disasters. The Association of Chief Police Officers (ACPO) was tasked with developing a UK DVI task force. The vision statement for UK DVI stated "*The Police Service within England, Wales, Scotland, and Northern Ireland will provide an appropriate, effective and professional DVI contribution as part of the overall response to a mass fatality incident, either in the United Kingdom, or where requested by HM Government overseas*" [7].

The DVI Process in the United Kingdom

We assume DVI is primarily composed of those officers who are occupied within the mortuary but the process of DVI is a vast mechanism that must be delicately balanced to ensure that two sets of data are accurately recorded and brought together so that there is a strong likelihood that they will be recognized as a match and identity will be conferred by the appropriate legal authority [8, 9]. It is a simple concept but it is a complex mechanism which has the potential to go wrong at so many stages and the process begins with the Casualty Bureau.

The Casualty Bureau

Casualty Bureau is a complex telephone handling and investigative system. The Bureau is first activated within the police force (known as the *host force*), where the incident has occurred. It issues a single free phone number to the media for dissemination to the public as quickly as possible after the incident. Depending upon the size of the incident, the volume of calls received may exceed immediate host force capability in which case they then request assistance from neighboring forces to activate their Casualty Bureaus until the system is large enough to cope with the initial influx of calls.

When a mass fatality incident takes place, the public thirst for information is often insatiable and unfortunately many calls made are not about those who may have been caught up in the incident and therefore, a filtering mechanism is essential. This is achieved through a primary system whereby callers are initially asked a computerized set of questions to which they may respond by pressing an appropriate key on their phone. In theory, the only people who should ever talk directly to a Casualty Bureau operative are those who are reporting that friends or family may be potentially involved in the incident.

The primary aim of the Casualty Bureau is to enable the police to compile a list of people who

Table 1 Casualty Bureau grading system for missing persons

Assigned misper grade	Criteria
Grade 1	Highly likely that the missing person was involved in the incident
Grade 2	Likely that the missing person was involved in the incident
Grade 3	Unlikely that the missing person was involved in the incident
Grades 4–6	Often not allocated at the outset of the incident. Leaves room for expansion within the system as the incident develops
Grade 7	Missing person was an accounted casualty but not a fatality
Grade 8	Missing person was located safe and well
Grade 9	Missing person was not involved in the incident

are likely to have been involved in the incident. This allows them to target families for the collection of antemortem (AM) information. From the answers to the questions, it is then possible to assess the likelihood of the reported missing person being involved in the incident and the SIM will grade missing person (Misper) information as shown in Table 1.

When the Casualty Bureau receives a phone call reporting someone missing, the system generates a unique reference number (URN) for the reported Misper and a second URN relating to the person who made the call. It should be borne in mind though the public may not be the only source feeding information into the Casualty Bureau. A mass fatality incident often has many injured survivors who will be hospitalized and many may self evacuate if not injured. The rapid set up of a Humanitarian Assistance Centre or Survivor Reception Centre is a good method to ensure that maximum data concerning all those involved in the incident are obtained.

Casualty Bureaus are generally large operations when the mass fatality event is an "open" incident. This refers to a scenario when it is not clear who is most likely to be a victim of the incident e.g., the London tube bombings. It is a smaller affair if the incident is a "closed" event e.g., an airplane disaster where there is a passenger manifest indicating an initial identity for those who might be involved e.g., United Airlines Flight 93.

Eventually, as a result of the filter system provided by the Casualty Bureau, the SIM will be in possession of a list of Grade 1 Mispers that are believed to have been involved in the incident and have not been located as a casualty in a hospital, have not self evacuated or contacted the casualty bureau to confirm their safety. In theory, this should be a list of people who have been killed and whose bodies remain at the scene awaiting recovery by the DVI teams. In practice, however, this is almost never the case, as the list of Grade 1 Mispers will initially be far larger than the number of fatalities. What the list of Grade 1 Mispers provides to the SIM is a list of families to be interviewed by a family liaison officer (FLO) who can then commence the process of harvesting AM information.

Antemortem Information

When the national UK DVI team is invoked, AM data is collected by FLOs using only Interpol yellow AM forms [10]. These forms and instructions on how to complete them can be downloaded from the Interpol website.

The URN assigned to the Misper by the Casualty Bureau will be transferred to the yellow Interpol AM forms. The FLO must harvest as much information as possible about the Misper during the interview process with family members and friends and this will include, but is not limited to, those listed in Table 2. It is important that maximum information is harvested during a single interview to prevent the intrusion of subsequent interviews during this difficult time for family and friends. It is essential that the information is accurate as any mistake made at this stage may result in a missed-match with the appropriate deceased individual. Attention to detail is vitally important [9].

The yellow Interpol DVI Antemortem Form and all AM material is then submitted to the DVI Antemortem Coordination Centre as soon as possible after completion of the interview process and a missing person file is duly opened. In the context of forensic human identification, the following AM materials are the ones most commonly sought for establishing the identity of the deceased as they

Table 2 Information to be secured by the Family Liaison Officer during interview with family or friends of the missing person (this list is not exclusive)

	Information to be secured by the family liaison officer
1.	Any medical and/or dental/odontological X-rays, mouth guards, dentures, etc., in the possession of relatives or friends
2	Names and addresses of any medical practitioners consulted by the missing person/potential victim
3.	Names and addresses of dentists and/or odontologists consulted by the missing person/potential victim
4.	Descriptions of jewelry worn and property usually carried by the missing person/potential victim
5.	Recent photograph/s (showing full face and/or teeth, tattoos, etc.)
6.	Buccal smear or blood sample taken from the biological parents or children of the missing person/potential victim
7.	Any tattoos, scars, piercings, or other significant physical characteristics
8.	Any object that may contain the sole fingerprints and/or DNA of the missing person/potential victim

represent the primary sources of identity as accepted by Interpol [8]:

- AM dental records;
- AM latent prints (usually, but not exclusively, finger prints);
- AM reference or surrogate DNA samples; and
- AM medical records listing a unique medical condition (this equates to, for example, an implant with a unique serial number e.g., hip replacement or pacemaker).

Visual identification of the deceased is not accepted by Interpol as a primary means of identification. This is based on well founded experience which shows that relatives are unreliable at accurate identification of the deceased as on many occasions these have proved to be incorrect [11].

Once the SIM has devised a strategy regarding who should be targeted for the AM harvest, other aspects of this must be addressed. This includes selection of which AM materials are to be utilized, from whom they have to be sourced and how will this be achieved. The primary identifiers to be targeted will be unique to each disaster as they are governed by the potential data that will be retrieved from the remains of the deceased [8].

The FLO must be aware of the benefits of determining the daily habits and lifestyle of the missing person as opportunities to retrieve AM data are unlikely to be restricted to the home address. For example, physical evidence of identity may be retrieved from the work place, sports club, car, hospital histology department, dental surgery, etc.

Dental Records

Original dental records are an essential part of any AM harvest [12]. As well as charting teeth, the dentist, odontologist, or orthodontist may also be a source of additional information e.g., existing gum shields, radiographs bleaching trays, dentures, bridges, crowns, etc [13]. Gum shields and templates for dentures may also prove to be a rich ground for reference DNA sampling. For obvious reasons it is more likely that an adult will have usable dental records for the purposes of identification than will the child and so other means may require to be explored for the nonadult deceased [12]. Copying of dental information onto the yellow Interpol forms should be done under supervision of a forensic odontologist.

DNA

The collection and subsequent veracity of both DNA and latent prints is wholly reliant on the standard of collection. A qualified scene of crime officer should be deployed with the FLO to retrieve this information.

In any AM harvest, recourse should always be made to medical records for the existence of material capable of yielding DNA that can be reliably attributed to the individual. This is frequently referred to as reference DNA, because the source of the material is confirmed [14, 15].

When it is not possible to secure reference DNA for a missing person, attention turns to items believed to have been used exclusively by the missing person and from which useful DNA may be extracted. These may fall into several categories but the most common are as follows:

- toothbrush
- razors
- hairbrush (with hair roots visible)
- gum shields
- jewelry (particularly studs or rings used in piercings).

In these circumstances, the extraction of cellular material from the exhibit and the raising of a DNA profile is not a proof in itself that the profile relates to the person who was believed to have used the item. To verify the reliability of profiles obtained from such items, where possible, DNA buccal swabs should be obtained from parents/children who form a part of the missing person's genetic familial line. Occasions may occur when there are no surrogate items to compare against a familial line, and here the parent/sibling/offspring DNA can be run to assess the potential for matches [16].

Finger Prints

The scene of crime officer must attempt to identify good sources for the missing person's latent prints. Experience has shown that the retrieval of latent marks is a task best undertaken by a specialist fingerprint officer who is guided by intelligence provided by the investigator [8, 17]. One of the first sources to be checked for potential information regarding prints of the missing person should be the criminal records office. It should also be borne in mind that in our increasingly security conscious work environment there are many opportunities to secure biometric data including finger prints from the human resources element of any major company.

Should a putative identification have occurred in the postmortem (PM) environment, it is good practice for the fingerprint expert to gain access to the personal areas of the individual to see if direct matches on fingerprints can be located. In some instances, other latent prints may be targeted e.g., palm prints or foot prints. The latter have proved to be quite effective in the identification of children.

Nonprimary Indicators of Identity

Most judicial authorities will require at least one primary indicator of identity to confirm a match between the deceased and the missing person i.e., DNA, fingerprints, dental information, or a unique medical condition. They are more comfortable if more than one primary indicator is present. However, in certain instances, it is not possible for the identification to be made on primary indicators and so the SIM and the judiciary must agree on how many secondary or indeed tertiary indicators they will require to be present before they will confirm a match between AM and PM data. A list of nonprimary indicators of identity can be found in Table 3.

Table 3 Examples of nonprimary indicators of identity

Secondary	Tertiary
Jewelry	Visual
Personal effects	Photographic superimposition
Distinctive clothing	Generic clothing
Accidental scars	Surgical scars
Birth marks	Body location (e.g., number seat on plane)
Tattoos	
Blood group	
Deformity	
Developmental abnormality	

The aspect of DVI that concerns the Casualty Bureau, the AM harvesting process and the AM coordination center is frequently referred to as the prematching "dry" side of DVI. Therefore, there is a concomitant "wet" side to the process and this encompasses the fields of body recovery and PM harvesting of information pertinent to the identity of the deceased.

Body Recovery

In all disaster scenarios, securing the safety of survivors is paramount and the emergency services rightly give this aspect priority. Once it is clear that there are no more survivors, then the site is secured by the police service and health and safety personnel assess its safety for the recovery process to commence. Every scenario is different and no single generic approach suits every event and therefore, we can only touch on the very basic processes of efficient body recovery in this section.

It is important that this work is carried out by fully trained personnel who have full cognizance of the requirements of victim identification and full understanding of forensic procedures in relation to evidential recovery [8].

The disaster area may be searched by a variety of specialists and teams including search and rescue, health and safety, antiterrorist, air accident, rail accident, etc., prior to body recovery operations. Each body is photographed *in situ* and an ACPO body recovery booklet (with integral URN) is commenced

at this stage. In this way, the URN and recovery booklet remain with the deceased from the point of discovery to the final matching process. The position of the body is recorded and it will be removed to a body holding area where a preliminary visual search may occur that will fast track information in relation to possible identity. The holding area is usually located close to the incident site but in an area that is well screened from public or media observation. Once the resilience mortuary is ready – the bodies are transferred to the mortuary holding area prior to PM examination.

Postmortem Process

The PM process is designed to mirror the nature of the AM information that has been collected as the principal goal to achieve a match between two sets of information – AM and PM [8]. When the UK DVI team is deployed, all PM information is recorded on the pink PM forms which can be downloaded from the Interpol website [10]. The resilience mortuary is directed by the SIM, the mortuary manager, and the lead pathologist.

Triage

A body ready for PM examination is logged out of the holding area and transferred to the first station. This is usually where the ACPO body recovery booklet is checked and the commencement of PM pink documentation commences with transfer of the URN. If items had been identified in the body holding area as being of merit for fast tracking identity, then they will be readily apparent in the body bag and can be brought to the attention of the SIM who will task this information back to the casualty bureau. This may include items such as mobile phones, identification cards, etc.

In the event of fragmentation or disruption of bodies, the presence of an anatomically trained forensic anthropologist in triage can be valuable [18, 19]. They will quickly be able to identify body parts and therefore permit both fast tracking of the part or reconstruction of the individual.

Photography

A full record is created of the PM process from the commencement to the termination of the postmortem process. The photographer will remain with a single body as it passes through several stations in the resilience mortuary and will take photographs of the deceased at every stage, where a change has occurred and of every exhibit or production that is seized from the deceased as the process continues.

Fingerprints

Fingerprints will be recorded from the deceased as will palm prints and depending upon the directive from the SIM, foot prints may also be recorded. The means by which this is undertaken (powder, ink, etc.) will depend on the situation and requirements of the incident [17]. Fingerprints are usually taken prior to removal of clothing to ensure that there is minimal damage to the skin from which the print is being recorded. Loss of the outer layer of the skin (epidermis) does make fingerprinting more difficult, but the sloughed skin may be retrieved perhaps from the body bag and each finger slipped over that of the gloved finger of the officer and a print recovered in that way. In the absence of the epidermis, a print can still be recovered from the deeper dermal layer although it is less reliable as a means of achieving a positive match [20]. The hands of the deceased must be cleaned afterwards as families may wish simply to hold the hand of their loved one before they are buried or cremated.

Radiography

Radiographic imaging of the deceased may be performed in different ways. Fluoroscopy permits a real time image of the deceased and while this might be vital for the purposes of screening for devices that may affect the safety of the forensic teams e.g., explosives, it is not the best medium for visualization of internal structures. Either flat plate radiography or multiple slice CT images are preferred [21–23]. These will highlight the presence of implants and trauma to the pathologist and the anthropologist and may generate images that could at a later date be compared with AM radiographs.

Forensic Pathology and Anatomical Pathology Technology (APT)

The strip search process is supervised by the pathologist and physically undertaken by the APT. This involves the systematic search of the deceased for artifacts prior to removal of clothing. This is undertaken by a skilled APT as it can prove to be extremely

difficult to remove clothing or personal effects (e.g., rings) and they are trained to achieve this with minimal disruption to the deceased. Personal effects and clothing are seized by the exhibits (productions) officers and processed in parallel with the remains of the deceased.

Once the body has been stripped, the proper PM examination will commence. This will start with a detailed search of the surface of the remains in search of scars, wounds, birth marks, tattoos, etc., and will culminate in a full PM examination [8]. Although it may not be necessary to attribute the cause of death to the deceased (e.g., victim of a bomb explosion), it may be necessary to take tissue samples from the driver of a train or the pilot of a crashed plane to satisfy investigative requirements. In addition, the internal examination may well prove vital to confirm the reason behind surface scars, to confirm implantation of devices and their removal to secure a unique serial number. The pathologist will also supervise removal of tissue or fluids for DNA sampling. All information pertaining to the PM examination is relayed to the scribe who completes a full Interpol descriptor on the pink PM forms.

Exhibits/Productions of Personal Effects or Relevant Artifacts

All evidence retrieved from the deceased, whether in relation to personal effects, or evidence related to the incident e.g., bomb shrapnel must be processed through an approved process [8]. This includes photographing and labeling each exhibit/production before recording it in an exhibits book. Some of these images e.g., of jewelry may prove to be important to show to families to aid in the identification process. While one could argue that in an accidental or natural disaster, it is unnecessary for such a formal forensic procedure to be undertaken, it is prudent and rarely is there criticism of excess protocol but there certainly is justifiable criticism of incomplete documentation. All exhibits are also recorded in the pink Interpol PM form.

Forensic Odontology

The odontologists usually work in pairs – one clean to scribe for the dirty partner. The dental remains of the deceased are recorded on the pink forms as are any dental interventions e.g., crowns, bridges, etc. The odontologist will frequently take their own radiographs using specialized equipment that will allow them to directly compare with AM dental surgery radiographs [12]. The whole body radiography usually does not provide sufficient clarity of detail for their requirements. A significant number of photographs will be taken to facilitate comparison with AM photographs as teeth, in a smiling image, may be directly superimposed onto the PM photographs.

Forensic Anthropology

The anthropologist has an important role to play when the bodies are disrupted or severely decomposed. They have the ability to identify small body parts and it should not be confused that they are restricted to identification of bone alone, as anatomically trained anthropologists are equally comfortable at identification of soft tissue body parts. Bodies that have advanced decomposition may require an evaluation of biological identity (sex, age, stature, and ethnicity) performed from the skeletal remains. The anthropologist can also assist the pathologist with the reconstruction of body parts (usually skulls) when ballistic trauma has shattered the normal anatomy and trajectories of missiles need to be evaluated [18, 19].

Upon completion of the PM examination, the body is returned to the mortuary holding area until a match has been confirmed.

Matching Centers

Matching centers bring together all AM and PM information [8]. Depending upon the scale of the operation this may simply be a paper exercise where pink and yellow forms can be directly compared if there are few deceased in the incident. However, with larger events e.g., Asian Tsunami, a paper comparison is unworkable. In this situation, all AM and PM data is logged into a computerized system (the potential for mistakes is high and attention to detail remains at the forefront of operational procedures). The preferred computerized system is Plassdata, which was developed by a Danish company [9, 24]. This system will automatically search all the AM and PM data and highlight potential matches. The computer does not of course recognize the subtleties of identification and therefore any potential matches must be examined by an appropriate expert. If a match is established then a series of quality checks are performed prior to the completion of

a reconciliation report and an Interpol comparison form.

Identification Commission

Depending upon the country of location of the incident, the reconciliation report and the Interpol comparison form will be presented to an identification commission [8]. This is headed usually by a judicial authority of a particular country. The role of the commission is to undertake the legal responsibility for the confirmation of identity of the deceased, its match to a missing person, and ultimately the release of the remains to family and friends.

The Commission will likely include the lead judiciary, the SIM, the lead odontologist, the lead pathologist, and any other experts that it deems necessary to present information pertaining to a particular case. If the judicial authority agrees that a match has occurred, then the body can be released from the mortuary holding area, embalmed (if necessary) and released or repatriated to loved ones.

Any mistake made throughout this process will result in either a missed opportunity to achieve an identification or a misidentification. Should the latter occur then two families are involved, as a body may be released to the incorrect family leaving the second family bereft of their loved one. This has happened in many situations and it is regrettable and to be avoided at all costs. This can be difficult when the conditions of body recovery or in the mortuary may be less than optimal, consumes more time, and mortuary teams tire. These are, however, not acceptable excuses and teams are trained to the highest level of evidentiary standards to prevent mistakes.

The United Kingdom now has training in place for both the "dry" and the "wet" side of operations. Family liaison officers are trained both by the National Policing Improvements Agency (NPIA) and the Metropolitan Police Service (MPS). Body recovery training is provided by NPIA and advanced mortuary skills are taught by the University of Dundee in conjunction with the Centre for International Forensic Assistance (CIFA) and NPIA [25]. Training is not, however, sufficient on its own as there must be regular updates and exercises to ensure that skills are practised and updated.

Although the concept of DVI is relatively simple – comparison of two data sets to secure a match – it must be appreciated that protocols and procedures must be of the highest standard. This is rarely a speedy process, but it must be an accurate process and often it is being undertaken in less than optimal conditions.

Preparation for a disaster has to rely on the "when" and not an "if" a disaster occurs, as they usually arrive with absolutely no warning.

SUE BLACK AND LUCINA HACKMAN

Discovery: Depositions

Introduction

A deposition is a method of obtaining evidence in common law legal systems, prior to a trial or hearing, to assist in the preparation of a legal case. As part of the discovery process, depositions allow each side to obtain information about the evidence relied upon by the opposing side. This enables the parties to prepare their own case, and, if necessary, depose their own witnesses to meet the evidence of the opposing side. A deposition is but one tool of pretrial discovery; some jurisdictions (such as the United States of America) favor depositions, while others favor other forms of disclosure such as affidavits. In England and Wales, for example, depositions are most common in Magistrate Courts[a] and may also be used in cases where persons are dangerously ill and may be later unable to give evidence in person at a trial.[b] Depositions may also be used in cases where a witness is unwilling or unable to attend court to give evidence in a trial or hearing.[c] Depending on the jurisdiction, failure or refusal to attend a deposition may result in the person being fined[d] or ordered to pay any costs resulting from his failure or refusal.[e]

The person giving evidence at a deposition is called a "deponent". The evidence is given under oath, and for this reason, the deponent can be charged with perjury or obstruction of justice if the evidence given is untrue.

A deposition is conducted in the presence of the lawyers for all parties, never in the presence of a jury, and sometimes in the presence of a judge or examiner of the court.[f] The deponent is asked questions by the lawyer for the opposing party, and the deponent's lawyer has the right to object to questions that are irrelevant, inappropriate, vague, misleading, hectoring, and so on. Deponents may also be questioned by the lawyer who retained them, so

as to clarify or respond to the answers elicited by the opposing lawyer. If an issue arises as to whether a deponent should answer a question or not, a judge or court officer may decide the issue.

Depositions are recorded and the transcript of the deposition can be used by all parties to prepare for the legal proceedings. The evidence given in a deposition can be used to file pretrial motions (such as a motion for dismissal of the proceedings), to limit the issues in the subsequent trial (for example, by identifying the areas of agreement between opposing experts), to create an opportunity for settling the case, as evidence in a trial or hearing, and to provide material to be used during examination or cross examination in any subsequent trial or hearing.

Preparing for a Deposition

It is essential that a deponent properly prepare for a deposition. This includes reviewing all relevant notes, case records, calculations, files, drafts, and statements related to the evidence that the witness will give. In some jurisdictions, deponents will be asked to bring their notes, files, or other materials with them to the deposition. This enables them to refresh their memory while giving testimony, and makes it more difficult for them to justify any variations in their evidence, which may appear later in the trial proper.

The evidence given in a deposition can be referred to by lawyers during subsequent legal proceedings. This may be problematic for witnesses whose evidence in the trial is not consistent with the evidence they gave in the deposition. For example, during a cross examination in a trial, the deponent may be asked "Is it not true that in your deposition, you said [xyz]? Was your memory better then? Or were you lying then or now?" It is essential that deponents prepare not only for the deposition but also thoroughly review their deposition evidence before giving evidence in later legal proceedings.

Attending/Giving Evidence in a Deposition

Depositions may occur in courtroom facilities or in other locations such as lawyers' offices. Attending a deposition attracts the same responsibilities as giving evidence in ordinary legal proceedings. All deponents are obliged to honor their oath and expert witnesses must fulfill any duties which are attracted by their special status as experts. For example, the duty of an expert to provide impartial, objective, independent assistance to the court, rather than to the party that called them, prevails in a deposition as much as it does in a trial or hearing.

When attending a deposition, deponents should listen carefully to the questions asked, wait for the entire question, and provide only considered answers. Deponents should not provide unsolicited information or move beyond their area of expertise.

Just as in a trial or hearing, answers given in a deposition are given orally, and gestures or sounds to indicate affirmative/negative should be avoided as they are likely to be unclear on a transcript. Experts, who need to refer to body parts, exhibits, photographs, maps, diagrams, and so forth, should ensure that they use adequate verbal descriptions to convey their evidence.

If a question is unclear, the deponent is entitled to ask for clarification before providing an answer. This is important because the transcript of the deposition will not show that the deponent did not understand the question unless he makes it clear at the time. By answering a question he did not understand, a deponent runs the risk of having to alter or contradict his deposition in any subsequent trial or hearing.

Generally, all questions must be answered (even if the only answer is "I do not know" or "I cannot answer that because it is not within my area of expertise"). A deponent whose lawyer advises them not to answer a question should not answer the question. If the lawyer objects only to the form of the question (for example, because the question is unclear), the deponent should listen carefully to the nature of the objection, and if necessary, ask the opposing lawyer to rephrase the question.

Lawyers for all parties will be assessing the performance of the deponent; appearance, manner, clarity of explanations, confidence, and credibility are issues not only in the trial but also in the deposition.

After a Deposition

After a deposition, a transcript of the evidence is prepared and copies are provided to all parties. If there are reporter errors on the transcript, a deponent may be able to correct them. Errors in the content of the testimony, however, are more difficult to correct

and any such changes made by a deponent may be the subject of comment in the subsequent trial or hearing. A copy of the deposition testimony is filed with the court; if a deponent is later unable to attend the hearing or trial, their deposition evidence may be used instead.[g] Even if the deponent does attend the trial or hearing, and gives more evidence there, their testimony at the deposition is treated as an additional witness statement.

Attending a deposition is an opportunity for the deponent to assess how well he was able to give the evidence. This does not mean that the deponent should alter the substance of the evidence; however, it may be possible for him to work out how to better communicate his scientific, technical, or medical evidence in a legal forum. It is permissible and highly recommended for deponents to review their deposition testimony before giving evidence in the subsequent trial or hearing.

Discovery: Discovery Motions

Introduction

Discovery motions are legal devices used by litigants in adversarial legal jurisdictions for compelling the opposing side to furnish information, which the law either permits or requires them to supply. The practice is highly regulated by statute or court rule in the state and federal court systems of the United States (*see* **Discovery in the United States: Civil Cases**; **Discovery in the United States: Criminal Cases**). This article explores the method used in the United Kingdom in both criminal and civil court cases.

Discovery motions as devices for eliciting information from an opponent are not used in civil law countries.

Discovery Motions in Criminal Proceedings

If the defense has reasonable cause to believe that the prosecution is not providing full disclosure (*see* **Discovery of Expert Findings**; **Discovery: Depositions**), the defense may apply for a court order compelling the discovery.[a] Since the advent of explicit disclosure requirements set out in the *Civil Procedure Rules* (which are expected to precipitate similar disclosure requirements in the *Criminal Procedure Rules*) courts in the United Kingdom have consistently approached disclosure as a significant element of a fair trial. It has been stated that "fairness ordinarily requires that any material held by the prosecution, which weakens its case or strengthens that of the defendant, if not relied on as part of its formal case against the defendant, should be disclosed to the defense. Bitter experience has shown that miscarriages of justice may occur where such material is withheld from disclosure. *The golden rule is that full disclosure of such material should be made*" [1].

Courts in the United Kingdom have also noted decisions of the European Court of Human Rights (ECHR) in which the ECHR has considered matters of disclosure. In any motion for discovery, considerations such as national security, the need to protect witnesses, or to keep secret police methods of investigation of crime, are likely to be weighed against

the needs of the party seeking discovery [2]. The ECHR has also specified additional reasons for which discovery may be denied, in that "the entitlement to disclosure of relevant evidence is not an absolute right. . . . In some cases, it may be necessary to withhold certain evidence from the defense so as to preserve the fundamental rights of another individual or to safeguard an important public interest" [3]. In any case, the ECHR has found that in order for a trial to be considered "fair" as per the requirements of *Article 6* of the *European Convention on Human Rights*,[b] any decisions to withhold material from the defense must be scrutinized by judicial authorities at a national level, on a case-by-case basis [4].

The current position in the United Kingdom in relation to motions for discovery in criminal proceedings appears to support three propositions [5]. First, the accused has a fundamental right to a fair trial, which includes an "equality of arms" between the prosecution and defense. This right entitles the defense, but not the prosecution, to seek discovery under both national law and under *Article 6* of the *European Convention on Human Rights*. The obligation on the prosecution arises even if it has not been specifically sought by the defense. Concomitant with this, the prosecution is obliged to disclose all material in its possession which would tend to undermine the prosecution's case or to assist the case for the defense. Thirdly, the right to disclosure is not absolute and may be curbed by competing interests, which include the public interest and the protection of witnesses. Any decision to withhold information is one which is not solely a matter for the prosecution. Material should not be withheld unless judicial scrutiny has deemed it strictly necessary on all the facts of the case.[c]

Civil Litigation in the United Kingdom

Under the *Civil Procedure Rules* for England and Wales, a party may put to an expert, instructed by another party or a court-appointed expert, written questions about his report. The questions may be put only once, must be put within 28 days of service of the expert's report, and must be for the purpose only of clarification of the report (unless the court gives permission or the other party agrees). Answers to such questions are then part of the expert's report.

Discovery in the United States: Civil Cases

Introduction

The general principles of discovery and disclosure of information in common law countries, excluding the United States, and in civil law countries, has been discussed elsewhere (*see* **Discovery of Expert Findings**; **Discovery: Depositions**; **Discovery: Discovery Motions**). In this article, the focus is on discovery and disclosure in civil litigation in US federal courts only.

"Discovery" is the legal term designating the duty of parties to civil litigation to disclose information about a pending action to the opposing side. While in years gone by, law suits in adversary system jurisdictions were seen as contests between parties during which each side sought to shield its evidence from disclosure so as to be able to surprise the opponent during trial, the modern approach has been to do away with what has sometimes been characterized as "trial by ambush". Current law favors free and full disclosure of all information relating to a case among the parties.

Recognizing that the broad availability of discovery methods may be misused by one side in litigation, so as to seek to overburden the opponent, special provisions have been included to make such abuses more difficult. To avoid misuse of the discovery process by serving upon the opponent excessive and oppressive demands for information of doubtful relevancy, provisions exist for the issuance of protective orders by courts. These provisions can also require the demanding attorneys to make payment of fees and expenses to the party retaining the expert.

Federal Rules of Civil Procedure

The Rules of Civil Procedure have seen significant changes since they were first enacted in 1937. Some major amendments were made to the discovery procedures in 1993, and again in 2006. The most significant rule for forensic experts relating to initially mandated pretrial discovery is contained in Rule 26(a)(2) – Disclosure of expert testimony – which provides the following:

> (A) . . . [A] party shall disclose to others the identity of any person who may be used at trial to present evidence under Rules 702, 703, or 705 of the Federal Rules of Evidence. (*See* **Federal Rule of Evidence 702** and **Expert Opinion: United States**).
>
> (B) Except as otherwise stipulated or directed by the court, this disclosure shall, with respect to a witness who is retained or specially employed to provide expert testimony in the case or whose duties as an employee of the party regularly involve giving expert testimony, be accompanied by a written report and signed by the witness. The report shall contain a complete statement of all opinions to be expressed and the basis and reasons therefor; the data or other information considered by the witness in forming the opinions; any exhibits to be used as a summary of or support for the opinions; the qualifications of the witness, including a list of all publications authored by the witness within the preceding ten years; the compensation to be paid for the study and testimony; and a listing of any other cases in which the witness has testified as an expert at trial or by deposition within the preceding four years.
>
> (C) . . . In the absence of other directions from the court or stipulation by the parties, the disclosure shall be made at least 90 days before the trial date or the date the case is to be ready for trial or, if the evidence is intended solely to contradict or rebut evidence on the same subject matter identified by another party under paragraph (2)(B), within 30 days after the disclosure made by the other party. The parties shall supplement these disclosures when required under subdivision (e)(1).[a]

As can be observed *supra*, subdivision (B) of Rule 26(a) sets out in great detail the type of information that must be contained in an expert's report of analysis, or in the appendices it must provide,[b] which also require that experts keep updating their curriculum vitae as they author new publications and are retained to testify as expert witnesses in other cases during a specified period of time – 10 years and 4 years, respectively.

In addition to the discovery provided by Rule 26(a)(2)(B), it is further provided, in subparagraph (5), that experts may also be compelled in some instances to participate in discovery requests made under other sections, such as

> (5) Methods to Discover Additional Matter. Parties may obtain discovery by one or more of the following methods: depositions upon oral examination or written questions; written interrogatories; production of documents or things . . . ; physical and mental examinations; and requests for admission.

The initial disclosures discussed so far are mandatory in all cases and require no court intervention or judicial order. The parties are required to provide voluntarily the information specified in the Rule. The scope of discovery is also specified in Rule 26. With respect to the counsel's preparation for trial, where experts have been involved either to testify at trial or to merely provide assistance in trial preparation, Rule 26(b)(4) – Trial Preparation: Experts – provides the following:

(A) A party may depose any person who has been identified as an expert whose opinions may be presented at trial. If a report from the expert is required under subdivision (a)(2)(B), the deposition shall not be conducted until after the report is provided.
(B) A party may, through interrogatories or by deposition, discover facts known or opinions held by an expert who has been retained or specially employed by another party in anticipation of litigation or preparation for trial and who is not expected to be called as a *witness at trial* only as provided in Rule 35(b) or upon a showing of exceptional circumstances under which it is impracticable for the party seeking discovery to obtain facts or opinions on the same subject by other means.
(C) Unless manifest injustice would result, (i) the court shall require that the party seeking discovery pay the expert a reasonable fee for time spent in responding to discovery under this subdivision and (ii) with respect to discovery obtained under subdivision (b)(4)(B) of this rule the court shall require the party seeking discovery to pay the other party a fair portion of the fees and expenses reasonably incurred by the latter party in obtaining facts and opinions from the expert.

Part (B), above, deals with the circumstance where a lawyer is informed that an opponent has received technical assistance from a consulting expert who is not expected to testify for the opponent. In that case, disclosure will be mandated only if the requesting party can show that there exists a special need to obtain information from the consulting expert, typically information that cannot be easily obtained in another manner. The provision may have been left intentionally vague to allow the courts to flesh out the Rule's parameters on a case-by-case basis. Elsewhere, the present author has explained under what circumstances this provision may apply:

> Among the exceptional circumstances which ought to warrant discovery are: (1) where the only known expert in the field has been retained by the opposing party; (2) where the expert retained by the opposing side has made an investigation which now, due to a change in the circumstances, can no longer be duplicated by a different expert, as where an analysis has consumed the substance to be analyzed, or materially altered it; and (3) where the information is available through effective discovery but only by the expenditure of excessive time and money and where a significant delay of the trial would be caused [1].

It is not always easy for a lawyer to discover whether an expert was retained in anticipation of providing opinion testimony at trial, or merely to consult on pretrial preparation. An attorney may have hoped to obtain a favorable opinion when he first contacted the expert, only to discover that the opinion received from the expert makes calling him as a witness undesirable. Perhaps the law ought to consider the information and advice given to the retaining attorney as privileged from disclosure in the latter case. To require disclosure would discourage lawyers from seeking as much information about the facts in the case as they possibly can learn, though there may be situations wherein the status of the expert might straddle both the role of witness and of assistant in trial preparation.

It is not uncommon for attorneys to seek off-the-cuff opinions on some aspect of a case by telephoning or consulting, informally, an expert without the conversation resulting in a retainer for either formal advice or an expert opinion related to disputed evidence. Rule 26 does not apply to such instances; it neither mandates nor regulates discovery of information from experts who were informally consulted but not retained.

The 2006 Electronic Discovery Amendments

Courts have dealt with electronic data storage for many years, while deciding disputed discovery issues on an *ad hoc* basis. In 2006, the Rules of Civil Procedure were amended to accommodate more formally the growing importance of the discovery of "electronically stored information" (ESI), a process that is also referred to as e-discovery. These amendments do not specifically mention expert witnesses, though they may have implication for laboratories and expert witnesses, generally, inasmuch as much of the data they consult and the examination results recorded and stored electronically.

Rule 26 includes, in its definition of matters subject to disclosure, "electronically stored information" and "data compilations" as a category of information, which must be disclosed at the outset of the litigation, and provides a procedure to be followed by attorneys when a party contends that the data is

inaccessible because of undue burden or excessive cost.

Other amendments to the rules relate to e-discovery as well. A new subsection added to Rule 16 addresses the scheduling of pretrial conferences, and provides that in its scheduling order a court may address ESI issues. Further, in Rule 33(d), it is made clear that ESI qualifies as a "business record" upon which answers to interrogatories may be based. Rule 34, on production of documents, now provides, as a default method, that ESI will be provided to the requesting party "in the form in which it is ordinarily maintained or in a form or forms that are reasonably usable." Whether this also includes metadata [2] is something that is not clear.

In order to know how to comply with today's e-discovery requirements, many attorneys will need to become far more familiar with computer operations and data storage systems than they were expected to be in years past. In the past, it was not unusual for attorneys trying civil law suits to bring into court boxes upon boxes of folders, files, and documents. In the future, discovery may well take a different form when seeking to obtain the knowledge contained in "gigabytes upon gigabytes of information that might be relevant to a case" [3].

Conclusion

The purpose of disclosure and discovery provisions applicable to civil litigation is to enable attorneys to learn all the information about the case that is possessed by the opposing side and which is not shielded from disclosure by evidentiary privilege rules, such as the attorney–client privilege, or some work-product rule applicable to certain trial preparation efforts of counsel. In civil litigation, disclosure obligations apply equally to plaintiffs and defendants.

End Notes

[a.] Federal Rule of Civil Procedure. Rule 26. General Provisions Governing Discovery; Duty of Disclosure, hereinafter Rule 26.

[b.] It will be observed that an expert's report in a civil case is required to contain far more detail than what is required of an expert in a criminal case (*see* **Discovery in the United States: Criminal Cases**).

Discovery in the United States: Criminal Cases

Introduction

Elsewhere, the general principles of discovery and disclosure of information that apply in common law as well as in civil law jurisdictions has been discussed (*see* **Discovery of Expert Findings**; **Discovery: Depositions**; **Discovery: Discovery Motions**). In this article, the focus is on discovery in criminal cases with special emphasis on discovery in federal criminal prosecutions in the United States.

As in civil litigation (*see* **Discovery in the United States: Civil Cases**), the term *discovery* embodies a legal concept delineating the duty of parties to a criminal prosecution to disclose information about a pending action to the opposing side. In the past half century, the trend has been toward free and open disclosure of most relevant information to all sides of the litigation. Discovery of information in criminal cases is not as wide or all-encompassing

as are the rules that pertain to civil litigation. The purposes of discovery are "preventing surprise at trial; narrowing the issues to be tried; and speeding the administration of justice by encouraging settlement (e.g., plea bargaining) of those cases where both sides know the strength or weakness of the evidence" [1].

Though the duty to disclose certain specific items of information about a case is mandated by either statute or court decision, today, much disclosure occurs informally. The informal discovery process starts with pretrial conferences between the lawyers, it continues thereafter at the preliminary hearing, and spans the entire duration of the trial. Today, many prosecutors and defense attorneys freely provide the information, which they know the law requires them to produce, obviating the need to file discovery motions. Resort to the courts needs to be followed only when the parties do not freely cooperate in the discovery process.

In earlier years, the duty to disclose information was a process, whereby information about a criminal prosecution flowed solely from the prosecution to the defense. Currently, however, many obligations of disclosure are mutual, requiring the defense to engage in reciprocal disclosure. While constitutional rights of an accused prevent the prosecution from compelling some specific types of disclosure from the defense [2], the prosecutor's right to obtain information from the defense may have particular applicability where forensic experts retained by the defense have examined evidence, or furnished opinions on technical issues relating to the evidence analyzed.

Constitutional Requirements

While the right to obtain disclosure of information from the prosecution is typically a matter of state or federal statute or court rule that depends for its specifics on the jurisdiction where the trial will be held, the US Supreme Court has overlaid the statutory duty of the prosecution by some universal constitutional mandates that apply regardless of jurisdictional boundaries and statutory provisions. While Congress and state legislatures may allow for additional discovery privileges, the constitutional safeguards afforded to criminal defendants cannot be lessened by local fiat.

While the US Constitution or the Bill of Rights (amendments to the Constitution) do not specifically mention a prosecutor's duty to disclose evidence to the defense, the Supreme Court has read this duty into several specific constitutional guarantees.

The Fifth Amendment's rights of a criminal defendant, as incorporated into the Fourteenth Amendment's due process clause, requires that evidence which exculpates the criminal defendant must be disclosed to the defense in state as well as in federal criminal trials [3]. In *United States v Agurs* [4], the Court clarified that evidence was "material" to guilt or innocence in one of three situations: (i) where the prosecution used false testimony it knew or should have known to be perjured [5]; (ii) where evidence both material and favorable to the defendant was withheld by the prosecution, after the defense had made a motion requesting the disclosure of such evidence [6]; and (iii) where the prosecution withholds other material evidence favorable to the defense.[a]

Federal (Statutory) Discovery Requirements

In addition to constitutional duties to disclose certain evidence to the defense, Federal Rule of Criminal Procedure 16,[b] governs pretrial discovery in federal criminal trials. There are two separate provisions contained in Rule 16 that impact on forensic experts: one deals with experts retained by defendant, and one applies to experts retained or employed by the prosecution.

The right of the defense to discover expert evidence in the possession of the prosecution is covered in Rule 16(a)(1). The text of this portion of the rule, as amended in 1993, provides the following:

> (a) Government's Disclosure.
> (1) Information Subject to Disclosure . . .
> (F) Reports of Examinations and Tests. Upon a defendant's request, the government must permit a defendant to inspect and copy or photograph the results of any physical or mental examination and of scientific test or experiment if:
>
> (i) the item is within the government's possession, custody, or control;
> (ii) the attorney for the government knows–or through due diligence could know–that the item exists; and

(iii) the item is material to preparing the defense or the government intends to use the item in its case-in-chief at trial.

(G) Expert Witnesses. At the defendant's request, the government must give to the defendant a written summary of any testimony that the government intends to use under Rules 702, 703, or 705 of the Federal Rules of Evidence1 during its case-in-chief at trial. If the government requests discovery under subdivision . . . [the reciprocal provisions compelling the defense to furnish its expert's reports to the prosecutor. Editor] and the defendant complies, the government must, at the defendant's request, give the defendant a written summary of the [expert witness] testimony that the government intends to use . . . as evidence at trial on the issue of the defendant's mental condition. The summary provided under this subparagraph must describe the witness's opinions, the basis and reasons for those opinions, and the witness's qualifications.

The right of the prosecution to discover evidence in the possession of the defense is contained in Rule 16(b)(1)(B) and (C). These provisions parallel those requirements imposed upon the defense using identical language, and thus make the discovery requirements reciprocal on both sides with one exception. The prosecution can discover expert information from the defense only if the defendant first requests and obtains disclosure of similar information from the government.

Rule 16 places some restrictions on the defendant's duty to disclose expert opinions by exempting material used by the defense in investigating the case or preparing a defense where the experts will not be asked to testify. These restrictions are somewhat technical. If forensic experts are in doubt as to their obligation under Federal Rule 16, they should seek guidance from the attorney who has retained them.

Forensic experts should also know that the duty to disclose evidence subject to discovery is a continuing one. Indeed, Rule 17 also provides that "A party who discovers additional evidence or material before or during trial must promptly disclose the evidence to the other party or the court. . .".[c]

While the Federal Rules of Criminal Procedure do provide, in Rule 17, for subpoenas to be issued by the court at the request of either side to produce books, papers, data, or other objects, the rules do not provide for the taking of discovery depositions in criminal cases.

State Statutes Regulating Discovery

In addition to the discovery obligations that arise from the US Constitution, all the States have their own disclosure and discovery provisions embodied in statutes or court rules. Many of the state provisions are patterned on Federal Rule 16, though considerable variation from the federal model can be noted. Most states also incorporate the constitutional requirements mandated by the US Supreme Court into the text of the state statutes or rules. Most states, but not all, make the right to obtain discovery by the defense reciprocal on the providing of similar information to the prosecution about defense experts. Some states provide for the right of litigants to depose prospective expert witnesses prior to trial–a right that is currently not available under Rule 16.

State discovery provisions may differ in at least two regards from the federal model:

1. whether expert information is available only upon motion and court order, as was the case under old federal rules, or self-executing upon mere request by the parties, as is the case in current Federal Rule 16; or
2. whether the state has a reciprocal right to discover expert information from the defense after the defendant has sought information from the state.

Because of the wide variety of provisions that exist, it is beyond the scope of this work to list or categorize the laws and rules of all 50 States on disclosure and discovery. As is true for experts retained or employed in federal prosecutions, forensic scientists must seek guidance from their individual state-licensed attorney to know the exact duties which the jurisdiction in which they practice imposes upon them, in regard to the duty to disclose information to the opposing side.

Conclusion

Since all jurisdictions have acquired a voluminous jurisprudence of decided court decisions on many aspects of the right of discovery and the duty to obtain disclosure of information, forensic experts should seek to become familiar with the local rules that apply specifically in their jurisdictions.

End Notes

[a.] This was the fact setting of United States v. Agurs, *supra* note 6, a murder prosecution wherein the defense pleaded self defense, and the state withheld evidence that the murder victim had a criminal record for violent crimes. Information becomes "material," the Court explained, "if the omitted evidence creates a reasonable doubt that did not otherwise exist."
[b.] Federal Rule of Criminal Procedure 16, hereinafter "Rule 16."
[c.] Federal Rules of Criminal Procedure, Rule 16(C) Continuing Duty to Disclose.

ANDRE MOENSSENS

Discovery of Expert Findings

Introduction

Discovery (also termed *disclosure* in some jurisdictions) is a pretrial process by which a party to a legal action seeks to gain access to documents or other evidence held by, or for, another party. Discovery allows the parties to find evidence, confirm evidence, identify issues, identify areas of agreement, and to avoid surprise evidence ("trial by ambush").

In forensic science, discovery is not limited to the expert report prepared for court. Discovery is intended to enable a party to ascertain the underlying method and results which created the opinion and conclusions reported in the expert's statement. In addition, discovery may be necessary to determine the significance of items not seized, examined, tested, or reported in the expert's statement. Discovery is also a means of investigating the validation and accreditation of methods, the training and competence of analysts, and contamination issues. The additional materials sought through the process of discovery may be contained in briefing papers, internal reports, staff training and performance assessments, laboratory records, case files, submission forms, labels, electronic data, apparatus printouts, calculations, notes, drafts, and correspondence.

Expert witnesses in most jurisdictions have a formal duty to keep accurate, up-to-date and thorough records of all dealings which relate to the matters set out in their reports for court. For example, the code of conduct of the Council for the Registration of Forensic Practitioners (CRFP) in the United Kingdom requires its members to "make and retain full, contemporaneous, clear and accurate records of the

examinations conducted, the methods, and the results, in sufficient detail for another forensic practitioner competent in the same area of work to review the work independently" [1].

Discovery in Common and Civil Law Systems

Formal processes of discovery are mainly a feature of *common law* jurisdictions (for example, the United States of America, the United Kingdom, Canada, and Australia), which use an adversarial legal process. Under common law principles, "the law" is sourced not only from legislation but also from precedents laid down by judges in equivalent or higher courts (*stare decisis*). In this system, the parties (rather than the judge) largely control the direction of the matter, the nature of the investigations, the list of witnesses, and the extent to which discovery of information is sought and pursued.

Conversely, legal systems based on Roman and/or Germanic legal traditions (for example, in France, Germany, and Italy) center upon codified laws. In these systems, legal decisions are based on legislative codes rather than on precedents from other courts (although judicial decisions may, in practice, be persuasive). Judges play a more active role in investigating incidents and determining how procedural matters are handled. Discovery in this context is usually actively controlled and investigated by the judge, rather than by the parties. The emphasis in this system is on the substance of the material sought for the investigation, rather than on the form of the discovery procedures.

In Germany, for example, discovery is governed by the *Criminal Procedure Code* (*StPO*) and the *Civil Procedure Code* (*ZPO*). Judges are duty-bound to *investigate* the charges against the accused, by finding and examining whatever material will assist in determining the truth. Formal procedures of discovery and considerations of rules of evidence are of minor importance in this model, compared with their importance in common law systems.

In 1989, Italy attempted a large-scale legislative reform to change the existing inquisitorial system to an "accusatorial" model (a combination of inquisitorial and adversarial features). This may have had some impact on the procedural criminal law relating to discovery; however, frequent subsequent legislative revisions largely seem to have returned to an inquisitorial, judge-led investigation of all relevant material held by expert witnesses for both the prosecution and defense.

Criminal and Civil Law Procedures

Even in a discussion of "discovery of expert findings", a distinction must also be drawn between *criminal* and *civil* matters. While the former is usually the prosecution of an individual by the state (for example, a murder trial), the latter is usually the action of an individual against another individual (for example, a negligence claim by a patient against a doctor).

Discovery in Criminal Matters

In criminal matters, in most jurisdictions, there is a constitution-level standard of protection for the accused. For example, *Article 6* of the *European Convention on Human Rights* [2] – *The Right to a Fair Trial* impliedly enables the accused in a criminal matter to have access to the evidence against him, including the expert evidence. Most of the laws of discovery in criminal proceedings focus on broad and automatic disclosure by the prosecution to the defense. This reflects the inherent imbalance of power between the state and the individual and seeks to bring an equality of arms to the criminal trial [3].

In England and Wales, the *Criminal Procedure and Investigations Act* (*CPIA*) 1996 and the *Criminal Justice Act* (*CJA*) 2003 govern the disclosure of "material of all kinds", which includes "information", "objects of all descriptions", writing, and tape-recorded information. The prosecution bears an *ongoing* duty [4] to disclose material to the defense, which might reasonably be considered capable of undermining the case for the prosecution or assisting the case of the accused [5]. The only legislative exceptions to this general rule of primary disclosure by the prosecution, are for material that a court has ordered it is not in the public interest to disclose, or which was obtained under a warrant issued under *s*2 of the *Communications Act* 1985 [6]. Although the *CPIA* and *CJA* confer responsibility for disclosure onto the prosecution and the police, rather than directly onto the expert witness, it is imperative that expert witnesses enable the prosecution and police to comply with their obligations under the Acts. Therefore, for most expert witnesses called by the prosecution, the range of material required for discovery is wide and the obligation is ongoing.

Discovery is also governed by case law in the United Kingdom, where full disclosure has been termed a *golden rule* of the criminal trial [7]. Cases such as *R v Ward* [8] have firmly established that a duty of disclosure exists irrespective of any request by the defense, it extends to *all* material matters that affect the scientific case relied upon by the prosecution, and that the duty is ongoing. *Ward* placed a clear obligation on expert witnesses who have carried out or know of experiments or tests, which tend to cast doubt upon the opinion being expressed ... to bring records of those tests to the attention of the instructing solicitor [9].

Failure by prosecution experts to disclose material (either to the prosecution or the defense) may result in a delayed prosecution, or cessation of the prosecution altogether, a successful appeal by the defense (that is, a finding that a conviction is unsafe), censure of the expert [10], or the inability to use expert evidence, which was not properly disclosed [11].

In the United Kingdom, primary disclosure by expert witnesses is usually initiated by the prosecution serving the expert's report on the defense. If the defense, or defense-retained experts, require further material from the prosecution, arrangements are made through the prosecution legal team [12].

In contrast, in France, the *Code of Criminal Procedure* enables investigating judges to control the disclosure of "available information helpful for the discovery of the truth," a list of expert witnesses, timely disclosure of expert reports, and so on [13]. Broad provisions go on to provide that a judicial police officer may order any person, public, or private establishment or organization, likely to possess "any documents relevant to the inquiry in progress", including those produced from a computer or data-processing system, to provide them with these documents. Failure to comply as quickly as possible can result in a fine or criminal sanction [14].

Discovery in Civil Matters

For discovery in civil actions, rules are usually set out in legislation and regulations. Arguments ordinarily arise as to the extent of the disclosure sought and the likely burden imposed on the party from whom disclosure is sought.

Disclosure in civil matters in England and Wales is governed by the *Civil Procedure Rules* (*CPR*) [15]. One of the objectives of the *CPR* is to ensure that parties are on an equal footing [16]. This harks back to the "equivalence of arms" theory, which posits that both parties in a legal action are entitled to know what weapons are held by the opposing side and to have the opportunity to arm themselves accordingly. The *CPR* defines "document" broadly, as meaning "anything in which information of any description is recorded" [17]. Disclosure is required of any documents relied upon by a party, and documents that support or adversely affect a party's case or another party's case [18]. The duty of disclosure is ongoing in civil matters; it continues until proceedings are concluded [19]. A party who fails to disclose or permit inspection of documents may not rely on that document in the proceedings [20].

Civil procedure in Germany is governed by the *Civil Procedure Act* (*Zivilprozessordnung, ZPO*), which specifies procedures from prehearing stages to the decision. Parties and witnesses can be sworn to tell the truth, with perjury or false statements being classified as criminal offences. Evidence is adduced in a number of forms, including site inspection, witness testimony (expert and lay), private or public documents, and evidence from the parties. As in criminal disclosure procedures, the evidence-taking procedures in civil matters are controlled by the judge.

Dissocial Personality Disorder *see* Psychopathy

Dissociation *see* Deception: Truth Serum

Dissociative Disorders

Despite the fact that dissociative disorders have been observed and written about since the founding of the disciplines of psychiatry (e.g., Freud [1] (reprinted 1995)) and psychology (e.g. Morton Prince, the founder of the *Journal of Abnormal Psychology* [2] and Pierre Janet [3, 4], they continue to be the focus of surprisingly contentious debate in the forensic setting. In the proposed revision of the Diagnostic and Statistical Manual of Mental Disorders (DSM IV-R), Dissociation is defined as a failure of the usually integrative aspects of identity, memory, perception, and consciousness [5].

Controversy has swirled around the disorder, in part because it is extreme and dramatic, involving significant amnesia and frequent alteration in identity, memory, and consciousness [6–9]. Patients with dissociative identity disorder (DID) experience sudden loss of memory, change from a sad, dependent, and helpless personality state to an angry, demanding hostile one in seconds, and may therefore find themselves in situations they cannot understand, such as awakening in a strange hotel room. One "identity" may inflict physical damage on their body as "punishment" for another, e.g., carving "I hate Mary" onto her forearm with a knife. The amnesia is often asymmetrical, with certain components of their personality structure being aware of what is going on while others are out, but not vice versa. The problem is not, however, that there are actually "multiple personalities" existing in one body, as the old name of the disorder implied, but rather a failure of integration of various aspects of identity, memory, and consciousness.

We are normally "different people" at work and at a party (hopefully), but we have continuity of memory and identity across these differences. Patients with DID do not. Their problem is not that they have more than one identity, but rather that they have less than one. The dissociative disorders involve fragmentation of self rather than a proliferation of selves. One DID patient told me she needed "Krazy glue" to put herselves back together. Other dissociative disorders include dissociative amnesia, in which periods of forgetting too extensive to be explained by ordinary forgetfulness, usually of a traumatic or stressful nature, occur, but not associated with fragmentation of identity [5].

Dissociative fugue involves sudden and unexplained travel coupled with loss of customary identity, without necessary assumption of a new identity [5]. Depersonalization disorder involves feeling detached from one's body – it is primarily a dissociative disorder of perception [5]. Dissociative disorder not otherwise specified involves dissociative symptoms that do not meet full criteria for the disorders described above [5].

Controversies Regarding the Diagnosis of a Dissociative Disorder

Legally, skepticism about the diagnosis of DID or dissociative amnesia has led to contentions that such a diagnosis could fail to meet Frye [10] or Daubert [11] standards. While such objections have been raised, the fact that these diagnoses continue to evolve in debates related to the *DSM* and other authoritative resources speak to their level of endorsement and support within the psychiatric community.

Diagnostic Criteria

DID was formerly called *multiple personality disorder* (*MPD*). Diagnostic criteria in the DSM-III included "The existence of more than one identity or personality state [12]." This seemed to imply belief in the independent existence of multiple personalities within one person. However, the crucial problem is really the failure of integration of various elements of identity, perception, memory, and consciousness. The DSM-IV workgroup on dissociative disorders took care to bring the nosology into conformity with descriptions of other major psychiatric disorders, relying on observable symptoms rather than inferences about mechanisms. Most importantly, it changed the name to DID to emphasize the key problem, which is fragmentation of identity. Also, the word "presence" was substituted for "existence" of "two or more distinct identities or personality states" (p. 529) [5, 13, 14].

Cross-cultural Generalizability

Dissociative symptoms involving alterations in identity, memory, consciousness, and somatic function have been observed in cultures around the world. In many Hispanic cultures, *ataques de nervios* has been associated with alterations in consciousness and physical function [15], and follows a history of physical and sexual abuse and drug-abusing caretakers [16]. Dissociative symptoms comparable to those described in the West have been observed in China [17], Japan [18], where they are often associated with a history of childhood abuse [19], India [20–24], Turkey [25–33], and the Netherlands [34–38], with a population prevalence for all dissociative disorders of 2.3% among young adults [39]. One community study found a surprisingly high prevalence of DID of 1.5% in the United States [40]. Despite this, it is frequently underdiagnosed [41].

Etiology: Trauma and Dissociation

The majority of dissociative disorders, especially DID and dissociative amnesia, have their origins in trauma. The essence of traumatic stress is helplessness and loss of control over one's body. There is growing clinical and some empirical evidence that dissociative symptoms, including alterations in identity, memory, and consciousness, occur as a defense during and after trauma, a means of maintaining mental control just as physical control is lost [42–49]. Furthermore, dissociation of emotions such as numbing of response to trauma may impede cognitive and affective processing of traumatic experience, leading to increased vulnerability to the development of posttraumatic stress disorder [50, 51]. Many people during and in the immediate aftermath of acute trauma report being dazed, unaware of serious physical injury, or experiencing the trauma as if they were in a dream. Sexually or physically abused children often report seeking comfort from imaginary playmates or imagined protectors, or by absorbing themselves in the pattern of the wallpaper. Many rape victims report floating above their body, feeling sorry for the person being assaulted below them. Similar experiences accompanied by physical anesthesia have been reported by corrections officers being beaten during a prison riot [52] and by accident victims [53].

There is strong evidence of a connection between trauma and dissociation [44, 48, 54, 55]. Trauma, especially early in life, repeated, and from relatives or caretakers, predisposes to dissociative disorders [9, 17, 41, 56–59]. DID can be thought of as a chronic, severe form of posttraumatic stress disorder [44, 48, 60]. For example, in a sample of 55 delinquent children, pathological dissociation was found to be associated with a history of intrafamilial, but not extrafamilial, trauma [61]. This suggests that dissociation may especially occur when role conflict with important family figures on whom one depends is involved, a condition that has been described as "betrayal trauma." [62, 63]. Keeping conflicting views of the same person in mind creates considerable tension and confusion and complicates memory storage and retrieval [64, 65].

Does the traumatized child remember the abusing parent as "friend" or "enemy," associated with feelings of warmth or terror? One study demonstrated

that high dissociators have more impaired memory for trauma-related words (e.g., incest) but not for neutral words, than do low dissociators. The high dissociators also had a greater history of trauma and significantly more abuse by a caregiver than did low dissociators. The authors concluded: "These results are consistent with the proposal that dissociation may aid individuals with histories of betrayal traumas to keep threatening information out of awareness" [64] (p. 488).

Controversies Regarding Amnesia for Trauma

Dissociative Amnesia

The most frequent legal question involving dissociative amnesia is the tolling of the statute of limitations. This can be a crucial problem in both criminal and civil cases involving childhood sexual and physical abuse. Typically for adults, the statute of limitations for events that occurred in childhood will have long passed. However, typically courts will allow a claim to be brought if the victim could not have reported the crime(s) within the tolling period due to amnesia. Does functional amnesia for traumatic experiences happen? Considerable controversy about this has emerged, e.g., [66, 67]. While it is true that emotional arousal typically leads an increase, not a decrease, in recall, there is also scientific evidence that blocking emotional arousal will block the emotion-related increase in recall. Cahill *et al.* [68], for example, administered a β-blocker which reduces activity of the sympathetic nervous system (common effects of its activation are increased heart rate and blood pressure) after showing an emotionally arousing film to subjects. The β-blocker interfered with the arousal-related increase in recall. This means that controlling emotional arousal also reduces the effect of arousal on recall.

While voluntary suppression of emotionally laden memories is less likely to be successful than that for neutral stimuli [69, 70], when people are motivated to forget, they are more likely to do so for trauma related than neutral memories [71]. The pressure to forget is greater when children are abused by a trusted caregiver: "a trusted caregiver might represent an unavoidable cue for memory retrieval. The only way to prevent persistent recall of damaging memories would be to adapt internally and to deliberately avoid thinking of such memories – in Freud's terms, to push them away from consciousness. Anderson and Green have now shown that even in the innocuous setting of the laboratory, and with stimuli as trivial as randomly paired words, powerful inhibition can be evoked. How much stronger must this inhibition be for objects central to our thoughts and emotions" (p. 319).

We process such vast amounts of information that we would be immobilized by it if we were consciously aware of even minor portions of our total information stores at the same time. We can function only by being strategically selective and accessing the needed information which is then restored when appropriate use has been made of it. To do otherwise would be like having every stored file in a computer open at once, which would overwhelm the central processor, or having all the contents of one's office file cabinets on the desk at the same time. Memory encoding, storage, and retrieval must involve decision rules that limit access of memories to consciousness.

There is indeed strong evidence that even extremely traumatic events may be forgotten. Leading memory researchers have carefully documented cases of it [72]. Numerous other investigators have reached the same conclusion [73–77]. Williams [78, 79] showed that 38% of a sample of women with documented medical histories of physical and sexual abuse (emergency room records) could not recall the incident when debriefed approximately seven years later. Another 14% reported that for some period of time they had not recalled the traumatic incident.

A recent article by Geraerts *et al.* [80] confirms that people do have discontinuous memories – available at some times and not others (*see* **Recollective Accuracy of Traumatic Memories**). Furthermore, they show that such discontinuous memories ($N = 41$; 37% corroborated) are no less reliable than those that have been held continuously ($N = 57$; 45% corroborated). They reported that independent corroboration of such forgotten and then retrieved memories was comparable to that obtained for continuous memories, with the exception of those memories recovered by a subgroup ($N = 16$) in therapy. The authors concluded: "This finding indicates that discontinuous memories are not, as has sometimes been suggested, inherently unreliable. This idea is supported by recent research showing that people reporting spontaneously recovered memories show a striking tendency to forget prior incidences of remembering when those prior

retrievals have taken place in a different retrieval context. This finding suggests that this group, as a whole, may simply be failing to remember their prior thoughts about a genuine incidence of childhood sexual abuse (CSA) (p. 566)." This study proves that memories of traumatic events can be forgotten for some period of time and then reliably recovered. Excluding the 16 who recovered memories that could not be corroborated in therapy, 41 of 98, or 40% of this sample responding to a newspaper advertisement about an abuse history reported discontinuous memories of their abuse history. If one makes the conservative assumption that only corroborated abuse actually occurred, this means that 15 out of a total sample of 114, or 13%, clearly had amnesia for documented childhood abuse. While this is a minority, it provides further evidence that dissociative amnesia for trauma can and does occur.

Amnesia for trauma can be understood in part as a reflection of the immediate effects of trauma on consciousness. To the extent that attention is narrowly focused during trauma, information may be encoded in rather limited form, for example, the "weapon focus" of assault victims, who can give elegant descriptions of the gun pointed at them, but recall virtually nothing else about the assailant [81]. Dissociation can further isolate memories, by separating them from common associative networks that would make memory retrieval easier [82–84]. There is evidence that congruence in mood between the state in which memories were stored and that in which they are retrieved improves recall [85]. Similarly, another form of salient state dependency involves the dissociative state itself. To the extent that individuals do enter a spontaneous dissociated state during trauma, the memories may be stored in a manner that reflects this state (e.g., narrower range of associations to context). There may be fewer cross-connections to otherwise related memories [82, 86].

Trauma can be understood as a sudden discontinuity in experience. This may lead to a process of memory storage that is similarly discontinuous with the usual range of associated memories. This may explain the "off/on" quality of dissociative amnesia and its reversibility with techniques such as hypnosis [87, 88]. Dissociated information is out of sight, but not out of mind. The information kept out of consciousness nonetheless has effects on it. Thus trauma can elicit dissociation, complicating the necessary working through of traumatic memories. The nature of the acute response to trauma may also influence long-term adjustment to it.

Concern has been expressed that individuals with dissociative disorders, because they tend to be hypnotizable [60, 74, 89–93], are therefore suggestible and subject to deliberate or inadvertent influence that could affect memory [6, 94–98]. All memory retrieval is subject to potential bias, including influence by the nature of the questions asked and other subtle or overt coercive aspects of the inquiry. Highly hypnotizable individuals are more easily influenced by the nature of questioning, whether in or out of formal hypnosis [99]. At the same time, repeated retrieval efforts will in general produce more correct new information [100, 101] as well as more incorrect responses, so repeated efforts to induce recollection can in fact improve it. No simple memory report should be taken at face value, and external corroboration is always helpful in evaluating memory reports.

Testimony following dissociative amnesia has been challenged on the basis of the reliability of formerly "forgotten" or dissociated information [8] p. 4169. For example, George Franklin was prosecuted for the brutal murder of a little girl decades later on the basis of the sudden recollection of his daughter, Eileen Franklin-Lipsker, allegedly because of her glance at her daughter when she was roughly the same age as the victim. Eileen claimed to have suddenly visualized witnessing her father commit the murder. I testified for the defense that while it was possible that she could have dissociated conscious memory of the murder, it was not plausible that there would have been of evidence of her having witnessed it in the form of a changed relationship with her father or willingness to travel with him in the van that was used in the murder. Furthermore, the witness lied about the circumstances of her sudden memory retrieval, initially claiming that it occurred under the influence of hypnosis, then changing her story after a visit to her mother, who was an attorney.

A fourth crucial issue was corroboration. The defense attorney was not allowed to show the jury newspapers that portrayed clearly all the details she had reported to the police, i.e., she reported nothing that only an eyewitness could have know. While Franklin was convicted, the conviction was overturned on constitutional grounds involving his right to present such evidence in his defense ([102] p. 11848). Clearly, testimony based upon information

that has not been held continuously in consciousness will be the subject of intense legal scrutiny.

Controversies Regarding Dissociation and Criminal Responsibility

Does the diagnosis of a dissociative disorder qualify for a not guilty by reason of insanity defense? The diagnosis of a dissociative disorder has been used as a basis for a not guilty by reason of insanity plea [103–105]. There are obvious reasons for concern about the easy application of such an argument [103]. In theory, anyone with a dissociative disorder could claim that some portion of their personality was unaware of what another was doing when a crime was committed. The judge in the Hillside Strangler case, in which a dissociative disorder was claimed as grounds for an not guilty by reason of insanity (NGRI) defense, opined that he was going to take the personality who committed the murders, put him in jail, throw away the key, and whatever the other personalities wanted to do was up to them.

Other than the practical problem of potentially absolving a whole class of psychiatric patients from criminal responsibility, the deeper issue is whether situations can occur, consistent with, for example, the *M'Naughten* standard, in which a person committing a crime is either unaware of the meaning and nature of his act, or unable to know that the act was wrong. In order to hold a defendant legally culpable, the law makes certain assumptions regarding the *mens rea*, the presumption that the perpetrator had the capacity and did indeed plan to conduct a criminal act, such as a murder, with malice aforethought. Typically, some component of a DID patient's personality structure will know what they are doing, and some component may well know it was wrong, but it may not be the same component in control of the person at the moment of the crime. This potential separation is not automatically grounds for an NGRI claim, since potential awareness of the meaning and nature of the act and its implications can exist even in a dissociated state. Courts have ruled that as long as whatever component of the personality meets the prevailing standard of criminal responsibility, the diagnosis of a dissociative disorder is not a mitigating factor [106, 107]. Other rulings have included evidence of cooperation among personality components in committing or covering up the crime [108].

A patient with a relatively unusual form of DID, which had begun not in late childhood but in his twenties, was accused of murdering his girlfriend, shooting her in the face. He had wandered around aimlessly after killing her and turned himself in to the police later that day. When I examined him, I learned that he had one dissociative "alter" personality, that of a former friend who had committed suicide several years earlier. This alter was, unlike the "host" personality, hostile and threatening to the examiner. The story that emerged was that his girlfriend was having an affair with a friend of his, and placed hearts on the calendar in their apartment on days when she had had an assignation.

On the day of her murder, she informed the defendant that she was leaving to see her lover. He went to the closet, took a gun out of a box, and told her he was leaving to kill the boyfriend. She tried to prevent him from leaving, apparently to protect her lover from harm. He then apparently hallucinated the face of his own alter superimposed on his girlfriend's face. The alter reported that he "said" to the defendant, "Go ahead, shoot." He reported shooting what he thought was the alter, thereby killing his girlfriend.

My conclusion at the time was that he did indeed have DID. He was, on formal testing, highly hypnotizable [99], and had clear dissociative symptoms. However, I told the counsel that I could not help provide an NGRI defense, because he knew he was killing someone (the "alter," if not his girlfriend), and he knew it was wrong. Counsel concurred, and did not call me as a witness. However, during the trial the defendant insisted on an NGRI defense. Counsel called another psychiatrist, who testified on the basis of my videotaped interview with the defendant that the condition met the criteria for an NGRI defense, and the court indeed found the defendant not guilty by reason of insanity, much to the surprise of his counsel.

Conclusion

Dissociation is a common response to trauma [42, 46, 77, 89]. Dissociative disorders are rare, but occur around the world, and can profoundly interfere with the integration of identity, memory, consciousness, and perception. Dissociative amnesia for trauma occurs, and may legitimately affect such legal issues

as the tolling of the statute of limitations. Dissociation has been employed as a mitigating defense in criminal cases, with varying success. The difficulty individuals with dissociative disorders have in integrating various aspects of their experience places extra responsibility on professionals helping them to integrate information about the mental processes that surround responses to traumatic experience.

DNA

Introduction

Forensic DNA profiling combines scientific disciplines of anatomy, cell and molecular biology, genetics, mathematics, and statistics. This article aims to explain some of the fundamental science underpinning the use of DNA in a forensic context. In particular, it examines the natural attributes of DNA that contribute to its suitability for use in the forensic field and a summary of the practical tools routinely applied to extract the vital information encoded within human DNA.

Fundamental Human Anatomy

The human body is a universe of working parts and functional interactions. We observe the physical manifestations of these interactions all the time, as we walk, talk, breathe, think, or eat. These gross or macroscopic functions of the human body, however, are driven by extremely complex interactions, occurring at the cellular and subcellular level.

Our bodies are made up of trillions of cells. Each cell has a prescribed function relative to its position in the body that is essential to healthy human life. The cells themselves are extremely complex and advanced

pieces of biological machinery. A cell is comprised of a cytosol, which is bound by a permeable membrane, and contains a host of miniature organs (organelles) including the nucleus. The nucleus contains DNA – the material that prescribes the cell's principal functional characteristics.

It may be useful to think of the cell as being like a factory. Membranes enclose the structure and separate different organelles, which can be thought of as departments with specialized functions. The nucleus is the central administration, containing in its DNA a library of information that determines cellular structure and processes. From it instructions are issued for proper regulation of the business of the cell. The mitochondria are the power generators. The cytosol can be thought of as the general work area, where protein machinery (enzymes) carries out the formation of new molecules from imported raw materials. There are special molecular channels in the membranes between compartments and between the cell and its external surroundings. These monitor the flow of molecules in the appropriate directions, similar to personal assistants and receptionists. Like factories, cells tend to specialize in function. For example, many of the cells in higher organisms are largely devoted to the production and export of one or a few molecular products.

Despite the diverse functions of the different types of cells that constitute the human body, each nucleated cell contains an identical copy of a common DNA molecule from which genetic information is read in a linear fashion. Since the amount of information needed to specify the structure and function of a multicellular organism such as a human is immense, the DNA molecule is extremely long. In fact, if the DNA from a single human cell were stretched end to end it would extend approximately 2 m.

Human cells live by a well-defined life cycle, itself, separated into several distinct phases. Similarly, the process of eukaryotic cell division can be divided into principle phases. Cell division can occur by mitosis that produces two diploid cells, or meiosis, which produces four haploid cells. Mitosis results in the production of two daughter cells that are identical to each other and to the parent cell and is the process of somatic cell replication (Figure 1). Our genetic information is carried to the next generation by the haploid cells known as *gametes* (spermatozoa in the male and the oocyte in the female). These cells are produced by meiosis during gametogenesis (or specifically, spermatogenesis or oogenesis; Figure 2). In either mitosis or meiosis, the DNA (on the chromosomes) must be duplicated and distributed to each daughter cell. An error in DNA replication is called

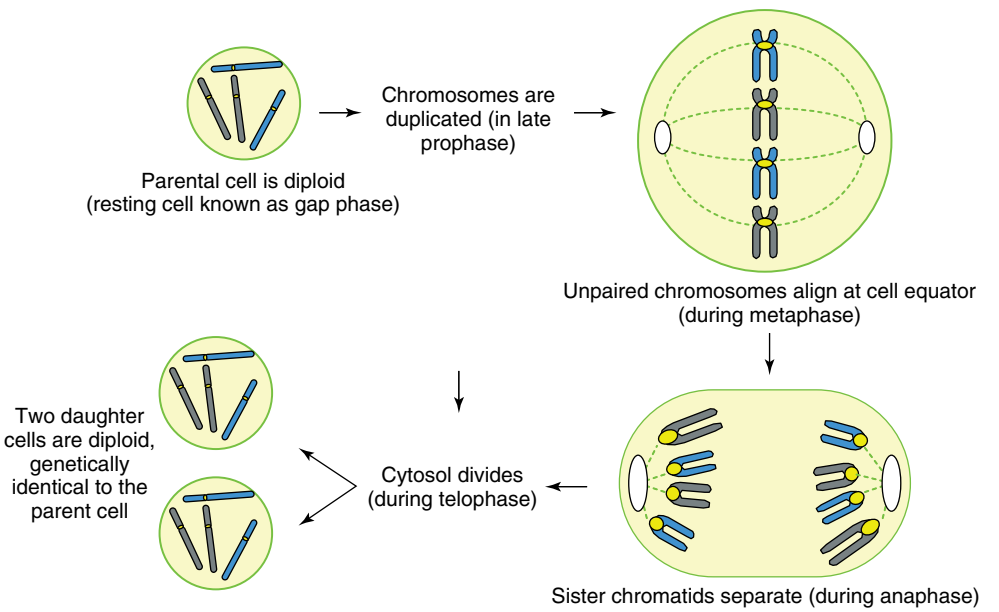

Figure 1 Diagrammatic representation of mitosis, the process of cell replication for adult or somatic cells

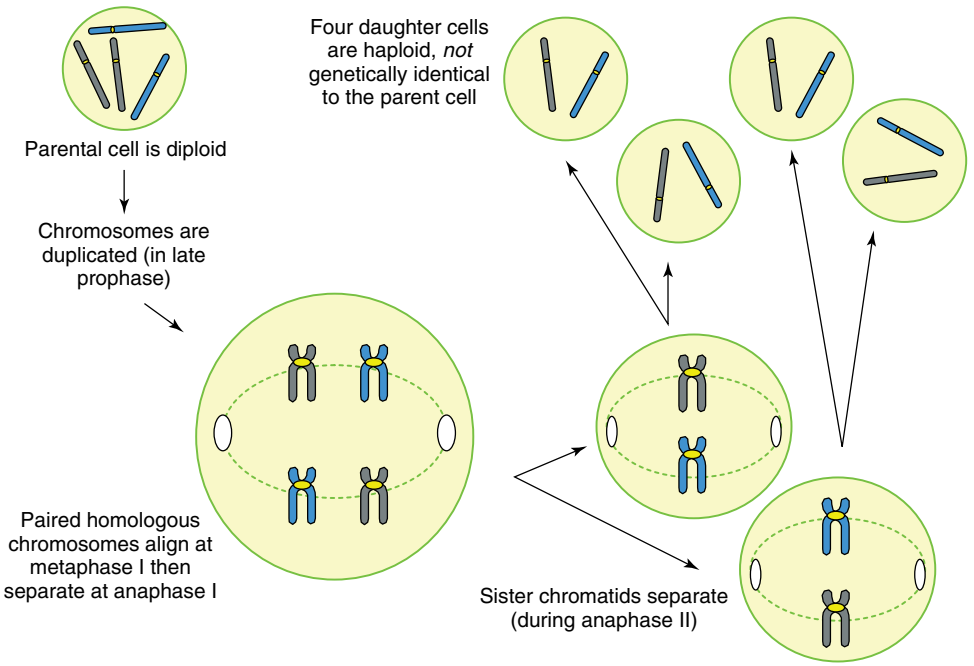

Figure 2 Diagrammatic representation of meiosis, the process of cell replication for germline cells or gametes

a *mutation*. If mutation occurs during replication of an adult cell only progeny cells within that person/organism are affected. This is known as *somatic mutation*. If mutation occurs in the gametes (or germinal cells) there is a possibility that it will be passed onto the offspring of the person/organism. This is referred to as a *germline mutation*.

This summary of basic cellular biology illustrates the first point as to the applicability of DNA analysis for forensic purposes. A replica DNA molecule exists in all nucleated cells in the human body. This means that cells existing in any individual's tissues, fluids, or organs carry a copy of the same DNA molecule. This means there are trillions of possible sources of DNA that can be targetted for forensic purposes. It also means that DNA can be cross-compared among various tissue types from the same donor.

The heritable characteristic of DNA is another advantage to its use in the forensic sciences. Familial, and particularly parental, relationships can provide information to the origin of a given DNA profile due to the known presence of inherited characteristics. This application of DNA profiling technology is often used in the identification of human remains or in the investigation of crimes involving disputed paternity.

Fundamental Genetics

A striking attribute of a living cell is its ability to transmit hereditary properties from one cell generation to the next. This power of self-replication is often attributed as the defining difference between the living and the nonliving. Since the beginning of human history, people have wondered how traits are inherited from one generation to the next. Although children tend to resemble one parent more closely than the other, most offspring tend to be a blend of the characteristics of both parents. The idea of a gene, a unit of hereditary information, arose in the mid-nineteenth century from the famous work of an Augustinian monk named Gregor Mendel. Predominantly working in agricultural science, Mendel found that by beginning with "parents" of known genetic background one had a baseline against which the pattern of inheritance could be measured.

The total genetic information carried by a cell, all the DNA in the nucleus, is referred to as the *genome*. Strictly speaking, this DNA is referred to as *nuclear DNA*. A small amount of the cells' total DNA content exists outside the nucleus, in the

mitochondria. Mitochondrial DNA (mtDNA) is also widely applied in a forensic context.

The genome of higher species is packaged into bundles known as *chromosomes*. Most nucleated human cells are diploid, meaning that the overall content of 46 chromosomes actually comprises one pair of each of the 23 chromosomes (two copies of each chromosome). Exceptions include the sex cells or gametes (spermatozoa or ova), which are haploid (a single copy of each chromosome). The human chromosomes are numbered from 1 to 22 according to their size (chromosome 1 being the largest, 2 the second largest, and so on). These 22 chromosomes are referred to as *autosomes*, as they do not play a role in sex-determination. The 23rd pair is the X and Y chromosomes that play a direct role in sex determination. This chromosomal pair is often referred to as *nonautosomes*.

During conception, parental haploid gametes fuse and form a progenitor diploid cell that is the origin for embryonic development. Owing to this diploidy, individuals who are DNA profiled show either one or two alleles at each DNA site (or locus). If an individual shows one allele, this implies that there are two copies of the same allele present on each of the chromosomes of that particular pair. This event is referred to as *homozygosity*, and we refer to the particular individuals' profile at that DNA site (or locus) as being homozygotic. In such cases, the individual has inherited the same allele from each parent. If an individual shows two alleles at a locus, it implies that there are two different alleles present on each of the chromosomes of that particular pair. This event is referred to as *heterozygosity*, and we refer to the particular individuals' profile at that locus as being heterozygotic.

The DNA molecule encodes for the functional activities of the cells in higher organisms with the packages of genetic information on the DNA referred to as *genes*. The DNA regions containing genes are called *coding regions* (or *exons*). Genes have a dedicated role in protein synthesis, with these products being in turn linked to one or a number of biological or biochemical functions. For the most part, these essential biological functions are the same from individual to individual. As such, exonic regions are highly conserved across individuals of the same species – that is they are almost identical genetically. Another reason for DNA sequence conformity in coding regions, or genes themselves, is that alterations to DNA sequences in these areas usually have some deleterious effect on the physical well being of the individual. The health effects reduce the likelihood of survival, mate selection, and reproduction and therefore are directly linked to the propagation of this individual's particular genotype. In population genetic terms, this link between genotype and ability to survive is referred to as *genetic fitness*. By this mechanism, a genotype that affects the fitness of an individual will become less prevalent, or even extinct, within a population. This is the notion of selection.

The entire DNA molecule is not made up of genes; in fact, only a little over 5% of the genome codes for the production of proteins. The remainder of the DNA is made up of noncoding regions, or introns. Despite their prevalence, the prescribed function of noncoding regions is poorly understood. Noncoding regions were initially presumed to be functionless and as a result were commonly, but inappropriately, referred to as *junk DNA*. Recent evidence proposes some functionality for certain noncoding DNA regions [1–3]. Interestingly, large areas of noncoding DNA, many of which are not implicated in regulation, are strongly conserved between species. This may be strong evidence that they too are functional. Although some ambiguity remains as to their exact role, it is foolhardy to assume that noncoding regions are redundant.

However, as noncoding regions appear to have less responsibility when it comes to the messenger characteristics of the DNA, they have not been exposed to the same evolutionary selection pressures as the coding regions. In essence, mutations can occur in the noncoding regions without affecting the genetic fitness of the individual. Over time, this has led to a high degree of polymorphism in the noncoding regions of the human DNA molecule as mutation has been allowed to continue relatively unchecked. Hypervariable loci, such as those used for forensic identification purposes, are common in the intronic regions.

There are three major varieties of polymorphisms that exist on the genome: minisatellites, microsatellites, and single nucleotide polymorphisms (SNPs). Minisatellites (or variable number of tandem repeats (VNTRs)) are large fragments of DNA which are comprised of sequentially aligned homologous units. The individual units are typically between 20 and 100 base pairs (bps) in length and are repeated consecutively up to 100 times. The overall molecular weight

(MW) of the locus is therefore determined by the number of times that the units are repeated. This is the polymorphic feature of these loci. Minisatellite loci are highly polymorphic and for that reason are powerful identification markers.

Microsatellites (or short tandem repeats: STRs), as the name suggests, are smaller versions of minisatellites. The same structural conformation exists in principle but, in comparison to minisatellites, the size of the individual units (2–8 bp) and the number of times they repeat (2–20) are reduced. Microsatellites were originally named as such as they were thought to solely be repeats of (cytosine-adenine) CA dinucleotide stretches. Microsatellites have been detected in every studied organism occurring at a higher rate than would be predicted purely on the basis of base composition. Microsatellites can be termed *simple* (an uninterrupted array of homologous repeat motifs), *compound* (repeat motif changes – two or more adjacent simple repeats), or *complex* (array is interrupted or contains several repeats of variable unit length). The overall MW of a microsatellite locus is still determined by the number of times that the units are repeated; however, the number of repeats is typically smaller for STR loci. Both VNTR and STR loci are length-based polymorphisms. This means that polymorphisms can be detected by standard electrophoretic techniques.

SNPs are loci where there is a variance in the individual base that exists at a particular position on the genome. SNPs are classified, and distinguished from single base changes, if the frequency of occurrence of the minor (less frequent) allele exceeds 1%. SNPs are the most common form of polymorphism on the genome, occurring approximately every 1000 bp (in unrelated individuals). SNPs can be bi-, tri-, or tetra-alleleic, meaning that the base that exists at a particular SNP position can vary between two, three, or four possible types. In practical terms, however, biallelic SNP loci are the only form of the polymorphism that are routinely detected and analyzed.

Aside from the polymorphic loci themselves, DNA has an additional level of variability that is introduced through processes such as assortment and recombination. These occur as part of the meiotic division that cells undergo during gametogenesis. Both assortment and recombination have the effect of shuffling genetic material and essentially randomizing the distribution of the diploid genotype into the haploid gametes. In assortment, the order in which chromosomal pairs align at the equator of the cell during metaphase is random. This means that the total number of gametic chromosomal combinations that can be formed from n chromosome pairs is 2^n (Figure 3). In humans ($n = 23$), meaning that over eight million combinations are possible among the haploid gametes of any individual.

Recombination, also known as *crossing-over*, involves the physical exchange of genetic material. In recombination, the arms of sister chromatids of a homologous chromosome pair can overlap during prophase I. This contact allows for the physical exchange of chromosomal segments and the genetic material that they carry (Figure 4). Without recombination the arrangement of alleles on a particular chromosome would remain coupled together. Recombination allows new (and possibly advantageous) combinations to be produced and adds another element of variability to the inheritance of DNA.

Aside from the shuffling effect of assortment and recombination, DNA may be subject to further mutational events during meiotic or mitotic replication. At the outset of cell division the DNA must replicate itself faithfully. Any errors during this replication process will introduce a difference between the parent and progeny cells. Such a mutation occurring during meiosis can lead to a Mendellian inconsistency between the biological parent and their offspring, as the parents' gametes have mutated to a haplotype that is inconsistent with the parental genotype. These mutations are more commonly observed on the paternal side, i.e., occurring during spermatogenesis, and are an important consideration in parentage or kinship investigations.

Microsatellite loci have a high mutation rate, in comparison with other polymorphic loci such as SNPs. This trend is observed for both autosomal and nonautosomal loci. In fact, microsatellite loci are thought to be located in mutational "hot spots" [4], that is, regions of the genome that are more susceptible to mutation due to their structure or location. A range of mutational models exist that describe the pattern of mutation of a particular locus. The model favored for microsatellite mutation is the model of slipped strand mispairing (SSM) during DNA replication.

Through the basics genetics, we understand that our genetic composition is comprised of equal proportions of DNA from each of our parents. We also

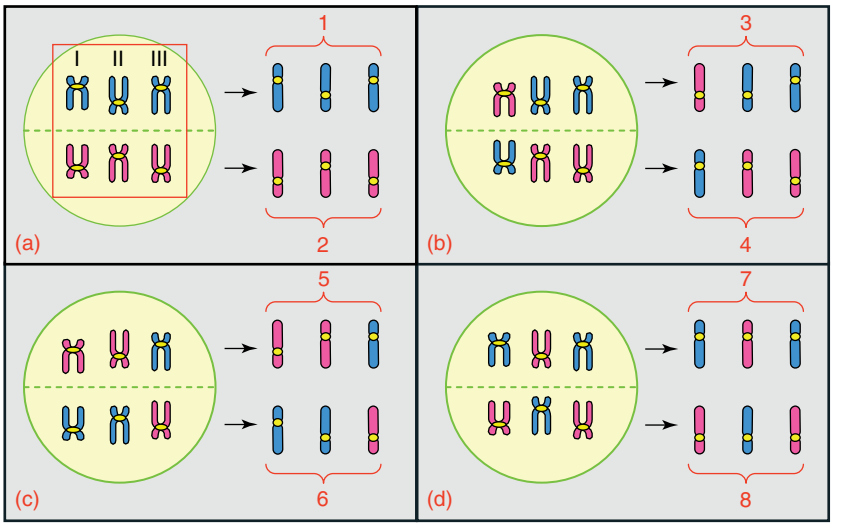

Figure 3 An example of the effect of assortment in generating haploid diversity. If there are three pairs of blue chromosomes (I, II, and III) which are duplicated during prophase to give three pink duplicate chromosome pairs. There are four different ways in which these three pairs of pairs can align at the equator of the cell during metaphase (a–d). After the two rounds of meiotic division this produces eight different possible haploid sets (1–8). The number of theoretical possibilities in a diploid organism is equal to 2^n, where n is the number of chromosomes in the haploid gamete

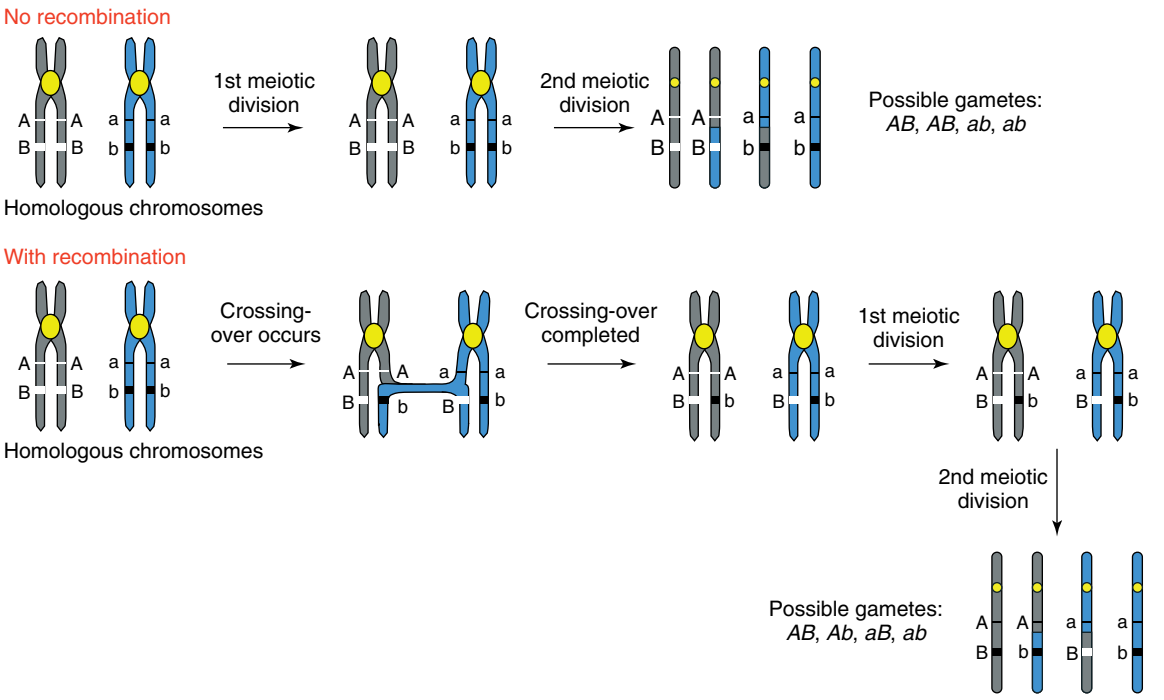

Figure 4 Representation of recombination showing its effect in shuffling the distribution of genetic material in the resultant gametes

understand that there are coding and noncoding segments of the molecule and types of loci that demonstrate considerable variability. We also acknowledge the role that mutation plays in shuffling and altering DNA characteristics, creating additional diversity within populations. The practical suitability of these characteristics is clear; however, it is the physical composition of the DNA molecule itself and its own inherent variation that provides scientists such a suitable template for analysis in a forensic context.

Fundamental Molecular Biology

The realization that DNA is the principle genetic molecule immediately focused attention on its structure. Likewise, the revelation that the structure of DNA was relatively simple [5] helped scientists to understand that genes had relatively similar three-dimensional structure and that differences between two genes resided in the order and number of the structural building blocks along the molecules and not in the molecules overall shape.

Structurally, DNA comprises two complementary chains of nucleotides twisted about each other in the form of a right-handed double helix. A nucleotide unit consists of a five-carbon sugar (2′-deoxyribose), a phosphate residue, and a nitrogenous base (either a purine or pyrimidine; Figure 5). The linking of the nucleotide units is formed via the phosphate residue through a phosphodiester bond between adjacent sugar groups. This series of bonds forms the sugar–phosphate backbone of the DNA strand and allows for the formation of extremely long polynucleotide chains, containing upward of 3 billion nucleotide units.

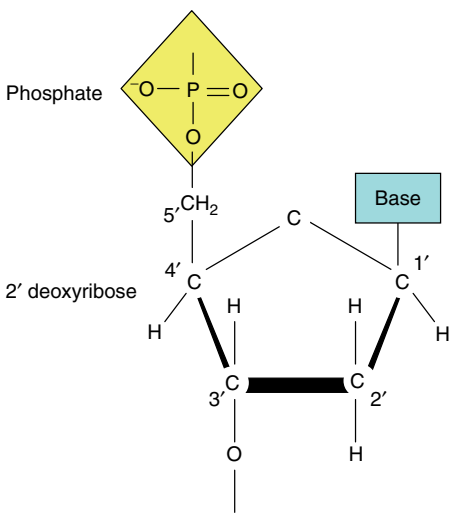

Figure 5 A nucleotide unit (or monomer). The nitrogenous base is either a purine or a pyrmidine. Nucleotide units are linked through a phosphodiester bond via successive phosphate residues and the free oxygen on the 3′ carbon

The backbone of the DNA is therefore a repetitious structure, which, due to its uniformity, is incapable of encoding information. The importance of the DNA structure is derived from the bases that are attached to each of the sugars of the polynucleotide chain. There are two types of bases which attach to the sugar group of the nucleotide, the purines (adenine (A) and guanine (G)) and the pyrimidines (cytosine (C) and thymine (T)). In contrast to the regular structure of the sugar phosphate backbone, the order of the purine and pyrimidine bases along the chain is highly irregular. The order of the bases along the polynucleotide chain is referred to as the *sequence of the DNA molecule* or *DNA sequence*.

Another vital discovery of the Watson and Crick model is that the two chains of the DNA molecule are made up of complementary pairs of bases, linked together by hydrogen bonds. The pairing of the bases follows simple and strict rules. Adenine is always paired with thymine and guanine is always paired with cytosine. No other pairings are possible due to the physical structure of the bases. The strictness of the pairing rules results in a complementary relationship between the DNA sequences on the two intertwined strands of the double helix. For example, a sequence of 5′-AAGCTG-3′ on one chain, the opposite chain must have the sequence 3′-TTCGAC-5′.

The revelation that the twisted strands of the double helix were always complementary meant that if the strands could be separated, and new DNA synthesized along each, the strict base-pairing relationship would see two identical double-stranded DNA molecules produced. In 1985, Saiki *et al.* [6] published an paper in which they described for the first time a method to simulate the DNA replication process in a laboratory environment. The technique was called the *polymerase chain reaction* (PCR). The PCR is essentially a sample preparation step. It allows for the continuous replication of subanalytical quantities of DNA to amplify it to a level such that routine analytical methods can be used for genotyping.

The discovery of the PCR has proven to be the catalyst for the modern biotechnology revolution. By 1988, the PCR had already ranked itself alongside cloning and DNA sequencing as an indispensable tool of molecular biology. The PCR has rapidly advanced the field of molecular biology. If the DNA sequence of a target region is known, the PCR allows for the replication and amplification of that region to the exception of the DNA, which is not required for analysis [7]. The *in vitro* replication of DNA, via the PCR, models the natural process of DNA replication. Each PCR cycle is one cycle of replication that theoretically doubles the amount of template DNA present in the sample. Each PCR cycle consists of three steps that are mediated by the temperature at which the reaction is proceeding and the relevant chemical and biological additives. The PCR is thermally controlled, readily automated, and is complete in 1–3 h.

The sequence of bases on the entire DNA molecule has now been determined [8]. It is accepted that with the exception of identical twins, no two humans contain identical DNA sequences. Therefore, an individual's DNA sequence is unique. Although extremely significant in principle, this fact does not have high practical relevance purposes as scientists are not yet able to designate the complete sequence efficiently and cost effectively. It is of more significance that differences exist on the DNA molecule and that this characteristic is another attribute of DNA that aids in its application in the forensic context.

Summary

In forensic DNA profiling, investigators collect biological evidence from crimes primarily with the purpose of assisting in the identification of the donor. The fundamental objective therefore is to differentiate individuals through analysis at the DNA level. In general, therefore, it is areas of difference on the DNA that are of more importance than those that are highly conserved. Both sequence variation and length variation have been utilized in forensic DNA profiling for many years. More recently, sophisticated techniques examining length variation at microsatellite loci are favored as the routine target of analysis.

To be useful in forensic context, the scientific procedure employed must be robust (able to produce a result from compromised samples), sensitive (able to produce a result from small amounts of original material), highly discriminating (able to provide a result which conveys a satisfactory degree of confidence), and accurate (involve minimal subjectivity or risk of error). The forensic community has many analytical tools already that satisfactorily address these requirements, but despite considerable progress the scientific community is still only beginning to understand the vast amounts of information resident on the DNA molecule and to develop technologies to allow its exploitation. Undoubtedly there is much more development to come, but already the implementation of DNA science into the forensic arena has had a tremendous and positive impact. This is primarily due to the inherent sophistication and informativeness of the DNA molecule itself.

DNA: an Overview

History of DNA Profiling

DNA profiling, as we know it today, developed thanks to two independent breakthroughs in molecular biology that occurred at the same time on different sides of the Atlantic. In the United States, the polymerase chain reaction (PCR) was developed by Kary Mullis of Cetus Corporation [1–3]. Almost simultaneously, the individual-specific banding patterns observed after restriction fragment length polymorphism (RFLP) analysis of repeated DNA sequences were discovered by Professor Sir Alec Jeffreys at the University of Leicester [4–6]. In its earliest incarnation, this technique termed as *DNA fingerprinting* by its creators was performed by restriction of 0.5–10 μg of extracted DNA using the restriction enzyme *Hin*FI, followed by Southern blotting hybridization with probes termed as *33.5, 33.6*, and *33.15*, designed to bind to multiple "minisatellites" present in the restricted DNA [6]. This multilocus probing (MLP) technique would result in the binding of probes to multiple independent DNA fragments at the same time giving rise to the traditional "barcode" pattern, that is, often visualized when one discusses about DNA profiling, even today. Differences in the number of times the probe sequence is repeated in each DNA fragment form the basis of the individual patterns observed on the autoradiogram image.

The Mendelian inheritance of these markers was established by the pedigree analysis of 54 related persons [4], and the individual nature of the banding pattern was further established by the examination of 20 unrelated persons [6]. The probability of two unrelated individuals carrying the same fingerprint was calculated from these data and was estimated as 3×10^{-11} for probe 33.15 alone, provided 15 bands could be resolved in the 4–20 kb size range on the autoradiogram (*see* **Autoradiograph**). The potential application of this technique to maternity/paternity disputes and to forensic investigation was recognized immediately by Jeffery's *et al.*, and was demonstrated by DNA fingerprinting of forensic-type samples, such as bloodstains and semen, in the same year [5]. Difficulties in interpretation of MLP images quickly resulted in single locus probes (SLP) for variable number of tandem repeat (VNTR) loci becoming the markers of choice for DNA profiling (*see* **Variable Number Tandem Repeats**).

The first report concerning the use of DNA profiling in a criminal investigation was published in 1987 [7]. This investigation used two unpublished SLPs to link semen stain samples, collected from two rape and murder cases that had occurred three years apart in 1983 and 1986 in Leicestershire, United Kingdom. The probability of this match occurring by chance was calculated as 5.8×10^{-8}. This result not only linked the two crimes but also exonerated an innocent man implicated in the murders and led to the first mass screening project undertaken for DNA profiling in the world [8].

The potential of DNA analysis for forensic science had now been demonstrated; the technology now required statistical validation by analysis of population frequencies and application to casework samples before it could progress. Early evaluation studies on MLP 33.15 provided optimistic support for the use of DNA for the personal identification and the identification of male rapists from a mixed male/female sample [9]. It does, however, also begin to uncover the limitations of this method. A mean success rate of only 62% for the DNA fingerprinting of donated vaginal swabs was observed and no typing was possible for blood or semen stains that had been stored for 4 years at room temperature, and difficulty in directly comparing related samples run on different gels was also cited as a potential problem [9]. Similar studies and European collaborations were undertaken on SLPs such as YNH24 and MS43a [10, 11]. Difficulties were again observed when interpreting gel images, with only 77.9% of 70 samples distributed between nine laboratories producing matching results when a 2.8% "window" for size differences between gel runs and laboratories was used [10]. It was recognized that subtle differences between laboratory protocols were responsible for some of the observed discrepancies, leading to a requirement for the standardization of laboratory methodology [10] and DNA profile interpretation [12, 13].

Such standardizations could improve the reproducibility of DNA typing results for MLP and SLP

marker systems, but in order to be applicable to forensic investigation, DNA systems must be robust and must be applicable to samples of a less than pristine nature or that consists of only a few cells. PCR was first applied to forensic DNA profiling for the investigation of the HLA-DQ-α1 gene (*see* **DQα**), a polymorphic gene that encodes a human leukocyte antigen cell surface protein, located in the major histocompatibility complex (MHC) class II region on chromosome 6 [14].

Two big breakthroughs occurred between the late 1980s and early 1990s that would form the basis of DNA profiling techniques that are recognized today. An alternative class of DNA marker, the microsatellite or short tandem repeat (STR) marker (*see* **Short Tandem Repeats**), was described by Weber *et al.* [15] and an alternative method for DNA visualization, PCR amplification, and fluorescent labeling of VNTR markers was also introduced [16, 17].

STR Analysis

STR markers are similar to the VNTR markers that were originally identified and utilized in DNA fingerprinting and SLP profiling. The difference between the classes of DNA marker lies in the length of the tandemly repeated DNA sequence. VNTRs contain 10–33 bp hypervariable repeat motifs [4] that must be observed over a size range of 4–20 kb [9] and SLP markers that are observed over a size range of 1–14 kb [10]. An STR marker repeat is composed of 1–6 bp repeat motifs [18], making the region of DNA that must be scrutinized very short (<1 kb). This length reduction is immediately beneficial to one of the problems encountered in SLP profiling; difficulty in analyzing degraded DNA [5]. The use of the multiplex PCR to amplify target sequences before visualization significantly reduces the amount of DNA required for analysis from microgram to nanogram amounts [18, 19]. The detection and visualization method of polyacrylamide gel electrophoresis and fluorescent detection using an automated DNA sequencer (model 370, Applied Biosystems, Foster City, CA, USA), in combination with an internal size standard (GS2500, Applied Biosystems) and GENESCAN 672 software (Applied Biosystems), also allowed for precise band sizing, answering problems of intra- and interlaboratory allele designation discrepancies that had been observed in SLP analysis [12, 20, 21].

One of the earliest multiplexed STR systems developed for forensic DNA analysis was a quadruplex reaction that amplified the STR markers HUMVWA31/A, HUMTHO1, HUMF131A1, and HUMFES/FPS [22]. These particular STR markers were selected from the hundreds of STRs identified throughout the human genome [23] based on a number of important parameters. Each STR must have a high level of allelic variability to maximize the discriminating power of each marker. Markers should have short PCR product length (<500 bp) to aid the analysis of degraded DNA. The chromosomal location of any potential marker should be checked to avoid closely linked loci, and tetranucleotide repeat motifs are preferred due to low artifact production during PCR amplification [24]. The overall match probability using this system was calculated as 1.3×10^{-4} for white Caucasian populations [18]. Validation studies carried out on this quadruplex system determined that 1 ng template DNA was optimal for amplification and analysis, that stutter bands up to 11% were observed at some loci, especially HUMVWA21/A, and that DNA mixtures in a ratio of 1 : 2 or 2 : 1 could be distinguished using this system [22]. Further validation studies were carried out on extremely compromised casework samples, collected from the victims of the Waco siege, which resulted in the identification of several individuals that was not possible by any other means [25, 26].

The quadruplex system described above was next developed into an octoplex as the application of DNA profiling to forensic casework increased. The new octoplex system coamplified the tetranucleotide STR loci HUMVWFA31/A (vWA), HUMTHO1 (THO1), D8S1179, HUMFIBRA (FGA), D21S11, and D18S51 [27]. The nomenclature used for naming these STR markers had been standardized now, to allow for easy comparison between different working groups [28]. This system also included primers for the amplification of a region of the amelogenin gene, which could be used to deduce the sex of the DNA sample being analyzed [29]. Optimization and validation studies on this octoplex system reduced the amount of template required for the generation of full DNA profile to just 500 pg, with partial profiles being generated from as little as 50 pg, the equivalent of just 10 diploid cells [27]. This octoplex became known as the *second-generation multiplex* (*SGM*) system, [30] and was used to populate the first national criminal intelligence DNA database,

which became operational in the United Kingdom in April 1995 [27]. The SGM system was human-specific, highly discriminating, with a probability of chance association calculated as 1×10^{-8} [31]. It could also be applied to degraded DNA samples and was capable of detecting and resolving mixed DNA profiles at ratios between 1 : 10 and 10 : 1 [30]. One final evolution would take place, the inclusion of a further four STR markers (D3S1358, D19S433, D16S539, and D2S1338), to produce the STR profiling kit, that is, currently used in the United Kingdom for forensic DNA profiling, population of the national DNA database (NDNAD) and for paternity testing.

The AmpFlSTR® SGM Plus™ System

The AmpF*l*STR® SGM Plus™ system, commercially produced by Applied Biosystems (ABI), a division of Perkin Elmer, Foster City, California, USA, was introduced in June 1999, and was validated for use in forensic casework in 2000 [32]. It was designed to replace the SGM system for forensic casework in the United Kingdom, to decrease the probability of a chance match occurring from 1×10^{-8} to 1 in trillions for unrelated individuals [32]. This greatly increased the statistical power of DNA evidence to be taken for scrutiny in the courtroom, while being back-compatible with DNA profiles already stored in the NDNAD. The statistical power of this new system was deemed so great that instead of calculating the exact match probability for a full DNA profile, it was recommended that an arbitrary conservative estimate of 1 in a billion be reported for the match probability between unrelated individuals, 1 in 1 million for parent/child relations, and 1 in 10 000 for siblings [33]. The characteristics of each STR marker are detailed in Table 1.

The AmpF*l*STR® SGM Plus™ PCR amplification kit can be analyzed by two DNA separation methods, capillary electrophoresis, or polyacrylamide gel electrophoresis. In this article, the analysis was performed by polyacrylamide gel electrophoresis using an ABI Prism™ 377XL DNA Sequencer (ABI). The ABI Prism™ 377XL DNA Sequencer was introduced by Applied Biosystems in 1995 and stopped its use in 2001 [44]. Automated fragment sizing of fluorescently labeled DNA fragments was achieved by the use of a scanning argon ion laser, which tracks back and forth across a "read-region" at the lower end of a vertical polyacrylamide gel. As each labeled DNA fragment passes the laser, the fluorescent dye is excited, resulting in emission of light. This light is then collected and separated by wavelength onto a charged coupled device (CCD) camera. The camera used on the 377 model is capable of detecting four different wavelengths simultaneously, allowing for the detection of three similarly sized PCR products in a single gel run, with inclusion of a separately colored size standard in each lane. The 377XL model was validated for forensic STR analysis in 1996, using the original SGM octoplex system [45]. The set of validation experiments carried out determined that complete resolution of 1 bp differences between fragments could be achieved up to 350 bp, sizing precision was increased twofold and sensitivity was increased by one-third, compared to the predeceasing 373A DNA sequencer [45].

Alternative DNA Markers

Autosomal STR markers have become the most utilized ones in both forensic and paternity DNA profiling. However, there are numerous alternative markers that can be interrogated when required. Another class of autosomal marker, the single nucleotide polymorphism (SNP), has been investigated for application to forensic casework and identification projects. SNPs, as the name suggests, are alterations of a single base pair and occur on average every few hundred base pairs throughout the human genome [46, 47]. The major advantage of SNP markers over STRs is the small size of the DNA target, making them very useful for degraded DNA analysis and disaster victim identification projects [48]. Reduced size STR amplicons have, however, been developed to analyze degraded DNA whilst remaining compatible with current DNA databases to allow easy searching in identification projects [49].

There are a number of disadvantages associated with the use of SNP markers instead of STRs. The comparatively low discrimination power of each locus requires that approximately 50 SNPs must be investigated to give match probabilities equal to 10 STR loci [50]. Mixture analysis is also complicated for SNP analysis are usually bi-allelic, but have also been observed to be tri- and even tetra-allelic. The use of a predominantly biallelic marker makes the distinction between mixtures and homozygotes difficult, especially for minor contributors, which may

Table 1 Characteristics of SGM Plus STR loci[a]

also display allelic dropout [50]. Owing to these problems and the financial implications of repopulating national DNA databases with SNP profiles, it is unlikely that SNP markers play a major role at the forefront of forensic DNA analysis in the foreseeable future. There are still some applications in related fields in which SNP markers are proven to be useful: determination of phenotypic characteristics, such as eye color [51, 52] and hair color, by variation in the melanocortin 1 receptor (*MC1R*) gene [53–55]. SNP markers can also be used to analyze the uniparentally inherited mitochondrial DNA (mtDNA) (*see* **Mitochondrial DNA: Profiling**) and Y chromosomes (**Y-Chromosome Short Tandem Repeats**), which are discussed in [56, 57].

DNA Extraction

In order for DNA from any given biological sample to be analyzed by a PCR-based method, it must first be purified from all organic and inorganic substances with which it is associated (*see also* **Extraction**). This process can become complicated during forensic investigation as DNA is often present on or in materials that are not usually encountered in the molecular biology laboratory. The extraction stage of DNA analysis is also the most susceptible stage to the occurrence of laboratory-induced contamination of sample material. For this reason, DNA extraction protocols, no matter which one is employed, must always be carried out in a dedicated laboratory, physically separated from downstream processes, especially PCR. Literature searching for DNA extraction of forensically interesting materials reveals tens, of various techniques, and variations on each of these. A brief listing of DNA extraction methods for commonly encountered forensic evidentiary samples is given in Table 2. Of the many techniques that have been proposed, the most commonly utilized ones are based on three techniques: organic cell lysis with phenol–chloroform purification, Chelex®100, and silica-based extractions.

The organic, phenol–chloroform method is the original DNA extraction technique to be applied to forensic (and archaeological) specimens [5, 58–60].

Table 2 List of materials commonly collected for DNA analysis during forensic investigations with reference to extraction methods

Substrate	Type of extraction	References
Blood	Silica	[63, 64]
	Chelex®	[62]
Bone	Silica	[65–70]
	Lysis/precipitation	[71]
	Phenol/chloroform	[66, 67, 72, 73]
Teeth	Chelex®	[74, 75]
	Phenol/chloroform	[76–79]
Hair	Phenol/chloroform	[58, 59]
	Chelex®	[62, 80]
	Alkaline digestion	[81]
	Silica	[80, 82]
Saliva	Chelex®	[62, 83–85]
Buccal cells	Phenol/chloroform	[86, 87]
	Silica	[88]
Maggots	Phenol/chloroform	[89–91]
Feces	Silica	[92–95]
	Phenol/chloroform	[94, 95]
Urine	Silica	[69, 96, 97]
Semen	Chelex®	[98]
Trace/cells	Silica	[99, 100]
	Organic	[99, 101–103]
	Chelex®	[104]

Although many subtle variations in buffer pH, chemical concentration, incubation time, and temperature have been introduced over the years, the basis of the technique remains the same. The detergent sodium dodecyl sulfate (SDS) is used to break down cell walls and lipids present in the sample, and proteinase K, a strong protease enzyme, is used to digest the proteins that protect the DNA molecule in its natural state. An additional component, dithiothreitol (DTT), can also be used to digest more robust materials such as keratinized hair and sperm cells and forms the basis of the differential extraction technique used for vaginal swabs with semen present. The differential extraction of the two cell types is possible as the sperm nuclei are impervious to SDS/proteinase K digestion because the nuclear membrane is reinforced with cross-linked thiol-rich proteins. This allows for digestion and removal of the female component from the mixture leaving intact sperm nuclei to be digested by the addition of a SDS/proteinase K/DTT mixture [5]. Once digested, phenol–chloroform is used to separate proteins into organic phenol layer from the nucleic acids in the aqueous chloroform layer. The nucleic acids must then be concentrated and purified from the hazardous chloroform solvent before further analysis. This is classically achieved by ethanol precipitation but can also be carried out using a commercially available centrifugal filter device, such as the Centricon®100 system [61].

Chelex®®100 was introduced as a medium for the simple extraction of DNA from forensic materials in 1991 [62]. This technique was designed specifically for use with forensic specimens and was intended to replace the organic, phenol–chloroform technique. The Chelex® method has three major advantages over the organic, phenol–chloroform methods: it is much faster, taking only 1 h compared to up to 24 h for the organic, it does not require multiple tube transfers, reducing the risk of laboratory-induced contamination, and it does not require the use of hazardous chemicals. Chelex® resin is composed of styrene divinylbenzene copolymers containing paired iminodiacetate ions, which act as chelating groups, binding polyvalent ions such as Mg^{2+} [62]. In this method, Chelex® resin is added directly to the sample from which DNA is to be extracted. Cell lysis and DNA liberation is achieved by a combination of alkalinity (pH 10–11) and heating at 100 °C. Initial testing performed on forensic-type samples such as blood, blood stains, semen stains, and hair demonstrated that the performance of Chelex® extraction was equal to that of phenol-chloroform methods and, in the case of blood, was less likely to allow the carryover of PCR inhibitors such as heme. Similar to organic methods, an additional DTT digestion step is required for DNA extraction from sperm [62].

Silica particles were first used for DNA extraction from human serum and urine samples. This method, similar to Chelex®, was designed to be more rapid and involve fewer tube transfer stages, to reduce the risk of sample contamination or DNA loss, than organic methods. The method uses a chaotropic agent, guanidinium thiocyanate (GuSCN) to lyse cells and inactivate nucleases, while simultaneously facilitating the binding of the freed nucleic acids to silica particles [69]. Once bound, the silica–DNA complex can be pelleted, allowing cellular debris and other non-DNA components to be removed and discarded. After washing, the purified DNA can then be eluted from the silica in sterile water or TE buffer. This method is extremely sensitive due to the strong binding affinity of silica particles for nucleic acids in

the presence of chaotropic agents and is subsequently adapted for use with ancient bone samples [70, 105]. The method does require some caution as GuSCN produces HCN gas on contact with acids and should therefore be kept in an alkaline solution at all times, and disposed of in 10 M NaOH.

The silica–DNA binding affinity has been utilized in the development of commercial kits such as the QIAamp® DNA kits produced by QIAGEN (Qiagen, West Sussex, United Kingdom) (described in **QiaAmp**) and the DNAIQ™ system produced by the Promega Corporation. Both systems have been tested and validated for use with forensic casework samples [63, 64] and both systems are compatible with automated robotic workstations [106–108]. The versatility and reproducibility of such commercial DNA extraction kits, especially QIAamp® products, has made them the choice of the forensic research community over recent years, as illustrated by their usage in the majority of research articles published over recent years.

DNA Quantification

Commercially produced DNA profiling kits, such as the AmpF*l*STR® SGM Plus™ PCR amplification kit described above, are optimized to produce DNA profiles from a narrow range of template DNA concentration. AmpF*l*STR® kits produced by Applied Biosystems are optimized to amplify 1–2.5 ng template DNA. The addition of insufficient template DNA can result in stochastic amplification. Stochastic amplification manifests as unbalanced amplification of heterozygote loci and can, if severe, result in allelic dropout, making heterozygotes to appear as homozygotes at the affected loci [109]. The addition of template DNA in excess can lead to the production of large stutter peaks that complicate the interpretation of DNA profile. The term *stutter* refers to the production of natural biological artifacts during the PCR. The currently accepted model for stutter generation is by a "polymerase slippage" model that results in the addition or, more often, deletion of a single repeat unit from the actual template size. The detection and classification of stutter play an important role in profile interpretation, especially if a mixture is anticipated or observed. If the stutter characteristics are unknown for a DNA profiling system, it is possible that such artifacts may falsely be reported as "actual alleles". It has been observed that stutter does not usually exceed 10% of the associated allele peak height, but with variation between both STR loci and alleles in the locus, stutter has been observed to approach 15% [110] in some cases. Percentage stutter is calculated using the peak height in relative fluorescent units (RFU) of the observed peaks. Figure 1 shows a typical stutter pattern at the STR locus FGA.

The most commonly observed nonbiological artifacts caused by the addition of template DNA in excess are termed as *pull-up* or 'bleed through' peaks. Pull-up peaks are produced when the GeneScan software program is unable to distinguish between the emission spectra of the fluorescent colors in the STR system. This phenomenon is visualized by the appearance of false bands in the overamplified fragment's size range in differently colored markers.

By quantifying all DNA samples before performing DNA profiling PCR, the production of such artifacts can be reduced or completely avoided. As with DNA extraction, there are numerous methods available to perform this function. The traditional method of DNA quantitation involves measuring the absorbance of the sample at 260 nm on a spectrophotometer. This method is simple to perform

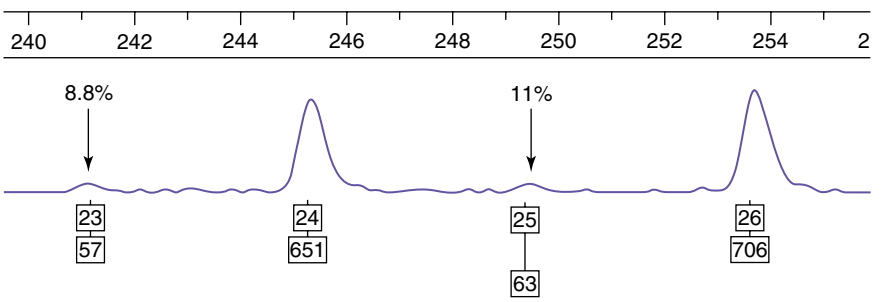

Figure 1 Example of typical stutter pattern of alleles 24 and 26 at STR locus FGA

and shows little sample-to-sample variation [111], making it a desirable technique. This technique does, however, suffers because of its simplicity. The technique is not species-specific, indicating that any bacterial or fungal DNA that has copurified with the DNA of interest cannot be distinguished from the human target DNA. Additionally, single-stranded DNA and nucleotides cannot be distinguished from double-stranded DNA by this method, which can also lead to falsely high quantitation readings [112]. A different approach to DNA quantitation is taken by the slot blot technique. This method is based on the specific hybridization of a 40-bp probe that binds to the human alpha satellite locus, D17Z1 [113]. Using this technique, DNA is quantified by visual comparison of sample band intensities with the band intensities of standards, produced from known amounts of DNA. This comparison can be performed either manually – but this allows for the subjectivity of individual interpretation, which can lead to differences between operators in quantitation – or electronically by computationally converting the band intensities into numerical values [114]. This technique shows a high degree of species specificity (human and primate) and can detect as little as 150 pg DNA in a standard assay [113]. Similar to the development of commercial DNA profiling kits, the development of commercial DNA quantitation kits has also progressed. Applied Biosystems produced the Quantiblot® human DNA quantification kit, similarly to the original technique of Walsh. Walsh *et al.* uses a probe that binds to the D17Z1 locus and has a lower detection limit of 150 pg [113, 115, 116].

An alternative method of DNA quantitation involves the use of a fluorescent dye, PicoGreen dsDNA quantitation reagent. This method was developed to allow high-throughput quantitation of multiple samples concurrently while increasing the sensitivity DNA quantitation methods. Picogreen is a Hoechst dye that can pass through the lipid membrane of live or fixed cells to form noncovalent bonds with AT-rich areas in the minor groove of double-stranded DNA [117]. The method utilizes the increased fluorescent intensity that is observed when PicoGreen binds to dsDNA. The fluorescent intensity of the PicoGreen dye is measured with a spectrofluorometer capable of producing the excitation wavelength of ~480 nm and recording at the emission wavelength of ~520 nm. The DNA is then quantified by comparison of the sample fluorescence with the fluorescence of a set of standards that are included in every sample run [118]. The biggest disadvantage to this method over the hybridization methods discussed previously is that this method is not specific for human DNA. Any animal, bacterial, or fungal DNA copurified with the human DNA of interest will contribute to the final reading and could give a falsely high DNA quantification. This method is, however, much more sensitive than the previously described methods, with a reported lower detection limit of 25 pg ml^{-1} [112].

The latest development in DNA quantitation is based on the technique of real-time PCR. The methodology was first proposed 15 years ago by Higuchi and coworkers [119] who, by including ethidium bromide in the PCR reaction, were able to continuously monitor the production of double-stranded DNA in "real time". By capturing the change in fluorescent intensity on video camera, the potential of this new development for specific DNA quantitation was realized [120]. There are several different approaches to real-time quantitation of DNA; they are all, however, based on the principle of fluorescent dye binding double-stranded DNA as it accumulates during the PCR process. As the technique is based on the PCR, DNA quantitation can be undertaken by targeting any specific region of template DNA, with many systems targeting the multicopy *Alu* sequence, which appears 500 000–1 000 000 times throughout the human genome [121–123]. This not only ensures that the technique is species-specific but also has allowed numerous variations, many designed to perform additional functions, such as independent quantitation of nuclear and mtDNA in a single reaction [124–127] and assessment of DNA quality [128, 129].

DNA Profile Interpretation

The methodologies, hardware, and software necessary for the generation of STR profiles are well established but constantly evolving. Regardless of the exact means of production, the interpretation of DNA profiles must remain constant. Using the earliest DNA profiling systems, based on RFLP analysis and Southern blot hybridization, it was proved to be difficult to standardize interpretations between different individuals and different laboratories. Significant differences in band sizing were regularly observed during collaborative exercises carried out by DNA testing

laboratories throughout Europe [10, 11]. Although measures were taken to standardize as many variables as possible including buffer system, gel running time and temperature, and DNA visualization method, there was still an uncertainty in interpretation uniformity between laboratories [10]. The breakthrough required for standardization of DNA profile interpretation of DNA profiles came with the switch to PCR amplification [1, 2] and the introduction of fluorescent labeling allowing digitization of DNA profiling results [16, 17]. These advancements paved the way for the development of universal guidelines and validation of commercially produced kits and instruments to allow for the accurate and reliable reproducibility of DNA profiling interpretation across independent laboratories worldwide. Validation experiments, designed to demonstrate the robustness of the system, must be carried out for all commercially produced forensic DNA profiling kits before they can be used for casework. Validation data for the AmpF*l*STR® SGM Plus™ Amplification kit, used throughout this article, were published in 2000 [32].

The first step toward standardization was the adoption of a common nomenclature for STR loci, including both the name of the marker and the numerical designation of each allele observed in the human populations tested. The basis for the currently used naming systems was brought about by the European DNA Profiling Group (EDNAP), which was formed in 1989 by members of the leading police organizations and universities involved in forensic stain analysis and paternity investigation at that time [130]. The next step in achieving complete interlaboratory concordance was the addition of the allelic ladder [131]. Allelic ladders are produced by creating a mixture of DNA samples containing all observed allelic variations in the human population and then amplifying this mixture with the primers used for each locus in a given STR kit. Once created, the allelic ladder is visualized in parallel with every set of samples so that a direct comparison can be made between the amplified fragment size and the fragment size of previously observed alleles for each allele at each marker. This ensures that slight variations in running conditions, such as those observed with Southern hybridization techniques, are not misclassified based on interrun fragment sizing differences [132]. The inclusion of allelic ladders also allows for the recognition of rare and novel, full and microvariant alleles that are not present in the allelic ladders for each STR kit [133]. The final leap toward accurate DNA profile interpretation was made with the switch from "home-brews" to commercially produced STR amplification kits and the use of identical or equivalent instruments in each laboratory throughout the forensic DNA typing community.

As a result of the standardization measures described above, the interpretation of single-contributor DNA profiles when sufficient template is entered into the reaction is a straightforward process. In the forensic setting, a large percentage of samples submitted for DNA analysis contain biological material from more than one source and result in mixed STR profiles. In order to produce a robust set of interpretation guidelines for mixed profiles, it is vitally important to have a thorough understanding of the amplification characteristics of biological and stochastic phenomenon in the electropherogram, from which the interpretation is made. The most commonly observed artifacts in a DNA profile are termed as *stutter bands*. They are generated during the PCR by slippage of Taq polymerase, resulting in the generation of a fragment one repeat unit shorter, or more infrequently longer, than the true allele. When the peak height of the amplified true allele is >4000 RFU in the electropherogram, stuttering is unavoidable when amplifying STR loci using Taq polymerase [134]. Each STR locus and even each allele in a STR locus has different stuttering characteristics, but stutter products are rarely observed to exceed a peak height in excess of 15% of the height of the associated allele. Any peak found in a stutter position with a height $>15\%$ of the related allele should therefore be considered as a potential true allele in a mixed DNA profile [134].

Another characteristic of the electropherogram that can mystify DNA profile interpretation is the balance of allelic amplification at heterozygotic markers. In a perfectly amplified DNA profile, the peak areas of each heterozygote allele should be equal. Differences in the amplification efficiency of each allele can, however, result in alleles being unequally amplified [134]. For a single source DNA profile produced from sufficient template (>1 ng), each shorter allele at a heterozygous locus will usually have a peak area greater than 60% of the associated larger allele [134]. Heterozygosity balance (Hb) is calculated as relative peak area differences of heterozygote alleles (Φ) for each locus. There are two similar methods used to

determine Hb for forensic DNA profile interpretation, both of which use the peak area in RFU. The first is calculated as Φ = smallest peak area/largest peak area, where a result of $0.67 > \Phi \leq 1$ indicates that the Hb is in the observed limits [134]. This calculation does not, however, provide any information as to which of the heterozygous alleles has been preferentially amplified during the PCR. This information is provided when Hb is assessed by the calculation, Φ = peak area shortest allele/peak area longest allele. In this case, a result of $0.67 > \Phi < 1.67$ indicates a balanced amplification, with Φ values < 1 indicating that the shortest allele of the pair has been preferentially amplified and Φ values > 1 indicating the opposite [135] (*see also* **Peak Height: DNA**).

The presence of additional bands in the electropherogram can also result from overamplification of template DNA causing saturation in fluorescent signal that cannot be resolved by the matrix files of the visualization software. These bands are termed as *pull-up* peaks due to their appearance in the raw data files, whereby a smaller peak is observed directly under the overamplified peak. When the dyes are separated to produce the electropherogram image, the smaller pull-up peak appears as an extra band, with excess blue signal producing green pull-ups and excess green signal producing yellow pull-ups. Pull-up peaks are easily recognized by the experienced DNA analyst due to their atypical morphology compared to true allele peaks and should not interfere with DNA profile interpretation [134]. If a pull-up peak is superimposed over a suspected true fragment, the sample can be diluted and reanalyzed to avoid fluorescent signal saturation.

Low Template DNA Profiling

The two biggest drives for developments in forensic DNA profiling are to improve sample throughput and technique sensitivity. Increases in sample throughput are achieved by automation of routine processes such as DNA extraction, sample loading, and DNA profiling interpretation coupled with effective laboratory management and sample tracking. While the sensitivity of DNA profiling reactions can also benefit from technological advances, the major advancements are achieved by optimization of reaction chemistries, investigation of alternate DNA markers, and use of additional stage processes.

One area of DNA profiling analysis that has received attention is the inclusion of a pre-PCR stage, designed to increase the total amount of template DNA available for STR analysis. A number of techniques, similar in their objective but differing in their means, can be described under the umbrella term of whole genome amplification (WGA) (*see* **Whole Genome Amplification**). As the term indicates, these techniques are designed to replicate all DNA present in a given reaction, with the intention of generating an unlimited source of template material for multiple downstream analyses. Techniques of this kind were first described in 1989, with the publication of a universal DNA amplification method, which used restriction enzyme digestion and ligation into plasmids to achieve its goal [136]. The next generation of WGA techniques appeared in the literature during the 1990s and like many other areas of molecular biology, it moved away from the cloning techniques to PCR amplification. The first PCR–WGA technique was termed as *primer extension preamplification polymerase chain reaction* (*PEP-PCR*) [137]. This technique utilizes fully degenerate 15-mer oligonucleotide primers and a range of annealing temperatures in a PCR to produce multiple copies of any template DNA present in the reaction. In his introductory article, Zhang *et al.* reported a minimum amplification of 30 copies for 78% of the human genome at a 95% confidence level from a single spermatozoon [137]. The limitations of PEP–PCR were also explored, with heterozygosity imbalance and locus dropout cited as the main concerns when the technique is applied to single-cell analysis. These observations were confirmed in the articles reporting the application of PEP–PCR to preimplantation diagnosis of single cells, whereby effects of stochastic sampling and amplification were observed for single-cell analysis [138–140]. Locus and allele dropout was also observed when PEP-PCR was applied to formalin-fixed tissues followed by microsatellite analysis [140].

Another method designed to perform the function of WGA has been termed as *multiple displacement amplification* (*MDA*). This method was first introduced in 2001 and differs from the previously described techniques by the use of an alternative enzyme, Φ29 DNA polymerase [141]. The method of replication is based on a rolling strand-displacement model that proceeds by constantly displacing the newly generated strand of DNA to form

a hyper-branched DNA replication structure, limited only by the reagents available [142]. The promise shown by this method has led to the development of several commercial WGA kits, for example, GenomiPhi WGA Amplification kit (GE Healthcare) and various publications advocating its use for human genome analysis [143–147]. All of these studies, however, have entered more than 10 ng DNA into the MDA reaction. Studies conducted using less than 10 ng template DNA have observed unequal amplification of genomic DNA when assessed by the use of forensic DNA profiling kits, similar or identical to those used in [148–150]. Of the numerous WGA method variations that have been published to date, none have yet demonstrated the unbiased amplification of microsatellite markers when very low template material is available for entry into the WGA reaction [151–153].

An alternate approach is the use of a nested PCR strategy, which involves the use of two primer sets, one designed to prime from positions within the original amplicons. Using this approach, the initial PCR performs the function of enriching the template DNA specifically in the regions of ultimate interest. The second, internal, amplification reaction can then be initiated from a greatly increased initial template amount. This approach was successfully applied to the forensic DNA analysis of charred human remains [154]. This approach, however, presents a heightened risk of laboratory-introduced sample contamination by requiring the manipulation of amplified human DNA, breaking a fundamental anticontamination principle of single direction work flow during forensic DNA analysis. A far simpler approach to increasing PCR sensitivity has, however, proven to be extremely successful and become fully integrated into forensic DNA profiling laboratories worldwide.

The term *low copy number* (*LCN*) DNA profiling was coined in a publication by Peter Gill of the Forensic Science Service (FSS) in 2000 and describes the analysis of less than 100 pg template DNA [110] (*see also* **Low Copy Number DNA**). LCN has come to be associated with the use of increased PCR cycles, but there are other techniques that claim to amplify small amounts of DNA. These can be collectively termed as *low template DNA* (*LTDNA*) analysis. Commercially available STR amplification kits, such as the AmpF*l*STR® SGM Plus™ kit, are optimized to produce complete and accurate DNA profiles when 1–2.5 μl template DNA is amplified for 28 cycles. Following this standard protocol, amplification of 100 pg DNA will typically result in severe allelic and locus dropout, or even complete failure. The sensitivity of this technique can be radically improved by simply increasing the number of PCR cycles, in the case of the AmpF*l*STR® SGM Plus™ kit, to 34 cycles [110]. The increase in sensitivity opens up the potential of forensic DNA profiling to analysis of many more sample types than had ever previously been imagined, most notably from fingerprints [155, 156], cigarette butts [101], and from the skin surface of manual strangulation victims [157–159] (*see also* **DNA: Sources of** for a further description of sources of DNA eveidence).

The improved sensitivity gained by the use of an extra six PCR cycles does, however, lead to additional issues in DNA profile interpretation. When undertaking any forensic DNA analysis procedure, the importance of anticontamination protocols cannot be underestimated. This is especially true when attempting to produce LTDNA profiles, for which the template DNA may also be of a degraded nature (*see* **DNA: Degraded Samples**). The sensitivity of the AmpF*l*STR® SGM Plus™ PCR amplification kit when employing 34 cycles is such that laboratory-derived contamination cannot actually be completely avoided [110]. The potential to acquire DNA profile information from minute template amounts can also lead to the production of partial DNA profiles, where both allele and locus dropout are observed. To combat these problems, along with an increased size of stutter bands and unbalanced amplification of heterozygous alleles, an entirely new set of DNA profile interpretation rules is required for LTDNA analysis.

The majority of the complications observed for LTDNA profiles are due to stochastic variation. For example, a stutter band generated in an early PCR cycle, unassociated contaminating alleles, or one of two heterozygous alleles can be preferentially amplified and therefore over-represented in the final DNA profile [160]. The random nature of stochastic variation means that the same stutter products or contaminating alleles will not be amplified identically in replicate analyses [110, 161] leading to the first rule of LTDNA analysis; an allele can only be reported if it is present in at least two repeated analyses [160]. Once this rule has been applied, all remaining bands in the DNA profile can now be scrutinized. For standard 28 cycle DNA profiling reactions, stutter peaks

are not observed to exceed 15% of the associated allele peak height; in LCN analysis, stutter products are much larger in the range of 20% when associated with peaks >10 000 RFU in area and 40% for associated peaks <10 000 RFU [162]. As this cannot be avoided, it must always be considered that the stutter peak could be masking an allele of a minor contributor in a mixed profile, and as such cannot be discarded simply as a stochastic artifact. Similarly for heterozygosity balance, where Hb Φ values are observed to be >0.67 (when using Φ = smallest peak area/largest peak area), under standard conditions, the minimum values observed during LCN analyses for most loci in the AmpF*l*STR® SGM Plus™ PCR kit were observed at a Hb Φ value of 0.2 [162]. It was also observed that, after repeated analysis, allelic dropout at known heterozygote loci occurred at a rate of approximately 10% per locus, but was not observed when the peak area of alleles was >10 000 RFU [162].

By the varying nature of LTDNA work, the majority of samples analyzed comprise DNA mixtures of dual or multiple contributors. Mixture analysis of standard or LTDNA profiles can be an extremely complex undertaking especially when more than two or three individuals have contributed unequally to a collected sample. In a working forensic casework environment, to avoid bias, mixture analysis is carried out without any knowledge of reference DNA profiles of potential contributors. As the work carried out for inclusion in this thesis was purely research-based, the interpretation permutations and mathematical rules required for unsighted mixture analysis are not further discussed in this introduction, especially as the interpretation of complex mixtures is today more likely to be performed by computational expert systems [163] to increase the speed at which the analysis can be completed and remove any subjectivity that may be introduced by individual DNA analysts.

The advantages of using a LTDNA protocol for DNA profile generation are clear when the analysis of minute trace evidence is required. These advantages do not, however, extend to the analysis of minor contributors to mixed DNA profiles. It has been noted that the use of LTDNA profiling does not convey any advantage over standard analysis when the minor: major DNA contributor ratio is below 1 : 10 [135]. This knowledge, combined with the additional complications of sporadic contamination, increased stutter, and heterozygote imbalance, ensure that LTDNA analysis is undertaken only when absolutely necessary.

DNA: Degraded Samples

Introduction

DNA is a relatively stable macromolecule and under certain circumstances has been known to persist for tens of thousands of years (*see* **Archaeology**; **DNA**) [1–3]. Samples of human DNA that are decades [4–6] and even centuries [2] old have been amenable to genotyping for forensic purposes as well. However, the environmental conditions to which most evidentiary samples are exposed are usually much less conducive to the preservation of the information content of the DNA molecules. Exposure to UV irradiation from sunlight, as well as to warm, moist environments has been found to result in degradation of DNA within a matter of hours [7]. Evidence samples that begin with only trace amounts of DNA are particularly at risk of only being partially detected due to degradation and/or inhibition of PCR amplification.

Characteristics of Degraded DNA Samples

It has been widely observed that alleles corresponding to larger fragments of DNA typically exhibit weaker signals/intensity than smaller alleles after exposure to some environments, ostensibly because they provide a larger target for damage to be accumulated [1].

In the absence of degradation and stochastic effects due to small sample sizes, the amount of genomic template associated with any given locus in an evidence sample should be equivalent (stoichiometric). Given that the amount of product generated during PCR amplification is generally proportional to the amount of starting template in multiplex reactions [8], total peak height or area between alleles and loci should be roughly equivalent. As a result, progressively falling peak heights from small to large (left to right) DNA fragments on electropherograms are commonly considered by forensic DNA testing laboratories to be an indication of degradation (Figure 1). However, the absence of laboratory quantitative thresholds associated with these trends has made declarations of degradation subjective and commonly supported simply by an examiner's "past training and experience". Difficulties in distinguishing between the effects of: physical damage to DNA molecules, the presence of chemicals that inhibit the PCR process [9, 10] and the fact that smaller DNA fragments are more efficiently amplified than larger ones during the PCR process [8] have complicated efforts to develop objective standards of identifying degradation.

Objectively Identifying Potential Degradation/Inhibition

The downward slope characterizing degraded or inhibited single-source samples can be measured. First, a best-fit linear regression through the heights of the peaks is drawn [11]. The data collection point is the point on the x-axis and the height of the peak is the point on the y-axis (homozygotes are divided in half). A slope is then calculated for the angle of the regression line and compared to a population of non-degraded samples (a collection of positive controls whose slopes have been separately calculated). If a given sample falls outside of the population of non-degraded samples at a given level of significance (e.g., $\alpha = 0.05$), then it can be flagged as being potentially degraded or inhibited. Such samples should be evaluated to determine the potential for allelic dropout, reduced assumptions for mixture components, and other issues.

Mini-STRs

A new set of primers has been developed to address the issue of degradation [12]. The distance between the primer sequence and the STR repeats has been shortened so that the amplified DNA product is significantly smaller. Smaller amplicons are less likely to be affected by the effects of degradation and inhibition. Applied Biosystems produces the MiniFiler™ test kit, which examines eight of the STR loci (D13S317, D7S820, D2S1338, D21S11, D16S539, D18S51, CSF1PO, and FGA) and the sex-determining locus Amelogenin [13]. All of the MiniFiler™ amplicon sizes are less than 300 bp. In some instances, the new primer sets have resulted in revealing primer binding site mutations resulting in peak height imbalances or null alleles. In other instances, the reported Mini-STR allele differs from a standard STR test due to a 4 bp deletion in the region between the standard STR primer sequence and the beginning of the STR repeat region. In those cases, the reported allele from a standard STR kit would be one less than what would be reported by a Mini-STR kit.

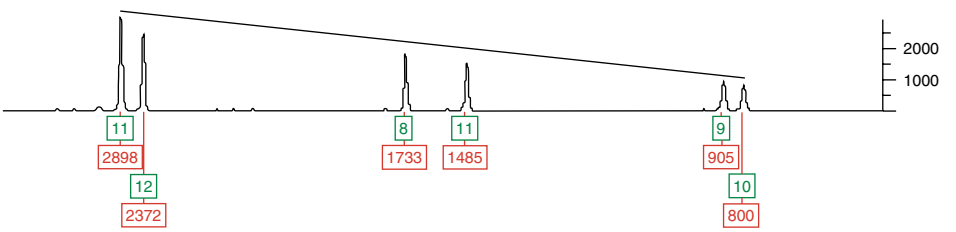

Figure 1 An electropherogram exhibiting signs of degradation or inhibition. Degradation and inhibition are marked by observing progressively falling peak heights as the size of the DNA product increases (left to right)

Y-STR Testing

Y-STR testing identifies the male contribution to a sample by targeting the Y chromosome (*see* **Y-Chromosome Short Tandem Repeats**). Y-STR testing also has the feature of producing small amplicons for a subset of the tested loci. For example, 6 of the 17 loci examined by the Applied Biosystems Yfiler® test kit produces product sizes less than 200 bp (DYS456, DYS389I, DYS458, DYS393, DYS391, and YGATAH4) [14]. Therefore, Y-STR testing may be a reasonable alternative when working with degraded samples (at the cost of less probative results).

Low Copy Number Testing

Samples containing low amounts of DNA often exhibit signs of degradation. However, it is not recommended that Mini-STRs or Y-STRs be used to alleviate the issues observed in the analysis of low copy number (LCN) DNA samples. Both the Yfiler® and MiniFiler™ test kits recommend a minimum starting template of 0.5 ng. Using less than the recommended amount of input DNA can still produce results at or below the stochastic threshold (*see* **Low Copy Number DNA**). The issues present with standard LCN DNA test results may still be observed, including allelic dropout, allelic drop-in, exaggerated stutter, and exaggerated peak height imbalance.

Addressing Inhibition

In some instances, it may be possible to distinguish between the effects of degradation and inhibition in that further purification of template DNA followed by reamplification can remedy problems associated with the presence of inhibitors. It is also possible that new extraction and amplification strategies will minimize the trends observed in peak heights for degraded/inhibited samples analyzed with currently popular methods [15].

Electropherograms can also appear degraded if the amplification mix is created improperly. Adding too little Taq polymerase can result in a profile that appears to be degraded. Adding too much EDTA in TE can sequester the magnesium ions, turning off the Taq, and again creating a profile that appears to be degraded or inhibited [8]. Further, adding too much template DNA will cause the PCR reagents to compete for template strands. The shorter fragments will be preferentially amplified, again resulting in a profile that appears to be degraded or inhibited. All of these issues can be identified by comparing the samples with the controls and references run in the same amplification. If the other samples appear to be normal, then it is likely the amplification setup is correct. In addition, reamplification can rectify the appearance of degradation or inhibition.

The Coroner's Inquest into the Death of Jaidyn Leskie

The Victoria Police Forensic Services Centre in Australia used the Profiler Plus® test kit to generate STR DNA profiles from two evidentiary samples associated with the deceased [16]. The DNA profiles that were detected were subsequently found to be consistent with the DNA profile of a rape victim associated with a distinctly separate investigation for which DNA testing was performed by the same laboratory less than one week earlier. Evidence at the inquest suggested that the rape victim could not have been involved in the death of Jaidyn Leskie. The testing laboratory suggested that the correspondence between DNA profiles of at least 7 (and as many as 12, after additional testing and review) STR loci associated with the evidence samples in the two cases may be a result of an "adventitious" (coincidental) match rather than due to contamination between the two analyses.

The small quantities of template available for PCR amplification from the investigation samples associated with the deceased, coupled with apparent degradation/inhibition, resulted in several peaks associated with the largest amplification products falling below 200 Relative Fluorescent Units (RFUs). One issue raised during the course of the Coroner's inquest was whether the most likely source of contamination from the rape investigation (an unmixed sample of the complainant on a condom) also qualified as being degraded/inhibited.

Comparison of the trends in peak height *versus* data collection point for the condom sample (Figure 2) were found to be significantly different than those of the sampling of 164 ostensibly nondegraded/inhibited positive control samples associated with this study or the positive control associated with the rape investigation. The condom falls below the threshold for variance in the sampling of positive

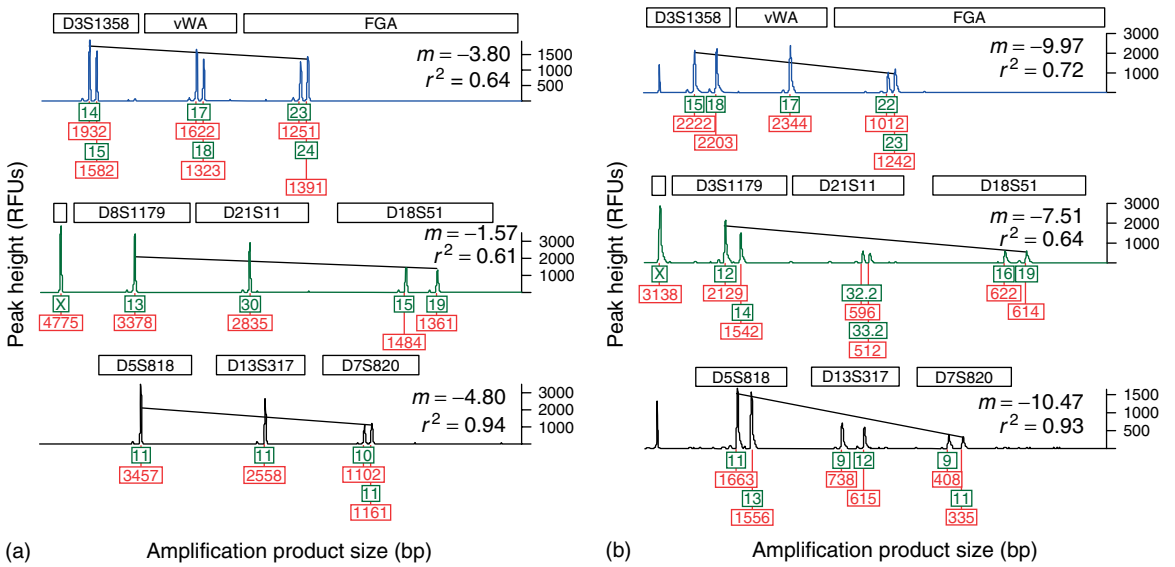

Figure 2 Electropherograms associated with a high-quality genomic DNA template (a) and with the condom sample from the rape investigation (b) that qualifies as being inconsistent with the sampling of positive controls

controls at the $\alpha = 0.01$ level. Thus, there is less than a 1% chance that a sample consistent with the sampling of positive controls (and thus presumably undegraded) would, by chance, exhibit the significant difference noted in the condom.

The Coroner ruled that the DNA testing result in the Leskie investigation was caused by contamination:

> "The match to the bib occurred as a result of contamination in the laboratory and was not an adventitious match. The samples from the two cases were examined by the same scientist within a close time frame" (G. Johnstone, Inquest into the death of Jaidyn Raymond Leskie. Coroner's Case Number: 007/98. July 31, 2006) [16].

Conclusions

Degradation and inhibition are common issues encountered during the course of forensic DNA casework review. Objective measures can be used to identify when a sample may be subject to degradation or inhibition based on linear regression slopes using the electropherogram. Inhibitors can be removed with an added purification step during the amplification process. New technologies like mini-STRs and some Y-STR profiling kits have the ability to resolve some DNA profiles that have been compromised by degradation. No matter how a degraded profile is resolved, the analyst must consider a variety of alternative interpretations (and have those additional alternatives be reflected in a lessening of the statistical weight associated with an evidence sample).

DNA: Sources of

Introduction

In 1987, the first report appeared in the literature describing the use of DNA profiling to assist in the investigation of a crime [1]. In this now-famous case, DNA profiling using minisatellite technology [2, 3] (*see* **Microsatellites**) was used for the first time to demonstrate that semen found on the bodies of two young women was likely to be from the same man and that the young man suspected by police was excluded as the source. Further investigations, including the "blooding" of several English villages, led police to identify Colin Pitchfork, who subsequently pleaded guilty to both crimes [4].

Since then, DNA profiling has evolved through a number of stages, each one resulting in increased sensitivity or discrimination. Now, large scale DNA databases to date, where large-scale DNA databases are in use in many countries, short tandem repeat (STR, *see* **Short Tandem Repeats**) multiplexes incorporating many loci and targeting autosomal and Y chromosomes are in common use and DNA profiling is recognized as a key part of crime solution and modern policing [5].

So where does the DNA come from that produces such startling results? The answer is, almost everywhere. Today, it is well recognized that DNA profiles can be obtained from samples that are too small to be seen and sometimes difficult or impossible to attribute to a particular cell type.

The samples include the well-recognized bloodstains, semen and saliva stains, and hairs as well as less common samples such as nasal and vaginal secretions, teeth and bone, skin, including dandruff, feces, chemically treated fingerprints, plant material, and insects (for examples, see [6, 7]).

In this article, by reference to case reports and articles published over the last 20 years and by drawing on this author's personal experiences and those of others as practicing forensic scientists, attempts have been made to convey the huge variety of sources of DNA evidence that can be encountered, recognizing the infinite variety of samples, substrates, and case circumstances that exist.

Blood

Blood, splashed and smeared, is probably the most popular image conveyed of a crime scene. Blood can also be present on garments worn by individuals and on weapons such as knives and baseball bats used to inflict injury. Of course, blood can also be present as a result of innocent transfer and may have nothing to do with the alleged crime committed. The examination of the patterns of bloodstaining (*see* **Bloodstain Pattern Interpretation**) together with the analysis of DNA determining the likely source of blood can provide powerful forensic evidence and is often used to reconstruct events.

Of course, bloodstaining may not be visible. Various reports in the literature have investigated the effects of the luminol test (*see* **Luminol**) on the ability to obtain DNA profiles [8, 9]. Luminol is used to visualize possible bloodstaining that has arisen from very dilute blood, typically associated with attempts to clean up a crime scene or as a result of a trail of blood left by, for example, the shoes of a participant in a crime. Application of the luminol reagent in combination with appropriate techniques to extract and amplify the trace amounts of DNA has not been found to be detrimental to the success of the DNA analysis procedure.

The Vaginal Tract

Menstrual blood contains components that distinguish it from circulatory blood although these are currently difficult to quantify. A typical menstrual bleed contains, in addition to circulatory blood components, broken-down tissue from the endometrium and plasmin, a compound that prevents blood clotting. Blood associated with assault of a sexual nature may therefore contain blood derived from a menstrual bleed and/or circulatory blood caused by injury to the vagina and surrounding tissue. Menstrual blood is mixed with varying proportions of vaginal secretions.

Vaginal secretions are always located on genital swabs collected from the vagina and also on other objects used to penetrate the vaginal tract. These secretions contain miscellaneous proteins originating from the upper genital tract such as the

oviduct, endometrium, and cervical mucus [10]. While difficult to identify specifically, the cellular material present provides a rich source of nuclear DNA. Thus, collection of such secretions by swabbing is often a successful source of DNA.

Semen

DNA analysis of semen formed the basis of the first reported use of DNA analysis in forensic science [1] and the use of DNA in the solution of crimes of sexual assault has had a profound effect on the effectiveness of forensic evidence in the resolution of crime. Seminal fluid or semen is a mixture of cells, spermatozoa, and a variety of organic and inorganic substances, and is a commonly encountered sample type in forensic casework.

Internal genital swabs are routinely collected from rape victims in most parts of the world. These swabs may be stained with semen, saliva, and blood as well as vaginal secretions. The DNA recovered from such swabs collected properly and stored dry or frozen is usually in good condition and the success rate from this type of sample is very high. Semen stains on clothing/bedding are also common.

Semen comprises seminal fluid with or without the presence of spermatozoa. Samples containing spermatozoa are rich in DNA and DNA analysis of such samples, where sperm are visible, is nearly always successful using polymerase chain reaction (PCR) techniques. A differential lysis treatment is commonly used on samples of this type (*see* **Extraction**) in order to separate the female epithelial material from the spermatozoa, thus simplifying the interpretation of the resultant DNA profiles.

The advent of Y-STR profiling techniques (*see* **Y-Chromosome Short Tandem Repeats**) has led to an increase in the successful analysis of semen in the absence of spermatozoa [11]. In such circumstances, DNA is recovered and selectively profiled from the small amounts of epithelial material present in the seminal fluid even in the presence of large amounts of female DNA. Of course, Y-STR profiling is also useful when spermatozoa are present in small amounts.

Semen can be present in the mouth following oral intercourse, and is sometimes found mixed with saliva in stains on clothing. Once again, differential lysis separates the spermatozoa from the epithelial cells present enabling amplification of both spermatozoa and epithelial fractions separately and analysis of the DNA profiles.

DNA can also be recovered from cellular material on condoms although the success rates for this type of sample can be lower because of the presence of inhibitory substances in the spermicides and lubricants or because of the moist environment on the condom surfaces.

Case study 1: "Condom–the Critical Link in a Rape" [12] In 1993, a report appeared in the literature of the successful analysis using variable number tandem repeat (VNTR) (see **Variable Number Tandem Repeats***) analysis of material collected from a condom. The circumstances of the case were typical. A young girl was sexually assaulted by a man using a condom. The condom, discarded by the assailant was recovered and found to be stained with blood on one side and semen on the other. DNA analysis showed that the blood could have come from the young girl supporting the medical evidence and evidence of the girl. The DNA profile obtained from the semen was consistent with having come from the suspect.*

A crucial step in the DNA profiling of evidence from cases of sexual assault is the identification of semen. This can be accomplished by the microscopic identification of spermatozoa if present, which is done by histological staining of the spermatozoa. The sensitive PCR systems used in laboratories today enable the DNA profiling of the spermatozoa on such slides and this can be enhanced using techniques such as laser microdissection [13] to facilitate the recovery of the sample. Histological slide collections made during the routine examination of sexual assault cases, over many years, provide an excellent repository of biological evidence for the investigation of old "historic" cases and many laboratories around the world are now utilizing such evidence in combination with their DNA databases to solve previously unsolved cases.

An alternative source of semen for analysis are the test papers produced during the presumptive test for semen, commonly known as the *acid phosphatase (AP) test* [14]. If stored in an appropriate condition,

these papers can provide sufficient biological material to enable the development of DNA profiles.

It is our experience [15] that DNA profiles can still be obtained from semen stains on garments after laundering using a range of normal washing conditions. Thus, so long as the approximate location of the semen stain can be approximated (such as the crotch of a pair of underpants), then it is possible to obtain a DNA profile presumably from spermatozoa adhering to the fibers of the material.

Trace DNA

A report published in Nature in 1997 [16] demonstrated that DNA could be recovered from items held or touched for a time as brief as few seconds. This work stemmed from the observation that DNA could be successfully recovered from the blade of a tomahawk that had been submerged for 12 h and was seemingly unstained and clean. This demonstrated that DNA profiling was possible from samples such as keys, pens, and handles, and it was suggested that the success of obtaining a DNA profile may be related to the individual's propensity to "shed" DNA and not necessarily the length of time that the person was in contact with the item. The propensity of an individual to "shed" DNA has been examined [17, 18] and factors influencing the shedding of DNA by individuals investigated. It has been found that there is significant variation in the amount of DNA a person sheds at any one time and thus whether a person is a good or bad "shedder" at any particular time is currently unpredictable.

The work described above and the experiences of others [19] led to the realization that DNA recovered from car steering wheels, computer keyboards, and other surfaces not necessarily stained with recognizable body fluids, could be an important source of DNA evidence.

One drawback with samples collected from these sources is the prevalence of mixed profiles from multiple contributors that may not be resolved into individual sources. Another is the observation that the last person to handle the item may not be the person from whom the DNA profile originated. Hence, there may be a temporal aspect to the deposition of DNA that must be considered when interpreting the DNA profiling results.

Case study 2: "DNA Profiling from Heroin Street Packages" [20] The authors of this study suspected that it may be possible to identify the individuals responsible for sealing the edges of the plastic packets used to contain small doses of heroin for sale. The proposition was that epithelial cells from these individuals might become trapped in the burnt edges of the packets and that this might provide useful evidence for investigators. Experimental work and analysis of case material showed that the method of sealing was crucial to the successful generation of a DNA profile and that individuals who handled the packages before and after sealing might also leave traces of DNA that could be amplified. Thus, although DNA profiles can be obtained from the sealed edges, and therefore from the sealer, they can also be obtained from other individuals who may have handled the packages.

Pipe bombs are easy to make and commonly used in America and elsewhere. When exploded, they generate a large amount of heat. During experimental trials, DNA was could be recovered and analyzed from such pipes after the explosion had taken place [21]. Critical factors of success were the ability to locate sufficient pieces of pipe and the degree of shedding of the person assembling and handling the pipe. This report serves to illustrate that what might be expected to be an extreme environmental insult may, in fact, not be as detrimental to the chance of success as expected.

Of course, legitimate transfer of DNA and/or cellular material from people to such items must be considered and never has Locard's principle "every contact leaves a trace" been truer. Its just that now, every contact leaves a trace of DNA that, if it can be collected either by visual observation, good guess work, or sometimes luck, can be compared to a reference DNA profile from an individual.

Low Copy Number and Single Cells

The successful amplification of DNA from a single cell using the second generation multiplex (SGM) multiplex and elevated cycle number [22], heralding

the beginnings of low copy number (LCN) techniques (*see* **Low Copy Number DNA**) [23]. In this first report, complete DNA profiles were obtained from 50% of the single source samples analyzed using elevated PCR numbers.

Subsequent to this report, there are many examples of DNA profiles being obtained from very small numbers of cells, including the use of laser microdissection to capture small numbers of sperm cells from histochemically stained microscope slides [13].

Case study 3: "A Tale of Two Robberies" [24] Two robberies were committed in different towns in Northern Italy. In one case, traces of saliva were detected on a pillowcase used to transport the stolen goods. In the second case, a pair of sunglasses was left behind in a bank during a robbery and cellular material was recovered from the nose and ear pieces of the frames. DNA profiles were obtained using LCN techniques and the profiles entered onto the local database. Immediately, the two DNA profiles linked together and additionally, the DNA profile of an individual on the database corresponded to the crime sample profiles.

Saliva

Saliva is a secretion of the mouth that is important in digestion and comprises cells and secretions from the salivary and parotid glands. Saliva has a high proportion of water and a low level of dissolved substances and cellular material, which can make it difficult to locate visually. Saliva is commonly encountered as a source of DNA evidence.

Perhaps the first example that springs to mind is the ubiquitous cigarette butt. Cigarette butts are often left by suspects as they contemplate committing a crime, waiting for an opportunity, or possibly as a means to steady nerves. It is not uncommon to find DNA from multiple contributors on cigarettes, a result of sharing, and indeed on occasion three or four people may have shared the same cigarette [25].

Case study 4: "A New Zealand Family Affair" A car was stolen and found several days later, several hundred kilometers from home. Inside were a number of cigarette butts that should not have been there. From these butts, six different DNA profiles were obtained, five of which corresponded to five members of a "family" on a DNA database. The sixth was consistent with being from a family member not present on the database.

Perhaps a word of caution. It is not unheard of for police officers to submit numerous cigarette butts from public areas, for example, outside banks or commercial premises, in the hope of uncovering possible offenders. Such untargeted sampling approaches can lead to innocent persons being investigated and laboratories being overwhelmed with unnecessary work. As in all things, a healthy dose of common sense is helpful.

Case study 5: "A Body in the Water" [26] Saliva swabbed from human skin has been used to generate DNA profiles, enabling association between a bite mark and a suspect even when the body had been submerged in water for several hours. In this particular case, the deceased had suffered extensive head injuries and sexual assault as well as a bite on her right breast. Cellular material was collected by swabbing and a DNA profile obtained. The profile obtained was a mixed DNA profile containing DNA types that could be attributed to the victim as well as the suspect. The DNA evidence was produced at trial and proved crucial to the resolution of the trial.

Saliva is also prevalent among samples left at scenes of more minor crimes, for example, burglary, where it is not uncommon for offenders to help themselves from the cupboards and refrigerators of their victims. In such cases, saliva can be located on bottles and cans [27] on bitten pieces of chocolate, biscuits, and fruit, and on cutlery and the rims of glasses and cups [6].

Saliva can also be recovered from the back of licked stamps and envelopes [28]. In this case, care must be taken as a stamp can yield not only evidence of who might have licked the gum, but also evidence of DNA from skin cells transferred by touching the outer, exposed surface of the stamp. The scientist should be careful to distinguish between these two possibilities. Saliva trapped between stamp and envelope is however protected from contamination and reliable results should be obtained free from extraneous DNA. LCN (*see* **Low Copy Number DNA**) techniques have aided in the effectiveness of this type of evidence as the amount of cellular material transferred to a stamp or envelope is likely to be low.

Fingernails

There are two main sources of DNA associated with fingernails. The first is the nails themselves [29]. The keratin structure of the fingernail does not contain DNA itself; therefore, the analysis of fingernails themselves is limited to recovering DNA from epithelial cells adhering to the nail. This analysis may be carried out in an attempt to determine the person from whom a nail piece came or as an alternative reference sample.

Alternatively, biological material scrapped from underneath the nail can be sampled and its source identified. The material trapped under the nails could be a variety of different body fluids or tissues such as semen, blood, saliva, skin, and vaginal secretions and could have been deposited in any number of ways. For example, a victim may scratch an offender during a violent struggle, or an offender may have digitally penetrated the victim during a sexual assault.

There are a number of reports of the successful analysis of such debris under the nails [30] including from under the nails of bodies submerged in water for periods of time [31]. Indeed, it has been shown that even repeated handwashing is not always sufficient to remove the evidence [30]. In order to interpret the results of such an analysis, it is important to know the background levels of DNA expected to be found underneath the fingernails in normal situations, one such study reports that the incidence of foreign DNA under fingernails appears to be low [32].

Case study 6: "The Persistence of DNA under Fingernails Following Submersion in Water" [31] Case one. A victim of homicide was found after submersion in bath water for 2–3 h. Mixed DNA profiles corresponding to the deceased and one other were obtained from the clipped nails. The male component of this mixture was found to correspond to the suspect, identified by a database search. Case two. A woman was seen falling into the harbor with her baby and her body was recovered 3 h later. DNA profiling was attempted on the fingernails clipped at the postmortem and the major male component was found to correspond to those of a colleague with whom an altercation had previously taken place. This information corroborated the accounts of several witnesses and no charges were laid.

Fingerprints

It is commonly understood that it is difficult but not impossible to obtain DNA profiles from fingerprints after enhancement [33]. In one comprehensive study, fingermarks were made on a variety of surfaces in blood and saliva. The fingermarks were treated to a wide range of chemical enhancement methods. In most cases, STR profiles were obtained using standard DNA profiling methods, showing that the many enhancement methods used were not significantly detrimental to the DNA profiling process. This mirrors our own experience where the difficulty arises when the fingermark is made by the greasy secretions of the skin only, in which case, elevated PCR cycle numbers (*see* **Low Copy Number DNA**) may be needed because of the small amount of available biological material.

Hair

The average human head contains between 100 000 and 150 000 hair follicles [34] with hair roots present in three stages of development known as *anogen, catagen*, and *telogen* (*see* **Hair: Microscopic Analysis**). On an average, 50–100 hairs are shed everyday, naturally or as a result of force and most of these are in the telogen phase. In the anogen phase,

the hair roots are actively growing and are rich in DNA. In the catagen, or breakdown phase, nuclear DNA is still relatively abundant. Telogen hairs, however, have little or no nuclear DNA associated with them [35] and it is telogen hairs that are most often encountered in forensic casework. Unless there is additional cellular material adhering to the root structure of a telogen hair, analysis is usually unsuccessful [36], using autosomal DNA typing methods. Alternative DNA profiling methods such mitochondrial DNA typing methods [37] or LCN techniques [38] have proved to be useful for the analysis of both telogen hair roots and hair shafts, which are also known to contain very little nuclear DNA. Indeed, LCN techniques have been reported to be successful in the production of nuclear DNA profiles from hairs recovered from Siberian mummies 500 years old [38].

Teeth and Bone

The use of teeth and bone as a source of DNA for forensic work is of primary importance in the identification of human remains. Among the most challenging requirements in forensic science, in recent years, has been the requirement to identify the victims of mass disasters, commonly known as *Disaster Victim Identification* (*see* **Disaster Victim Identification**).

Where possible human remains are identified using dental records and fingerprints, this is not always possible. Early attempts of extracting DNA from bones from decaying and/or compromised bone samples were often unsuccessful due to the degraded nature of the DNA that was recovered and the VNTR DNA typing methodology employed. However, nuclear DNA can be recovered from these cells in sufficient amounts for DNA analysis by PCR [39].

With the advent of PCR techniques, it was possible to amplify degraded DNA and samples of bone and teeth that had been exposed to severe trauma became more useful sample types. The bodies for which identification using DNA is typically required may be from recently deceased individuals as a result of explosive or fire trauma such as following the Waco incident [40] or Spitsbergen aircraft crashes [41], or the bodies and body parts might be "old" such as those recovered from grave sites where notable historic figures such as the Romanov family [42] and Jesse James [43] were thought to be buried. Less newsworthy, but nonetheless important, are missing person cases where body identification is required. [44, 45].

Success has been shown to depend less on the age of the bone and more on the conditions under which it has been kept and amplification of fragments of mitochondrial DNA from ancient bone thousands of years old has been reported [46].

Recent use of short amplicons (*see* **Mini-STRs**) and single nucleotide polymorphism (SNP) technology have increased the utility of these samples and provided increased chances of successful profiles.

An advantage of using bones and teeth for forensic purposes is that stringent washing/cleaning techniques can be employed to minimize the possibility of contamination with extraneous DNA and this is of particular importance when considering the analysis of historic or ancient specimens.

Teeth, in particular, provide a rich source of nuclear DNA within the coronal pulp and radicular canals of the tooth [47], although these sources decrease with age and disease as additional dentin is deposited on the internal surfaces.

The external structures of teeth (dentin and enamel) provide an excellent physical barrier and great protection to the mtDNA and nuclear DNA found within teeth, thus conferring teeth with a great advantage and making them a reliable source of DNA for forensic purposes in situations where other samples such as bone may prove unsuccessful.

Formalin-Fixed Paraffin-Embedded Tissue Samples

Formaldehyde-fixed and paraffin-embedded tissues provide a valuable resource for forensic analysis [48, 49]. Such tissues, stored by hospital departments, can provide direct reference material for late comparison with human remains. In addition, forensic examination can be employed to determine whether or not tissue samples showing signs of disease have been wrongly attributed to patients following allegations of mislabeling or similar.

Fecal Material

Fecal material in the form of stools or stained tissue paper is found in a small but not insignificant number of associated with burglary scenes,

in particular. Fecal material contains, among other things, solid indigestible remains of consumed food, large amounts of microbial material, and other compounds known to inhibit the PCR reaction. Early attempts to recover DNA from fecal samples relied upon the use of mtDNA analysis; however, the introduction of DNA extraction methods capable of substantially removing PCR inhibitors [50, 51] has enabled nuclear DNA-based PCR methods to be utilized improving the evidentiary usefulness of this sample type.

Unusual Sources

Lice, Flies, Mosquitoes, and Maggots

Insects, particularly flies, are frequently associated with crime scenes, and the colonization of bodies by insects after death is used to determine the postmortem interval [52] (*see* **Entomology**). It has been shown that it is possible to recover sufficient human DNA from the crop contents of maggots recovered from corpses to obtain DNA profiles, using not only mtDNA techniques but also conventional autosomal STR typing methods [53]. Results were obtained from maggots recovered from corpses showing putrefaction and from maggots of several different fly families. Thus results were obtained from blow flies, flesh flies, and house flies.

Case study 7: "Body on the Beach" [55] The body of a woman was found on a beach. Inquiries led investigators to a suspect, and, upon examination of his home, a mosquito and a small bloodstain corresponding to a blood meal were found on an inside wall. The STR DNA profile obtained corresponded to that of the victim indicating that she had been in the vicinity of the address. When taken into account with other scientific evidence, a strong case was made and the suspect was convicted.

In a similar investigation, mtDNA profiling results were could be obtained from individual human crab lice that corresponded to their human source. In other words, successful mtDNA analysis has been reported of the blood meals of the human louse, thus providing an alternative avenue of investigation when such lice are found on clothing [54].

The Contact Lens

The vacuum cleaner bag has long been regarded as a source of possible fiber evidence, but due to the sensitivity of current DNA profiling techniques, trace amounts of biological material vacuumed away either deliberately or by chance can now be recovered from this most unexpected source.

Case study 8: "The Contact Lens" [56] Following a report of a sexual assault committed three days earlier, investigators searched the contents of a dust bag from a vacuum cleaner and retrieved numerous fragments of a contact lens, allegedly knocked from the complainant's eye. A DNA profile, from a single source, and corresponding to that of the complainant was obtained, confirming her presence at the address and the loss of a contact lens as described by her. Faced with this evidence, a guilty plea was entered and a new avenue for potential DNA evidence was uncovered.

Plant Material as Forensic Evidence

In recent years, the suitability of plant material as forensic evidence has begun to be recognized (*see* **Botany**; **Wood**). A number of publications have appeared in the literature describing its application.

Cannabis

A number of alternative methods have been described for the analysis of *Cannabis sativa* L. [57] including DNA sequencing of specific regions of the chloroplast DNA [58] genome suggested as a method to confirm the presence of cannabis. Other studies [59] have utilized STR typing to investigate genetic variability of cannabis plant material. While their findings were unable to fully distinguish between drug and fiber accessions, the STR markers were highly polymorphic and showed significant differentiation between individual plants that had not been clonally produced.

Grasses

Recently, PCR-based methods to distinguish between grass species have been reported. By investigating the mitochondrial sequences of 20 phylogenetically representative grass species, researchers were able to identify sufficient informative sequences (indels) in the grass mitochondrial genome to enable correct identification of 25 unknown grass samples. Thus, grass collected from items associated with crime scenes promises potential as an investigative tool [60].

Magic Mushrooms

Possession of hallucinogenic fungi is a criminal offense in many countries; however, not all closely related fungi contain the hallucinogenic ingredients and, therefore, unambiguous determination of a particular species can be of value in a criminal investigation. PCR-based DNA methods have been described [61] that in combination with phylogenetic approaches, specimens can be separated into hallucinogenic or nonhallucinogenic species.

Trees

A number of genetic approaches can be used to analyze leaf and other plant tissue from trees and this can be used to provide associative evidence in criminal casework.

Case study 9: "Disassociation with a Burial Site" [62] A pregnant woman's body was found buried within a few meters of a group of three sand live oak trees, Quercus geminata. Dried leaf material was found in the boot of a suspect's car. STR markers were developed that enabled a comparison between the dried leaf material from the car and the trees at the burial site. In this case, the DNA evidence showed that although the leaves in the suspect vehicle appeared to have come from three different trees, the results were not consistent with them having come from the three trees at the burial site.

Other groups have used different approaches to analysis. The amplified fragment length polymorphism technique has been used to investigate the potential of association of plant material from the red maple, *Acer rubrum*. [63] The results showed that within a closed set of trees, identification was possible but that interpretative difficulties arose when considering a larger group or geographical area.

Summary

Since the first reports of the use of DNA profiling to solve a forensic case, DNA profiling has evolved through a number of stages, each one resulting in increased sensitivity or discrimination, to date, where large-scale DNA databases are in use in many countries, STR multiplexes incorporating many loci, and targeting autosomal and Y chromosomes are in common use, and DNA profiling is recognized as a key part of crime solution and modern policing. The seemingly limitless nature of the sources of DNA for forensic analysis continues to impress and as forensic scientists cast their net wider into the plant and animal kingdoms, the possibilities for the future seem endless.

DNA Databases and Evidentiary Issues

Introduction

DNA profiling and the compilation and use of forensic DNA databases are most often discussed with reference to the operational impact, the effect on intelligence-led models for forensic and policing practice, and the broader justice system ramifications such as the catalysis of legislative change, the increased socio-legal debate, and emergent aspects of jurisprudence. In this entry, the focus is refined to cover specific evidentiary issues associated with the use of DNA databases. The specific issues raised by the use of familial searches will not be treated here (see [1, 2] for the statistical issues and [3, 4] for some ethical considerations). The approach of familial speculative searches consists in searching a full profile left on a crime scene in the DNA database. No full match is returned, but a partial correspondence (on relatives sharing more of their DNA than unrelated persons, this partial match could indicate that the crime stain was left by a close relative of the person with whom the partial match was found) is obtained.

The collation into databases of DNA profiles taken from persons convicted of, or otherwise connected to, crimes has been a focal point of development efforts in the field of forensic biology for at least the past decade. The scale of database growth and use is now considerable, particularly in populous Western democracies. Databases in the United Kingdom, the United States, and Europe alone now house over 10 million profiles, and their use has resulted in almost 1 million intelligence links (Table 1).

Along with the increase in the volume of cases brought about by the introduction of DNA databases, there has also been an alteration to the types of crimes and evidence submitted for biological analysis. Initially, DNA profiling was applied primarily to serious crimes, whereas, in recent times, it has contributed to the investigation of a far broader spectrum of crimes, most notably extending to include vast numbers of property crimes [5]. An important aside to the broadened role that DNA evidence now plays in the criminal justice system, thanks largely to the introduction of DNA databases, has been the need for forensic scientists and administrators to operate in what is a more public environment with arguably greater levels of awareness and accountability.

While the investigative changes and rewards have been substantial, progress in the area of DNA databasing has also brought some measure of controversy. Much of the controversy is not associated with the investigative use of databases but rather with the areas where they intersect with evidentiary or other predominantly legal issues. For example, the enactment of specific legislation to allow broad-scale collection and storage of DNA samples from offenders, arrestees, and, in some cases, citizens otherwise associated with crimes has naturally brought comment on associated legal and ethical concerns [6]. There have been specific issues to consider in the courts also. Although the legislative regimes have assisted in easing troublesome issues in areas such as informed consent, they have brought challenges on interpretation that range from procedural issues to constitutionality. Approaches to evidence interpretation are also required to adapt to this changed environment so as to provide a framework to assist in the communication of outcomes across the interface of the forensic and legal sectors, most often in the form of expert evidence in criminal proceedings. As with other parts of the process, there have been specific issues in forensic statistics that have emerged through the use of DNA databases. The critical issues include (i) a refocusing on the likelihood of adventitious matches between profiles and robustness of interpretation models and (ii) controversy around

Table 1 Summary of the size and effectiveness of major DNA database programs

Database	Combined	United Kingdom	Europe	United States
Date	–	Jan 2007	Jan 2007	July 2007
Total profiles	10 498 199	4 103 509	1 444 916	4 949 774
Offender profiles	9 729 432	3 790 551	1 173 451	4 765 430
Crime profiles	768 767	312 958	271 465	184 344
Investigations aided	969 428	762 280	154 282	52 866

the appropriate approach for reporting a DNA match statistic in cases where the suspect was identified by a database search.

Adventitious Matches

As the discriminating power of DNA multiplexes has increased, the reasonable question that has arisen is, *when can a DNA profile match be considered proof that two DNA samples have come from the same source?* The FBI announced a policy on this in November 1997 [7] and others have supported the appeal of such a position [8]. While not declaring "uniqueness", the FBI policy encourages the use of the term "source attribution", which is intended to describe the situation where "to a high degree of scientific certainty" the source of the stain can be assigned to a particular individual [9]. This policy suggested that a match probability of less than $p = 3.9 \times 10^{-11}$ will confer a 99% confidence that the evidentiary profile is "unique" in a population of equivalent size to the United States (or $N =$ 260 million). While the simplicity is appealing, this move was controversial and has been criticized for its subjectivity [10] and the fact that the estimates were based on assumptions of independence at the population level [11]. We have previously stated our philosophical concern about scientists taking decisions such as these out of the hands of the courts [12].

While there is some effort in the advocacy of this approach to stress that source attribution applies only within the context defined by the case, and does not extend, for example, to the entire human population [13], there remain many risks with this approach. The semantics of the distinction provided describe an intent that is similar to categorization, that is, the only acceptable proposition out of a defined set of alternatives, or, one of a kind. However, the effect of the approach aligns more with individualization, itself implying the one – the only. This misapprehension is obvious in the reflections on the policy from areas of the legal community. The American Prosecutors' Research Institute announced the policy by saying; "... Jurors may be spared technical and often confusing explanations of population genetics and statistics because DNA examiners will be able to testify to a matching DNA profile without qualifying the match with complicated mathematical probabilities. Furthermore, now that the FBI policy has paved the way for definitive identifications of an individual as the source of an evidentiary DNA sample, other laboratories conducting DNA analysis may soon implement similar policies" [14]. In *Young v State of Maryland*, the appellate court concluded (at 56–57) "when the random match probability (RMP) is sufficiently miniscule, the DNA profile may be deemed unique. In such circumstances, testimony of a match is admissible without accompanying statistics. In place of the statistics, the expert may inform the jury of the meaning of the match by identifying the person whose profile matched the profile of the DNA evidence as the source of that evidence" [15]. It is incongruent to speak of uniqueness in the context of the handful of people associated with a case, and not anticipate misunderstanding.

While it is the vanishingly small random match probabilities (RMP) that are derived from direct matches between 10 and 15 locus short tandem repeat (STR) profiles that have encouraged approaches such as the assignment of source attribution, the collation of large-scale DNA databases has refocused this issue somewhat. If a database of individuals is of size N, with C entries on the crime stain database, this implies that there are $N(N-1)/2$ pairs of individual profiles, $C(C-1)/2$ pairs of crime profiles (involved in the crime-to-crime matching process), and NC person-to-crime comparisons during the matching of the two databases to each other. These numbers are not always on peoples' minds, and it is interesting to see how quickly they become large. With their increasing size comes the increasing likelihood of adventitious database matches [16].[a] In Table 2, we have estimated the number of matches expected in databases of various sizes (N) for a profile with an RMP of 1×10^{-9} or 3.9×10^{-11} (the FBI source attribution threshold).

For the purpose of this illustration there is no population substructure in the theoretical database, nor has there been any consideration given to the presence of relatives. The difference between this simple predictive model and an actual database is that a proportion of crime profiles are partial or derived from mixtures, implying that they do not have all loci scored. Such samples will have a higher RMP than full profiles and would be expected to match more frequently with other samples. Of course, there will be related people on the database and, for these people, the match probability will be larger than the match probability between unrelated people. These

Table 2 Crude demonstration of expected number of adventitious matches in databases of varying sizes

DB size	No. of comparisons	Expected number of matches	
		$RMP = 1 \times 10^{-9}$	$RMP = 3.9 \times 10^{-11}$
1	0	0	0
10	45	0	0
100	4950	0	0
1000	499 500	0	0
10 000	49 995 000	0	0
100 000	4 999 950 000	5	0
1 000 000	499 999 500 000	500	19
4 765430[(a)]	11 354 659 159 735	11 355	443
10 000 000	49 999 995 000 000	50 000	1950

[(a)] Size of combined offender DNA index system (CODIS) offender database (July 2007)

related people will increase the number of person-to-person matches but these are not considered as adventitious hits. The extent of relatedness in "offender" databases could be high. Likewise, there will be crime samples originating from people who are related to persons on the database. This increases the number of adventitious matches. A substructure is also present at the population level.

Accommodating these factors in predictive statistical models is a difficult task, largely because of the structure of databases and the fact that the match probabilities between two people, or between people and crime samples, are not constant. This matter has been tackled previously by [17] and is also addressed by Triggs and Buckleton [16]. Even without such models, it is possible to get the flavor of anticipated results (as illustrated in Table 2) and to understand clearly that adventitious matches between people on the database are expected to occur. Likewise, adventitious matches between crime samples and people are also expected. This is more likely in circumstances involving partial profiles on the database or from crime samples.

The likely event of adventitious matches seems counterintuitive for those unaccustomed to the mathematics, and we imagine it could confuse or alarm the general public. Perhaps for this reason, the issue has recently emerged in court as part of evidence questioning the validity of DNA match statistics. On occasions, these issues have been raised on the basis of observed results from databases of forensic DNA profiles. For example, reports exist in the literature relating to parentage- [18] and kinship [19, 20]-testing experiences that describe observed levels of matching or allele sharing that appear high in the context of associated DNA match statistics. There have also been anecdotal reports of coincidental matches at nine or more STR loci. All of these observations have involved comparisons with a database of some kind. One of the more noted recent examples was initiated following the observation of a single incident of an adventitious match within the Arizona State DNA Identification System (SDIS) [21]. A full search of the Arizona DNA offender database identified 144 partial matches; 122 nine-locus, 20 ten-locus, 1 eleven-locus, and 1 twelve-locus match (both of the latter two involved full siblings). At the time of the search, the database contained 65 493 profiles with an average RMP estimated to be less than 4.5×10^{-10} [22]. This finding caused alarm and led to legal requests for both State and Federal databases to be handed over in their entirety to independent researchers to undertake a full evaluation of the extent of allele and profile sharing [23]. There are many problems with using databases in this manner, mostly relating to what has to be done when a match is observed. Matching profiles may be the same person sampled twice under the same, similar, or different names, or they may originate from twins, close relatives, or unrelated people. Investigating this requires a considerable multiagency effort. The only advisable scientific safeguard is confirmation at additional STR or single nucleotide polymorphism (SNP) loci.

Some of the alarm surrounding the Arizona matches undoubtedly arose from misinterpretation of the data. As mentioned earlier, what is often overlooked in these circumstances is, first, that the critical information is the total number of comparisons

involved, and, secondly, how the observed number of matches compares with that expected from the statistical models underpinning estimates of the RMP. This comparison has been made by [24] who gives the expected figures for 9- and 10-locus matches respectively as 100 and 3, using a model that assumes no relatedness in the database. While the observed number of matches exceeds the number predicted by this simplistic model, one can see that the number of observations is not as alarmingly high as one may have intuitively thought them to be.

One of the limitations of forensic statistical approaches, and one for which they are often criticized, is the inability to empirically validate the estimates produced, and thereby, the models that underpin them. This is compounded by the fact that the numbers themselves are so large (or small) that they raise justifiable concerns about the level of accuracy. As the examples above show, large DNA databases are a pool of empirical data that, despite the limitations mentioned earlier, can provide some realistic basis by which theoretical estimates could be evaluated.

Weir [25] first addressed this issue using combined Australian profile data (~15 000 nine-locus profiles) and focussing not only on the fully matching profiles but also on those that partially match (for example, a profile where eight loci fully match and one allele or no alleles of the last locus match). The breakthrough made by Weir was to observe that the partially matching profiles do not suffer from the disadvantage that they may be the same person. Curran *et al.* [26] have recently extended this approach to include corrections in expected estimates for the common relationships, siblings, cousins, and parent/child, as well as unrelated persons. A variety of large datasets were utilized comprising diverse population groups (such as Caucasian, New Zealand Maori, and Australian Aborigine). The comparison of observed and expected numbers of partially matching profiles shows that, when subpopulation effects and relatedness are accounted for, the existing statistical models give an excellent fit to empirical observations.

From this aspect of databases, some interesting observations have emerged. The assembly of large databases of DNA profiles has brought the issue of adventitious sharing of DNA into sharp focus, which in turn raises questions about policies such as source attribution. Associated with DNA, there remains a significant issue around the expectation of the uninitiated. Most of the general public see DNA as a unique identifier and are befuddled when adventitious matches occur. These misappropriated expectations are easily exploitable by anyone wishing to denigrate the basis of the DNA match statistics, as, at first blush, the facts appear to contradict the model. Ironically, where the DNA databases themselves have generated this confusion, they also provide a resource for resolving long-held ambiguity about the validity of statistical estimates. In fact, the scientific analysis of these data that has so far been undertaken [25, 26] provides perhaps the strongest direct evidence yet as to the robustness of forensic DNA interpretation models.

Estimation of DNA Match Statistics after a Database Search

The strength of the DNA evidence resulting from an intelligence database match is often presented without any mention that the hit was obtained from a database. It is usually not in the suspect's interest to let a jury know that he or she has a sample on the DNA database. The question of whether searching a database for a match affects the strength of the evidence has been discussed extensively and forcefully in the literature. Unfortunately, there is much confused writing, and it would be very difficult for a court to make a reasoned decision based on a simple assessment of literature recommendations.

The issue was first countenanced in the first National Research Council (NRC, [27]) report, which suggested that the loci used in the matching process should not be used in assessing the weight of evidence (page 124):

> The distinction between finding a match between an evidence sample and a suspect sample and finding a match between an evidence sample and one of many entries in a DNA profile databank is important. The chance of finding a match in the second case is considerably higher ... The initial match should be used as probable cause to obtain a blood sample from the suspect, but only the statistical frequency associated with the additional loci should be presented at trial.

The second NRC report (NRC II, [28]; Recommendation 5.1, pp. 133–135) recommended that an adjustment be applied by multiplying the RMP by the number of people on the database. Using an example of an intelligence database of 100 000 and a multiplex

with an RMP of 1×10^{-6} would result in an adjusted database match probability of 0.1 being reported to the court. This approach is often referred to as the *Np* rule.[b] The conservativeness of this recommendation becomes extreme as the size of the database increases. For example, if the database were to hold the profiles of the entire world, and there was only one matching individual, logically this would provide an irrefutable association, yet, should *Np* be employed, the discriminating power of the match would be reduced by a factor of 6 billion.

In addition to the two NRC reports, [29–32] have also suggested that the match probability be multiplied by the number of people on the database. Lempert [33] suggests multiplying by the size of the suspect population and not the database. Morton [34] suggests confirmatory markers or the use of the *Np* approach. The DNA Advisory Board [13] highlights the question as being *especially important*, and favors the approach of [30], which it describes as being *more comprehensible* and *always conservative*.

The general consensus among noted authors in the field is that the evidence is slightly stronger after a database search and hence no correction is required [16, 35–47].

For a considerable portion of its history, the use of forensic DNA evidence in court fought to gain general acceptance. Having achieved a stage where its general suitability was less contentious, DNA evidence has at times struggled due to the difficulty the courts endured in interpreting its technicality. The present debate that is taking place around whether an adjusted (Np) or an unadjusted match statistic (p) should be presented impinges on both these fronts. Differences of opinion run the risk of being perceived as a lack of general acceptance across the expert community, and the technicalities of the issue could easily overwhelm lay court participants.

In the recent trial, [48] DNA evidence was excluded at trial under [49] due to the *raging debate* in the scientific literature on the issue of database match statistics. This was seen to indicate a lack of *general acceptance* in the scientific community and thereby preclude admissibility. This ruling was overturned on appeal. The appeal court ruling goes to some lengths to describe the issue. It cites three key approaches that could be used to estimate DNA statistics in the circumstance of a DNA database search that has resulted in a suspect's identification and subsequent trial. These were termed the *rarity statistic*,[c] which estimates how rare a profile is in a given society, the *database match probability*, which estimates the probability of a chance match from a particular database (calculated by *Np*), and the *Balding and Donnelly approach*, which gives a full consideration of the evidence in context (based on [38]). The Appeal court held as follows:

> there is no controversy ... as to the accuracy of the various formulas ... each approach accurately answers the question it seeks to address ... Instead, the arguments raised by each of the proponents simply state that their formulation is most probative, not more correct ... Thus the debate is one of relevancy, not methodology ... and as such there is no basis to exclude the evidence in this case ... What is and is not relevant is not appropriately decided by scientists and statisticians ... determining what is and is not relevant is a hallmark responsibility of the trial judge and that responsibility is not appropriately delegated to parties outside the court.

While the ruling in *Jenkins* is appreciative of the issues, it does not greatly assist as it gives equal legitimacy to all approaches. In fact, the debate occurring among scientists *is* on this quintessentially legal issue, as it hinges not upon the mathematics *per se* but on which statistic or statistics will help the jury appreciate the fact of a DNA match. To this end, another US appeal court ruling was more direct [50]. In dismissing the fact that the appellate was first identified as a possible suspect based on a database search as something that *simply does not matter* (at p. 15), the court also stated that "Jenkins does not convince us that the probability of obtaining a cold hit from a search of the CODIS database matters." (at p. 20).

The relevant question that must be assessed is, "Is the defendant the source of the DNA recovered from the crime scene?" For the purpose of an example, let us say that the questioned sample is a semen stain located on intimate swabs from a complainant in a sexual assault. The jury may embrace the proposition advanced by the prosecution (referred to as Hp) that the defendant is the source of the DNA on the swabs. Alternatively, it may embrace another proposition, possibly advanced by defense counsel (referred to as Hd). In general terms, this is that the defendant is not the source of the DNA on the swabs, but rather it has originated from an unrelated person who just happens to share the same profile as the defendant.

Evidence that informs the jury as to the plausibility of this alternative proposition is therefore relevant.

If the defendant is selected for reasons that have nothing to do with his DNA profile, and no one else is tested, the chance of the match under the coincidence hypothesis is the RMP, p. However, if the defendant was selected following a database search (i.e., he was not the only person considered), this requires additional analysis. The frequentist argument is that, because a match following a search is much less surprising than a confirmation match following on from other evidence of association, Hd is much more plausible than p would suggest. Np indicates how probative the match is with respect to the hypothesis that the database contains the source of the crime scene DNA as opposed to the alternative hypothesis that the crime scene DNA came from someone not represented in the database. In other words, it estimates how often searches of database's that do not include the true source generate an adventitious hit. But, as Kaye succinctly states [51]:

> the database is not on trial. Only the defendant is. The DB match is only relevant to the extent that it affects the probability that the defendant – not the database – is the source. Thus, it appears that asking how probable a search of a particular database is to generate a false cold hit is the wrong question. The jury ought to be thinking about how probable the cold hit on the defendants profile would be when the specific defendant is, and is not, the source of the crime scene DNA. The likelihood ratio formed with these probabilities is the appropriate measure of the probative value of the DB match. This LR is more complex than the figure pertaining to the simple confirmation case. It includes not only the fact that the defendant matches but also the fact that everyone else in the database has been excluded. It can be shown that when this additional information is incorporated in the LR, the resulting number can be no greater than $1/p$. Consequently, introducing p as the indicator of probative value is not prejudicial. It understates the incriminatory power of the DNA evidence ....

We have previously summarized the mathematical argument [16] and reprise that proof here. For a population of size N, we index the suspect as person 1 and the remaining members of the population as $2 \ldots N$. The first $1 \ldots M$ of these are on the database. We call the hypothesis that person i is the source of the DNA: H_i. Because the suspect is indexed person 1, the hypothesis that the suspect is, in fact, the source of the DNA is H_1. The remaining hypotheses, $H_2, \ldots, H_N$ are those hypotheses where the true offender is one of the $N-1$ "other" people from the population. Before we examine the evidence, each person has some probability of being the offender $Pr(H_i) = \Pi_i$. The suspect is on the database and has been genotyped and we call his genotype G_s. The crime sample from the swabs has been typed and found to have the genetic profile G_c. The search of the database reveals that $G_c = G_s$ and that there are no other profiles on the database match (this latter requirement is unnecessary and a generalization is easy). We now know that the $2 \ldots M$ people on the database, other than the suspect, do not match. The remaining $M+1, \ldots, N$ members of the population have genotypes $G_{M+1} \ldots G_N$, which are unknown to us. We require the probability $\Pr(H_1|G_c, G_1 \ldots G_M)$.[d]

$$\begin{aligned}
&\Pr(H_1|G_c, G_1 \ldots G_M) \\
&= \frac{\Pr(G_c|H_1, G_1 \ldots G_M)\ \Pr(H_1|G_1 \ldots G_M)}{\sum_{i=1}^{N} \Pr(G_c|H_i, G_1 \ldots G_M)\ \Pr(H_i|G_1 \ldots G_M)} \\
&= \frac{\Pr(G_c|H_1, G_1 \ldots G_M)\ \Pr(H_1|G_1 \ldots G_M)}{\left(\begin{array}{c}\Pr(G_c|H_1, G_1 \ldots G_M)\ \Pr(H_1|G_1 \ldots G_M) \\ +\sum_{i=2}^{M} \Pr(G_c|H_i, G_1 \ldots G_M)\ \Pr(H_i|G_1 \ldots G_M) \\ +\sum_{i=M+1}^{N} \Pr(G_c|H_i, G_1 \ldots G_M)\ \Pr(H_i|G_1 \ldots G_M)\end{array}\right)}
\end{aligned} \tag{1}$$

In the equation above, we have split the denominator into the suspect, the other people on the database, and those other people in the population who are not on the database. Further, we assume $\Pr(G_c|H_1, G_1 \ldots G_M) = 1$. This assumption, in words, is that the crime sample should match the suspect if it did indeed come from him. This gives

$$\begin{aligned}
&\Pr(H_1|G_c, G_1 \ldots G_M) \\
&= \frac{\Pr(H_1|G_1 \ldots G_M)}{\left(\begin{array}{c}\Pr(H_1|G_1 \ldots G_M) \\ +\sum_{i=2}^{M} \Pr(G_c|H_i, G_1 \ldots G_M)\ \Pr(H_i|G_1 \ldots G_M) \\ +\sum_{i=M+1}^{N} \Pr(G_c|H_i, G_1 \ldots G_M)\ \Pr(H_i|G_1 \ldots G_M)\end{array}\right)}
\end{aligned} \tag{2}$$

Because we know that the $2 \ldots M$ "other" people on the database do not match $\Pr(G_c|H_i, G_1, \ldots G_M) = 0$ for $i = 2$ to M. This gives

$$\Pr(H_1|Gc, G_1 \ldots G_M) = \frac{\Pr(H_1|G_1 \ldots G_M)}{\Pr(H_1|G_1 \ldots G_M) + \sum_{i=M+1}^{N} \Pr(G_c|H_i, G_1 \ldots G_M)\ \Pr(H_i|G_1 \ldots G_M)} \tag{3}$$

Under most conditions, we assume that the nonmatching people do not change our view of the match probability. However, making this assumption and

assuming that the genotypes do not affect the prior gives

$$\Pr(H_1|G_c, G_1) = \frac{\Pr(H_1)}{\Pr(H_1) + \sum_{i=M+1}^{N} \Pr(G_c|H_i, G_1)\ \Pr(H_i)} \quad (4)$$

We compare this with the equivalent probability for the same match without a database search

$$\Pr(H_1|G_c, G_1) = \frac{\Pr(H_1)}{\Pr(H_1) + \sum_{i=2}^{M} \Pr(G_c|H_i, G_1)\ \Pr(H_i) + \sum_{i=M+1}^{M} \Pr(G_c|H_i, G_1)\ \Pr(H_i)} \quad (5)$$

Under any set of priors, equation (4) gives a larger value for the posterior probability than equation (5) since the denominator is larger in equation (4). Hence, reporting the approach leading to equation (5) is always conservative. In other words, the "no correction" approach is always conservative. Up to this point, we have not made any really contentious assumptions (although we accept Balding and Donnelly's argument that the search also informs the match probability). If we now assume that every person has the same prior chance of being the true offender (this assumption is quite contentious) and we write $\Pr(G_c|H_i, G_1)$ as p in equation (4), we obtain

$$\Pr(H_1|G_c, G_1) = \frac{1}{1 + (N - M - 1)Pm} \quad (6)$$

as compared to

$$\Pr(H_1|G_c, G_1) = \frac{1}{1 + (N - 1)Pm} \quad (7)$$

Again, equation (6) gives a larger posterior probability than equation (7). The mathematical solution leads to the conclusion that the evidence is stronger after a database search and reporting the standard match statistics is always conservative. Another simple explanation of this proof is given in [39].

In summary, there is consensus on certain issues in this area. Estimating Np and p seeks to answer different questions and that one is not intended to substitute the other. There is no support for the original NRC recommendation. The weight of scientific opinion is against the use of Np, and this is supportable by mathematical proof and logic. The issue itself has not received extensive coverage in the scientific literature since the initial dispute in the late 1990s. This is not to say, however, that the debate is exhausted. It is only in the past 12–18 months that significant legal challenges have emerged in this area – which is indicative of the slower rate of technology adoption in the legal system. Duly considering issues such as these is a matter for science, and this particular issue has been researched and critiqued at the time of DNA database emergence. But the fruits of this process are only now being absorbed into jurisprudence. In addition, this is happening in such a way that the duration, extent, and weight of the scientific debate is diminished. While this is frustrating to us, it also serves as a tacit reminder of the need for prompt, robust investigation of scientific issues, and suitable disclosure through publication. It also reinforces the folly in assuming that knowledge or practice that is the scientific norm will be perceived as such by the courts, and that in the least any assessment of the fact will occur along different lines, and often for different reasons.

Conclusion

Despite DNA databases having established themselves in a practical sense, there remain some peculiarities regarding the integration of outcomes from DNA databases into evidence. The one peculiarity that has precipitated issues in court in the United States and Australia has been the occurrence or anticipated occurrence of adventitious matches. It has been shown in this article that adventitious matches occur at a rate that we can approximately predict. Most risk accrues from partial profiles and people on the database who have close relatives offending. This risk can be best ameliorated by adding discriminating power either to the database samples or at the confirmation phase, or by using all available trace evidence in addition. However, there is also a more subliminal risk associated with adventitious matches, which occurs through a lack of awareness of the likelihood of their occurrence and the subsequent influence this can bring to bear on public confidence regarding evidence interpretation models.

A residual debate is also going on regarding the correct method to interpret a database hit. The mathematics is very difficult to explain to a lay person and would certainly be difficult to explain in court. A simple census of informed opinion would show that some commentators hold an opinion favoring each side of the correction or no correction

debate; however, most seem on the "no correction side".

End Notes

[a.] Adventitious matches refer to genuine links provided through the DNA database where an individual could not have been involved in a given case but who shares a common DNA profile with the crime scene sample purely through coincidence.

[b.] Where N_p indicates that the random match probability p is multiplied by the size of the database, N.

[c.] Referred to throughout this section as the RMP.

[d.] That is, the probability that the suspect is the source of the DNA, given the genotype of the crime profile and the remaining genotypes on the database.

Documents: Authentication of

Authentication, or identification, is the legal concept that before documents and physical evidence can be admitted into evidence, preliminary proof must be presented that, at least *prima facie*, the proffered evidence is what it purports to be. The requirement of authentication exists for all forms of inanimate evidence, though it has particular application to documentary evidence because of its effect on the rule against admitting hearsay evidence in common law jurisdictions.

In jurisdictions such as the United States that retain reasonably strict rules on authentication, such foundation evidence requires a testimonial sponsor. Applicable statutes, court rules, and decisional law provide the requirements for such foundational proof.[a] In some common law jurisdictions, the authentication rule is more relaxed, especially with regard to documentary evidence. In civil law countries, a variety of approaches to authentication exist and no generally recognized authentication principle is noted.

The authentication requirement is a safeguard against the introduction of unreliable evidence. It is one that is more of concern to lawyers and judges than to experts. However, because forensic experts deal with documents and other physical evidence on a daily basis, some familiarity with the rules on authentication is helpful.

Authentication of documents requires a preliminary showing to the court that a document offered in evidence is truly what it purports to be. Proof of authenticity is not required to satisfy a "preponderance of the evidence" standard. The evidentiary threshold for authentication is fairly low. The evidence must simply be sufficient to satisfy the judge controlling the procedure that it is likely what its proponent claims it to be. Any doubt raised regarding the authenticity of a document, or indeed regarding the genuineness of any other evidence, can be submitted to the trier of fact in the form of contrary evidence, or by cross-examination of the sponsoring witness.[a]

There are essentially four different ways in which an adequate foundation for the admission of documentary evidence can be presented: (i) by having the purported maker of the document take the witness stand and who is then asked for an affirmation or admission of its genuineness; (ii) by the testimony of eyewitnesses who were present when the document was executed and can testify that it is what it purports to be; (iii) by the testimony of a nonexpert person who is familiar with the handwriting of the purported maker of the document from other transactions in which the witness and purported maker have been involved in the past; or (iv) by calling a witness, duly qualified as a forensic document examiner, who can compare the questioned writing with known exemplars of the purported author's writing.[b]

Photographs and X rays are a form of documentary evidence for which special authentication rules exist. As to photographs, a testimonial sponsor must be able to state from personal knowledge that the photograph fairly and accurately depicts what it is purported to portray. This does not require that the photographer testify. What is required is that a person with a connection to the issue can testify to its accuracy. The introduction of X rays into evidence requires a preliminary showing that (i) the apparatus was properly operating and maintained; (ii) the operator was qualified; and (iii) some proof that this particular representation is connected with the case being litigated. This is generally satisfied by a showing that, at the time the picture was printed or machine-tape rolled, some notation was made as to the human subject of the X ray.

Voices on tapes or sound recordings also require authentication.[c] Such authentication can be provided in ways similar to those used for documentary evidence: either by the maker of the recording or by testimony of a person who recognizes the voice on the recording through familiarity of long standing.

Some documents may be admitted without the type of authentication proof described above.

The "ancient document" rule permits writings that are 20 or more years old at the time they are offered, and that were located in a place of natural custody and under conditions that create no suspicion as to their authenticity, to be considered *prima facie* authentic.[d] Foundation testimony is required as to both the document's age and the location where it was discovered.

In literally every jurisdiction, official documents or certified copies of public records are self-authenticating. They can be admitted without a testimonial sponsor.[e] In some jurisdictions, evidence rules make other categories of documents self-authenticating as well.

Satisfying the rules of authentication permits documents to be introduced in a legal proceeding, but that does not mean that such documents will be admitted necessarily as substantive proof of their contents. An attempt to prove the contents of documents potentially raises "hearsay" issues that are independent of authentication requirements. Because of the impact of the rule against hearsay testimony, other concepts may also need to be considered by the forensic expert seeking to utilize documents as proof of their substantive content (*see* **Hearsay Evidence**).[f]

End Notes

[a.] Article IX of the Federal Rules of Evidence set out the requirements for authentication of things and identification of persons. The federal rules are hereinafter referred to as FRE followed by the applicable rule number.

[b.] FRE 901. FRE 901(b)(3) regarding expert witness testimony also permits the trier of fact to visually make a determination of authenticity by comparing the proffered document with authenticated standard writings of the purported author.

[c.] For example, FRE 901(b)(5) covers the identification of voices, and FRE 901(b)(6), the ways in which telephone conversations can be authenticated.

[d.] See FRE 901(b)(9) on ancient documents and data compilations.

[e.] FRE 902 provides for self-authentication of domestic and foreign public documents, certified copies of public records, official publications, newspapers and periodicals, acknowledged documents, certified domestic records of regularly conducted business or activity; genuineness of trade inscriptions and marks, and several other categories. FRE901(b)(7) also deals with public reports and reports.

[f.] FRE Article X discusses the impact and requirements of the best evidence rule and its impact on proof of the contents of writings, copies of writings, summaries of writings, recordings, and photographs. FRE 1001–1006.

DQα

The location and function of the human leukocyte antigen (HLA) DQA1 locus has been well studied in biological sciences and population genetics. The DQA1 locus contains a region of 242 bp within which some of the bases are polymorphic from person to person. This type of variation is known as a *sequence polymorphism*, as distinct from a length-based polymorphism that characterizes a variable number of tandem repeat (VNTR) or short tandem repeat (STR) locus. This polymorphic region was the target of the first commercially available polymerase chain reaction (PCR)-based forensic DNA profiling system, known as *HLA-DQα* [1, 2]. The HLA-DQα system amplified the entire HLA-DQA1 locus and used presynthesized typing strips with immobilized sequence specific oligonucleotide (SSO) probes to detect six distinct alleles (1.1, 1.2, 1.3, 2, 3, and 4) that combined to form 21 possible genotypes. Following the hybridization of PCR products to the typing strips, genotypes were visualized by reverse dot-blot chemiluminescence. The HLA-DQα system was sensitive, rapid, and self-contained and as a result was very widely used in forensic analysis throughout the early 1990s [3].

In a later version, the three subtypes of the DQA1 4 allele (4.1, 4.2, and 4.3) were distinguishable and allowed a total resolution of 8 alleles and 28 genotypes. The enhanced test was renamed HLA-DQA1, to better reflect the naming convention of the genetic community. Adding this extended genotyping capacity increased the discriminating potential of the test – which in all other ways functioned the same as the earlier version. The technique was expanded again to the system known as AmpliType® PM+DQA1, or polymarker. Polymarker was the earliest commercially available example of a multiplex PCR system as it coamplified the HLA-DQA1 locus and five other polymorphic loci (LDLR, GYPA, HBGG, D7S8, and GC).

The HLA-DQA1 and ploymarker loci have been widely used in population studies to support forensic evidence interpretation [4–8] and examine diversity and population interrelatedness. As the polymorphic characteristics of these loci are point mutations associated with coding regions, these markers are suitable candidates for population studies. The HLA-DQA1 system was well suited to the analysis of a wide range of forensic samples [9–10]; however, it was difficult to resolve mixed profiles as the genotyping method complicated the designation of a minor contributor and background color development.

Drug Analysis

Introduction

Drug abuse and trafficking of controlled substances is a global problem. The purpose of analysis of illicit drugs is to examine the seized samples for the presence of scheduled drugs for the criminal justice system.

The seized drugs may be in several forms: powders, tablets and capsules, plants or dried vegetable materials, and liquids. There are a number of steps involved in the analysis of illicit drugs. The first step is a screening (or preliminary test) using basic chemical tests to establish a likely class of substance. These include color tests or precipitation reactions as well as microscopic examination. The second step is performed using thin layer chromatography (TLC) to tentatively identify the actual substance. Finally, a confirmatory test is performed using a validated instrumental method. This third step also quantifies the amount of illicit substances present in the sample and the best method for this is mass spectrometry; however, other validated techniques can be used if mass spectrometry is not available.

Techniques used in the screening and confirmation of illicit substances are described, including cannabis, amphetamine, methamphetamine, opium alkaloids, other opiates, cocaine, lysergic acid diethylamide (LSD), phenethylamines, and indoleamines (psilocybin). The analytical methods used must be appropriate for these purposes.

The sections below describe the techniques used and provide examples for a few illicit substances.

Instrumental Techniques

Thin Layer Chromatography (TLC)

TLC is one of the most widely used techniques for the separation and identification of drugs owing to its simplicity, reliability, low cost, and selectivity of detection [1]. Many compounds can be detected by examining a plate containing a fluorescent indicator under 254 and 365 nm ultraviolet (UV) light. Spray reagents such as acidified potassium iodoplatinate (platinic chloride/potassium iodide/concentrated hydrochloric acid in water), FPN reagent (ferric chloride/perchloric acid/nitric acid), fluorescamine (fluorescamine in acetone), Dragendorff spray (modified bismuth subnitrate), Marquis reagent (mixture of formaldehyde and concentrated sulfuric acid), and Mandelin's reagent (ammonium vanadate in sulfuric acid) are used to visualize substances on the plate. The distance traveled by the compound divided by the distance traveled by the developing solvent is the Rf (retention factor).

High Performance Liquid Chromatography (HPLC)

High performance liquid chromatography (HPLC) is especially useful for compounds that are thermally labile and provides a very convenient and accurate method of detection. Various types of detectors, which are nondestructive, such as an absorbance detector (ultraviolet/visible (UV/Vis) spectrophotometric detector), a photodiode array detector, a fluorescence detector, a refractive index detector, an electrochemical detector, and a conductometric detector are used [2].

Gas Chromatography (GC)

Gas chromatography (GC), which uses a gas as the mobile phase, is appropriate to analyze a wide range of chemicals that have volatility to be in the gas or vapor phase at or below 400 °C. Analytes are traditionally identified on the basis of peak retention time; however, it is dependent on the nature of the response from the detector [3]. There are various types of detectors, such as a thermal conductivity detector (TCD), a flame ionization detector (FID), an electron capture detector (ECD), a flame photometric detector (FPD), and a flame thermoionic detector (FTD) [1]. Most commonly a mass spectrometer (MS) detector is used.

Gas Chromatography Mass Spectrometry (GC/MS)

The use of GC with MS has become the routine method for the identification of most drugs, because the specificity and sensitivity of gas chromatography mass spectrometry (GC/MS) are very high [4]. Most analytes can be separated and identified by using a capillary column GC using a suitable temperature program coupled to an MS. GC/MS is applicable in the analysis of a large range of compounds including narcotics. MS produces characteristic spectra that

can be easily used to identify unknown compounds. Electron impact (EI) spectra obtained by the impact of high energy electrons on the sample is the most common form of ionization. Libraries of spectra are available to assist in the identification process.

Ultraviolet/Visible (UV/Vis) Spectrometry

The UV/Vis spectrum is recorded in a spectrophotometer. UV/Vis spectroscopy corresponds to electronic excitations between the energy levels that correspond to the molecular orbital of the systems. It is suitable for quantitative analysis for the characterization of drugs [5].

Infrared (IR) Spectroscopy

Infrared (IR) is the study of the scattering, reflection, absorption, or transmission of IR radiation in the spectral range 800–1 000 000 nm (0.8–1000 μm) [2]. Fourier transform infrared (FTIR) spectrometers are now available in most laboratories. They are faster and can work with smaller samples compared to traditional IR instruments. The difficulty with the IR analysis of drug samples is the presence of other materials that interfere with the spectrum; however, IR analysis can give valuable information on chemicals that are not normally suitable for GC/MS analysis [6].

Nuclear Magnetic Resonance (NMR) Spectroscopy

Nuclear magnetic resonance (NMR) spectroscopy is the only technique that can provide a detailed solution to the structure of small proteins and polynucleotides. It has become one of the foremost methods for molecular identification. This technique is very powerful because it combines detailed information at the atomic level with the possibility of understanding whole molecule properties [7].

Capillary Electrophoresis (CE)

Capillary electrophoresis (CE) can separate a wide variety of solutes, including compounds that are highly polar, thermally labile, and/or nonvolatile, with high efficiency and selectivity. It is a complementary technique to other separation methods such as HPLC. It is especially useful in the area of drug profiling, because it is able to give information on enantiomeric drug purity.

There are micellar electrokinetic chromatography (MECC), capillary zone electrophoresis (CZE), and cyclodextrin (CD)-modified CZE in CE techniques [8–10].

Liquid Chromatography Mass Spectrometry (LC/MS)

Liquid chromatography mass spectrometry (LC/MS) has made huge advances and become powerful in drug testing. Electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI) are the most widely used interfaces between LC and MS.

Currently, LC/MS/MS is employed to detect trace amounts of drugs because MS/MS improves signal-to-noise ratio, which provides the lower limits of detection and quantification. MS/MS has become a very powerful tool in microdetermination of drugs [4].

Examples of Analyses of Illicit Drugs from Seized Materials

Cannabis

Each country has its own penalties for trafficking and growing cannabis (marijuana). In Canada, growing more than 50 plants can lead to a sentence of 14 years. Singapore imposes death penalty on anyone convicted for trafficking in more than 500 g cannabis, though cannabis is now decriminalized in some parts of Europe.

The main psychoactive compounds in cannabis and cannabis resin are Δ-9-tetrahydrocannabinol (THC), cannabinol (CBN), and cannabidiol (CBD), of which THC is the most potent component. When samples are submitted for testing, they are first weighed before analysis. To conduct a microscopic test, a small amount of the material is softened with chloral hydrate in 10% sodium hydroxide solution [11, 12]. For chemical analysis, leaves and resin are cut or pulverized into small pieces, and about 10 mg is extracted with methanol.

Cystolithic trichomes, containing a deposit of calcium carbonate, and noncystolithic trichomes secreting resin are observed under the microscope (Figure 1) [13].

The presence of cannabinoids in the sample is indicated by two color tests: the Fast Blue B salt test and the Duquenois test. For the Fast

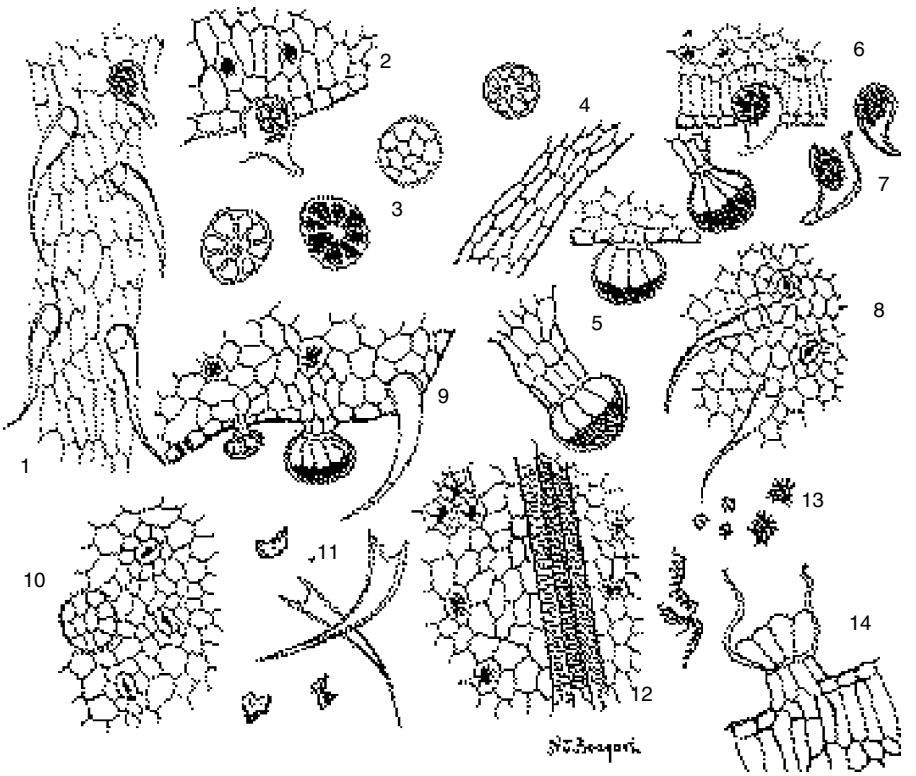

Figure 1 Cannabis powder seen through the microscope, enlarged 200 times (http://www.unodc.org/unodc/en/data-and-analysis/bulletin/bulletin_1950-01-01_4_page003.html) [13] [Reproduced with permission from UNDOC.]

(1) Fragment of bract with pointed unicellular covering hairs and hairs with cystoliths of calcium carbonate.
(2) Fragment of epidermis with a broken cystolithic hair and twin crystals of calcium oxalate.
(3) Four resin-secreting hairs seen from the front: one is still swollen with resin, two are empty, and the fourth (beside 3) still has its cuticle.
(4) Fragment of pedicel of a secretory hair.
(5) Three secretory hairs: two pedicellate, one sessile: the oleoresin is swelling and dilating the cuticle.
(6) Fragment of upper epidermis of leafstalk with cystolithic hair.
(7) Two detached cystolithic hairs: one intact, the other broken.
(8) Fragment of lower epidermis of leaf or bract with two covering hairs and two reniform stomata.
(9) Fragment of fruit bract with a covering hair and two secretory hairs in different stages of development; two twin crystals of calcium oxalate in the parenchyma; stoma on left extremity.
(10) Fragment of lower epidermis of inflorescent bract: three reniform stomata, one young sessile secretory hair with cuticle (seen from the front).
(11) Two broken unicellular covering hairs; three small pieces of solidified resin.
(12) Fragment of floral peduncle with two spiral vessels and one pitted vessel; twin crystals of calcium oxalate and a group of three sclerified cells. On the right, broken spiral vessels such as are frequently found in the preparations.
(13) Isolated and twin crystals of calcium oxalate.
(14) A pedicellate secretory hair; the cuticle is broken and has released its oleoresin

Blue B salt test, the prepared samples are shaken with chloroform. A vivid red color in lower chloroform layer is obtained. For the Duquenois test, vanillin/acetaldehyde in ethanol is added to the extract followed by concentrated hydrochloride, which results in a purple color [11, 12].

The developing solution of xylene: *n*-hexane: diethylamine (25 : 10 : 1) is commonly used for the

separation of cannabinoids. Visualization is carried out by the Fast Blue B solution, which gives a red, orange, and purple spot to THC, CBD, and CBN for each.

The quantitative analysis of cannabis samples is carried out by GC/MS and the EI spectra is compared with spectra of authentic THC. Usually, the THC content is calculated and used for drug profiling (*see* **Drug Profiling**).

Amphetamine and Methamphetamine

Penalties are different among countries for possession, trafficking, and manufacturing of amphetamines. In the United States, the law imposes a 10-year sentence for trafficking in 50 g of methamphetamine and possessing 5 g with the intention of selling. However, more severe penalties are given in some other countries: a death sentence is demanded for manufacturing more than 50 and 20 g of methamphetamine in China and Thailand, respectively, and trafficking in over 250 g in Singapore, and possessing over 50 g in Malaysia.

When samples are submitted for testing, the total amount is recorded. In the case of powders, crystals, and tablets, they are pulverized into powder and two aliquots of about 10 mg of the powder are used for analysis. One is dissolved in water for a precipitation test and the other is dissolved in methanol for TLC and instrumental analysis.

In TLC, addition of Marquis reagent (formaldehyde solution – concentrated sulfuric acid) to powder or liquid gives a light brown color followed by deep brown and finally black. Simon's reagent (solution 1, 20% aqueous sodium carbonate solution; solution 2, 50% ethanolic acetaldehyde solution; solution 3, 1% aqueous sodium nitroprusside solution) gives a deep blue color for methamphetamine and other secondary amines and pink to red color for amphetamine and other primary amines.

When 10% tetrachloroauric acid reagent is added to the prepared aqueous solution, fine needlelike crystals are formed. To check for the presence of chloride, silver nitrate reagent is added, which gives a white curdy precipitate of AgCl.

In TLC methanol/concentrated ammonia (100 : 1.5) is used as the developing solvent [12]. Amphetamine shows pink or violet color and methamphetamine shows pinkish orange color when Ninhydrin reagent is sprayed. Acidified potassium iodoplatinate reagent gives dark violet color on a pink background. Cyclohexane/toluene/diethylamine (75 : 15 : 10), methylethylketone/dimethylformamide/concentrated ammonia/isopropanol (130 : 19 : 1 : 30), and chloroform/methanol (1 : 1) can also be used as the developing solution [14].

GC/MS is considered the method of choice for confirmation. More recently, CE has become a complementary analytical tool to classical GC and HPLC [15]. Increasing scientific attention is being directed toward identification of optical isomers. The optical isomer test can be used in profiling illicit methamphetamine seizures [16]. Amphetamine and methamphetamine have one asymmetric carbon in their molecular structure and these optical isomers have different pharmacological activities. Samples submitted for analysis are in the D-, L-, or DL-forms. CE or HPLC equipped chiral column are useful for separation of optical isomers. GC/MS can be used with nonchiral column after derivatization by chiral reagents such as (*S*)-(+)-α-methoxy-(trifluoromethyl)phenylacetyl chloride ((*S*)-(+)-MTPACl), *N*-(trifluoroacetyl) prolyl chloride (TFPCl), and α-methoxy-α-(trifluoromethyl)phenylacetic acid (MTPA).

Opium Alkaloids and Other Opiates

Some countries inflict a heavy punishment for possession, trafficking, and manufacturing of heroin and morphine; for example, a death sentence for manufacturing more than 20 g heroin in Thailand, trafficking in over 15 g heroin, 30 g morphine, 1.2 kg opium in Singapore, and possessing over 15 g morphine in Malaysia.

Positive identification of opium requires confirmation of the following main alkaloids of opium: morphine (10–20%), codeine (0.2–0.8%), thebaine (0.2–1.0%), papaverine(0.5–1.0%), and noscapine (0.75–10%).

After weighing the seizures, morphological and microscopic examinations are performed. For chemical analysis, in case of poppy plants, around one-fourth of a capsule is taken and extracted with methanol. Leaves are dried and then pulverized into fine pieces and about 50 mg of the pieces is sampled. In the case of raw opium, 10 mg of the specimen is taken and extracted with methanol for the screening and confirmation test. In order to identify heroin, about 10 mg of the sample is taken and dissolved in

methanol for the screening and confirmation test. Several extraction solvents can also be used: a mixture of methanol and ammonia water; methanol; diluted hydrochloric acid; diluted sulfuric acid, etc. The pH of the extraction solution is adjusted to 9.2 with 10% ammonium water [12].

Raw opium may be distinguished from other opium preparations by the presence of plant debris, meconic acid, and the trace alkaloids. The residue will contain poppy capsule fragments and occasionally pollen grain. The poppy capsule fragments are epidermis composed of five- to six-sided cells with strongly thickened walls and sometimes with stellate lumina: infrequent anomocytic stomata, approximately 17 μm long, or sometimes circular. Occasional subspherical pollen grains with three pores are also observed [17].

Marquis, Fröhde, and Mecke reagents for visualization and the resulting colors are compared with those obtained from the reference morphine alkaloid (Table 1). To identify the opium, meconic acid color test is also required.

The developing solvent for TLC is ethylacetate/methylalcohol/concentrated ammonia (85 : 10 : 5 v/v). Acidified potassium iodoplatinate solution is used as the spray reagent [12]. This method allows separation of opiates, such as 6-acetylmorphine (6-AM), heroin, and acetylcodeine [12].

GC/MS is a reliable, simple, and sensitive method but HPLC procedures are more often used for the determination of opiates than GC/MS. HPLC is the method of choice for the quantitative determination of morphine and related alkaloids [18, 19]. However, the run times are somewhat long. CE gives a superior separation of the alkaloids found in crude morphine, poppy straw, and opium preparations and provides a faster and less costly analysis with quantitative results than HPLC [20]. MECC provides an excellent separation of the highly complex mixture of neutral and acidic impurities present in heroin [8–9].

Cocaine

Each country has its own penalties for trafficking and possession of cocaine. In the United States, the possession with intent to sell 50 g of crack cocaine would draw a 10-year mandatory minimum sentence. Singapore imposes death penalty on anyone convicted of trafficking in more than 30 g of cocaine. After weighing the samples, the powders and crystals are pulverized into powders, of which about 10 mg is taken. Cocaine crystals and powder are dissolved in methanol for chemical analysis. In the case of coca leaves, 0.5 g of leaves is ground and sonicated in methanol, or alternatively, soaked in 0.1 N hydrochloric acid. The drug is extracted with chloroform. The chloroform layer is collected and dehydrated with anhydrous sodium sulfate [12]. Immersion of coca leaves in boiling ethanol for a short period and extraction with hot methanol results in effective extraction of ecgonine-type alkaloids and minimizes the breakdown of cocaine [21]. Cocaine tablets are ground and sonicated in methanol prior to analysis.

Cobalt thiocyanate test or the modified one (Scott test) that gives a blue color indicates the presence of cocaine. A quantity of 5% methanolic sodium or potassium hydroxide is added to the test sample and warmed. It gives a characteristic odor in the presence of cocaine [11, 21].

Cocaine is classified as crack cocaine (cocaine base) and cocaine HCl. They are weighed, dissolved in water and ethanol to observe the solubility, and treated with the silver nitrate solution for the chloride test, which gives a white curdy precipitate indicating the presence of chloride. The crack form of cocaine is a free base and soluble in hexane, while the hydrochloride form is insoluble [12].

Four TLC solvent systems are used to distinguish the opiate-like drug: chloroform/dioxane/ethyl acetate/ammonia (25 : 60 : 10 : 5), 0.81; methanol/

Table 1 Results of color test for opiates

Alkaloids	Marquis reagent	Fröhde reagent	Mecke reagent
Morphine	Purple violet	Purple becoming gray/purple	Dark green
Codeine	Purple violet	Blue/green	Green/blue
Heroin	Purple violet	Purple becoming gray/purple	Dark green
6-acetylmorphine	Purple violet	Yellow/green	Dark green
Papaverine	No color	Light green	Dark blue

ammonia (100 : 1.5), 0.59; cyclohexane/toluene/diethylamine (75 : 15 : 10), 0.56; and ethylacetate/methanol/concentrated ammonia (85 : 10 : 5), 0.7. Acidified potassium iodoplatinate and Dragendorff's reagent are applied as the color spray [12, 21].

GC/MS is preferred to identify cocaine with a high degree of sensitivity and selectivity [22]. The IR method is particularly useful for identifying illicit cocaine in crystal or powder form. Using IR spectrometry, cocaine base and cocaine hydrochloride can be differentiated [1, 23].

LSD (Lysergic Acid Diethylamide)

Punishment of drug offenders for LSD differs among different countries. For the possession of LSD in Canada, if tried by indictment, an offender gets a maximum penalty of $5000 and a three-year imprisonment. LSD-related samples such as LSD tainted paper and candies are shaken in tartaric acid for tests. The pH of the filtrate is adjusted to be 8–9 with 10% ammonia water and the solution is extracted with dichloromethane. Then, the extracts are dehydrated with anhydrous sodium sulfate [12]. After the dichloromethane is removed, the residue is finally dissolved in ethanol.

The presence of LSD is indicated by a blue fluorescence [11]. Then, a drop of Ehrlich reagent is added over the spot. A blue to purple color shows the presence of LSD [18, 22].

The melting point is measured with the dried sample. The melting point of the tartrate salt of LSD is 198–200 °C and that of free base of LSD is 80–85 °C [12].

The developing solvents used and the R_f values of LSD are as follows: chloroform/methanol (9 : 1), 0.5; methanol/concentrated ammonia (100 : 1.5), 0.8; chloroform/acetone (20 : 80), 0.6. Ehrlich reagent is used as the color spray [12, 24], displaying a blue-purple color with this reagent.

Selective extraction and derivatization by silylation of the indole nitrogen of LSD is necessary for GC/MS analysis. Alternatively, HPLC separation together with fluorescence detection is applied; however, it lacks sensitivity and specificity. Consequently, LC/MS/MS can be used as the method of choice for LSD determination [25]. LSD, lysergic acid methyl propyl amide (LAMPA), and iso-LSD are resolved in less than 5 min using CE [8–10].

Phenethylamines

Singaporean law imposes a maximum penalty of 10 years in jail and a $20 000 fine for possession and up to 20 years in jail for trafficking of ecstacy. Other countries have their own punishment for possession of ecstacy.

Phenethylamines include amphetamines and designer analogs such as methylenedioxymethamphetamine (MDMA), methylenedioxyamphetamine (MD A), methoxymethylenedioxyamphetamine (MMDA), methyldimethoxyamphetamine (DOM), dimethoxybromoamphetamine (DOB), dimethoxyethylamphetamine (DOET), dimethoxyamphetamine (DMA), paramethoxyamphetamine (PMA), and trimethoxyamphetamine (TMA).

After weighing the seizures, coarse particles or crystals if any are pulverized into powders and 10 mg of powder is sampled for the screening and confirmation test. Crystals and powders are usually weighed without drying; however, dried samples are used for the measurement of melting point and FTIR analysis. Tablets are ground to a fine powder and the sample solution is prepared with methanol without any pretreatment.

The most important color tests for phenethylamines are the Marquis and Simon's tests. The results of the major color tests are shown in Table 2 [26].

The TLC plate is developed with the two types of developing solvents (1) chloroform/acetone/methanol /concentrated ammonia (15 : 12 : 3 : 0.1) and (2) methanol/concentrated ammonia (100 : 1.5)). Simon's reagent and acidified potassium iodoplatinate reagent are used for identification [12].

Even though derivatization of phenethylamines is not mandatory, the selectivity and specificity of the mass spectra of phenethylamines are improved by silylated derivatization. In the GC/MS analysis, the order of elution for underivatized phenethylamines on DB-5 and DB-1 columns is as follows: PMA<MDA<DMA<MDMA<DOM< MMDA<DOET<TMA<DOB.

Indoleamines (Psilocybin and Psilocin)

After weighing the seizures, about 20 mg of the suspected psilocybe mushroom is ground to powder and extracted with methanol, while powders, tablets, and capsules of psilocybin are pulverized into powder and dissolved in methanol.

Table 2 The results of the major color tests for phenethylamines[a]

Color test	MDMA	MDA	MMDA	DOM	DOB	DOET	DMA	PMA	TMA
Marquis	Dark blue/black	Dark blue/black	Purple	Yellow	Yellow → green	Yellow brown	Green → dark green	NR → Light green	Orange
Simon's	Deep blue	NR	NR	NR	NR	NR	NR	NR	NR

[a] Reproduced with permission from Ref. 26. © UNDOC, 2006
(NR) – no reaction

Commonly two types of TLC developing solvents are used: Solvent 1 is methanol/28% aqueous ammonia (100 : 1.5) and solvent 2 is 1-butanol/acetic acid/water (2 : 1 : 1). Ehrlich reagent and *p*-dimethylaminocinnamaldehyde are used as spray reagents [27]. When Ehrlich reagent and *p*-dimethylaminocinnamaldehyde are sprayed, psilocybin gives gray-violet to violet color while psilocin gives blue color.

For GC/MS analysis, indoleamines are analyzed with or without derivatization. It should be noted that direct injection of psilocybe mushroom extracts or psilocybin sample solutions on capillary columns without derivatization will convert psilocybin to psilocin by thermal dephosphorylation and accordingly only psilocin is detected. For the derivatization, trimethylsilyation derivatization is commonly used. The quantitative analysis for psilocybin and psilocin are performed by HPLC or liquid chromatography electrospray ionization mass spectrometry (LC/ESI/MS).

Drug Profiling

Introduction

Illicit drug profiling is the process of extracting components called *profiles* from drug seizures. The term *drug* is used as a generic term to include all illicit products controlled under the UN conventions and protocols on narcotic and psychotropic drugs, and drug traffic [1–3].

These components of the profiles can vary. They can be chemical, such as residual solvents or impurities resulting from illicit drug synthesis, or physical such as the impression of a logo in tablets such as ecstasy tablets. The detection and the recording of these "profiles" result from different analytical methods. This provides data amenable to comparisons between different illicit drug seizures for detecting similarity or identity. The resulting information may be used as objective information useful to decrypt the drug trafficking organization and distribution pattern for law enforcement purposes (intelligence) or used in a more traditional manner as evidence in court for demonstrating that two seizures are composed of the same illicit products.

Heroin, cocaine, ATS, and cannabis constitute the main substances subject to organized trafficking and

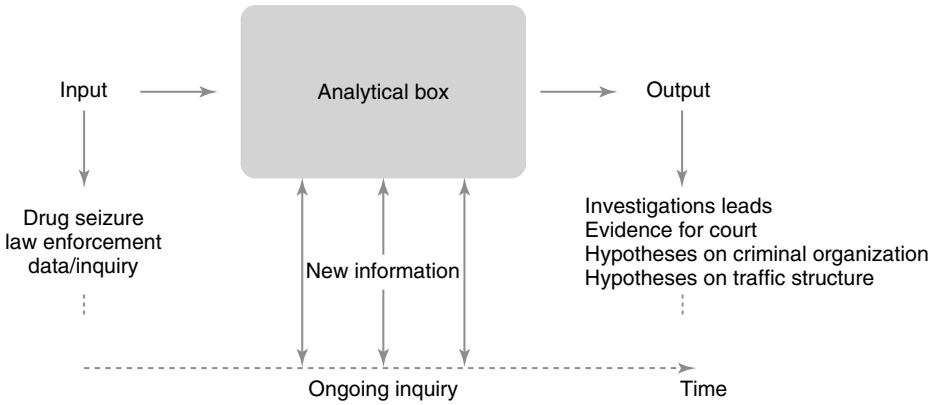

Figure 1 General concept of drug profiling process

are extensively used in the community. These illicit products are the focus of the debates both in the scientific literature and in the political arena. They also constitute what is perceived as a major health problem in most consumer countries. Therefore, from a profiling perspective, the focus is mainly on these four illicit substances.

The Drug Profiling Process

The drug profiling process is described in Figure 1.

The input starts with a drug seizure from a law enforcement activity and by gathering the circumstantial information available, i.e., the context in which the seizure occurred. The other source of information is obtained from the seizure itself, its analysis and interpretation. The combined information may be analyzed and interpreted within the analytical box (described hereafter) in order to extract pertinent outputs from this data. During this ongoing task, the inquiry remains active, may provide new information, or may use investigative leads obtained from the intelligence process as outlined in the analytical box. The output can come from various sources but, in any case, the aim is to extract useful information to pursue complex investigations, understand key elements of a criminal activity, make reasonable hypotheses on criminal organizations or on the structure of the drug trafficking and, finally, provide evidence for the court.

This analytical box is not a black box, but an organized analytical process to discover and understand phenomena of a complex nature (criminal activity, criminal organization, etc.). It uses an iterative approach that could be schematized as follows:

1. Tacit knowledge obtained from research – establishing analytical protocols [4], classifying discriminating factors [5], indicators from the chain of drug production [6], and transformation to the final product seized on the street [7], validating a database from past cases [8]. This is a key element in order to be able to extract knowledge from new cases.
2. The preliminary action for new cases consists in collecting pieces of information obtained from the drug trafficking that is known or perceived. This step is of major importance; indeed, without information, the intelligence process is stopped and cannot be achieved. These pieces of information consist of the drug seizure itself and all information (telephone call, informant data, bank transaction, etc.) gathered by different investigators.
3. Analytical data are obtained (i.e., extraction of profile for the drug seizure) and the results are organized in a database of relevant data (*see* **Cocaine**; **Opioids**; **Drug Analysis**).
4. Once this is completed, the interpretation process is initiated producing "forensic" intelligence (information extracted from the seizure profiles), which is combined to inquiry intelligence obtained from the investigative data [9]. The two sources of intelligence are combined to produce useful knowledge on drug trafficking both from an operational and a strategic perspective.

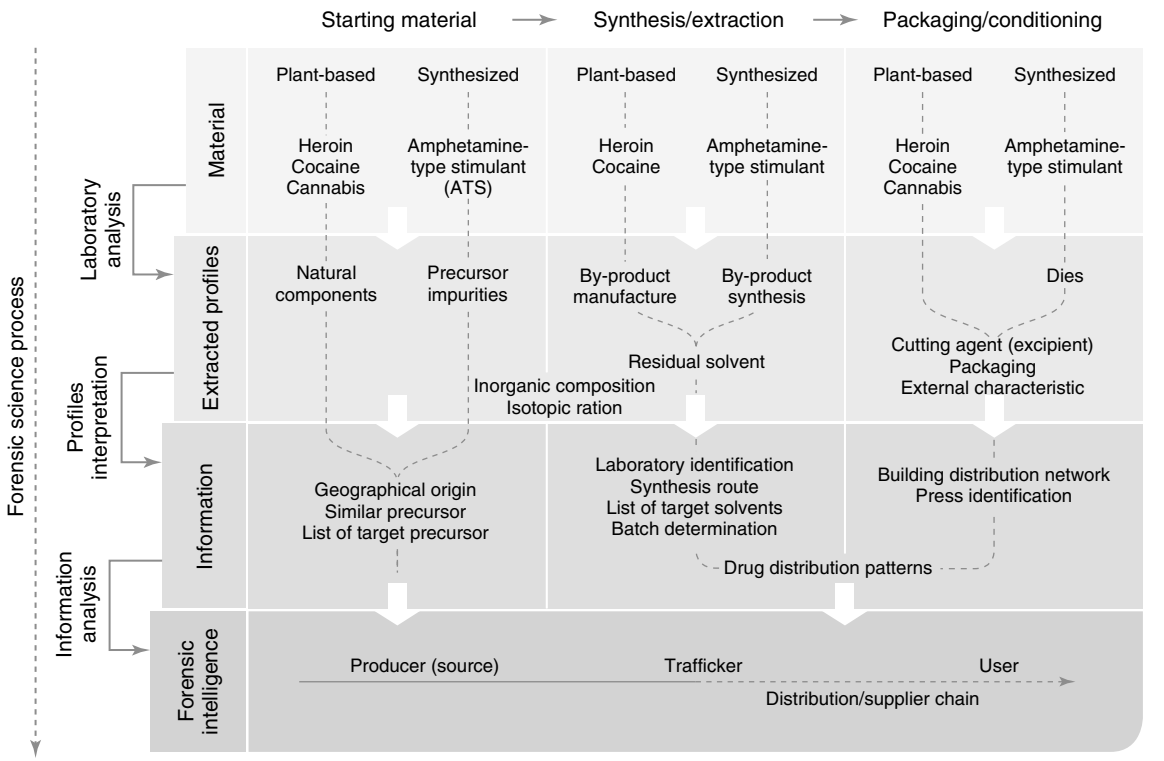

Figure 2 Forensic science processes

Within this framework of drug profiling, the focus is on the scientific process that allows the extraction of profiles from drug seizures. A major distinction concerns the nature of the starting material. If the raw material is "plant-based" (cocaine, heroin, and cannabis) or originates from synthetic precursors (ATS), the manufacturing process is drastically affected and influences the type of data that can be extracted from the seized products.

Figure 2 highlights the contribution of each production step to the chemical composition (the profile or "signature") of the final product. The raw materials such as coca leaf and opium, used for the production of cocaine and heroin, have a different composition depending on the geographical area and growing conditions, mainly because of climatic and soil differences (traces of origin). These differences could also be observed in the case of synthesized drugs if precursors are of natural origin, but the composition of the final product of the latter depends largely on the quality and the nature of the precursors. Therefore, the type of information may differ significantly and the localization of an origin is mostly unrealistic.

The extraction of the raw material and the syntheses that may follow in order to obtain the final product are crucial parts of the production process, strongly influencing the composition of the final product. Many variables such as the chemical recipes, the selected chemicals, the scale of the reaction, purification steps, etc., influence the diversity observed between production batches. Each of these variables has an impact on the formation and the proportion of so-called by-products found in the final product. The by-products are found both in the production of drugs of natural or synthetic origin. This is often referred to *traces of production* or incorrectly *production impurities*. Finally, the illicit substance is conditioned, packaged, split into batches for dealers active in the illicit market. This phase is also of major interest due to the addition of cutting agents and to the packaging characteristics that can provide additional information about the network of distribution and the dilution of the active ingredients

down to the consumer, at the end of the distribution process.

A classification of the information of this chemical/physical profile may have significantly different meanings depending for whom the forensic intelligence is intended. The first and often most sought after intelligence information takes a political dimension. It is focused on a national and international control of illicit products. This may play a significant role in geostrategic negotiations and interactions. The second type of information that is traditionally understood under the terminology "drug intelligence" is strategic and operational information about regional and local traffic structure and organization. This is mostly used for law enforcement purposes and local prevention or fight against drug-related criminality. The third, but nevertheless an important purpose is evidential. The demonstration of criminal activity, its extent, the participation in a traffic organization, and the relation to other criminals may offer sufficient strength for the court to decide on the most serious offense related to organized crime.

Support to National, International Policies (Regulatory Authorities)

Support to policy is a category of information centered on national, international, and geostrategic preoccupations. At this level, the priorities are oriented to identify or establish illicit drug distribution patterns or trafficking routes, to target the production (monitoring methods used for clandestine manufactures and location of the production), and identify the source of precursors. In order to support the authorities in their strategic choice, drug profiling research has developed dedicated methodologies. The identification of a geographical source of production is a perfect example of drug profiling research that has been directed to supporting policy initiatives.

Each manufacturing step contributes to the final chemical/physical profiles of the illicit products as demonstrated in Figure 2. In the case of plant-based materials, the natural components present in raw material have been used to determine their geographical origin. Indeed, within a region, the climatic conditions influence the proportion of natural compounds typical of the origin or source of the initial product. Furthermore, the clandestine manufacture process could also be specific of a location, producing a correlated combination of by-product compounds [10].

The determination of geographical origin necessitates extensive knowledge of localized variations through the maintenance of a database of specimens from known geographical sources. This could be done by having specimens seized directly in the production zone and in illicit laboratories. However, the maintenance of such an up-to-date database is problematic due to the difficulties of obtaining reliable specimens of known and authentic origin. Other complications arise from the fact that the growing conditions could evolve, as well as the manufacturing process inside a given region. These modifications influence the pattern of natural and by-product compounds present in an illicit drug seizure. In order to make a pertinent prognosis of the geographical source of an analyzed sample, these modifications have to be included in the database; otherwise the quality of the results may quickly become useless.

For heroin samples, the opium, the raw material, is extracted from the opium poppy, *Papaver somniferum*. The major component of opium is morphine, an alkaloid (basic natural chemical compound with a nitrogen atom in the molecule that may react with an acid to make a salt), that is transformed by acetylation into diacetylmorphine, also known as *heroin*. During the extraction of morphine from opium and its transformation into heroin, other alkaloids are also coextracted and acetylated (if they have a reactive group). Papaverine, noscapine, acetylthebaol, acetylcodeine, and 6-acetylmorphine are such compounds present in relatively high proportions and are a reflection of proportions found in a given geographical source.

The literature refers to major alkaloids that are mostly analyzed using gas or liquid chromatographic methods. The combination of the ratios of these alkaloids allows a classification of drug seizures into four different general regions of origin. Those regions are widely defined as Southwest Asia, Southeast Asia, Mexico, and South America [11, 12].

In the specific geographical location of heroin seizures, by-products of the manufacture are analyzed in addition to the usual compounds present in the material in order to determine the source of production. The strategy of combining multiple types

of profiles is often promoted to elicit more refined information.

Geographical origin determination has also been thoroughly studied for cocaine seizures. The composition of *Erythroxylum coca v. coca* whose leaves contain the cocaine alkaloid is also influenced by climatic and environmental conditions. During the extraction of cocaine, other alkaloids present in the leaves are coextracted. Ecgonine methyl ester, norcocaine, *trans*-cinnamoylcocaine, *cis*-cinnamoylcocaine, benzoylecgonine, and trimethoxycocaine are all alkaloids present in relatively high proportions in seizures of cocaine and are used in conjunction with other minor impurities to predict a geographical origin. Owing to the selectivity, high sensitivity, and reproducibility of gas chromatographic techniques, these methods are the methods of choice for the analysis of these components that are often present in low concentration in the matrix of cocaine samples [13, 14].

It must be noted that geographical source determination is a difficult task due to the underground and illicit nature of the products and the lack of true source references. Most studies use investigative information to locate probable locations but confidence levels can rarely be defined accurately.

The determination or an inference of geographical origin for synthetic drugs is not possible, since precursors and the synthetic methods used are not specific to a region. Samples having a similar chemical profile can only be related to an individual laboratory. However, such a laboratory could be located anywhere and the information has to be used differently to products obtained from natural sources. The chemical profile of an ATS sample shows impurities obtained from precursors (which may also have impurities if they are manufactured clandestinely) and from the synthetic pathways used [15, 16]. Theoretically, it is possible to determine if two seizures have originated from the same precursor and/or if they have been synthesized according to the same synthesis route by monitoring this set of impurities. This information plays a major role in helping to detect modifications in the precursors or chemicals used (according to the synthetic pathway), thus allowing a more efficient international perception of the synthetic methodology and setup needed for production. This can help in targeting production and decreasing the diversion of synthetic drug precursors.

Again, it is important to emphasize that the interpretation of the data in order to determine if the precursors come from the same clandestine source or synthetic route is difficult and must rely on an up-to-date database of so-called authentic specimen representative of the interpretation that is pursued.

Other constituents of heroin, cocaine, and ATS matrices have also been used for geotracing. Recently published methods claim successful classification of source using isotopic abundance of ^{13}C and ^{15}N. Isotopes are atoms whose nuclei contain the same number of protons, but a different number of neutrons. The exposing number placed before the chemical symbol of the element indicates the isotope, which is equal to the number of nucleons (neutrons plus protons). For example, carbon has three natural isotopes which are noted: ^{12}C, ^{13}C, ^{14}C. The isotopes ^{12}C and ^{13}C are stables, whereas the isotope ^{14}C is unstable (radioactive). On earth, the quantity of atoms of each isotope is constant. Only the distribution of the atoms within the molecules is variable and depends on the process of isotopic fractionation. The isotope ratios of compounds can be modified by a phenomenon of discrimination of mass due to biological, chemical, and physical processes. Thus, isotope ratios of an element depend on its origin and its history.

This methodology has been successfully applied to locate seized cocaine in four different regions of Colombia, Bolivia, and Peru. Isotopic ratios have also been used successfully for classifying cannabis and heroin samples [5].

Drug profiling analyses also offer the possibility to map the solvents used during the manufacturing process. Local changes in regulations may be witnessed in the illicit productions. This aspect has been studied for heroin, cocaine [17, 18], and ATS [19]. Such data may be a crucial source of information for detecting new trends in the chemicals employed and may offer the possibility to inform the concerned authorities about these evolutions.

Support to Law Enforcement Investigation

Drug profiling is an important tool for investigative purposes. The analytical results are collected through a systematic process in which each new sample analyzed is compared with existing entries of an organized memory built upon earlier cases stored in a dedicated database.

The intelligence supplied by the information extracted from the data, using previously described analytical methods, can be used operationally to try to decipher and understand the structure of the drug market. It also has the potential to detect new phenomena or new trends in the illicit drug network distribution.

The links highlighted between seizures can be directly included in the enquiry in the same way that other information collected by law enforcement agencies are being used. The chemical/physical link is not directly meant for evidential purpose but rather to help formulate reasonable and useful investigative orientations; the interpretation is not limited in determining whether the seized specimens have exactly the same history. The correspondence between two profiles is considered in a wide range of interpretations and has to be combined with investigative data. It is a piece of intelligence in the course of the inquiry.

The applications may range from a confirmation of a hypothesis of connection inferred by law enforcement officers on the basis of inquiry information or the diversion of the investigation in other, unsuspected, directions [20] or may even lead to completely new investigative hypotheses. This analysis is only possible if an extensive database recording previous cases exists and the methodology for extracting potential links has been dedicated to such a purpose. The extraction and management of such information further requires the development of a specific management structure developed through research. This management aspect includes an important inference mathematical tool regarding the grouping of similar samples into chemical/physical classes. This clustering step utilizes supervised (where previous knowledge on the distribution inside the chemical/physical classes of the samples stored in the database is needed) and nonsupervised statistical measurements. The utilization of supervised methods like the soft independent modeling of class analogy (SIMCA) or artificial neural network (ANN) type are elegant tools for assigning new analyzed samples into preexisting classes.

Different authors have investigated these kinds of methods and demonstrated their potential value [21, 22]. It needs initially the creation of a mathematical model for each class. This model is used as a reference to determine if a new candidate belongs to an existing chemical/physical class. The calculation of the model utilizes statistical fundaments regarding the determination of thresholds for evaluating whether seized specimens belong to a same batch. This threshold is set by the scientist according to the needs of the investigation. The initial hypothesis usually states that it is possible to evaluate the intra-variability of a batch of production by analyzing large seizures and, by analyzing many unrelated seizures, it is possible to determine inter-variability arising from different productions. The models could also be trained according to different hypotheses such as the determination of a geographical origin or the assignment of a synthetic route. The requirements for the training of these models are the availability of sufficient samples representative of the different classes to which the new analyzed specimens potentially belong.

It is crucial that this information is given in timely fashion to the law enforcement agencies. Indeed, if the information provided by the profiling process is not timely, or does not reach potential users, there is no reason to maintain a database and to develop a complex architecture of pattern recognition. Furthermore, it is necessary to demonstrate how useful this information can be, despite the complexity. Spectacular successes of utilization of links in a law enforcement context have shown the potentially rich dividends that can be gained using drug intelligence information. This has to be presented to convince users because it is complex and may not be directly intuitive. Diverse attempts have been done by different authors [20].

If the information gathered by chemical/physical links is not correctly integrated and understood by investigative officers the information may be used erroneously and will discredit the whole profiling process.

One major difficulty is the lack of centralized analyses due to jurisdiction boundaries that slows down the utilization of chemical links. Indeed, it is not easy to understand that a profile extracted in a laboratory is not directly comparable with a profile highlighted in another one for an end user of the information. The problem is complex because the harmonization of analytical methods in order to obtain comparable results is not an easy challenge. It would be preferable to have one single laboratory centralizing both analyses and drug intelligence routine, but this is often organizationally impossible to set up. Indeed, it is not sufficient to

apply a kit in order to obtain compatible data. The principal problem encountered is the reproducibility of the data between different partners [23]. Nevertheless, recent research has shown that harmonization of methods is not a utopia using new generation analytical instruments and could be realized under a strict control of the analytical conditions. Such an approach is actually promoted through different European and international research projects and constitutes the basic foundation for developing a common utilization of drug profiling data in an intelligence-led perspective. Ideally, internationally collected databases could have an important impact for intensifying the utilization of profiling information by law enforcement agencies on a regional or international level.

Evidence for the Court

Using drug intelligence in the investigation of drug trafficking will often lead to arrests and further seizures of substantial amounts of illicit material that is evidence in itself of criminal activities. The result of linkage is therefore rarely, if at all, needed for court purposes. But when handling specific cases, one typical question that arises from prosecutors or law enforcement officers is whether it is possible to establish a specific link between two illicit drug seizures and then linking the two persons in possession of these illicit substances in the same way. This comparison of specimens originating from selected cases, also called *case to case comparison* is at the present time privileged in the different laboratories active in drug profiling. The aim is to demonstrate that the selected samples have a common history [4]. If this hypothesis can be verified, then there is evidence of trafficking or distributing linkage. However, in order to use this data for evidentiary purposes, it is advised that the information coming from different analytical techniques is combined. For example, many authors advocate the combination of the analysis of major alkaloids compounds for the comparison of two heroin samples; followed by the analysis of minor alkaloids [24] (trace-level acidic and neutral impurities), occluded solvents, isotopic analysis [5], elemental analysis [25], as well as cutting agents [7] present in the sample. In an ideal linkage, the chemical signature of the specimens should correspond. The two compared samples share apparently an identical history from their geographical origin and manufacturing processes to the distribution network (*see* **Evidence Interpretation: a Logical Approach**; **Statistical Evidence in Court**) .

For this type of analysis and opposed to geographical determination it is not necessary to maintain a database since the samples are already preselected. In contrast, the interpretation of the results of the comparison require a complete background knowledge about the process of illicit drug manufacturing allowing experts to interpret differences and similarities observed between the "chemical signatures" of the compared samples.

The case where the features are identical is a theoretical concept and is never encountered in reality. Indeed, even in a same batch of production of heroin or cocaine there is some variation due to the nonhomogeneity of the specimen (intra-batch variation). The inter-batch variation (variation between production batch in a single laboratory) has also to be evaluated. Unfortunately, there is not a lot of information available regarding the variation of chemical profiles between different batches for a same laboratory and also the size of a batch. However, the chemical profile being highly dependant of the manufacturing method, any modification will affect the profile of the illicit drugs [6]. This is supported by evidence that the manufacturing conditions of the laboratories in Afghanistan or in Colombia are rather crafty. Also, any manipulation from the original batch chemistry will create a difference (two different dealers diluting specimens in a different way) that will be increasingly difficult to interpret without some background knowledge.

However, the notion of batch variation is more defined in the domain of ATS. Several illicit laboratories have been dismantled in Europe and important batches of production have been sequestered. This opportunity has permitted laboratories to determine that the intra-batch variation is rather small. This is mainly due to the manufacturing conditions that are more controlled with the synthesized illicit products than with plant-based drugs [4].

Furthermore, the analytical process itself introduces differences between analyses of the same specimen (this is an indication of the reproducibility or relative error of the analytical method). The role of the expert is to interpret these differences in order to conclude if the specimens came from

the same batch or not. The scientific literature contains descriptions of methodologies developed for interpreting the results. They range from visual comparisons of chromatograms to the use of advanced multivariate analysis like ANNs. Multivariate analysis is necessary for conducting these calculations since the results of illicit drug analysis are described by many variables (multivariate data). Multivariate analyses consider these variables in the form of a matrix allowing the possibility of performing complex calculations. More information is available in [26].

An attempt to determine the intra-batch variation consists in studying the homogeneity of specimens within a same seizure or, if available, coming from the same batch (for example, if one clandestine laboratory has been dismantled and batches prepared for distribution can be analyzed) and evaluate the homogeneity of the specimens. This evaluation, based generally on statistical measurements such as correlation or distance measurements [27], could be used to determine a threshold value below which it cannot be concluded that a given specimen came from a specific batch.

This threshold is set high in order to avoid false positives and to have a high level of confidence regarding the highlighted correspondence. The evaluation of any such link should be combined with other sources of information like that obtained from studying the packaging and the cutting agents [28].

Finally, when two observed profiles correspond, there is a need to determine whether the methodology was discriminating and whether the highlighted features are common or rare. This is of major importance for interpreting corresponding profiles. For example, the strength of evidence of two corresponding profiles of cutting agents will be quite different if the profiles contain only lactose or if it shows a complex and rare mixture of five different types of sugar. Cutting agent could be of two different types. The diluents (sugars, starch, ...), who have no pharmacologic effects, are substances added to the illicit drug in order to increase the mass and, by the way, the profit. In contrary adulterants (lidocaine, phenacetin, ...) have pharmacologic effects and are added both for increasing the mass and also modifying the effects of the consumption of illicit drugs.

Various methods of comparison and decision theories have been developed in the literature to determine whether two specimens come from the same batch of fabrication. A continuous approach based on likelihood ratios can be used combined with a statistical method based on thresholds [29]. This is an efficient tool for the scientists to measure the strength of the scientific evidence in forging his opinion.

Conclusions

Profiling consist in the extraction of illicit drugs signatures. These signatures are dependant of various features like the nature of the starting material, the manufacturing process and chemicals used. As presented in this article, the profiles extracted from the analysis could provide relevant information about the nature and the structure of illicit drug trafficking and solid investigative leads and reliable evidence in a recognized area of organized crime. This information is addressed at different level. Differentiation has been done between information oriented to support national, international policies (determination of geographical origin, determination of synthesis routes), law enforcement investigation and evidence for the court.

This approach, combine with a close cooperation with law enforcement agencies, has already demonstrated is potentiality to be an efficient an objective tool in the fight against illicit drugs trafficking.

Drug Testing: Urine

Introduction

Urine testing has become the most frequently performed type of analysis in forensic toxicology, perhaps with the exception of alcohol. To standardize the testing and to provide a legally defensible procedure, a number of counties have issued standards and guidelines. These include the United States (through SAMSHA), the United Kingdom, and Australia.

Guidelines concentrate on a number of drug/drug classes including amphetamines, opiates, cannabis, cocaine, and benzodiazepines. In the United States, PCP is also included. Occasionally other drugs are tested, including barbiturates, methadone, buprenorphine, etc.

Basis of Drug Testing in Urine

Urine drugs-of-abuse testing is used essentially for two specific purposes: compliance and safety. The compliance environment would typically be correctional (custodial and community) as well as alternatives to custodial sentencing such as drug courts. In this environment, the requirement is for the individual to remain drug free and drug testing is undertaken to ensure compliance with that requirement. In the workplace environment, the emphasis is on safety and risk management. Companies undertake drug testing to reduce the risks associated with the use of impairing drugs in the workplace. This is achieved by identifying individuals whose lifestyle choices may lead them to use drugs in the workplace and possibly seriously endanger themselves and other individuals. This testing may include preemployment screening. Workplace testing definitely stresses the deterrence value of testing as well as the rehabilitative processes associated with the identification of these individuals.

Why Do We Test Urine?

Urine is a high-volume specimen, which is easily obtainable by a medically noninvasive process. Under normal conditions, it is sterile and contains high concentrations of water-soluble metabolites, which are markers for drug use. From an analytical point of view, urine is a good matrix for the laboratory to work with and given the high concentrations, sensitive sophisticated screening techniques are not generally required.

The body acts to remove drugs predominately by either biliary or urinary excretion aided in the majority of cases by metabolism. In the case of drugs, metabolism refers to chemical modification of the drug molecule mainly occurring in the liver producing a drug metabolite, which is less toxic and more water soluble. The increased water solubility aids excretion by the kidneys.

The kidneys filter blood to produce an initial filtrate rich in low-molecular-weight substances such as drug metabolites in large volumes of water. Selective reabsorption of water and essential substances such as glucose by transportation to the blood then occurs. The ability of other substances to reenter the blood stream without assistance depends upon their ability to penetrate the membrane surrounding the blood capillaries. This process is called *passive diffusion*. Fat-soluble substances such as parent drugs diffuse at much higher rates than water-soluble metabolites, with the consequence that water-soluble drug metabolites are lost to the urine and very little parent drug reaches the urine.

The kidneys also have a concentrating effect on the water-soluble metabolites. The initial filtrate is formed in an adult at 125 ml min^{-1} while urine under normal hydration conditions is formed at 1 ml min^{-1}, meaning that over 99% of the water has been reabsorbed. The metabolites that were previously in approximately 100 ml of blood are now in 1 ml of urine. Their concentration is therefore typically 100-fold higher than blood.

Collection of Urine

Testing consists of several steps: the collection of the urine specimen, dispatch to the laboratory, and laboratory analysis. Once the donor's identity has been established, the donor proceeds to provide a urine specimen under conditions of privacy; however, witnessed collections are possible in custodial or court-directed situations. While the specimen is being provided, the collector prepares the paperwork, i.e., a declaration of the donor's ownership of the specimen, consent for analysis, and chain of custody. The collector then establishes the validity of the sample (see the sections "Substitution" and "Adulteration"). Once this has been accomplished, the collector may

carry out an on-site drug test and/or an adulteration test or prepare the sample for dispatch directly to the laboratory.

If laboratory analysis is required, the specimen is usually split into two equal specimens, one of which is designated the referee specimen. Both are labeled with two unique identifiers neither of which should ideally include the name of the donor. The containers are then sealed with tamper evident tape, which is dated and initialed. The donor is required to sign the paperwork, which is marked with an identifier common to the specimens by the collector. At the time of signing, the donor is made aware of the drug/drug classes to which he/she is consenting for analysis. The specimen containers are placed in a transportation container along with their unique paperwork and dispatched to the laboratory in accord with any relevant regulations or legislation.

How is Laboratory Testing Carried Out?

The first step in the laboratory process is to inspect the specimens and accompanying paperwork for tampering and inconsistencies before completing the chain of custody section and finally entering the data for the specimens into the laboratory's tracking and registration system.

Laboratory testing is a two-step process, an initial screening test (*see* **Toxicology: Initial Testing**) followed in the case of a positive screen by a confirmatory test. The screening test is invariably an immunoassay and the confirmatory test is some form of chromatography (gas or liquid) coupled with mass spectrometry (MS) – *see also* **Confirmation Testing: Toxicology**.

Immunoassays

A drug immunoassay depends upon the interaction between an antibody raised against a specific drug/metabolite and the drug/metabolite itself. An antibody can be thought of as a molecule in an animal's blood, which seeks out a specific foreign substance and locks onto it with the purpose of disabling its action. This process is part of the normal immune response of animals. In this case, the antibody locks or binds to the drug/metabolite to which the antibody was made (raised). This is similar in concept to a lock (the antibody) and its key (the drug/metabolite). Binding of drug/metabolite is detected in various ways that may involve enzymes linked to a color reaction, radioactive atoms, gold colloidal particles, or fluorescent molecules. The response depends upon how much binding occurs.

In urine drugs-of-abuse testing cutoffs are normally applied. A cutoff is the concentration of drug/metabolite at or above which the specimen is considered to be positive for that drug/drug class. Cutoffs are set for various reasons: (i) to ensure uniformity of analytical performance between laboratories, (ii) to detect a certain population of drug users, and (iii) to exclude courtroom defenses such as passive smoking.

A lower cutoff will mean a longer detection time and cutoffs are usually set to detect a certain proportion of users within that population. Separate cutoff tables exist in standards/guidelines for both screening and confirmation. As an example, the screening cutoff concentrations for three guidelines/standards are listed in Table 1:

The response of the immunoassay varies with concentration of drug/metabolite; hence, the assay (or instrument) is set to record the presence of drug/metabolite above the response expected for the cutoff (calibrating the instrument).

Immunoassays provide a fast, cheap analysis and can rapidly eliminate the negative samples from the presumed positive samples. They can, with reasonable accuracy, identify samples within a group, which require a more probing analysis by a technique

Table 1 Screening cutoff concentrations ($ng\,ml^{-1}$)

	United States	Australia / New Zealand	United Kingdom
Amphetamines	1000	300	300
Benzodiazepines	N/A	200	200
Cannabis metabolites	50	50	50
Cocaine metabolites	300	300	300
Opiates	2000	300	300
Phencyclidine (PCP)	25	N/A	25

that is more accurate i.e., MS (see below). However, immunoassays are not entirely accurate when it comes to determining concentration (lack of sensitivity) and sometimes other closely, structurally related compounds can cause interference. This is called *cross-reactivity* and the best example would be codeine producing positive immunoassays for antibodies raised to morphine. This problem of immunoassays is called *specificity* and can cause potential misidentifications where drugs that can be obtained "over the counter" can be confused with illicit drugs. The lack of sensitivity and specificity in immunoassays also leads to false positives and false negatives.

A false positive occurs when the immunoassay produced a positive result, but the confirmation step found the sample to be negative. The failure to confirm does not mean necessarily that there was no drug/metabolite present in the sample as it may simply mean that the drug/metabolite concentration was below the cutoff (a sensitivity problem) or there is a cross-reacting substance present (a specificity problem). A false negative occurs when the immunoassay produces a negative result, but had it gone to the confirmation step, it would have been positive.

Mass Spectral Analysis (MS)

The ability to detect, identify, and determine the concentration of a drug/metabolite in a specimen by MS consists of several steps:

1. the extraction of the substance from the specimen by the use of a solvent and preparation, if necessary, of the extract for chromatography;
2. the chromatographic separation itself; and
3. the detection by MS after the separation.

Chromatography is a separation technique that uses the molecule's physiochemical properties as the basis of separation with a liquid or solid matrix in a column. Under a given set of conditions, the time to detection (retention time) is characteristic of the molecule. The MS is set to detect ions derived from the analytes. Often, the MS is only monitoring three major ions from the analyte.

The most commonly encountered ion is nominally given an abundance of 100% and all other ions are given percentages to this base ion. The MS, therefore, detects ions with definite mass-to-charge ratios and which have a definite relationship to one another in regard to how commonly they are encountered (their abundances).

MS not only unequivocally identifies the substances present but also calculates the concentration of a specific molecule or molecules of interest in the specimen (quantitation). This is achieved by preparing a number of standards of known concentration, which are measured in the same way as the unknown specimen. A calibration curve is produced and the response obtained from the specimen is used to calculate the concentration of the specimen from this response curve.

For example, if a specimen comes to the laboratory and is tested by an immunoassay for various classes of drugs and returns a positive test to the amphetamine class assay, this specimen is then subjected to confirmatory analysis for one or more of the amphetamine drugs such as amphetamine, methylamphetamine, or methylenedioxymethylamphetamine (MDMA, Ecstasy). The laboratory may only target these three amphetamines or include a number of other amphetamines known to be used in the jurisdiction. The MS is set up to monitor at least three ions for each drug. In this mode, the MS is said to be working in selected ion monitoring mode (SIM). On analysis, the ions monitored for each drug must be coincident and have the correct relative abundances and the expected retention time. The data from the standards allows the production of response curves for the separate drugs and using the data from the specimen, the computer can calculate the concentrations of any drugs found to be present. *See also* **Confirmation Testing: Toxicology**.

If, for example, methylamphetamine and its metabolite amphetamine are detected, they are only reported if their concentrations exceed the confirmatory cutoffs applied to these substances.

Defeating the Process

The main methods used to defeat or obfuscate the testing procedure can be divided into substitution and adulteration of the specimen and occur at the point of collection.

Substitution

The term is self-explanatory and is the substitution of the donor's specimen by the urine of another

person, nonhuman urine, a liquid that appears to be urine or the direct addition of water to a specimen. The main defense against substitution is temperature measurement. Provided the specimen's temperature is measured within 4 min, the measured temperature of a freshly voided urine specimen is between 33 and 38 °C or 90 and 100 °F [1]. All guidelines/standards require temperature measurement (a process called *validity testing*) and should the temperature fall outside the permitted range, a second specimen can be required of the donor. It is possible under freezing conditions for temperatures to fall below the lower limit; however, this has more to do with the temperature in the collection center and ensuring that the specimen container is not at a low temperature.

Most people who attempt substitution carry the urine in a container, usually a condom, strapped to their body; however, the heat transfer using this arrangement is usually not sufficient to ensure that the required temperature range is reached. There are, however, more extreme ways of obtaining the correct range such as women who carry the condom internally (in correctional environments) or sports people who self-catheterize with another person's urine. Commercial products on the internet include a container, which can be filled with urine and which uses a battery-operated heating unit controlled by a thermostat. Freeze-dried and certified drug-free urine can be purchased on the internet for the purpose of substitution.

Animal urine or liquids that look like urine can also be used. Temperature is again the primary check that can be done; however, particularly, in the case where the specimen is not urine, it is possible to carry out an on-site creatinine test (see the section "Substitution"), which may help assess the validity of the urine specimen.

Adulteration

Adulteration can be divided into two forms: (i) substances that when ingested can alter the concentration of drugs in the urine and (ii) substances directly added to a urine specimen in order to compromise the analysis of the specimen for drugs.

Water Loading. The most common attempt at adulteration is the deliberate ingestion of large volumes of water called *water loading* with the purpose of diluting the drugs/metabolites in the urine to a point where the concentration falls below the cutoff level and, consequently, cannot be detected. If a person were to ingest a liter of water within a short period of time, their average rate of production of urine would increase from approximately 1 to about 8 ml min^{-1}, which has the effect that the drugs/metabolites previously found in 1 ml are now in 8 ml (an eightfold dilution). The restoration of a normal rate of production of urine could take up to 3 h [2]. Drinking larger volumes of water will have even more effect; however, the process is self-limiting as one cannot exceed the theoretical excretion capacity of the kidneys (approximately 20 ml min^{-1}). The ingestion of large volumes of water can be life threatening (water intoxication), but the vast majority of individuals will become violently ill before this level is reached.

Water loading can be quite successful; however, this depends on the concentration of drug/metabolite in the urine before water loading occurred and this will depend on the amount of drug ingested, how long drug elimination has been occurring, and the type of drug involved. The practice is likely to be more successful with cannabis than with other common drugs of abuse, since the concentration ranges found in cannabis are narrower than with the other drugs and, therefore, the probability of forcing the concentration below the cutoff is greater.

The most obvious method of detecting water loading is the lack of color. While vitamin B tablets can impart some color to the urine, the measurement of creatinine concentration in the urine is an easy and objective method. Creatinine is a natural product present in all mammalian urine as a product of muscle metabolism and the excretion rate of creatinine is dependent upon muscle mass, age, exercise, and diet. A creatinine concentration below 200 mg L^{-1} is associated with possible dilution, while a concentration below 50 mg L^{-1} is not considered to be human urine. There are some difficulties, however, with the 200-mg L^{-1} limit, as certain diseases, e.g., diabetes insipidus will produce low creatinine concentrations and women, particularly of small stature, can have low creatinine levels without having what is considered an abnormal creatinine level. This occurs since women have lower muscle masses than men and people of small stature will have a lower muscle mass. Creatinine levels can be measured accurately in the laboratory or, in a less-accurate fashion, by doing an on-site adulteration screen [3]. If a collector suspects water loading, a second sample can be requested.

Ingestion of an Alkalizing Agent. Sodium bicarbonate or baking soda is commonly ingested by amphetamine users to elude detection of amphetamines in their urine. Most drugs are either weak acids or weak bases and can exist in two forms, either an electrically charged water-soluble form or an electrically neutral fat-soluble form. The form that predominates at any time depends on the pH (the degree of acidity or alkalinity) of the environment they find themselves in. By ingesting sodium bicarbonate, the user raises the pH of their urine (makes it alkaline) and this favors the electrically neutral form allowing the amphetamine to reenter the blood stream by passive diffusion (see earlier) with the consequence of a much lower amphetamine concentration in the urine [4]. There are two advantages for the user: (i) to drive the concentration below the cutoff and escape detection and (ii) to prolong the action of the drug by producing higher circulating concentrations in the blood for longer periods of time. This practice is not without danger as excessive ingestion of bicarbonate can lead to life-threatening metabolic alkalosis.

Unfortunately, pH manipulation is difficult to prove as sodium bicarbonate, even if it was to fully saturate all body cells, would only raise the pH to 8.2 or slightly above the normally accepted upper pH value of urine of 8.0. Amphetamine users need to be tested carefully as they will sometimes display a positive in a group of negative tests and such a positive may be the result of not enough bicarbonate to adequately cause the concentration to drop below the cutoff. Other common drugs of abuse form highly water-soluble metabolites and are little affected by changes in pH.

Substances Added to Urine. These substances can be further subdivided into (i) household items and (ii) commercial products, available for the express purpose of defeating a drug test.

The most commonly used household substance is bleach, the purpose of which is to chemically react with drug/metabolite and change it to a substance, which cannot be detected by the analytical procedures used [5]. Bleach does this very successfully by oxidation, which is the mode of action of many of the commercial adulteration products. Owing to its smell, bleach, either liquid or solid, is usually detected. Hydrogen peroxide is also used as an oxidant but, in household strength, appears to be less than successful.

Acids or bases are sometimes used to prevent the immunoassays working, but they can easily be detected by a pH test. Detergents and liquid soaps can be detected by cloudiness or by swirling the specimen and looking for the appearance of rainbow-colored bubbles. There is a great deal of folklore involved in this area and many products have been used including iodine, eye drops, salt, detergent, and drain cleaners with varying degrees of success [6, 7].

The first point that needs to be made regarding commercial products is that the processes are almost all directed at the prevention of detection of cannabis. The first commercial products to appear were based upon household-type adulterants and included detergents and so-called herbal diuretics. Interestingly, the herbal diuretics can include vitamin B preparations and a substance called *creatine*, a body-building supplement. Owing to the close structural similarity between creatine and creatinine, and since some creatine will be transformed to creatinine, it has been added to these preparations with the belief that it will falsely elevate the creatinine level. In fact, its contribution to the creatinine level is relatively low.

The substances that follow are all added directly to the urine and are not ingested.

Glutaraldehyde, a disinfectant, was another early favorite, which is capable of irreversibly binding the enzyme used in the laboratory immunoassay, making the assay incapable of detecting the presence of a drug/metabolite. Fortunately, laboratory immunoassay instruments return an abnormally low rate of change of absorbance, which will be flagged as an invalid result [8]. Glutaraldehyde can be detected by using a "keto" stick or an on-site adulteration test; however, the test is not specific and detects substances called *ketone bodies* in the urine. Ketone bodies are present in individuals who are undiagnosed diabetics, diabetics who are not under proper control, and people who are fasting or on high-protein diets.

Inorganic nitrites such as potassium nitrite have also been used. Nitrite and all the following adulterants have one thing in common in that they are all oxidants i.e., they chemically react with the drug/metabolite to form a new substance, which is not detected by the immunoassay or the MS. The chemical reaction induced by the addition of nitrite proceeds quickly only in acid conditions; hence, it is entirely conceivable that an immunoassay will still be positive when the specimen reaches the laboratory. The interesting part occurs when the sample

is sent for confirmation in that, during the sample preparation stages, the reaction rate speeds up destroying the metabolite, usually a cannabis metabolite, which is being searched. Again, fortunately, laboratory scientists add a set amount of a substance, which is structurally similar to the metabolite being measured so that the solvent extractions for samples and standards are independent of the extraction efficiency. This added chemical is called the *internal standard* (IS) and should be seen in every sample by the MS including the negative samples and is a component of good quality control to ensure that all laboratory procedures have been adequately carried out. Since nitrite destroys the IS as well, any loss of this substance should generate alarm signals [9].

Another oxidant now commonly used is pyridinium chlorochromate (PCC), a chemical containing the metal chromium. This adulterant, which is sold in various preparations, can be more successful in the destruction of drug/metabolite than preparations containing nitrite and the immunoassay may produce a negative result [10]. If the specimen is analyzed by MS, the IS undergoes destruction in the same manner as urines containing excess nitrite. Urines to which PCC is added have a distinctive orange tinge, which, over a period of time, turns to a green hue due to changes in the form of chromium present. If on-site drug testing is carried out, the test strips often stain yellow in the presence of PCC.

A more recent adulterant is a combination of hydrogen peroxide and an enzyme that destroys the hydrogen peroxide, namely, peroxidase. Peroxide oxidizes the metabolite and the evidence for its presence is destroyed by the enzyme peroxidase [11]. Preparations containing the oxidant potassium iodate are also being sold.

The solution to the adulteration problem is to do an on-site adulteration test at the point of collection where another specimen may be demanded and before these chemicals have the opportunity to work [12].

Interpretation

Opiates

Although most guidelines/standards contain only two opiates, morphine and codeine, it is these two substances that cause the most interpretation problems to toxicologists. The difficulty relates to morphine, which can arise from four sources, the administration of heroin, morphine itself, codeine, or poppy seeds. It can, therefore, be difficult at times to decide whether the presence of morphine in a specimen is due to illicit use.

Heroin can be found in very low concentrations and for short periods of time in urine due to its short persistence time in blood, its high fat solubility favoring reabsorption by the kidneys, and its lack of stability in water. The unique metabolite 6-acetylmorphine (6-AM) appears in the urine and can be detected for an average of 4 h (using a 10-ng ml^{-1} cutoff) after a heroin administration [13]. Its confirmed presence in a urine specimen is unequivocal proof of use of heroin. However, the major metabolite morphine (mainly as glucuronides) is present for up to three days, which means that the presence of a large concentration of morphine in the absence of 6-AM may still represent heroin or morphine administration.

Codeine administration can be problematic, since over 90% of the Caucasian population and less than 50% of the Asian population produces morphine as a metabolite. Initially, the ratio of the codeine concentration to the morphine concentration highly favors codeine; however, as the time interval increases from the administration, the ratio favors morphine since codeine is eliminated at a faster rate than morphine. In the terminal stage of a codeine elimination, it is possible to only detect morphine (typically below 1000 ng ml^{-1} of morphine) and this could lead to an erroneous conclusion that heroin/morphine was administered [14].

Poppy seed ingestion is a common defense to explain the presence of morphine in a specimen. The seeds contain both morphine and lesser amounts of codeine and their ingestion can produce a positive morphine response. The amount of morphine present is dependent on how much was ingested and what strength of morphine was present. Typically, the morphine concentrations are low, i.e., less than 2000 ng ml^{-1} and the urine will be negative within 24 h [15]. There are people, however, who abuse poppy seeds and make a boiling water infusion with large amounts of the seed to make a poppy seed tea, which produces levels far above the typical levels. Interestingly, poppy seed abuse has been associated with bakers because of their ready access to large amounts of seeds [16]. Eastern Europeans also tend to use large amounts of poppy seeds in their cooking, e.g., poppy seed cake.

As a consequence, the source of low concentrations of morphine in urine cannot be interpreted. In the United States, the guidelines were modified to raise the cutoffs to alleviate the problem but other standards persist with lower cutoffs, which makes interpretation impossible at low morphine-positive concentrations.

Cannabis

Tetrahydrocannabinol (THC), the active ingredient of cannabis, is a very fat soluble substance, which will slowly accumulate in the fatty tissues of the body with chronic use of cannabis. After cessation of cannabis use, the accumulated THC will slowly diffuse out of the fat into the blood stream where it is metabolized to form water-soluble metabolites that will appear in the urine. The most common metabolite is known as *carboxy-THC*. It is the presence of this and other metabolites that produce positive cannabis tests even though the person concerned may not be recently using the drug. In comparison with other common drugs of abuse, the time taken to produce a negative result in a chronic cannabis user is quite long and can lead to the erroneous conclusion of reuse. Conversely, chronic cannabis users can rely upon this to reuse and explain a positive in terms of the long withdrawal period (*see* **Cannabis**).

When monitoring cannabis withdrawal, it is unscientific to rely upon the concentration of the major metabolite, carboxy-THC, as the concentration of any substance in the urine is dependent on the volume of urine being produced at the time. When a person does not drink sufficient water, the kidneys will decrease their production of urine by reabsorbing water and, consequently, the urine produced will be more concentrated and the concentration of carboxy-THC will therefore increase. Conversely, if water is drunk in excess of the body's requirements, the kidneys will dump more water and the urine will be dilute resulting in a lower concentration of carboxy-THC. It is therefore possible, if the individual is close to the cutoff, to have consecutive results where a negative test will turn to a positive one even though the person has not been reusing.

To solve this problem, the carboxy-THC concentration is normalized to the creatinine concentration. This is the ratio of carboxy-THC to creatinine in the urine i.e., the concentration of carboxy-THC divided by the concentration of creatinine. Since both substances coexist in the same volume of urine, the ratio is independent of that volume and hence the ratio does not depend upon a person's fluid balance. The ratio is therefore the appropriate parameter to monitor compliance with cannabis withdrawal.

If the creatinine-normalized carboxy-THC ratio increases significantly between consecutive tests, the suspicion of reuse arises. If the ratio is equal to or greater than 1.5 times the previous ratio, there is a high probability of correctly predicting new drug use [17]. The ratio should decrease as time elapses; however, an increase of greater than 50% in the ratio is generally accepted as reuse.

Perhaps the most misunderstood aspect of cannabis testing is associated with the detection period. For a casual user (once-a-week use) the detection period is 2–4 days [18]; however, it is in the detection period of a chronic user (uses at least once per day) where the myths and distortions arise. The longest recorded consecutive immunoassay positive period in scientific literature associated with cannabis withdrawal is 46 days [19]. The test used had a 20-ng ml^{-1} cutoff, which is 2.5 times more sensitive than the usual cutoff of 50 ng ml^{-1} and with no normalization of creatinine concentration.

A more recent study [20] was conducted in 1999, using prison inmates, showed that the longest period of detection for frequent heavy users at a 15-ng ml^{-1} cutoff was 17 days. The generally accepted period for the clearance of chronic users is within 21 days; however, there will be some individuals who will be positive for longer periods due to their pharmacokinetic profile, but these individuals are in the minority. Cannabis withdrawal should be monitored by taking specimens twice a week and analyzing them by MS in a laboratory using creatinine normalization. Immunoassays should not be replied upon solely due to the contribution of cross-reacting cannabinoids.

The argument that a positive urine result for cannabis is the result of passive inhalation rather than active smoking is frequently encountered. The passive inhalation of cannabis has been extensively studied. The studies concluded that while it was possible to produce a positive result, the conditions under which this occurs are quite unrealistic [21].

On-Site Immunoassays

Increasingly, as an option, the initial immunoassay test is being carried out on-site (at point of collection) rather than in the laboratory. This has several advantages, particularly, in that it removes 95%+ of samples in workplace testing that need to be sent to a laboratory and it provides a status report on an individual's risk profile to the management, allowing them to make a determination on the work status of the individual. The former advantage decreases the amount of paperwork required, which, in turn, decreases the risk of mistakes as well and, furthermore, decreases the costs of transportation. The latter advantage allows a company to discharge its obligation in relation to a safe working environment as required under legislation or work orders. Another advantage, particularly in a custodial or a community corrections environment, is the higher admission rates of drug taking by individuals when they actually witness the result of the test.

It would be unrealistic to expect that an on-site device does not have disadvantages. This technology uses a lateral flow immunoassay (similar to a home pregnancy test in technology) and, if used properly, has almost the same accuracy as a dedicated laboratory instrument. However, equivocal results are more likely if the true result lies close to the cutoff. Fortunately, there are few specimen results that are close to the cutoff. Equivocal results are due to the slightly different sensitivities of tests conducted on-site and in the laboratory.

Lack of specificity in any type of immunoassay can only be addressed by changing the antibody used in order to lower cross-reactivity. False negatives, as they are not apparent, can only be assessed by analyzing a number of immunoassay-negative samples in the laboratory by MS.

Conclusions

Urine testing using accepted international standards is a well established, legally defensible, comparatively cheap, mature technology, which is capable particularly by use of on-site testing of providing timely results. The specimen can be collected in high volumes in a medically noninvasive manner and when it comes to obtaining drug-taking history in terms of days, it remains the specimen of choice. It is ideal for compliance and random workplace testing as an alternative to expensive laboratory tests, but it is not the specimen of choice for very recent usage. As with all specimen types, it has its strengths and weaknesses but, if conducted and interpreted properly, it is unlikely to be seriously challenged as the most popular means of drugs-of-abuse testing in the near future.

Drug-Facilitated Sexual Assault

Introduction

When a drug's pharmacological effect on a person causes incapacitation and that person then becomes the victim of a criminal act, it is often referred to as a *drug-facilitated crime* (*DFC*). While it is generally thought that the drug must be secretly administered to a person for it to be considered a DFC, any time a person commits a crime by taking advantage of the debilitating effects that a drug (or combination of drugs) has on another individual (whether that individual was surreptitiously administered the drug or voluntarily took it), a DFC has occurred. The key is that the drug(s) must assist the criminal action. Most often when we consider DFCs, we speak of drug-facilitated sexual assault (DFSA), but robberies, homicides, and drug-smuggling have also been facilitated by taking advantage of the pharmacological effects of drugs and, in essence, using the drugs as "weapons".

The prevalence of DFCs will never be fully recognized. That is because a common challenge with these cases is reporting of the crime. In many cases, the victim suffers from amnesia. In other instances, the victims of DFCs may be uncertain of sequences of events and facts, so they may delay reporting in order to try to piece together the information that they do remember. Any delay makes it much more difficult for the toxicology laboratory to identify any incapacitating agents that may have been used.

Drugs Used to Commit DFC

There are over 50 drugs known or suspected to have been used to commit DFCs. Most are fast-acting strong central nervous system (CNS) depressants that mimic ethanol intoxication. They generally cause relaxation, euphoria, and decreased inhibitions at low doses; amnesia, impaired perceptions, difficulties in walking and maintaining balance, impaired speech, and drowsiness at moderate doses; and complete loss of motor functions, vomiting, incontinence, unconsciousness, and possible death at the highest doses. At the higher doses, the effects are likened to those of general anesthetic agents. In fact, many of the drugs

that have been used are currently, or once were, used as anesthetics. Because the CNS depressant effects of these drugs generally imitate one another, it is highly unlikely that one can determine the drug used in a DFSA case simply by symptoms alone. Instead, it is vital that a thorough, sensitive toxicological analysis be performed on the best available evidence following standard forensic practices in order to improve the laboratory's chance of identifying any likely incapacitating substances hours, days, or weeks after that drug was ingested.

Many of these drugs are well known as *recreational drugs of abuse, prescription medications*, or *over-the-counter pharmaceuticals*. While surreptitious administration does occur in DFCs, in most cases the drugs are probably self-administered by the eventual victim who may not be fully aware of the effects of the drug, particularly when co-ingesting it with other strong CNS depressants. Further, it requires some preparation on the part of the criminal in order to slip a drug into the drink of a crime victim. Most drugs are in a solid, tablet formulation. Simply dropping a pill into a drink is usually not an efficient means of secretly giving the drug to someone, because the pill will not likely dissolve immediately and may fizz as it begins to dissipate into the beverage. Additionally, since most tablets contain insoluble, cellulose-based fillers, a portion of the tablet may not completely dissolve into the drink and will instead leave a grainy residue. For that reason, it is common to see pills predissolved into small volumes of ethanol-based solutions, filtered to remove the insoluble materials, and then transferred into small eyedropper-type bottles. Additionally, some drugs such as gamma hydroxybutyrate (GHB) and drugs found in gelatin capsules are already in a liquid form, thus minimizing the preparation that is required for tablets.

Ethanol

By far, ethanol (or alcohol) is the most common "drug" used to facilitate crimes. This is due to its acceptance as a social drug throughout most of the world. In most DFCs in which ethanol plays a primary or contributory role, the alcohol ingestion is voluntary; however, surreptitious administration of ethanol has been known to occur.

There are numerous factors that affect the level of intoxication reached from drinking ethanol. Some variables are easily controlled such as the type of alcoholic beverage consumed (beer, wine, or mixed-drinks), the size of the beverages, and whether ethanol is consumed with or after eating a meal as opposed to an empty stomach. All of these variables have an effect on ethanol's absorption into the bloodstream. The faster ethanol is absorbed and distributed throughout the body (including the brain), the more intoxicated the user generally becomes. Additionally, as with all CNS drugs, the more ethanol that is consumed the more severe the intoxication will become.

Because ethanol impairment has been so extensively studied in relation to operating motor vehicles, a lot is known about its behavioral effects on people. Users generally pass through different phases of intoxication beginning with a subclinical stage where there are no appreciable symptoms of intoxication. The next phase is one of euphoria where the user becomes more talkative and social as they experience diminished inhibitions. This is followed by a stage of excitement where they may begin to feel drowsiness, have indications of emotional instability, and impaired perceptions, memory, and comprehension. The more serious stages of confusion, stupor, coma, and death follow. Through these later stages, the user may experience severe disorientation, lack of coordination, slurred speech, vomiting, blackouts, unconsciousness, anesthesia, and respiratory depression.

Ethanol is generally eliminated following zero-order kinetics. This allows for the average elimination rates for both men ($0.015\,g\,dl^{-1}h^{-1}$) and women ($0.018\,g\,dl^{-1}\ h^{-1}$) to be used to predict the blood ethanol concentration of an individual based on the number, type, and size of the drinks that they consumed in a given evening. This is a useful exercise to evaluate the role that ethanol may have played in contributing to the symptoms that the DFC victim described. However, factors such as chronic alcoholism, genetic factors, and liver disease must also be considered because they can affect these elimination rates (*see* **Alcohol**).

GHB and Analogs

Of all the drugs used to facilitate sexual assault and other crimes, GHB and its metabolic precursors, gamma butyrolactone (GBL) and 1,4-butanediol (1,4-BD), are probably among the most favored. Unfortunately, this statement can only be based on circumstantial evidence. Solid proof of such is difficult to

obtain because GHB, GBL, and 1,4-BD have strong sedative, amnesiac effects and, more importantly, are very rapidly eliminated after ingestion. To further complicate the matter, GHB is a metabolite of gamma-aminobutyric acid (GABA), a natural neurotransmitter in humans. Thus measurable amounts of endogenous GHB are found in blood ($<2\,mg\,l^{-1}$) and urine specimens ($<10\,mg\,l^{-1}$) of most humans. Therefore, after ingestion, GHB is not likely to be discriminated from endogenous concentrations of GHB after 2–8 h in blood specimens or 6–12 h in urine samples.

GHB, GBL, and 1,4-BD are also very popular "club drugs". Thus, it is also common for victims of DFCs to have voluntarily ingested the drug, unaware that doing so would make them vulnerable.

Individuals exposed to GHB or one of its analogs can pass from a completely alert state to deep unconsciousness within 10–15 min after ingestion. Because of GHB's rapid clearance, the GHB-assisted sleep generally only lasts about 3–5 h, after which the individual awakes and feels unusually refreshed.

GHB, GBL, and 1,4-BD are nearly always administered as an oral solution. They are rapidly absorbed with peak plasma concentrations occurring within 30–60 min. GHB's absorption is likely to be capacity limited and may be enhanced when it is absorbed on an empty stomach.

GBL and 1,4-BD are rapidly metabolized into GHB (Figure 1). Thus their pharmacological effects mimic those of GHB. GHB is also rapidly and extensively metabolized such that less than 5% of an oral dose is excreted unchanged in the urine.

Benzodiazepines

As a drug class, the benzodiazepines are likely to be the most commonly used prescription medications used to commit DFCs. Benzodiazepines are one of the world's most widely prescribed drug classes primarily as anxiolytics, anticonvulsants, anesthetic adjuncts, hypnotics, and muscle relaxants, and for the treatment of obsessive-compulsive disorders. They are also very popular drugs to use in DFCs. This fact demonstrates the important role that drug availability has in DFCs. The perpetrator of DFCs often has personal experience with the drug effects. This may be through prescription or occupational use, but it is also very common to see benzodiazepines recreationally abused in combination with illicit drugs such as opiates and cocaine.

Benzodiazepines are administered orally, intravenously, or intramuscularly. With oral benzodiazepine ingestion, absorption into the bloodstream is nearly 100% because of their very high lipid solubility. However, the rate of absorption (and thus the rate of activity) is dependent upon the benzodiazepine itself. Generally speaking, most benzodiazepines reach their peak blood concentrations within 30 min to 6 h after ingestion. As discussed earlier, if the tablet formulation of a benzodiazepine is dissolved in an alcohol or aqueous solution to facilitate its surreptitious administration, the absorption rates should be faster and peak effects should be felt significantly earlier than if exposure occurs via a normally administered tablet.

Benzodiazepines are classified according to their elimination half-lives (Table 1). Obviously, the short-acting benzodiazepines (e.g., midazolam and triazolam) are detected for much shorter periods than long-acting benzodiazepines (e.g., diazepam, clonazepam). Additionally, the long-acting benzodiazepines tend to exhibit a longer and more severe "hangover" side effect than do their short-acting counterparts.

Metabolism of benzodiazepines is extensive by the liver via dealkylation, deamination, hydroxylation, or reduction. The hydroxyl products are further metabolized by conjugation with glucuronic acid and are the major urinary products of benzodiazepines. The cytochrome P450 3A (CYP3A) enzyme family is involved in the metabolism of many benzodiazepines, so it is important to recognize the effects of coingestion of drugs that inhibit this enzyme system

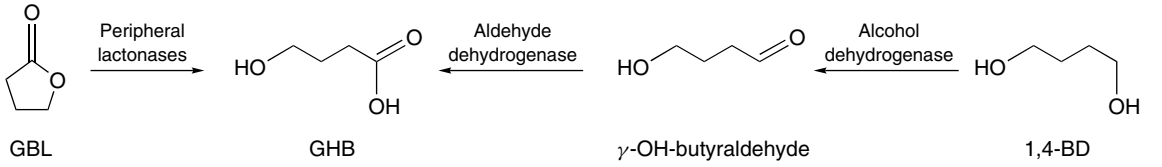

Figure 1 GHB, GBL, and 1,4-BD metabolism

Table 1 Benzodiazepines and their elimination half-lives

Benzodiazepine	Examples of trade name(s)	Half-life
Alprazolam	Xanax	Intermediate
Bromazepam	Lectopam, Lexotan	Intermediate
Chlordiazepoxide	Librium	Intermediate
Clonazepam	Clonopin, Klonopin	Long
Clorazepate	Tranxene	Short
Diazepam	Valium, Ducene	Long
Estazolam	ProSom, Eurodin	Intermediate
Flunitrazepam	Rohypnol, Hypnodorm	Long
Flurazepam	Dalmane	Long[(a)]
Halazepam	Paxipam	Long[(b)]
Lorazepam	Ativan	Intermediate
Midazolam	Versed	Short
Nitrazepam	Mogadon	Long
Oxazepam	Serax, Serepax	Intermediate
Prazepam	Centrax, Vertran	Short
Temazepam	Normison, Restoril	Intermediate
Triazolam	Halcion	Short

[(a)] Flurazepam has a very short elimination half-life, but its metabolite's half-life is long

[(b)] Halazepam has an intermediate elimination half-life, but the half-life of its metabolite is long

and their effects on benzodiazepine metabolism. For example, cimetidine, diltiazem, fluoxetine, verapamil, antifungals, antibiotics (e.g., erythromycin and clarythromycin), and protease inhibitors are all known to inhibit the CYP3A enzymes and potentially others. Grapefruit juice has also been shown to inhibit these enzymes. If these enzymes are inhibited, normal metabolism of the benzodiazepines will be altered and their resulting pharmacological effects may be enhanced (*see* **Benzodiazepines**).

Marijuana

Marijuana (or cannabis) continues to be the most widely abused illicit drug worldwide. It is typically self-administered through smoking, although there are numerous cases of its surreptitious administration to individuals in food.

The primary psychoactive analyte of marijuana is Δ^9-tetrahydrocannabinol (THC). Variability in smoking characteristics (i.e., number, duration, and spacing of puffs; hold time; and inhalation volume) strongly influence the concentration of THC that a person is exposed to.

THC can be measured in plasma within seconds after inhalation of the first puff of a marijuana cigarette. Therefore, the brain is rapidly exposed to THC following marijuana smoking. While the behavioral effects of euphoria and relaxation are generally the desired effects from marijuana use, an acute toxic effect of marijuana is CNS depression (e.g., lethargy and reduction in short-term memory). This CNS depression is enhanced when ethanol is coingested with marijuana.

The major metabolic route of THC is via hydroxylation by the hepatic cytochrome P450 enzyme system. This results in the production of the active metabolite, 11-OH-THC, which is oxidized to an inactive metabolite, THC-COOH. THC-COOH forms a conjugate with glucuronic acid, which enhances the compound's water solubility. THC-COOH, in both its free and conjugated states, is the primary metabolite seen in urine samples.

Owing to its high lipid solubility, THC will accumulate in fat where it will slowly release back into the bloodstream. This allows for extended detection times for THC and metabolites when laboratories are utilizing very sensitive analytical methods.

Generally speaking, THC-COOH excretion can occur for days after ingestion. This long elimination half-life, as well as the enterohepatic recirculation of THC, makes it very difficult to estimate the time of drug exposure when analyzing a urine sample. It

becomes even more difficult when the urine sample is from a chronic marijuana user. With some exceptions, a urine sample from a naïve user of marijuana will have measurable amounts of THC metabolites for one to seven days after smoking a single marijuana cigarette, depending upon the sensitivity of the analytical methods used to measure these metabolites (*see* **Cannabis**).

Ketamine

Ketamine is a dissociative anesthetic that is structurally similar to the more recognized recreational drug, phencyclidine (PCP). Like GHB, ketamine has also become a trendy drug of abuse and is considered a "club drug". Most users abuse ketamine for its hallucinogenic properties. Because of ketamine's popularity in veterinarian medicine, there have been numerous reports of its theft from veterinarian clinics.

Ketamine can be administered through intravenous, subcutaneous, intramuscular injections, nasal insufflation, smoking, or oral ingestion. In addition to hallucinations, it is known to produce irrational behavior and strong CNS depression resulting in impaired speech, amnesia, and "out-of-body" experiences. A particularly interesting effect of this drug is that thought processes are impaired while under its influence. It has been reported that an individual's memories of events while under the influence of this drug can be altered or shaped by an outsider telling the person what is happening to them. While an individual is under the influence of this drug, they may appear to be awake, but in a trancelike state.

Ketamine is metabolized to norketamine and dehydronorketamine. Conjugates of hydroxylated derivatives of the parent drug, as well as its metabolites, are excreted in the urine for at least 72 h after ingestion.

MDMA

Unlike most of the other drugs used to facilitated crimes, 3,4-methylenedioxymeth-amphetamine (MDMA) has more hallucinogenic and stimulant-type properties instead of strong CNS depressant effects. The desired pharmacological effect for users of MDMA, however, is its ability to heighten the user's senses. While taste, hearing, seeing, and smelling are all enhanced, the pleasure associated with touch while under MDMA's influence can increase the likelihood of sexual contact. At very high doses, symptoms may also include nausea and vomiting, profuse sweating, teeth grinding, and, on rare occasions, coma and hypotension.

MDMA is typically administered orally and is rapidly metabolized to numerous metabolites, including a related drug; methylenedioxyamphetamine (MDA). Using sensitive analytical techniques, MDMA and MDA may be detected in the urine for one to four days after oral administration (*see* **Amphetamine**).

Opiates

Like benzodiazepines, opiates represent another large drug class used to facilitate crimes (Table 2). Besides the strong CNS depression caused by opiates, they also act as, and are generally prescribed as, analgesics. The analgesic effect is believed to be particularly important in DFSA cases. Many DFSA victims report briefly waking during their assault, looking up and seeing the perpetrator assaulting them, but falling back into an unconscious state before they can fight off their attacker. These awakenings are believed to occur because of a sudden infliction of pain such as when penetration occurs, or if their head or arm is suddenly injured by banging against the floor, a headboard, or a nightstand. The analgesic effects of the opiates minimize the likelihood of this awakening occurring due to such sudden pain. However, it should be noted that the effectiveness of individual opiates will vary from one opiate to the next and from one person to the next.

Most opiates are best absorbed via parenteral administration. Gastrointestinal absorption is also generally effective, but the extent of the pharmacological effects varies depending upon the degree of first-pass metabolism of the individual opiates. Many of the opiates ultimately form glucuronide metabolites that are primarily eliminated in the urine (*see* **Opioids**).

Antihistamines

In recent years, there has been an increase in the abuse of some of the antihistamine drugs. This abuse is in large part due to their availability and the strong CNS depressant effects of some of these drugs. In particular, diphenhydramine, brompheniramine, chlorpheniramine, and doxylamine have the potential for strong sedative effects. These effects are variable

Table 2 Narcotic and nonnarcotic analgesics

Drug	Examples of trade name(s)	Half-life
Buprenorphine	Buprenex, Subutex	Short
Butorphanol	Stadol	Intermediate
Codeine	Codral forte	Short
Dextromethorphan	DM, DXM	Short
Dihydrocodeine	DHCplus, Synalgos-DC	Short
Fentanyl	Actiq, Duragesic, Sublimaze, Innovar	Short-intermediate
Heroin		Short
Hydrocodone	Anexsia, Hycodan, Lorcet, Lortab, Norco, Pancet, Vicodin, Zydone	Short
Hydromorphone	Dilaudad, Palladone	Short
Levorphanol	Dromoran, Levo-Dromoran	Intermediate
Meperidine (Pethidine)	Demerol, Mepergan	Short
Methadone	Dolophine, Physeptone	Long
Morphine	Avinza, Astramorph, Duramorph, Kadian, MS Contin, Oramorph, Roxanol	Short
Nalbuphine	Nubain	Short–intermediate
Oxycodone	Oxycontin, Oxyir, Roxicodone, Percodan, Percocet, Percolone, Roxicet, Tylox	Short
Oxymorphone	Numorphan	Short
Pentazocine	Talacen, Talwin	Short
Propoxyphene	Darvocet, Darvon, Wygesic	Intermediate

from one user to the next. In fact, children may actually exhibit a paradoxical effect in which these antihistamines act as CNS stimulants rather than depressants.

Antihistamines are readily absorbed after oral administration with the onset of action generally occurring within an hour of ingestion. The half-life of antihistamines vary considerably so detection times after administration may range from hours to days, depending on the particular antihistamine consumed.

Other drugs

There have been many other drugs used to facilitate crimes. Most recently, the drugs zolpidem and zopiclone have increased in popularity in DFCs, concurrent with their increased prevalence as prescription medications throughout the world. A number of centrally acting muscle relaxants such as cyclobenzaprine and meprobamate have also been observed in DFCs, as have barbiturates, some antipsychotics (e.g., clozapine, thioridazine, and chlorpromazine), and the sedative tricyclic antidepressants (e.g., amitriptyline and desipramine). While not technically a drug, solvents have also been used to incapacitate a person in order to commit a crime against them. The original "Mickey Finn", chloral hydrate, is still available in some countries and used to knock out victims of DFCs. As new sedative medications continue to emerge, the list of drugs that have or can be used to facilitate a crime will continue to expand.

Toxicological Specimens for DFC Investigations

It is generally accepted that urine is the most useful specimen in the majority of investigations of DFCs. Since drugs and metabolites are concentrated in urine specimens, and thus are more readily detectable, the value of urine specimens is clear when trying to determine if an individual was exposed to a drug days before the specimen was collected. Current recommendations by the Society of Forensic Toxicologists (SOFT) DFSA Committee are that urine specimens be collected as soon as possible after a DFC, not to exceed 96 h after the suspected drug exposure. If possible, 100 ml of urine should be collected to ensure that enough of the specimen is available for the laboratory to perform a sensitive and thorough analysis.

After ingestion, most drugs are below detectable levels in the blood within 24 h, therefore limiting the usefulness of this specimen. In those cases in which blood can be collected a short time after drug ingestion, the combination of blood and urine specimens can provide a clearer picture as to the window of exposure to the drug. Blood specimens should be placed into collection tubes containing sodium fluoride. In addition to urine, at least 7–10 ml of blood should be collected when it can be provided within 24 h of the suspected drug exposure.

Oftentimes a victim of a DFC does not present to medical and/or law enforcement personnel until weeks (or longer) after the alleged crime. At this point, it is no longer possible to find evidence of a drug in a blood or urine specimen. In these cases, hair specimens have shown promise as a specimen of choice; particularly when newer analytical instrumentation with superior sensitivity is used. However, hair does present additional challenges compared to blood and urine specimens. Thorough studies of the incorporation of all of the drugs that can be used for DFC into hair have not been conducted. This makes a negative result in hair very difficult to interpret.

A positive hair result can also be challenging. Head hair grows at a rate of approximately 1 cm per month. Segmental analysis of hair is necessary to pinpoint the portion of hair that corresponds to the growth period during the alleged drug exposure and to demonstrate that the drug was not ingested outside of that growth period. For example, if a month before an alleged DFC, the victim took a strong sedative, the hair test must not confuse that ingestion with any drugs ingested the night of the DFC. Only laboratory personnel skilled with handling hair specimens in this matter should be relied upon to attempt segmental analyses so as to not cause inaccurate conclusions (*see* **Hair: Toxicology**).

In some cases, another useful specimen may be vomit from the victim. Most drugs are capable of causing nausea and vomiting to some degree. If a drug is not fully absorbed before vomiting occurs, the drug may be readily detected at relatively high amounts in a vomit stain. Both ethanol and GHB, two of the most common drugs used for DFCs, are known to cause vomiting from their ingestion. Unfortunately, vomit is not generally useful for these two drugs because of the volatility of ethanol and the natural presence of GHB in humans. Most other drugs may potentially be detected in vomit stains.

Toxicological Analyses in DFCs

Over the years, specimens collected in investigations of DFC have at times been completely consumed or prematurely discarded because the specimens were sent to laboratories that did not have appropriate methods or instrumentation to adequately carry out the toxicological analyses. In general, clinical laboratories may not be able to detect subtherapeutic concentrations of these drugs. Therefore, these laboratories should not be relied upon to determine if an individual was exposed to a drug when the specimens are collected more than a few hours after the suspected drug exposure. Forensic toxicology laboratories may not be able to provide much better service, unless they have taken the steps needed to improve the sensitivities of their methods.

To improve consistency in results provided by laboratories, the SOFT DFSA Committee developed a chart of the most prevalent drugs associated with DFCs and their recommended maximum detection limits when analyzing urine specimens (Table 3). These recommended detection limits are based on published analytical methods using standard laboratory instrumentation (e.g., gas chromatography mass spectrometry (GC-MS) or liquid chromatography mass spectrometry (LC-MS)). The group's goal in developing this document was to encourage laboratories to evaluate their current capabilities and make improvements, as necessary. Furthermore, this tool provides a means of simplifying communication between analytical toxicologists and their customers, usually law enforcement personnel.

There are a number of approaches that a laboratory may take to reach the SOFT DFSA Committee maximum detection limits. Laboratories may choose to increase the specimen volume they would typically use to analyze for these drugs in their more routine cases. They should also consider a hydrolysis step in their procedures for drugs that form conjugated metabolites (e.g., benzodiazepines, opiates, etc.). Derivatization of polar metabolites combined with analysis using selective instrumental detectors (i.e., gas chromatography electron-capture detector (GC-ECD), GC-MS with negative ion chemical ionization, etc.) may also improve detection limits. Technological advances lead to improved instrumental sensitivity, so many laboratories can improve sensitivity simply by ensuring that they are using instrumentation that is less than five years old. There

Table 3 Society of Forensic Toxicologists (SOFT) DFSA recommended maximum detection limits for urine specimens

Target drug/metabolite	Recommended maximum detection limit
Ethanol	10 mg dl^{-1}
GHB and analogs	10 mg l^{-1}
Benzodiazepines	
Alprazolam	10 μg l^{-1}
Chlordiazepoxide	
Diazepam	
Hydroxyalprazolam	
Lorazepam	
Nordiazepam	
Oxazepam	
Temazepam	
7-Amino-clonazepam	5 μg l^{-1}
7-Amino-flunitrazepam	
Clonazepam	
Flunitrazepam	
THC-COOH	10 μg l^{-1}
Barbiturates	
Amobarbital	25 μg l^{-1}
Butalbital	
Pentobarbital	
Phenobarbital	
Secobarbital	20 μg l^{-1}
Antidepressants	
Amitriptyline	10 μg l^{-1}
Citalopram	
Desipramine	
Desmethylcitalopram	
Desmethyldoxepin	
Doxepin	
Fluoxetine	
Imipramine	
Norfluoxetine	
Norsertraline	
Paroxetine	
Sertraline	
Over-the-counter medications	
Brompheniramine	10 μg l^{-1}
Chlorpheniramine	
Desmethylbrompheniramine	
Desmethylchlorpheniramine	
Desmethyldoxylamine	
Dextromethorphan	
Diphenhydramine	
Doxylamine	
Opiates and nonnarcotic analgesics	
Codeine	10 μg l^{-1}
Hydrocodone	
Hydromorphone	
Meperidine	
Methadone	
Methadone Metab (EDDP)

Clonidine	$1\,\mu g\,l^{-1}$
Ketamine	
Norketamine	

$mg\,dl^{-1}$, milligram per deciliter $mg\,l^{-1}$, milligram per liter $\mu g\,l^{-1}$, microgram per liter

is no single approach to ensure that all of the drugs that may be used to facilitate DFCs are analyzed at adequate sensitivity, but a combination of the above tactics greatly improve the laboratories chances of adequately screening for these drugs.

Conclusions

While DFCs have probably occurred for hundreds of years or longer, in recent times a concerted effort by law enforcement, medical professionals, the media, and toxicologists have raised the public's awareness of these crimes. While the true prevalence of these crimes will never be fully recognized, acknowledging the many challenges that come with these cases also provides insight as to how to improve chances of successfully investigating allegations of a DFC.

MARC A. LEBEAU

Drug-Impaired Driving

Introduction

Every year more than a million people in the world are killed in traffic crashes and many millions more are injured. Beside the heavy and tragic burden on those directly affected, there is an enormous economic impact, costing countries between 1 and 4% of their gross national product. Driving is a very complex task, requiring the cooperation of several different cognitive and psychomotor functions at once. Crashes can be the consequence of many different factors, which can be classified into three categories: the road, the vehicle, and the driver. A crash is rarely attributable to only one factor, indicating that it is very difficult to precisely determine in what percentage of crashes alcohol or drugs have contributed.

Influence of Drugs on Performance

The effects of drugs on performance can be studied by means of experimental studies, in which different doses of a certain drug are administered to volunteers, and the effects on performance are measured and compared to a placebo or a positive control. The performance of the volunteers can be evaluated by means of tests that assess the different psychomotor and cognitive functions, by means of tests in a driving simulator, or by "real" driving tests [1–3].

Alcohol

Alcohol is a central nervous system depressant. Many studies have already been performed to determine the effects of acute alcohol ingestion on cognitive functions and driving performance. These studies found that numerous driving-related skills are degraded beginning at low blood alcohol concentrations (BACs). Several skills have been shown to decrease with increasing BAC, such as prolongation of reaction time performances and lowering of coordination performance [4, 5]. (For further information *see also* **Alcohol**.)

Cannabis

A cannabis user feels euphoria, relaxation, and increased social interaction with frequent laughing and experiences changes in perception (visual, audible, sensory, or time perception). The users are aware of the effects of the drug, and this awareness increases with higher doses. Cannabis acutely reduces some cognitive and psychomotor skills such as learning, equilibrium, coordination, tracking ability, memory, perception, motor impulsivity, and vigilance, and these effects are mostly dose dependent [6, 7].

Cannabis can also have an effect on behavior. The influence of cannabis on human risk taking is unclear. The results of experiments in laboratory settings are contradictory, while in some driving studies (with rather low doses) users are aware of the impairment and often compensate their driving style by driving more slowly, overtaking less, or keeping longer distances from other vehicles. Nevertheless the driver is still unable to completely compensate for the loss of capability in some psychomotor skills [8].

Some deleterious effects of cannabis appear to be additive or even synergistic with those of alcohol, and the combination of both substances results in a prolongation as well as enhancement of their effects. Driving studies revealed that drivers under the influence of both alcohol and cannabis were less attentive to traffic approaching from side streets, while the use of either cannabis or alcohol (at low doses) had no effect [9], and that the combination of cannabis and alcohol generated an additional decrement in control of lateral deviation on top of the decrement caused by either cannabis or alcohol [10]. The detrimental effects of other drugs such as cocaine can also be reinforced by additional intake of cannabis [11]. (For further information *see also* **Cannabis**.)

Amphetamines

Amphetamine causes a strong central stimulation and euphoria. The user thinks he can do everything and will take more risks. In addition, amphetamine widens the pupils (mydriasis) and reduces sleepiness leading to insomnia, but after some time (hours or days depending on the pattern of use), the subject is exhausted and falls asleep (crash phase). Amphetamine can improve some cognitive functions such as divided attention performance and verbal interaction [12]. However, tests in driving simulators reveal that the intake of amphetamine causes a decrease in overall simulated driving by inducing problems such as incorrect signaling, failing to stop at a red traffic light, and slowing reaction times. The

decrease in simulated driving ability is only observed during daytime, which is consistent with the tunnel vision associated with amphetamine consumption [12, 13]. It is also important to note that the doses of amphetamine administered in these experimental studies were very low (10–30 mg) and thus not representative of the doses that are generally taken by abusers (100–1000 mg/day) [1].

Studies investigating the effect of amphetamine in sleep-deprived persons revealed a positive effect on psychomotor functions [14, 15]. The effects of amphetamine on cognitive functions in sleep-deprived persons are less obvious. Both positive and negative effects as well as no effects have been assessed [12, 14].

Methamphetamine like amphetamine is a central nervous system stimulant that may cause restlessness, euphoria, dizziness, dysphoria, tremor, and insomnia.

Ecstasy (methylenedioxymeth(yl)amphetamine, MDMA, XTC) is a "designer" amphetamine, indicating that it is synthesized to resemble the effects of amphetamine. It causes a weaker stimulation of the central nervous system than amphetamine, but it can also cause sensory disturbances, nausea, dizziness, ataxia, muscular rigidity, sweating, restlessness, and tremor.

Ecstasy acutely causes decreases in attention, short- and long-term memory, verbal memory, visuospatial skills, executive functioning, and prediction of object movement under divided attention [16–18]. It also leads to improved psychomotor performance on a battery of tests, such as movement speed and tracking performance in a single, as well as in a divided attention task [16]. Tests in driving simulators however revealed that the intake of ecstasy can decrease performance by increasing speed and speed variation, and inducing problems in car following, while some tasks are not influenced (reaction time, lateral control), and may even be improved (e.g., lateral control) [17, 19].

Other psychoactive substances such as alcohol can reinforce the deleterious effects of ecstasy, and cause some additional negative effects [20]. On the other hand, the use of ecstasy can diminish some, but not all detrimental effects of alcohol, while other negative effects of alcohol can be reinforced [17].

During the crash phase following the use of amphetamines, the subject feels very tired, unable to combat sleep and depressed. This phase can last for several days [21]. (For further information *see also* **Amphetamine**.)

Cocaine

Cocaine is extensively metabolized to a variety of compounds. The major metabolites are benzoylecgonine, ecgonine, and ecgonine methyl ester and they are often targeted in analyses.

The desired effects of cocaine are similar to those of the amphetamines, but the onset is slower and the duration is longer. The use of cocaine can partially reverse performance decrements in sleep-deprived persons [22]. In rested persons, some studies found no effect of the use of cocaine on psychomotor or cognitive skills [23], while other studies assessed an improvement in psychomotor performance (decreased reaction time), attention, and learning [24].

Cocaine can partially diminish performance decrements caused by alcohol consumption. The use of a combination of alcohol and cocaine decreases psychomotor impairment and improves performance on cognitive tests when compared to the use of alcohol alone. Cocaine also decreases the subjective feeling of drunkenness caused by alcohol [11, 25]. Detrimental effects of other drugs such as cannabis can be reinforced by cocaine [11].

A depressive phase follows the use of cocaine, with the subject feeling very tired, depressed, nervous, and unable to combat sleep [1]. (For further information *see also* **Cocaine**.)

Heroin

The user generally feels intense euphoria ("rush") accompanied by a warm flushing of the skin, dry mouth, and heavy extremities, and alternates between a wakeful and drowsy state. Few experimental studies have investigated the acute effects of heroin in humans. Several studies confirmed the acute effect of heroin on subjective sedation and miosis [26, 27]. One study found a trend toward a decreased performance on the circular lights task, which measures psychomotor performance [28]. In another study the administration of heroin impaired performance on a reaction time task [26]. However the doses used in these experimental studies ranged from 2 to 20 mg, while average daily doses in a chronic, tolerant user range from 300 to 500 mg of heroin [1]. (For further information *see also* **Opioids**.)

Epidemiology and Risks

Prevalence of Drugs in the General Driving Population or in a Subset of Drivers

The prevalence of drugs in the general driving population can be estimated by means of roadside surveys, in which samples of randomly stopped drivers are analyzed. Results of roadside surveys have shown that about 1–2% of drivers stopped during roadside surveys tests positive for drugs in saliva. Higher prevalence rates were found in studies using urine as sample (6–12%) or in studies where samples were only collected during weekend nights (6–15%) [29].

In some studies, samples of a subset of drivers are analyzed. Such studies have shown that drugs are prevalent in 19–50% of drivers injured by a traffic crash, 6–35% of drivers killed by a traffic crash and 55–99% of drivers suspected of driving under the influence of drugs (DUID) [29]. These figures can vary strongly, because the methodology used in the different studies can differ in many aspects. For example, some studies used blood as biological matrix, while others used urine or saliva. As these matrices have different detection times, this can have an influence on the results [30]. Furthermore, the methodology of the studies can differ in the type of drugs included in the analysis and the kind (and sensitivity) of analysis method used.

The most prevalent drug in most of these studies is cannabis. Other important drugs are amphetamines, benzodiazepines, and opiates.

Besides analyzing biological samples of drivers, the prevalence of DUID can also be assessed by interviewing persons. A disadvantage of this method is the possibility of underestimation of the prevalence. Such interviews have shown that about 3.6% of the general population, 15% of the young people, and 85% of drug users state ever to have driven after having used drugs [29]. In the United States in 2005, an estimated 10.5 million persons aged 12 or older reported driving under the influence of an illicit drug during the past year [31].

Risks Associated with DUID

By comparing the prevalence of a certain drug in the general driving population to the prevalence in drivers who were involved in a traffic accident, some studies tried to estimate the accident risk. Several studies have already shown that an increasing BAC is associated with increasing accident risks [32, 33]. Other studies have calculated the accident risks associated with other psychoactive substances. The impaired motorists, methods of roadside testing and assessment for licensing (IMMORTAL) study in the Netherlands revealed that drivers under the influence of benzodiazepines alone have a relative risk for an accident that is three times greater than the risk of a drug-free driver. The highest risk was associated with the use of drugs in combination with alcohol ($\geq$0.8 g l^{-1}), namely a 179 times higher risk [34]! A study that was performed in Canada, for example, showed that the crash risk associated with driving under the influence of cocaine, benzodiazepines, and cannabis is respectively 5, 2.5, and 2.2 times higher than that of a person who has not consumed these drugs [33].

Some studies have made a more thorough analysis than calculating the risk of being involved in a traffic crash, and have estimated the risk of being responsible for a traffic crash while DUID. The results of these types of studies indicate that increasing BACs are associated with increasing risks of being responsible for an accident [35]. They also show that driving under the influence of cannabis increases the risk of being responsible for a crash. The risk of being responsible for an accident even increases with increasing cannabis concentration in the blood, indicating a causal relationship between cannabis and crashes. The risk of being responsible for a fatal accident when driving under the influence of cannabis and alcohol is approximately equal to the multiplication of the risks when driving under the influence of cannabis or alcohol alone [35]. Responsibility analyses have also shown that benzodiazepines and cocaine are associated with increased risks of being responsible for an accident, and that the risk is higher for a combination of alcohol and benzodiazepines than for benzodiazepines alone [36, 37].

Legislation

Each developed country has its specific legislation to deal with DUID. There is a lack of uniformity in the way in which nations approach the drugged driving problem. Generally there exist two major types of DUID legislation, namely "impairment" legislation and "*per se*" legislation [38].

Table 1 Analytical cutoff limits in blood, plasma, or serum as agreed upon or proposed in different countries (all concentrations in ng ml^{-1}, except Sweden where it is in ng g^{-1})

	Germany[a]	Belgium	France	Sweden	Switzerland
Sample type	Serum	Plasma	Blood	Blood	Blood
Amphetamine	50	50	50	30	15[b]
MDMA	50	50	–	20	15
MDEA	50	50	–	20	15
MDA	–	–	–	20	–
MBDB	–	50	–	20	–
Cocaine	–	50	50	20	15
Benzoylecgonine	150	50	50	20	–
Morphine (free)	20	20	20	5	15
THC	1	2	1	0.3	1.5

MDMA, 3, 4-methylenedioxy-*N*-methylamphetamine; MDEA, 3, 4-methylenedioxy-*N*-ethylamphetamine; MDA, 3, 4-methylenedioxyamphetamine; MBDB, 3, 4-methyl-1-(3,4-methylenedioxyphenyl)-2-butanamine; THC, Δ9-tetrahydrocannabinol

[a] Lower cutoffs have been proposed, but they are not yet used everywhere

[b] For Switzerland also the cutoff is 15 ng ml^{-1} for methamphetamine; for all analytes, an error margin of 30% is added to the cutoff

Impairment Legislation

In impairment legislation, the prosecution must demonstrate that the driver was impaired, not fit to drive or "under the influence" depending on how the law is interpreted. The analysis of drugs in body fluids only provides corroborating evidence as to the cause of the impairment. This kind of legislation is subjective and requires the assessment by a medical doctor or a specially trained police officer. As a consequence many of the countries with this kind of legislation experience difficulties in obtaining convictions. Examples of countries with "impairment" legislation are Norway and the United Kingdom.

"Per se" Legislation

A "*per se*" law prohibits driving if drugs are present in blood, serum, plasma, or oral fluid above a certain threshold. Since the prosecution does not have to prove that the driver was impaired, this kind of legislation facilitates the enforcement process. The threshold concentrations, or cut-offs, used are analytical detection limits, meaning that any detectable concentration of a drug constitutes an offense. Therefore these laws are sometimes called *zero-tolerance* laws. Presently, Germany, Belgium, Sweden, France, Finland, Luxembourg, Switzerland, Denmark, a number of Australian states, and 14 states of the United States have introduced "*per se*" legislation in addition to the "impairment" legislation. The analytical cutoffs of Germany, Belgium, France, Sweden, and Switzerland are given in Table 1.

There is no consensus on the analytical cutoffs between the different countries. This lack of consensus can be partially attributed to the use of different biological matrices (serum in Germany, plasma in Belgium, and whole blood in Australia, France, Sweden, and Switzerland) and the different consequences of a positive result: for example, in Belgium there is a penal sanction that follows a positive result, while in Germany there is an administrative sanction. The effectiveness of "*per se*" legislation in increasing the number of prosecutions has already been demonstrated in some countries. For example, in Finland there was a slow increase in the number of samples that were investigated until 2002. However since the introduction of "*per se*" legislation in 2003 there was a cumulative monthly increase in the number of samples (Figure 1) [39].

In Sweden, immediately after the zero-limit law came into force, the number of cases of DUID submitted by the police for toxicological analysis increased sharply and was 10 times higher in 2005 than before the new legislation. Nevertheless it was found that Sweden's zero-concentration limit has done nothing to reduce DUID or deter the typical offender because recidivism is high in this population of individuals (40–50%). Many traffic delinquents in Sweden are criminal elements in society with previous convictions for drunk and/or drugged driving as well as other offenses. The spectrum of drugs identified in blood samples from DUID suspects has

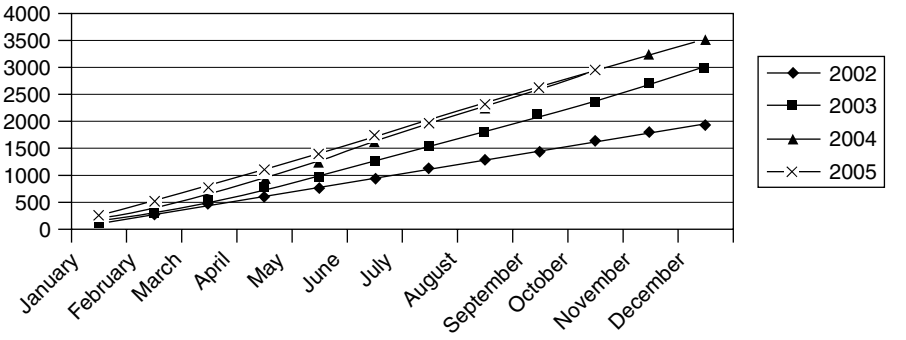

Figure 1 The cumulative monthly increase in the number of samples after introducing the zero-tolerance law in 2003 in Finland [Reproduced with permission from Ref. 39. © P. Lillsunde, 2005.]

not changed much since the zero-limit law was introduced [40].

Detection of Drugs in Drivers

Roadside Detection

Since many years, police officers involved in road safety have expressed the need for a rapid and reliable roadside screening test for drugs, similar to an alcohol breathalyzer. This would help them to determine which drivers have to provide a blood sample, or to take immediate administrative measures like confiscating the driver's license or impounding the vehicle. As illegal drugs are not released in measurable amounts in the breath, roadside drug testing must be based on other specimens (*see* **Oral Fluid Toxicology**).

Roadside detection tests are mostly immunoassays, which are read visually or by a small electronic reader. At first, urine was used for roadside drug testing because of the high drug concentrations. Unfortunately for some substances such as cannabis, the metabolites can be detected for a long time after chronic use. Consequently, the presence of drugs in urine does not necessarily indicate impairment. Another disadvantage of urine is the necessity of sufficient privacy during the sample collection. Nevertheless, roadside urine screening in Belgium significantly decreases the number of unnecessary confirmatory blood analyses for DUID [41]. An example of an on-site urine test for drugs is given in Figure 2.

In recent years, the interest in the use of oral fluid as biological matrix has increased significantly, as this matrix displays some particularly interesting properties. First of all, oral fluid can be obtained easily by nonmedical personnel in a relatively noninvasive and observable way. There is also some correlation with impairment. The results of the European project roadside testing assessment (ROSITA) indicated that for most drugs of abuse the correlation with blood is better for oral fluid than for urine. Nevertheless, the results of ROSITA and the follow-up project ROSITA 2 indicated that none of the currently available on-site oral fluid drug testing devices is reliable enough to be recommended for roadside screening for drivers [42]. However, the experience in the state of Victoria in Australia shows that random roadside oral fluid testing of drivers for methamphetamine, ecstasy, and cannabis has a deterrent effect: the level of awareness of drivers of random oral fluid testing increased from 78 to 92%, 33% of illicit drug users stated that the drug tests had influenced them (primarily to avoid taking drugs when they are going to drive) and the proportion of drug-using respondents who drove while under the influence of drugs dropped in the after period from 45 to 35% (Swann, P. 5-12-2005. Baltimore, Maryland, USA. Rosita 2 meeting. *Personal Communication*). On the other hand, the oral cavity can be contaminated by intranasal and smoked drug use, leading to extremely high concentrations in oral fluid. It is also difficult to obtain sufficient sample volume for the analysis, and the concentrations of 9-tetrahydrocannabinol (THC) and benzodiazepines in this matrix are low [43].

Evidentiary Analysis

Blood is considered to be the best matrix for confirmation analysis, because the presence of drugs

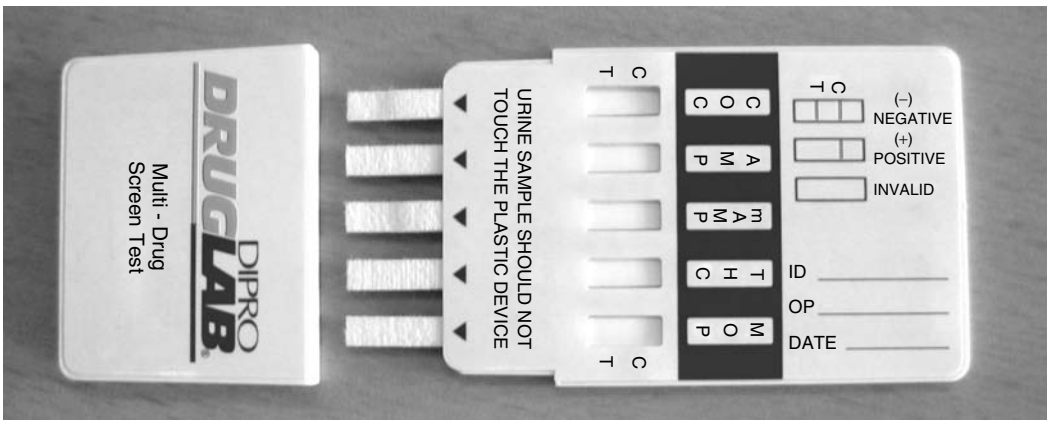

Figure 2 An example of a multidrug on-site urine test: the tips should be placed in the urine sample (urine should not touch plastic device). At the C level, a line should appear, indicating that the test is valid. At the T level, the presence of a line indicates a negative result and the absence a positive result

in blood corresponds best with recent use and impairment. In many countries with "*per se*" legislation, the only legally allowed evidence for DUID is confirmation of the presence of drugs in blood. A review on drugs of abuse monitoring in blood for control of DUID was recently published [44]. The most widely used method is gas chromatography coupled to mass spectrometry (GC-MS) because of its sensitivity and specificity. However, the procedure is labor intensive and time consuming, as solid phase extraction and derivatization are necessary for sample preparation. In addition, different methods are often needed to quantify different drug classes. Therefore, liquid chromatography (tandem) mass spectrometry (LC-MS(MS)) procedures have been introduced for different classes of drugs for confirmatory analyses or even for screening and confirmation in one step. Several laboratories are developing methods that detect a large series of different drugs in one procedure in a small sample volume [45].

Another biological specimen that is used for evidentiary analysis in the context of DUID is hair. In Germany, Italy, and other countries, hair analysis is used for license (re)granting to drug dependent persons. The hair samples are first screened by immunoassay and positives are then confirmed by high pressure liquid chromatography (HPLC), capillary electrophoresis (CE), GC-MS, or LC-MS. The major practical advantage of hair testing compared with urine and blood testing for drugs is its larger detection window, which is weeks to months, depending on the length of hair shaft analyzed. Other advantages of hair are its stability and ease-of-transportation. A disadvantage of the use of hair as biological matrix is the possible contamination by exposure to drugs in the air and the absence of correlation with recent use because of the delayed appearance of drugs in hair [46–48]. (For further information *see also* **Hair: Toxicology**.)

Conclusion

There is an increasing knowledge regarding the influence of drugs on performance, and the prevalence of drugs other than alcohol in road traffic. Experimental studies clearly show that many drugs can have a detrimental effect on driving performance. These negative effects are often even more pronounced when drugs are combined with alcohol. Results of epidemiological studies confirm the detrimental effects of drugs on driving performance. These studies show that DUID is associated with increased crash risks and increased risks of being responsible for a traffic crash. They also show that these risks increase even more when drugs are taken in combination with alcohol compared to when drugs are taken alone.

Regarding DUID there is a clear move toward "*per se*" legislation, although some countries at this time have decided to stay with impairment legislation, and some have both (e.g., Australia, Germany etc.). The detection by the police of drivers under the influence of drugs can be done by means of screening tests. In

recent years, the interest in oral fluid screening tests has grown significantly. Studies however have shown that none of the currently available on-site devices are reliable when used alone. More recent methods developed for confirmation analysis use HPLC with tandem mass spectrometry.

It is possible that future developments could lead to on-site screening of capillary blood obtained by a finger prick and confirmation of the presence/absence of drugs by analyzing dried blood spots. Possible advantages of this approach would be the easy transportation (no need for refrigeration or shipping on dry ice necessary), the stability of parent substances at ambient temperature, and less risk of loss of sample (e.g., breakage of glass tube of blood) or of infection.

Duty to Protect ***see*** Duty to Warn

Duty to Warn

Introduction

Historically, a physician's paramount duty is to his or her patient. The Hippocratic oath, upon which many modern medical students still swear prior to graduation, specifically mentions the concept of confidentiality: "Whatever I see or hear in the lives of my patients, whether in connection with my professional practice or not, which ought not to be spoken of outside, I will keep secret, as considering all such things to be private" [1]. Stated otherwise, confidentiality is the obligation of a clinician to keep a patient's privacy intact. Given the personal and intimate nature of patient complaints, confidentiality of these complaints is one of the bedrock principles of the physician–patient relationship.

Mental Health and Confidentiality

Physician–patient confidentiality is nowhere as important as in the field of mental health. Mental illness is highly feared and stigmatized in most cultures. It is therefore difficult for most persons suffering symptoms of psychosis or depression to disclose their symptoms and seek help. Once they do, it is important they feel comfortable openly discussing their problems. Since most psychiatric symptoms are subjective, there are few objective tests to diagnose mental illness, so a clinician must rely upon frank patient disclosure. Lastly, most mental health treatment involves both medication and therapy, and openness and trust are critical in the establishment and maintenance of a therapeutic relationship [2]. Consider an attorney who develops significant depressed mood. If she does not believe her communications to a therapist will be kept confidential, she may well be reluctant to provide an honest recounting of symptoms, or even seek help in the first place. A clinician therefore takes the duty of patient confidentiality seriously. With few exceptions, therapists cannot reveal any patient information without the express permission of that patient.

Exceptions to Confidentiality

Although the clinician's duty to preserve confidentiality in patient communications is long established, there are exceptions where confidentially may be ethically and legally breached. In cases where there is no legal mandate to breach confidentiality, some authors recommend an ethically driven approach of using "consultation" and "carefulness" to guide the communication of patient information [3]. In other cases, for example infectious disease, communication is legally required. In 2007, a US attorney with multidrug resistant tuberculosis took several transatlantic flights. Officials in numerous countries were made aware of his name and condition, in efforts to test and treat persons he may have infected [4]. His confidentiality was breached because others were endangered.

There is precedent in medicine, therefore, for breaching patient confidentiality to protect the public, although such breaches should be ethically limited in scope to what is necessary to achieve public protection. In mental health, this situation is represented by the "dangerous patient exception" [5] to patient privilege, which recognizes that a court might require the testimony of a therapist to protect others. For example, psychiatrists in most jurisdictions can legally petition the involuntary commitment of a person, based on dangerousness to self or others. If a depressed attorney tells his psychiatrist he is going to kill himself, the psychiatrist is not ethically or legally liable for revealing patient communications about suicide in court testimony.

Although the dangerous patient exception allowed psychiatrists to testify in the court about patients who were dangerous to self or others, this exception did not include a threat of serious physical harm until *Tarasoff* (*see also* **Dangerousness: Risk of**; **Violence Risk Assessment for Mental Health Professionals**).

Confidentiality vs. Privilege

Although confidentiality and privilege are sometimes used interchangeably, they have two very different meanings. Confidentiality is the duty of the clinician to keep patient information private. The privilege of private communication, in contrast, belongs to the patient.

Tarasoff v. Regents of the University of California

Tarasoff I

In 1968, Tatiana Tarasoff and Prosenjit Poddar both were students at the University of California at Berkley. After briefly dating, Poddar assumed a more serious relationship existed, and became depressed when Tarasoff did not feel the same. In the course of therapy at the University mental health clinic, Poddar revealed thoughts of killing a woman readily identified as Tarasoff. Poddar's psychologist contacted the University police to detain Poddar, but since he appeared to be rational to police when questioned, they let him go. Poddar stopped going to therapy, and two months later fatally shot and stabbed Tarasoff.

Tarasoff's parents sued both the mental health clinic and the University of California. In 1974, in what has become known as *Tarasoff I*, the California Supreme Court ruled that since Poddar's psychologist did not warn Tarasoff, he did not sufficiently protect her. The court stated, "When a doctor or psychotherapist, in the exercise of this professional skill and knowledge, determines or should determine, that a

warning is essential to avert danger . . . he incurs a legal obligation to give a warning" [6].

Both the defendants and the American Psychiatric Association (APA) protested this decision and requested a rehearing. In an *amicus curaie* brief the APA supported the defense on the grounds that mental health professionals are unable to predict dangerousness with any special accuracy, and the Tarasoff ruling would damage confidentiality, the cornerstone of the therapeutic relationship.

Tarasoff

In 1976, the California Supreme Court reheard the Tarasoff case and established a duty to protect: "When a therapist determines, or pursuant to the standards of his profession should determine, that his patient presents a serious danger of violence to another, he incurs an obligation to use reasonable care to protect the intended victim against such danger." Duty to warn was merely one option of how to protect [7]. The court responded to the APA's concerns that the Tarasoff duty would breach patient confidentiality by recognizing the precedent of the dangerous patient exception. In a now-famous quote, Judge Tobriner commented, "the protective privilege ends where the public peril begins" [7].

Controversy and Tarasoff

Duty to Warn, or Duty to Protect?

Although the final Tarasoff ruling clearly established a duty to protect, this duty has often been misinterpreted by both courts and therapists as a duty to warn [8]. This confusion is clearly reflected in the subsequent history of Tarasoff in California, in which the courts emphasized warning to the exclusion of any other type of protection [9].

After the second Tarasoff decision in 1976, which created a duty to protect, several court cases found therapists at fault for failing to predict dangerousness. For example, therapists were found liable for failure to warn third parties of a patient's inability to drive [10]. Although some clinicians felt that therapists had only themselves to blame due to "overstated claims of capacities to predict and treat aggressive behavior" [11], California mental health professionals sought an "immunity statute" to provide some protection from the liability for failure to predict dangerousness. In 1986, the California Civil Code was enacted as a "Tarasoff immunity statute". This statue "made clear that victims had to be readily identifiable and was intended to establish warning as one way . . . (to) discharge the duty to warn or protect" [9].

Despite this statute, the Tarasoff duty continued to be misunderstood as a duty to warn. This misinterpretation was evident in two California Court of Appeals cases involving former police officer G. Colello, who killed first his exgirlfriend's lover (K. Ewing), then himself. Mr Colello had communicated his intent to harm Mr Ewing to his father, who reported this to Dr Goldstein, Mr Colello's therapist. Mr Colello was hospitalized but soon discharged, despite communication of the threatening statements Mr Colello made to his father [9].

Mr Ewing's parents sued both Dr Goldstein and the hospital. The court ruled that therapists had a duty to protect solely by warning, regardless of whether they judged this to be the best way of protecting. A therapist could therefore be held liable if he decided to protect potential victims of his patient by, for example, involuntary hospitalization, but not warning. Moreover, this duty would be established whenever a therapist believed a threat to be credible, without any risk assessment or evaluation of dangerousness. A therapist could therefore breach patient confidentiality and issue a warning, based merely on a patient's verbalization of threat (or communication of threat to family members), regardless of whether the threat was credible. As a result of persistent lobbying by California mental health groups, a 2006 amendment to the California Civil Code returned the Tarasoff duty to a duty to protect [9]. At present, therapists in California can now individualize their responses to assessed risks, a recommended approach [12, 13].

The Therapeutic Relationship

Many therapists worried that if they were unable to guarantee confidentiality under Tarasoff, patients would either avoid honest disclosure in therapy or eschew therapy altogether. A variety of studies, however, have showed that issuing a Tarasoff warning has had a minimal effect on the therapeutic relationship [14].

Criminalization of Tarasoff

After *Tarasoff*, some argued that the decision allowed for "criminalization" of the doctor–patient relationship. In subsequent California cases, the courts mandated the testimony of a therapist if that therapist

had given a warning under *Tarasoff*. The therapist had to testify not only about the warning but also about other communications that might provide justification for the warning. One author noted in 1992 "the continuing erosion of confidentiality has resulted in psychiatrists or other mental health professionals becoming prosecution witnesses at the criminal trials of their own patients" [8]. In one instance a psychiatrist even surreptitiously gathered evidence that was ultimately used in testimony against his patient [15], an action that seems to go against the root of medicine's precept, "do no harm".

Outside of California, court rulings seem to leave open the possibility of continued "criminalization". In 1996, the US Supreme Court found in *Jaffee v. Redmond* a patient–therapist privilege, but acknowledged exceptions to this privilege. In the line of duty, police officer Redmond shot and killed Allen, a man she believed was brandishing a weapon toward a third party. Allen's estate (Jaffee) disputed this and sued for damages. The prosecution discovered that Redmond sought counseling after the shooting, and demanded the therapist's notes for cross-examination. When the therapist refused, the judge instructed the jury that the notes had likely been "unfavorable" to Redmond. The jury found for Jaffee.

This decision was overturned by the court of appeals (seventh circuit), which cited that "reason and experience" under Rule 501 of the Federal Rules of Evidence compelled the trial court to recognize and protect a therapist–patient privilege. The US court of appeals agreed, but found that this privilege could not be uniformly protected. In a footnote to the decision, the court stated, "... we do not doubt that there are situations in which the privilege must give way, for example, if a serious threat of harm to the patient or to others can be averted only by means of a disclosure by the therapist" [16]. This decision seems to leave room for courts mandating disclosure by a therapist in court proceedings, including criminal [17].

The Legacy of Tarasoff

The United States

In the past 30 years, 27 states have adopted *Tarasoff*-defining statues [9]. In adopting these statutes, courts have used a variety of approaches, and reached a variety of conclusions. Given the variety of court reactions, and the ever-changing nature of *Tarasoff*, one author concludes, "even in states that have *Tarasoff* statutes, clinicians must continue to rely on their clinical and ethical judgment, rather than statutory guidance, when considering potential protective disclosures or future drafts of protective disclosure statutes" [18].

Canada

In Canada, the courts have recognized a common law exception to doctor–patient confidentiality in the area of public safety [19], but in general have not legislated a duty to protect. The province of Ontario has probably come closest to such legislation. In 1998, the province organized a medical expert panel on duty to inform, "to consider the duty of Ontario physicians in circumstances where a patient threatens to kill or cause serious bodily harm to a third party". After reviewing the *Tarasoff* case and literature on risk assessment, the panel concluded that although the principle of confidentiality should be closely guarded, it should be superseded in the cases of suspected serious harm. The panel recommended the following: physicians have a duty to inform a third person when a patient threatens to cause serious harm to another person, and "it is more likely than not the threat will be carried out". The panel concluded that "the need to protect the public from likely risk of serious harm supersedes a physician's duty to keep patient information confidential", and recommended "a standard of practice for the assessment of risk when a threat is made, and this standard should be enforced" [20].

In 1999 the Supreme Court of Canada heard the case, *Smith v. Jones*, and determined that three factors should be considered before confidentiality should be breached in favor of public safety: (i) is there a clear risk to an identifiable person or persons; (ii) is there a risk of serious harm or death; and (iii) is the danger imminent? Although this case did not establish a legislative duty to protect, it did clarify questions that Canadian mental health professionals should ask when assessing risk of violence [19].

Europe

Most European courts, while recognizing that psychiatrists might need to breach confidentiality in cases of patient dangerousness, have not issued *Tarasoff*-type statuary duties. At the time of this writing, however, some speculate that the European Court of Human

Rights' Ruling in *Osman v U.K.* (2007) may bring about such statues [21].

Australia

Although there is no case law in Australia that specifically protects clinician–patient confidentiality, the criminal courts have exercised discretion in requesting the disclosure of privileged information. In the civil courts, however, confidentiality is specifically protected by statute in Victoria, Tasmania, and the Northern Territory. In New South Wales, the privilege of clinician–patient confidentiality is suggested by general law [19].

In 1999, the Supreme Court heard the case *Clifford v. Victorian Institute of Forensic Mental Health and Anor*. In this case, local police refused to provide a search warrant to obtain a psychiatric file that might contain information relating to a homicide. The court concurred, finding that "public interest immunity" applied to the files [19].

The Duty

What then is the duty of a therapist when he or she is worried about a potentially dangerous patient? Historically, it has long been recognized that breaching confidentiality in such cases has merit. State and legislative action since the Tarasoff rulings, however, suggest or mandate a duty to protect. Today's mental health practitioner must, therefore, balance the duty of patient confidentiality, with a duty to protect others if that patient is a threat.

Most agree that the best way of determining threat is an assessment of patient dangerousness. When Tarasoff was first heard it appeared that mental health professionals had no ability to predict dangerousness [22]. In the past three decades, however, researchers and clinicians have developed successive "generations" of risk assessment tools that show some predictive accuracy [23]. Despite this increased accuracy, however, it is still up to individual clinicians to judge when a patient seems sufficiently dangerous such that duty shifts from the patient to the public. One study showed that clinical judgment varies widely on this issue [24]. It is possible that incorporating risk assessment into training would help standardize clinical judgment [25] (*see* **Risk Assessment: Patient and Detainee**; **Violence Risk Assessment for Mental Health Professionals**).

The Future

The jurisprudence on the duty to protect continues to evolve. Prudent clinicians should become familiar with laws and statues in jurisdictions in which they practice. Professional associations also regularly address issues such as duty to protect, and issue helpful guidelines.

Earprints: Interpretation of

The Use of Earprints for Person identification

Burglars may listen at doors or windows before breaking and entering. Oils and waxes on their ears will then leave prints that can be made visible using techniques similar to those used when lifting fingerprints. Such prints appear to be characteristic of the ears that made them and may be used for person identification or to link various cases. In May 2006, suspected burglars were convicted in the Netherlands for a large series of burglaries that were linked by the presence of similar earprints, as well as toolmarks of what was believed to be the same adjustable wrench.[a] In June 2008, a similar success story was recorded from Belgium when a number of suspected burglars were convicted after earprints provided part of the evidence.[b] In the Dutch case, the earprint evidence was challenged and subsequently accepted in appellate court.[c]

Success stories such as these spark enthusiasm for the use of earprints among police officers and prosecutors. The application of earprints as evidence in court has, however, also frequently been the subject of criticism on the grounds that the process of individualization was considered to be subjective (e.g., [1–3]). Indeed, formal protocols for collecting earprints have not yet been implemented. There are also no generally accepted methods for analyzing and comparing earprints. In the United States, a conviction for murder was overturned in 1999 after an appellate court ruled that the earprint evidence was not generally accepted by the forensic science community under the Frye standard [4]. Prosecutors later dropped the charges. In the United Kingdom, the public image of earprints reached a low point with the case of Mark Dallagher, who was accused of murdering an elderly woman and convicted in 1998 on the basis of earprint evidence. In 2004, when it was found that his DNA did not match the DNA that was recovered from the original earmark, all charges against him were formally dropped.

The possibility that the DNA evidence was contaminated should, however, not be ignored. The print was secured by officers who did not intend to perform a DNA analysis, therefore not taking precautions to prevent contamination. The equipment that was used could easily have been contaminated from the previous cases. Also, the original mark had been stored for years on a nonsterile surface before DNA was recovered, as Kieckhoefer *et al.* [5] pointed out.

Some restraint on the use of earprints for person identification is, however, advised. An earmark is usually left in a publicly accessible area before the crime itself is committed (e.g., on the *outside* of a building before a break-in). Furthermore, no accurate indication of the time of its formation may usually be inferred.

With respect to the Dallagher case, it was reported that the window on which the earmark was discovered had been cleaned three or four weeks before the murder took place [6]. The presence of his earprint at the window of the murdered woman could be

considered suspicious, and reason for questioning. Without additional evidence, however, it would not provide sufficient grounds for a conviction for murder as all it implied was that Dallagher listened at the house of the murdered woman within the three to four weeks period leading up to the murder.

A more fundamental point of criticism may be that the study of earprints as a quantitative and rigorous discipline is immature. Standard tools and methods for analyzing earprints are not yet available. As there is no fully automated system for comparison available, the process of individualization at this moment involves visual comparison of the crime scene print with control prints of a given suspect. In this process, one records similarities and differences. Van der lugt [7], in explaining the procedure, quotes Tuthill [8] in saying that one should form an opinion on whether or not the similarities are of such number and significance as to preclude the possibility of their having occurred by mere coincidence. One should further make sure that there are no differences, except "those that can be accounted for" [7]. But when are differences sufficiently small or insignificant as to claim that we can account for them? And when is the degree of similarity of such significance as to preclude the possibility of it having occurred by mere coincidence? Moreover, when can corresponding individual characteristics be said to *agree*? One should keep in mind that not even characteristics in two prints from the same ear will ever be identical. In practice, judging agreement means judging the degree of similarity between various characteristics. As degrees of similarity usually vary continuously, the term *agreement* is difficult to define objectively.

Indeed, subjectivity is an important factor that can diminish the evidential value of earprints. Human experts are required to make the final judgment about individualization, even when automatic systems are used to analyze the forensic data. On the issue of subjectivity in fingerprint individualization, Stoney [9] commented: "The modern image processing techniques used to classify fingerprints may provide an illusion of complete objectivity, yet only a list of most likely matches from a database are provided, and the expert will have to compare and make conclusions." This would also be the case for earprint individualization. Some level of subjectivity would therefore have to be accepted. It may, however, be mitigated using an appropriate program of training and proficiency testing. Progress has been made in developing quantitative methods for comparing large samples of earprints. The search is on for operator-invariant procedures that can be used to calculate the match probability for a combination of two prints. It is hoped that, by combining image-processing techniques and large, representative samples, tools can be developed that will assist experts in making objective statements on individualization. Finally, there is a growing consensus that this should preferably be done using probabilistic terms [10, 11].

Automatic Matching and the Probability of a Match

A number of initiatives toward (semi-)automated classification or matching of earprints have been undertaken. Image-processing algorithms to extract features from the anthelix area were presented by Valvoda [12], quoted from [11]. In 2005, Rutty *et al.* [13] presented their concept of a more elaborate "computerized earprint identification system". Their research, however, was based on a database containing 800 prints of 800 different ears, and therefore did not allow the possibility to verify if selected parameters offered, besides a high interindividual variability, also a sufficiently small intraindividual variability. In line with Ingleby *et al.* [14], Rutty *et al.* proposed to calculate centroids of imprinted areas. Parameters generated using the position of these centroids offer clues for individualization. In both the studies, it was assumed that the effect of variation in applied pressure would be overcome by the use of centroids. As we showed in Meijerman *et al.* [15], however, the imprints of morphological structures do not only narrow or widen due to a chance in applied pressure. To some extent, features can change position in relation to each other as well.

Partners in "FearID", an international research project aimed at the individualization of earprints, have also attempted to design a (semi-)automatic matching system for earprints. For this purpose, multiple earprints of 1231 different persons were collected and analyzed. To facilitate the detection of the various imprinted anatomical structures for analyses, the shape and position of the imprinted ear surface in each analyzed print was manually indicated. This was done by drawing a spiral-shaped polyline from the apex of the anthelix to the lowest point of the imprinted earlobe (Figure 1). The use of

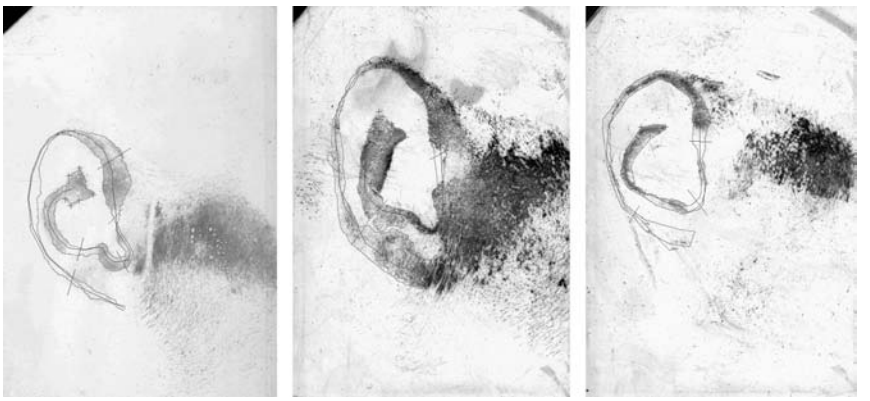

Figure 1 Imprinted earprint features captured in a spiral shape. The longitudinal center line is the indicator line, transverse lines indicate transitions between gross anatomical feature zones [Reproduced with permission from Ref. 23. © Barge's Anthropologica, 2006.]

image-processing techniques to find the imprinted ear surface meant that the manual labeling did not need to be extremely precise. We refer to Van Munster *et al.* [16] for further reading on image processing for earprint analysis.

A number of approaches to automatic classification and matching were then explored. Contours of the imprinted ear surface were used to calculate the width and curvature of the various parts in the spiral shape. This data was then compared among prints ("weighted width comparison" and "angular comparison"). Additional information for classification was provided by the variation in relative intensity along the spiral shape. The operator further annotated minutiae, landmarks, and other characteristics in each earprint, and indicated transitions between the imprinted gross anatomical features in the spiral shape. This generated additional data for comparison that was analyzed using a method called *vector template matching* [5]. The performance of the weighted width comparison of earprints appeared to be operator independent [17, 18]. Achieving interoperator objectivity in vector template matching based on manual annotations, however, appeared more problematic. Performance of the method appeared to vary significantly when prints were annotated by different operators [19].

In addition to the described semiautomated approaches, we have applied a method to match earprints fully automatically [20]. As the method requires no human input, it allows objective and repeatable earprint comparisons that are free from observer bias. Furthermore, it can handle tasks that are very time consuming for a human expert to consider. In this method, referred to as *keypoint matching*, algorithms automatically detect and describe the salient regions – "keypoints" – in an earprint and use them to match the corresponding anatomical features. Keypoints can be detected and described using various methods, but the experiments conducted so far have been conducted using the methods described by Lowe [21].

The method was initially tested using a sample of 36 right-earprints from six pairs of identical twins [20] and is shown in Figure 2. For each earprint in the sample, keypoints were located and described. The appearance and constellation of the described keypoints in each earprint could then be compared with those found in all the other prints of the sample. The number of matching keypoints between any two prints was chosen to indicate the level of similarity between these prints. These results could then be used to construct a ranking list, or "hit-list", for potential matches. In this setting, keypoint matching provides a tool for recovering matching earprints from a large database. The possibility to assess the evidential value of an assumed match between two earprints is another potentially valuable application of this method. There is a need for methods to describe the weight of evidence – in this case an earprint comparison – as a likelihood ratio, the numerator of the ratio being the probability of obtaining the evidence,

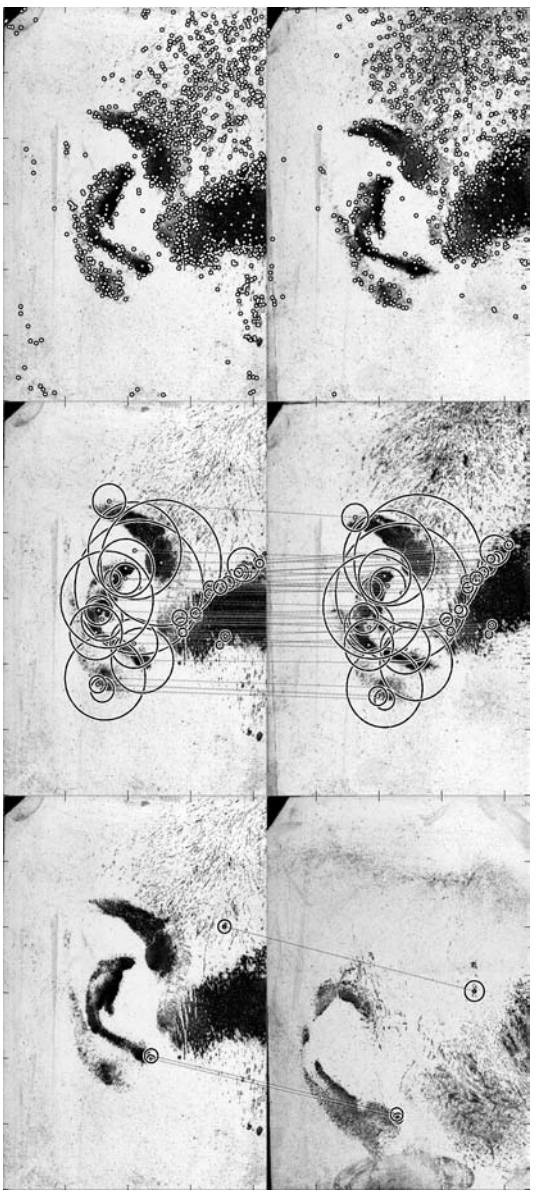

Figure 2 Keypoint matching illustrated. For reach pair of illustrations, the print on the left is the same. The upper pair shows all detected keypoints in two different prints of the same ear. For the middle pair dotted lines join matching keypoints. In the lower pair three keypoints matches to a print from a different ear are shown (note that prints do not need to be aligned) [Reproduced with permission from Ref. 23. © Barge's Anthropologica, 2006.]

given that the earmark was made by a certain person (usually the prosecution hypothesis), and the denominator being the probability of obtaining the evidence, given that the earmark was made by someone else (usually the defense hypothesis) [1]. The development of fully automatic methods for comparing earprints is an important step toward this goal. Firstly, because they are not the subject to observer bias and secondly because they make the task of analyzing large samples tractable and open the possibility of making reliable probabilistic statements based on large-number statistics. In the case of keypoint matching, similarity scores between earprints can be generated automatically and by using control samples it is possible to measure the frequency with which certain similarity scores are obtained when comparing the prints obtained from the same individual or from different individuals. Thus, the probability of obtaining a certain earprint given either the defense or prosecution hypothesis can be represented by the probability of obtaining a given similarity score given either hypothesis. The sample containing 36 prints from 6 pairs of identical twins is a good testbed for developing automatic methods because the earprints from twins show strong similarities and distinguishing individuals is challenging. However, it is not an appropriate sample for estimating likelihood ratios for routine earprint comparison. Firstly, it is by no means representative of earprint population in general and secondly, it only contains 12 individuals. Making more reliable estimates requires work on a large, well-defined sample. As a result of the FearID research project, a working sample containing three to four prints per ear of both ears of 772 persons is available for research. An additional validation sample further contains a similar number of prints per individual from another 459 persons. In a preliminary and unpublished study, using keypoint matching on a sample of 1552 ears showed promising results; when these prints are compared to a single print from a different, randomly chosen donor none show more than 10 keypoint matches, whereas when a different print from the same donor is used over 60% showed more than 10 keypoint matches. Further work is, however, required to refine the technique and gather rigorous statistics.

Intraindividual Variation

At this point, we would like to emphasize the importance of studying intraindividual variation in

addition to interindividual variation in prints. For an earprint to have evidential value in a forensic setting it needs to posses a set of features for which not only the interindividual rate of occurrence is low but the intraindividual rate of occurrence is high. In order to be able to test the latter, the research database of earprints should be compiled in such manner that realistic intraindividual variation is taken into account. In the following section, we briefly summarize the results from a number of studies exploring possible sources for variation in different prints from a single ear.

Changes in the amount of oils and waxes present on the ear surface due to, for instance, variation in outside temperature or whether the ear was recently cleaned or not could in theory influence the dimensions and/or intensity of the imprinted area. In turn, this might affect the area in which characteristics can be found. It may also affect the visibility of such details. We therefore collected multiple earprints from a number of ears. From each ear, prints were collected before and after the ear was cleaned. We then compared print-mass, which is a measure for the size and intensity of the imprinted area. No evidence for a significant decrease in the mass of prints created by cleaned ears was observed [22]. To determine if the imprinted details are of equal quality, it would require further investigations into the stability of characteristic features (i.e., valuable for individualization) in prints of recently cleaned ears.

Another – more often explored – source of intraindividual variation in earprints is the variation in pressure that is applied by the ear to the surface during listening [23–25]. We have tried to induce changes in applied force between different listening efforts of individuals. We varied the level of ambient noise while recording the force that was applied during listening, but no significant effect from the level of ambient noise on applied force was observed [26]. Listening to either sound or silence did also not appear to significantly affect applied force [27]. We did, however, note a significant effect from changes in the level of the target sound. When the sound level was reduced in between listening efforts, it appeared to cause the listeners to apply more force [26]. In addition, we observed that listeners generally applied less force during their first listening effort. We assumed that – unfamiliar with the procedure – our subjects were more cautious during first listening efforts.

It should be noted that equal variation in applied force did not necessarily lead to equal intraindividual variation in the prints. For some ears, small changes in force appeared to have a relatively large effect on the prints, while for other ears relatively large changes in force seemed to have little effect on the appearance of the prints [15, 26]. Prints of the same ear may further be affected by a change in pressure distribution [15, 26, 28]. The duration of listening also appeared to affect the appearance of an earprint. We found that the mass of prints significantly increased with length of listening [29]. Kieckhoefer *et al.* [28] showed that fidgeting of the ear during listening increased the amount of imprinted surface.

When compiling a research database, or collecting a number of control prints from a suspect, experience gained about the factors that affect the appearance of a print may be exploited to induce a broad range of realistic intraindividual variation. For example, applied listening force appears to be generally lower during a first listening effort. A loud target source during this attempt, or a relatively short duration of ear-surface contact, will increase the chance of yielding a print with a relatively low print-mass.

Finally, during various studies into the force applied while listening, we have noted that intraindividual variation in applied force is comparatively small when compared with the interindividual variation [26, 27]. This observation was confirmed by Kieckhoefer *et al.* [28]. To prevent the introduction of unrealistic intraindividual variation in a set of prints, which would likely impede the search for diagnostic features and lead to misrepresentations of the probability scores for a match between prints, we would advise that, if possible, reference prints of the suspects are "functional earprints", i.e., taken after actual efforts at listening.

Education and Accreditation in Forensic Science

Introduction

Forensic science is the quintessential multidisciplinary field. It incorporates methods, theories, and concepts from practically every science including chemistry, physics, biology, mathematics, statistics, and many disciplines of medicine. If a science has a public or legal application, it is a forensic science. On one level, education in forensic science could be accomplished by giving students a strong scientific background and then either allowing them to learn forensic science by applying this knowledge on the job, or by adding classes that teach the student how to apply scientific knowledge to the sometimes peculiar circumstances of scientific evidence analysis. For much of its recent history, especially in the United States, that has been the way the forensic science is taught. Many early "forensic science programs" were little more than a chemistry or biology degree with an internship in a crime laboratory. In some cases, the program was largely based on criminal justice, with little "hard" science coupled with a crime lab internship. These types of programs still exist but are becoming discredited.

Since forensic science is mainly applied science, what is wrong with teaching it at the college level this way; a science education with an internship? Actually there are several things wrong with this approach. First, and most important, it assumes that forensic science is "only" the application of science to criminal matters. In fact, there is much more to forensic science. It is part of the criminal justice system and the ultimate consumers of forensic science are judges, juries, prosecutors, defense attorneys, victims, and defendants. In addition to the science itself there are considerations of expert testimony, law and jurisprudence, ethics and quality assurance and control including accreditation of laboratories, certification of forensic scientists and proficiency and competence testing as well as development of standard methods of analysis for various types of evidence. One of the major shortcomings of forensic science has been and continues to be a lack of attention to the forensic part of forensic science education. Over the years, this has caused significant problems within the field. Many crime lab directors (the main consumers of many forensic science graduates) mistrust forensic science education because it does not deliver what it promises and they rely instead on graduates from "real" science programs and then train them on the job.

Another problem with the "hard science plus internship or on the job experience" model of forensic science education is that it denies the existence of a body of knowledge that is unique to forensic science. There are several disciplines that are unique to forensic science. They have few or no applications outside the criminal or civil law context. These include fingerprints and other friction ridges, handwriting and printed word analysis including inks and papers, and firearms and other tool marks. They are also (incorrectly) disparaged because they involve only physical comparisons and do not use the methods of scientific inquiry. It is no coincidence that there are few courses in the US forensic science education programs in these areas of forensic science.

Finally, the traditional method of forensic science education inhibits its recognition as a profession in its own right. Among the hallmarks of a profession are that it has a body of specialized knowledge and a strong educational foundation. If education programs do not recognize this and offer the forensic as well as

the science part of forensic science, then it will not be regarded or respected as a profession.

Fortunately this situation has been changing. There are an increasing number of forensic science education programs in the United States and other countries that offer both the hard science and forensic aspects of forensic science in their degree programs. There is now a movement to accredit forensic science education programs using consensus standards that contain a broad spectrum of topics that help define forensic science as a profession (see below). There are a number of reasons for these changes. One of the important catalysts has been the development of DNA typing. The stringent requirements of DNA methodologies and their history in medical science require that attention be paid to the forensic aspects of biological applications. The increase in public awareness of forensic science from TV shows, books, and movies has put more attention on the forensic sciences and increased interest among prospective students. This, in turn, has caused explosive growth in the number of forensic science education programs. Prospective students, crime lab directors, and criminal justice officials have demanded that there be some order and rigor in such programs. As will be demonstrated later, this has given rise to the forensic science education program accreditation movement that is now taking place in the United States.

Structure of Forensic Science Programs

The website of the American Academy of Forensic Sciences (AAFS) (www.aafs.org) currently lists more than 140 forensic science education programs in the United States. Some estimates place the number of programs in the United Kingdom at more than 300. There are both undergraduate and graduate forensic science programs worldwide. In the latter, the vast majority of programs are at the master's degree level. There are few doctoral degrees in forensic science worldwide.

Undergraduate Programs

There are many models for undergraduate forensic science degree programs. One of the more popular ones is to have a "concentration in forensic science" within a Bachelor of Arts or Science degree. Most commonly the degree is in chemistry, although some are in biology. A few are in criminal justice, but these are only a small fraction. A number of colleges and universities have a forensic science department or program and offer a "Bachelor of Science degree in Forensic Science". Some of these programs are called *Criminalistics*, others are *Forensic and Investigative Sciences,* others are *Police sciences* and there are other variations. These programs are characterized by their strong background in chemistry and biology with supporting forensic science lecture and lab courses as well as criminal investigation, law, criminal justice, etc. Internships and a research component are required or strongly encouraged in most or all of these programs. At this writing, the great majority of forensic science programs in the United States are on the undergraduate level as are most of the new programs. This is probably due to the lower cost and higher student count in undergraduate programs. They take advantage of existing science and criminal justice courses and, because research is not as high a priority as it would be in a graduate program, lab facilities tend to be less expensive.

Undergraduate forensic science curricula vary widely but most have an introductory course that may be open to all students, not just those in the major. It is not uncommon for such classes to attract hundreds of students. There are also usually a few forensic science laboratory courses that teach students how to apply scientific concepts to evidentiary materials and how to interpret the results. Many programs also have courses in crime scene investigation and those that cover ethics, quality assurance, crime lab culture, the law, etc.

Master's Degrees

Like bachelor's programs, master's degrees are also offered in a number of venues. Most of the master's programs today offer "Master of Science in Forensic Science". These programs may offer concentrations in "forensic chemistry", "biology", "computer forensics", "anthropology", and "other disciplines". The most common are chemistry and biology. Other institutions offer a concentration in forensic science within a science department such as a "Master of Science in chemistry with a concentration in forensic science".

Master's degree programs generally span 30–40 credit hours. Requirements for admission are usually

a bachelor's degree in a science or forensic science. There are relatively few graduate programs and competition for spots can be fierce. It is not unusual for students to have grade point averages (GPAs) (US GPAs) of over 3.5/4.0 in order to gain admission. Some programs attract more than one hundred applications for a dozen or so spots.

Since students in graduate programs have a strong science background when admitted, most of the coursework in the program is in forensic science and related areas. Since most of the students will not have a forensic science background there is at least one graduate-level introductory course in forensic science and at least one law and forensic science class. There are also advanced lab courses in the various science areas. Some programs have courses in one or more areas of criminalistics, such as firearms and tool marks or questioned documents. Most programs have a research component and it is common for a master's thesis to be required although, exceptions are often made for students who are already working in a forensic science lab. Internships are also available in most programs.

PhD Programs

There are very few doctorate programs worldwide at this writing. This may be due to a combination of factors including cost to the university, cost to the students, lack of a reliable source of research funding, lack of student fellowship and assistantship money, and scarcity of qualified faculty. Most crime lab systems do not recognize the value of having a PhD for a bench scientist job and do not pay graduates any more money than they would a qualified candidate with a BS or MS degree.

There is an increasing need for PhD graduates in forensic science. They are needed to staff the mushrooming forensic science education programs, to perform research in industry and government and to take on administrative roles in forensic science. Some universities are attempting to address these needs by offering a forensic science concentration within a science PhD program. At least one university offers qualified students the opportunity to obtain a PhD in a science and a master's degree in forensic science at the same time. The dual program takes no longer than the PhD alone because the two departments share elective courses and the master's thesis may be waived if the doctoral dissertation has a forensic science component.

Accreditation of Forensic Science Education Programs

In recent years, public attention to forensic science has increased dramatically owing in part to the proliferation of forensic science related television shows, movies, and books. This has resulted in unprecedented demand for forensic science education programs. The number of students who have expressed a desire to major in forensic science has exploded, prompting many colleges and universities to respond by creating numerous forensic science programs. At some institutions, forensic science is the most popular major on the campus. Many of these new forensic science programs were started hastily, by people who have no significant background in forensic science education or practice, and often without sufficient resources. The result has been a veritable hodgepodge of offerings; some very good and some deplorable. With more than one hundred offerings in the United States, it is difficult or impossible for students or crime lab directors to discern which programs are scientifically and forensically sound. In response to this crisis, the AAFS and the National Institute of Justice (NIJ) teamed up to formulate a solution: development of standards for undergraduate and graduate forensic science programs and creation of a mechanism of accreditation of programs that would measure them against these standards. In the United Kingdom, the Forensic Science Society has launched an accreditation scheme for higher education courses in forensic science. This scheme accredits only three main areas; crime scene investigation, laboratory analysis, and evaluation and presentation of evidence.

The Forensic Science Education Programs Accreditation Commission (FEPAC) was formed in 2002. Its policies and procedures manual, which can be found at www.aafs.org, describe its beginning and development as follows:

> The American Academy of Forensic Sciences (AAFS) was established in 1948 to promote education for and research in the forensic sciences; to encourage the study, improve the practice, elevate the standards, and advance the cause of the forensic sciences; to promote interdisciplinary communications; and to plan, organize, and administer meetings, reports, and other projects for the stimulation and advancement of these and related purposes.

An assessment of forensic sciences published in 1999 by the National Institute of Justice (NIJ) entitled *Forensic Science: Review of Status and Needs*, described the educational and training needs of the forensic science community as "immense." Among the recommendations contained in the report was the establishment of the following:

- National standards for education in forensic sciences,
- An independent, community-wide, consensus-building, standard-setting body such as a technical working group for education in forensic sciences, and
- An accreditation system for forensic science education programs.

The NIJ established a technical working group for education and training in forensic sciences (TWGED) in 2001 for the purpose of recommending sample curricular guidelines for educational programs in forensic sciences. The results of TWGED's deliberations were delineated in a research report published in 2003, entitled Education and Training in Forensic Sciences: A Guide for Forensic Science Laboratories, Educational Institutions, and Students.

Acknowledging the importance of an accreditation system for academic programs built on the foundation of TWGED, the AAFS in 2002 established an ad hoc committee, called Forensic Education Programs Accreditation Committee, to explore issues related to the development of such an accreditation system. In 2004, the committee became an official standing committee of the AAFS at which time its name was changed to Forensic Science Education Programs Accreditation Commission (FEPAC).

The Policies and Procedures manual of FEPAC also describes the Commission's role, mission, and composition as follows:

Authority. FEPAC is responsible for, and has final authority over, the standards used for the evaluation of college and university forensic science programs for purposes of accreditation, judgments involving compliance with those standards, and accreditation decisions.

Composition. FEPAC is composed of eleven Commissioners. Five Commissioners are forensic science educators, five are forensic science practitioners, and one is a representative of the public. All Commissioners (except the public member) must be either a Member or Fellow of the AAFS. To serve as a forensic science educator, an individual must be a faculty member or an administrator at a college or university that offers a FEPAC-accredited forensic science program. At least three of the forensic science practitioners must be members of the American Society of Crime Lab Directors (ASCLD). No two educators may be from the same institution, nor may any two practitioners be from the same agency.

The representative of the public may not be (1) an AAFS member; (2) an employee, member of the governing board, owner, or shareholder of, or consultant to, either a forensic science program or the institution in which the forensic science program is located; (3) a member of any trade association or membership organization that is related to, affiliated with, or associated with FEPAC; or (4) a spouse, parent, child, or sibling of any individual identified in (1), (2), or (3).

The FEPAC Chair may appoint committees to assist the Commission with its operational responsibilities, and these committees may include nonvoting members to the Commission.

Selection of Commissioners. FEPAC solicits nominations for positions on the Commission from its relevant constituencies, including forensic science programs, ASCLD, the Criminalistics Section of AAFS, regional forensic science organizations, forensic science certification bodies, and government agencies such as the NIJ, the National Institute of Standards and Technology (NIST), and the U.S. Department of Education. FEPAC reviews the nominations it receives and prepares from among the list of nominees a slate of individuals to serve on the Commission. FEPAC then recommends the slate to the President of AAFS, who appoints individuals to serve on the Commission after reviewing FEPAC's recommendation.

Chair of the Commission. The Chair of the Commission is elected annually by the members of the Commission and must be either a forensic science educator or a forensic science practitioner. The new Chair shall take office on the last day of the annual AAFS meeting. The Chair may be reelected.

Terms of Office. The term of office for all Commissioners is three years, with appointments made on a staggered basis. After serving one term, a Commissioner may be reappointed to a second three-year

term. However, no Commissioner may serve more than two consecutive three-year terms.

The ten individuals appointed by the President of AAFS in 2002 to be members of the Forensic Science Education Programs Committee will serve as the charter commissioners of FEPAC from February 2002 until February 2005. A public member will be appointed to the Commission by the President of AAFS during that period.

Beginning in February 2005 and continuing in February 2006 and February 2007, the President of AAFS will, after reviewing a slate recommended by FEPAC, appoint new Commissioners to replace the charter members of the Commission, according to the following schedule: In February 2005, one charter forensic science educator and one charter forensic science practitioner will be replaced. In February 2006 and again in February 2007, two of the charter forensic science educators and two of the charter forensic science practitioners will be replaced. All new appointees will serve three-year terms and may be reappointed to one additional term.

At this writing, 16 institutions have had their forensic science programs accredited by FEPAC and 10 more are in process. The Commission receives about a half dozen applications each year. A list of the accredited programs is maintained on the AAFS website. TWGED's publication on standards; "Education and Training in Forensic Sciences: A Guide for Forensic Science Laboratories, Educational Institutions, and Students", is also on this website.

The Future of Forensic Science Education

Assuming that the resources are available, the future trend in forensic science education will undoubtedly be toward more graduate-level programs. The demand for master's degree programs is very strong and expected to stay that way. The job market for graduates of all forensic science programs is strong and is especially so for master's graduates. There is also increased activity toward the formation of PhD programs and several should debut in the next few years. There are however, significant structural impediments that have been and will continue to hamper progress in forensic science education:

1. Qualified faculty

Since there are few PhD programs in place, there are very few qualified PhD forensic scientists being produced that could staff forensic science programs. There are only a handful of postdoctoral programs available for scientists who want to get some practical experience in forensic science. The FBI offers a visiting scientist program and the NIST offer postdoctoral opportunities. The Armed Forces Institute of Pathology and a few private labs offer postdoctoral training for biologists and medically trained scientists. The great demand for faculty is causing administrators to hire chemists and biologists with no forensic science experience and then getting them an "externship" in a crime lab to gain some experience. This is better than nothing but cannot adequately substitute for faculty with real crime lab experience.

2. Funding for graduate students and research

There has been a general trend toward disinvestment in scientific research by the Federal Government in recent years. The amount of funding for forensic science has always been extremely limited. It has gotten a bit better in recent years when the Government, through the NIJ, has been funding DNA technologies. Most of this money has gone to increasing capacity of crime labs to perform DNA typing, although some has also gone to research. The NIJ also provides some limited funds for general forensic science research and student support. This effort is hampered by the increased tendency to earmark the NIJ budget for pet Congressional projects and by competition from Federal laboratories for these scarce funds. A much larger investment in forensic science research and student support will be necessary if the quality of forensic science programs is to continue to increase.

3. Continued growth in forensic science education programs

At some point the number of graduates from forensic science programs will outstrip the demand for them in the job market. This is already occurring among graduates from bachelor's programs, who are becoming less competitive in the job market compared to master's degree graduates. FEPAC's accreditation efforts will hopefully help identify the best programs. There are also signs of Federal links developing that would give some monetary preferences to accredited institutions. This may help weed out the poorer quality programs over time.

Summary

Forensic science education is experiencing explosive growth today because of heightened public awareness brought on by increased attention by the media and by the publicity generated by real cases such as O.J. Simpson. This has caused a proliferation in educational degree offerings. Information from the United Kingdom suggests that some programs are undoubtedly a consequence of the need to attract students to science faculties with failing traditional scientific programs. Many of these programs are not legitimate forensic science degrees and do not serve the forensic science community well. Development of reputable programs is hampered by the lack of faculty resources and research and student support. An effort by the NIJ and the AAFS has resulted in the formation of a Commission that accredits forensic science programs against strict educational standards. This will give crime lab directors and prospective students some tools to use to evaluate forensic science educational programs for quality.

Elder Abuse: Policy

- Steven, 52 years old and unemployed, convinces his elderly, bed-bound aunt who has severe Arthritis to fire her home care attendant and hire him instead. While under Steven's care, she develops severe pressure ulcers.
- Edith, now 78 years old, has repeatedly been beaten and threatened by her husband throughout their 48-year marriage.
- Sheila persuades her elderly father, who has an advanced dementia, to sign a power of attorney, which he does not understand. She uses it to raid his savings account.
- Posing as a government worker, a man in Canada contacts elderly Americans claiming that he needs information to update files. He uses the information to empty their bank accounts.
- Vivian, who lives in a skilled nursing home, is sexually molested by a nursing assistant.
- A 92-year-old woman provides care to her bed-bound, 103-year-old sister. Years earlier, the sisters had made a pact, each promising never to let the other be institutionalized. When the younger sister runs errands, she locks the older sister in their apartment.
- Janet, who is in her 50s, applies for a volunteer job visiting frail elders. Two months later, she marries one of the clients, Rod, who is 87. Janet quits her job, replaces Rod's children as the beneficiaries of all his investments, and prevents them from visiting or talking to him by phone.

These scenarios demonstrate the varied ways that elders suffer harm by others. But do they all constitute "elder abuse"? Surprisingly, the answer depends on whom you ask.

Although elder abuse has been recognized for over 25 years, there is still widespread disagreement

about what it is and is not. Consider the following definition of elder mistreatment created by a panel of experts convened by the National Academy of Sciences (NAS) in 2002 to review and evaluate the research on elder abuse:

> *(a) Intentional actions that cause harm or create a serious risk of harm (whether or not harm is intended) to a vulnerable elder by a caregiver or other person who stands in a trust relationship to the elder, or (b) failure by a caregiver to satisfy the elder's basic needs or to protect the elder from harm* [1].

As definitions of elder abuse go, the Council's is relatively narrow. It requires that elderly victims be "vulnerable", which means that they have cognitive, physical, or communication deficits that compromise their independence and judgment. Applying the requirement, therefore, eliminates acts of abuse against "well elders" who have no such impairments. Some researchers, agencies, and governments include the vulnerability requirement; others do not. The Council's definition further limits mistreatment to situations in which abusers are caregivers or in "trust relationships" with their victims, which includes family members, friends, acquaintances, paid caregivers, and fiduciaries. This requirement excludes abuse by strangers.

Unlike the Council's definition, which requires that the abuse be intentional, other definitions cover situations in which harm results from recklessness, ignorance, or lack of resources, knowledge, or skills. Some definitions require that the mistreatment be ongoing as opposed to single acts, and some require that the conduct result in significant physical, financial, or emotional injury.

Variations in how elder abuse is defined account in part for the widely different incidence and prevalence estimates found in the literature as well as the divergent and sometimes conflicting profiles of victims, abusers, and risk factors. The National Council estimated that between one and two million Americans aged 65 or older have been injured, exploited, or otherwise mistreated [1].

The definitions used to classify the various subcategories of elder abuse also vary widely. They too may or may not require that victims have impairments, that perpetrators be in positions of trust, that the abuse be intentional and ongoing, or that it have significant consequences.

- *Financial abuse* ranges from simple theft to complex financial manipulations [2]. Much of the literature on financial abuse focuses on situations in which persons in positions of trust coerce, manipulate, or trick elders with diminished capacity into surrendering assets. Perpetrators may, for example, persuade these elders to sign checks, deeds, wills, or powers of attorney that benefit themselves. Perpetrators may also gain access to elders' assets through guardianship, marriage, or adoption. When the "vulnerability" and "trust relationship" requirements are absent, financial elder abuse may include theft or fraud by strangers, including predatory lending, telemarketing scams, or identity theft against well elders [3].
- *Physical abuse* generally refers to intentionally or recklessly causing bodily injury, pain, or impairment. Examples include striking, pushing, burning, and strangling elders, and using physical or chemical restraints. Several specific forms of physical elder abuse have been the focus of recent attention, including domestic violence, homicide/murders, and suicide/homicides. An emerging body of research suggests that older women are likely to experience domestic violence, which may have begun earlier in life or may begin or escalate in old age. For others, the violence begins when they enter into new relationships [4, 5]. In some cases, the violence is linked to such age-related factors as retirement and heightened dependency.
- *Elder homicides and murders* are likely to be concealed or staged to look like deaths by natural causes, suicides, or accidents [6, 7]. The cause of death may be suffocation, strangulation, starvation, neglect, overmedication, undermedication, drowning, causing someone to fall, poisoning, or arson. *Elder homicide-suicides* typically involve elderly men killing their spouses or intimate partners and subsequently committing suicide [8]. Because these killings are likely to be prompted by the physical decline, hospitalization, or institutionalization of either partner, they may be mistaken to be "double suicides" or "mercy killings" whereas closer scrutiny reveals that one partner was not a willing participant.
- *Sexual abuse* is nonconsensual sexual contact of any kind with an older person. It includes rape; molestation; lewd or lascivious conduct; coercion

through force, trickery, or threats; or sexual contact with any person who lacks sufficient decision-making capacity to give consent [9–11]. Elderly victims of sexual abuse are most often females and are likely to have impairments that make them dependent on others. Abusers include spouses and intimate partners, other relatives, paid caregivers, and acquaintances.

- *Verbal or psychological abuse* includes the use of words, acts, or other means to cause fear, humiliation, emotional stress, or anguish. Victims may be threatened with violence, deprivation, or institutionalization; or they may be berated, infantalized, humiliated, ridiculed, cursed, ignored, or isolated.
- *Neglect* is the failure of any person who has responsibility for an elder to provide the level of care that a reasonable person in a like position would provide. It includes failure to provide medical, health, or mental health care; to assist in personal hygiene; to prevent malnutrition or dehydration; or to protect against health and safety hazards. Because victims of neglect depend on others for care, it can logically be assumed that they have mental or physical disabilities. Perpetrators include family caregivers, paid attendants, long-term care facilities, and others who have a "duty" to provide care. Some researchers and practitioners distinguish between unintentional or intentional neglect, with the former resulting from such factors as caregivers' lack of resources, physical strength or stamina, emotional stability, maturity or skills to meet elders' needs. Intentional neglect is when perpetrators withhold needed care out of malevolence or malice or for financial gain (e.g., perpetrators want to hasten elders' death because they stand to inherit).

Other forms of elder abuse include the *violation of basic human rights, abduction,* and *abandonment*. Human rights include the right to privacy, to confidentiality, to associate with whomever one chooses, to exercise choice, and to refuse psychotropic medications or involuntary confinement. *Abduction* includes taking elders from their residences and preventing them from returning through force, coercion, or undue influence. *Abandonment* is when caregivers willfully desert or forsake elders under circumstances in which reasonable people would continue to provide care. Elders may be left unattended in public settings or hospital emergency rooms. Caregivers may leave elders alone without adequate provisions, quit, or move away without arranging for substitutes. Multiple forms of abuse are often found to coexist.

Abuse in Long-Term Care Facilities

Although most discussions of elder abuse focus on abuse in domestic settings, abuse also occurs in long-term care facilities [12]. It includes acts of violence, neglect, psychological abuse, or financial abuse by employees, visitors, and other residents; but often refers to management practices that endanger residents. These include facilities' failure to provide adequate staff, to screen or supervise employees, or to protect residents from abusers. In these situations, culpability may rest with supervisors, management, or corporate entities. Facility-related abandonment or abduction includes the discharge of patients into unsafe situations.

Detecting and Evaluating Abuse

Detecting and evaluating abuse and neglect can be extremely complex, and each type poses specific challenges. A common barrier is victims' unwillingness to disclose what has happened to them out of fear, shame, or loyalty to their abusers. Others are unable to describe what has happened as a result of physical, cognitive, or communication deficits. There are few reliable diagnostic or forensic markers. For these reasons, examiners typically look for constellations of factors, including physical evidence, victims' and abusers' behaviors and interactions, and the plausibility of explanations that are offered.

Many of the frequently cited indicators of physical abuse have been extrapolated from research on general populations. They include fractures to the head, neck, and spine [13]; injuries consistent with being grasped, squeezed, or restrained [14]; and signs of strangulation, including neck pain, soreness, petechiae, raspy voice, difficulty in swallowing, lightheadedness or head rushes, fainting and unconsciousness, red eyes, ligature marks, and loss of control of bodily functions [15]. Other commonly cited indicators include abrasions, defensive injuries, multiple bruises in various stages of healing, multiple skin

tears in locations other than arms and legs, and spiral fractures with a rotational component and in areas other than wrists, hips, or vertebrae [16].

Because elders bruise more easily than young people, fall more often, and are more likely to have illnesses and conditions that mimic abuse and neglect, there has been mounting attention in recent years to exploring abuse markers and evidence-based data specifically for elders.

A study that documents the occurrence, progression, and resolution of "natural" bruises, conducted by the University of California, Irvine (UCI), provides baseline data that can serve as the basis for evaluating nonnatural bruising [17]. The study revealed that bruises on the palms, soles of feet, face, neck, chest, abdomen, or buttocks are unlikely to occur accidentally among elders and that the color of bruises, previously thought to be helpful in "dating" injuries, has not been found to be consistent with elders. A study of burns in the elderly, handicapped, and disabled populations suggests that the markers of inflicted burns are similar to those found in child abuse and include characteristic patterns, a story that does not fit the injury, and a delay in seeking medical care [18].

Another study to identify potential markers of abuse examined coroners' reports of elderly nursing home residents in Arkansas after the state passed a rule requiring nursing homes to report all deaths to local coroners. The study identified four categories of markers that pertained to (i) patients' physical condition and quality of care (e.g., untreated injuries; multiple and untreated pressure ulcers, malnutrition; (ii) facilities' characteristics' (e.g., unchanged linens, strong odors; (iii) inconsistencies (e.g., between documented and observed care; and (iv) staff behaviors (e.g., staff who follow investigators too closely, lack of knowledge and concern about residents [19].

Victims' and perpetrators' behaviors are also important factors in assessing physical abuse (*see* **Elder Abuse: Risk**). Physical abuse may, for example, be revealed by frequent emergency room visits or implausible or conflicting explanations for how injuries were sustained. In the case of elder homicides, for examples, perpetrators may arrange for the hasty cremation of decedents to avoid detection. Investigations of homicide-suicides may include psychological autopsies (*see* **Psychological Autopsy**) to disclose whether both partners had suicidal tendencies.

Evaluating neglect is complicated by the fact that the symptoms of natural diseases may resemble abuse and neglect. Pressure ulcers (also known as *bedsores* or *decubitus ulcers*), which are lesions caused by pressure that results in damage to the underlying tissue, are a key indicator in neglect cases but there is disagreement about whether they can be prevented even in the best of circumstances [20]. In evaluating ulcers, investigators therefore often consider how they are cared for, and review medical histories and records, which is critical.

Evaluating neglect by caregivers may also be complicated by legal considerations. As described earlier, neglect is by persons who have a duty to provide care. That duty may be created by contractual arrangement (the caregiver is paid) or by virtue of a relationship (the parties are married) and persons who do not have a "duty" to provide care cannot be held civilly or criminally liable for neglect. However, the extent to which family members and others are legally responsible has not been clearly established. Courts have determined that people have a duty to provide care to spouses who are incapable of deciding whether they need help [21] and, in a precedent-setting case, the California Supreme Court[a] determined that an adult child is only criminally liable for a parent's care where the duty is affirmatively accepted.

In the case of verbal and psychological abuse, assessment is complicated by the fact that actions or words that can be extremely traumatic to some, may not be damaging to others. While these differences stem from personal differences and different norms within families, it appears that culture also plays a role. For example, a study comparing cultural attitudes toward various forms of abuse found that Caucasian elders were more tolerant of verbal abuse than elderly Korean Americans [22].

Financial elder abuse cases can be extremely complicated to detect and investigate [23, 24]. Victims may not be aware that they have been abused or refuse to cooperate in legal proceedings. They may not discover abuse until long after it has occurred. Determining whether or not elders have the requisite capacity to make financial or legal transactions can also be extremely complicated, as described later in this chapter. This may be especially difficult if it requires recreating what happened in the past and proving what an elder with diminished capacity understood at an earlier period of time. Critical

documents may be in the possession of abusers or financial institutions [25].

Evaluating whether or not abusers are in positions of trust can also be complex. Some, who are strangers to begin with, befriend elders intending to exploit them. For example, "sweetheart scams" are crimes in which offenders use deceptive romantic overtures to gain access to older peoples' assets. Even perpetrators who contact their victims by phone and never meet face-to-face may establish trust and confidence through repeated contacts, by playing upon their victims' loneliness or sympathy, and by endearing or ingratiating themselves [3].

Causes and Risk Factors

The reasons abusers commit abuse are as varied as the definitions and examples offered earlier (*see* **Elder Abuse: Risk**). They include the following:

- **Financial motives**

In many abuse cases, the underlying motive is greed, a sense of entitlement, or financial exigency (perceived or real). Offenders may perceive elders, particularly elders with diminished capacity, as easy targets for exploitation, with some experts even suggesting that certain perpetrators who are not criminally inclined to begin with decide to abuse when they gain access to elders' assets and realize that the abuse is unlikely to be discovered [26]. Caregivers may feel that they deserve more compensation than they receive, and family members who stand to inherit may believe that an elder's assets are "almost" theirs anyway. Financial motives are not limited to financial abuse [27]. Perpetrators may physically abuse or intimidate elders to get them to surrender assets, or neglect those in their care to render them compliant or hasten their decline or death if they stand to inherit victims' estates.

- **Interpersonal conflict**

The role of interpersonal conflict in elder abuse is not well understood. There is evidence to suggest that some abuse by caregivers stems from unresolved conflicts that started before the onset of disability (see "Caregiver issues"). In some cases, the motivation may be revenge or "pay back" for previous abuse [28, 29].

- **Perpetrators' dysfunction**

Perpetrators may have mental illnesses; personality disorders; or addictions to drugs, alcohol, or gambling. Sexual abusers include "gerontophiles" with specific sexual inclinations toward the elderly [30], some of whom seek out employment in "victim-rich" environments like long-term care facilities [31]. Sexual predators are also increasingly being admitted to nursing homes as residents [31, 32].

- **Caregiving issues**

Caregivers may abuse or neglect because they are under severe stress, exhausted, inexperienced, or reluctant to perform the caregiving role. They may lack skills, empathy, or understanding [33]. Although it was previously assumed that stress was associated with the level of care provided, many now believe that other factors play a greater role in predicting abuse. These include poor "premorbid relationships" between caregivers and care receivers (the relationship was poor prior to the onset of disability) [34, 35], verbal or physical abuse by care receivers, carers' level of anxiety, and carers' perception that they are not receiving adequate help [34, 36].

- **Power and control**

The drive for power and control has long been recognized as a primary motive for domestic violence. Perpetrators, whose power stems from physical dominance and social privilege, use violence or the threat of violence to subjugate their intimate partners. In recent years, it has been recognized that elders also experience domestic violence for these reasons [37]. Some suicide-homicides appear to be motivated by perpetrators' need to exercise power and control, and, in one-third of cases, there was a history of domestic violence [8].

Perpetrators of elder abuse may also exercise power and control for financial gain. "Undue influence" is when individuals who are stronger or more powerful get weaker people to do things they would not have done otherwise, using various techniques or manipulations over time. They may isolate the weaker person, promote dependency, or induce fear and distrust of others. The abuser tries to convince the vulnerable person that friends, family members, or caregivers have malevolent motives and cannot be trusted. This is sometimes referred to as creating a "siege mentality" [38, 39].

- **Dependency**

Perpetrators are likely to be dependent on the people they abuse [1, 40]. Adult children who abuse their elderly parents are likely to be unemployed, unmarried, and dependent on their victims. Some studies have found that victims who are dependent on their abusers are also at heightened risk [1] with some proposing that a "mutual web of dependency ' may exist wherein victims depend on their abusers for care, and abusers depend on their victims for financial or emotional support and housing [41].

The National Academy group reviewed factors that heighten the risk of abuse and neglect. They divided them into categories on the basis of the extent of supporting evidence. Risk factors validated by substantial evidence include a shared living arrangement, social isolation, victims' dementia, and pathological characteristics of abusers, including mental illness, hostility, alcohol abuse, and abuser dependency [1]. "Possible" risk factors include gender (agency samples universally find that most victims are women although it is not clear whether this is accounted for by the fact that there are more women in the elderly population or that they are actually at greater risk), and being Black [42, 43]. Contested risk factors include victims' physical impairment and dependence on their abusers, and intergenerational violence within families [1]. The risk factors associated with institutional abuse by staff include burnout, aggression from residents, negative attitudes toward residents, and age (perpetrators tend to be younger than nonabusive employees). Other contextual factors include such factors as staff shortages [44].

Consequences

Elder abuse may affect victims' psychological, physical, and financial well-being. The consequences of physical abuse include fractures, depression, dementia, malnutrition, and death. Early studies suggested that nearly 50% of all reported incidents of abuse resulted in physically apparent trauma [45]. A pioneering study of the impact of abuse and neglect on victims' physical status suggests that victims are more likely to die prematurely [46]. Some states have acknowledged that the impact of violence against elders is likely to be greater than for younger persons by enhancing penalties for violence against elders.

Although neglect is sometimes viewed as less serious than acts of commission, its impact can be extremely serious, even leading to death. Failure to provide adequate nourishment to frail individuals can quickly lead to dehydration or malnutrition. When left untreated, pressure ulcers may cause sepsis. Failure to provide adequate assistance or medication can lead to accidents or illnesses becoming worse.

Financial abuse can have devastating consequences because replacing lost assets is generally not a viable option for retired individuals or those with physical or mental disabilities [47] and the depletion of assets may result in elders becoming dependent upon family members or public assistance. Psychological consequences include the loss of trust in others or in one's own abilities, stress, isolation, depression, hopelessness, or even suicide [48].

Emotional reactions to abuse include anger, helplessness, reduced coping, sleep disturbances, eating problems, denial, fear, anxiety, feelings of learned helplessness, alienation, guilt, shame, and posttraumatic stress syndrome [49]. Although abused elders are more likely to experience depression or psychological distress, there is no way of knowing whether these conditions were present before the abuse started or were the result of the abuse [50–52]. In comparing older and younger female trauma victims, however, Acierno and his associates [53] found a lower incidence of depression and posttraumatic psychopathology among older victims.

Capacity and Consent

Victims' mental capacity and ability to give consent are critical considerations in elder abuse cases (*see* **Capacity to Consent to Medical Treatment**; **Capacity for Independent Living**; and **Guardianships of Adults**). In particular, determining whether clients have decision-making capacity may be a critical consideration in evaluating and proving abuse. For example, proving financial abuse may involve demonstrating that a perpetrator induced an elder to sign a contract for which he or she lacked the requisite capacity. Victims' capacity further dictates the extent to which they can participate in planning for their own care and the interventions that are needed and available to them.

Current thinking acknowledges that mental capacity is a cluster of mental abilities that people use

in their everyday lives, and that different skills are needed for different mental tasks. Decision-making capacity refers to people's ability to make and communicate decisions, understand the consequences of their actions, and act in their own self-interest. It is also task-specific. Determining whether someone has decision-making capacity requires looking at the decision in question and whether the person has the mental skills that are needed to make it.

Professionals are generally in agreement about how to evaluate decision-making capacity for certain decisions but not others. For example, there is general agreement among lawyers about "testamentary capacity", which is the capacity needed to execute wills: people must understand what a will is, have a basic plan for distributing their assets to heirs, know the nature and extent of their assets, and be able to identify or recognize potential heirs and beneficiaries. There is less agreement, however, about how to evaluate other decisions that are commonly questioned in elder abuse cases. These include the capacity to get married, give gifts, consent to sexual relations, and select and supervise home care workers.

One form of decision-making capacity is "consent", which is agreeing to actions, transactions, or services proposed by others. It requires that the person understands the act or transaction and is acting freely and voluntarily, and is not under the influence of threats, force, or duress. In the case of informed consent for financial decision–making, for example, the person making a transaction must be provided with information and have the mental capacity to understand and appreciate it. Furthermore, they must be acting voluntarily and be free from coercion [38].

Services and Interventions

The primary response to elder abuse in the United States was patterned after the response to child abuse. Overwhelmingly, states passed laws requiring those who are likely to discover elder abuse to report to adult protective services (APS), which investigate and substantiate reports, and either provide follow-up services or refer clients to other agencies that can.

While the number of elder abuse cases reported to APS program has risen substantially, suggesting that the system is successful in providing victims with access to help, there have been problems associated with it. Unlike their colleagues in CPS, APS workers can only intervene with the consent of clients unless one of the two conditions apply: (i) when abuse constitutes criminal conduct, it must be reported to the police; and (ii) when clients lack capacity to consent to services and the potential negative consequences of failure to act are high, involuntary interventions may be needed. While these exceptions may seem straightforward, they are not. As described in the last section, there are no universally accepted standards for how to determine when someone has or lacks capacity to consent to services. As more cases are handled criminally, many service providers are beginning to recognize when abuse constitutes criminal conduct and they must, therefore report to police.

Most abuse cases, however, do not fall within these two categories, which means that victims must voluntarily agree to services. Many refuse help out of fear, shame, or loyalty toward their abusers. In the last 15 years, as practitioners have come to better understand the formidable social, physical, cultural, and financial barriers that victims face in seeking help, they have become more successful in offering help. Drawing from the fields of domestic violence, substance abuse, victim advocacy, and psychology; they have become more adept at engaging clients who were previously dismissed as "resistant" or "reluctant". Clinicians and advocates have come to better understand how perpetrators exercise power, control, and undue influence; and how to counter these forces. Recognizing that many victims choose to remain in violent relationships, practitioners in the field of elder abuse prevention have borrowed approaches from the field of domestic violence such as safety planning, options counseling, shelters, and support [52, 54–56].

Common services needed by victims are listed below. Their availability varies significantly across the country [57].

- **Shelters**

Elderly victims may need shelter in a variety of circumstances. Some require safe haven to avoid further victimization. Others need shelter when they have been evicted from homes or apartments, abandoned by caregivers, when abusive caregivers have been fired or arrested, when essential utilities have been discontinued, or when their homes are unsafe or unhealthy as a result of abuse or neglect. A variety of shelter options have been designed, including rooms in battered women's shelters that have been adapted

for women with disabilities, temporary stays in residential care facilities or senior apartment houses, and free-standing shelters that have been designed specifically for elderly victims.

- **Services for caregivers**

The risk of abuse by caregivers can be reduced by enhancing caregivers' skills, providing them with information about disease progression and how to manage difficult behaviors, and reducing stress through services like respite care, support groups, counseling, and financial relief.

- **Counseling**

Group or individual counseling may be needed to alleviate the immediate and long-term traumatic stress associated with abuse, provide emotional support, assist victims explore their options, and address such issues as codependence, depression, and diminished self-esteem.

- **Emergency funds**

These funds may be needed for food, emergency caregivers, mortgage payments, transportation, utilities, locks to secure victims' homes, court filing fees, and repairs and relocation costs.

- **Legal assistance**

Victims may need help to secure orders of protection, annul bogus marriages and adoptions, sue for civil recoveries, create or revoke powers of attorney that have been misused, handle guardianships (a legal proceeding in which courts appoint individuals or agencies to manage the personal and/or financial affairs of vulnerable people who lack sufficient mental capacity to manage on their own (*see* **Guardianships of Adults**).

- **Victim witness assistance programs**

These programs help victims whose cases are in the criminal justice system. They provide information to victims about the court process and the status of their cases; court accompaniment; and assistance in securing compensation, restitution, and community services.

- **Mental health assessments**

These assessments are often needed to determine if elders are capable of meeting their basic needs, making decisions about services, entering into contracts, offering testimony, and protecting themselves against abuse. Assessments of alleged abusers' mental status are sometimes needed to determine if they pose a danger to others and need treatment. Assessments range from simple "shorthand screening tools" to comprehensive batteries of tests.

- **Support services**

These services decrease vulnerability to abuse and neglect by enhancing the independence of elders with physical and cognitive limitations and reducing their reliance on others. Examples include daily money management, meals, attendant care, adult day centers, friendly visitors, and telephone reassurance programs.

Multidisciplinary Teams

The diversity and complexity of abuse cases makes it unlikely that any single agency has all the resources, services, or expertise needed to handle all situations. For that reason, many communities have organized multidisciplinary teams (MDTs), which provide a forum for professionals from diverse disciplines and agencies to discuss difficult abuse cases; learn what services, approaches, and resources are available from other agencies and disciplines; share information and expertise; identify and respond to systemic problems; and ensure offender accountability.

Typically, teams include health and social service providers, law enforcement personnel, Ombudsmen, mental health care providers, physicians, advocates for persons with developmental disabilities, lawyers, domestic violence advocates, financial institutions, money managers, case managers, and many others.

In the last decade, specialized teams have emerged in response to the increasingly diverse and complex types of abuse being reported [58, 59]. Several communities have formed financial abuse specialist teams (FASTs), which include members with expertise in such areas as real estate, insurance, banking practices, investments, trusts, estate and financial planning, and other financial matters. Elder fatality review teams, which were patterned after child and domestic violence fatality review teams, evaluate injuries and causes of death, attempt to distinguish accidental from nonaccidental deaths, shed light on events leading up to deaths, identify systemic problems and aid in prosecutions. Teams include coroners/medical examiners, law enforcement (local, state and, in some situations, federal), prosecutors, state agencies that oversee long-term care facilities, and others. A few

communities have developed teams with a medical focus.

The Legal System Responds

Although elder abuse was traditionally viewed as a social service concern, there has been a trend in recent years to hold perpetrators accountable by strengthening and extending the use of civil and criminal remedies and penalties. States have enhanced penalties for crimes involving elders, passed laws that make abuse cases more financially viable for attorneys, and extended domestic violence laws to cover some situations of elder abuse. Police departments and prosecutors' offices have developed specialized elder abuse units. More cases are also being seen in civil courts.

To improve elders' access and safety, courts have designed safe and comfortable waiting areas, instituted special calendars, and assigned court staff to provide extra assistance to elders. The Alameda County (California) Elder Protection Court, established in 2002, features a separate calendar (in the late morning) for elders seeking restraining orders. In some situations, when elders are unable to appear in court, the proceedings are conducted in chambers, with a judge issuing orders by telephone. Self help clinics and services provide access to courts by people who cannot afford lawyers. San Diego's Family Justice Center, which houses police, prosecutors, forensic experts, and victim advocates from public and private nonprofit agencies in the same building has in recent years begun to serve abused elders. The first forensic center designed exclusively for elder abuse was launched in 2003 at the University of California, Irvine's College of Medicine [60]. The center has been replicated in other communities.

Conclusion

Since elder abuse first came to light in the late 1970s, researchers, policy makers, advocates, and practitioners have struggled to respond to this highly complex and multifaceted problem. Drawing from the fields of child abuse, domestic violence, family caregiving, and victim advocacy; communities have fashioned a variety of new services, policy, and practices. As new research emerges and practitioners gain insight and expertise in handling cases, the challenge now is to mold these disparate elements into a comprehensive, coherent, and cohesive service response system.

Elder Abuse: Risk

Stan and Eugene

Stan could not remember a time when he did not hate his grandfather, Eugene. After all, this was the man who virtually abandoned him when his beloved grandmother died, eight years after his mother left Stan with her parents. Not yet a teenager and Stan had to manage on his own. Eugene provided housing and sometimes brought in food, but that was the limit of his support.

Like Stan's mother had done before him, Eugene did what he wanted. It did not matter who or what might be harmed in the wake. Eugene loved hanging out with his friends at bars or the races. Occasionally he would travel to Las Vegas and spend days, sometimes weeks, gambling and socializing, until he was broke. All this left little money for household expenses and no time for Stan.

Stan is in his late 20s now. Frequently unemployed and still living in his grandfather's house, he has a well-deserved reputation for binge drinking, a quick temper, and violent behavior. Stan admits, "It just happens. Someone ticks me off and winds up in intensive care". A school counselor once diagnosed Stan as having a personality disorder.

Eugene is in his early 70s and suffers from dementia along with a host of other chronic conditions, largely resulting from long-term alcoholism and neglect of health. Eugene is frail, no longer the massive figure that brought fear to Stan, both for his size and for the brutal discipline he imposed. Eugene also is forgetful and occasionally disoriented. He increasingly becomes anxious leaving home.

Brushes with the law and other authorities are common for Stan. Before quitting school, he spent more time truant or in detention than attending class. His violent temper and general disregard for people and property resulted in a three-year prison sentence. Recently he went to jail for so severely beating Eugene that the older man was hospitalized for nearly a month, recovering from multiple injuries, including broken hip, jaw, and ribs. The trigger for the abuse was when Stan came home and discovered that Eugene forgot to light the pilot for the gas stove and fumes filled the dwelling. "How could he be so stupid? He drives me mad", explains Stan. Over the years Eugene and Stan frequently fought, usually both verbally and physically. However, the balance of power shifted as Eugene aged and his health deteriorated, with Stan becoming the victor in any dispute, although never before with such serious consequences.

Causes versus Risk Factors

The causes of elder abuse and mistreatment are complex and challenging (*see* **Elder Abuse: Policy**). The US Congress in 1981 provided an early summary of proposed theories for why elder abuse occurs, including caregiver stress and burden; insufficient community resources for caregivers; retaliation for past child abuse; ageism; acceptance of violence for expressing frustration and anger; lack of close family ties; resentment of the victim's dependency; and stress or life crises experienced by the perpetrator, such as mental health problems, alcoholism, or unemployment [1]. Only a handful of these theories have survived scrutiny more than a quarter century later, although most remain entrenched beliefs of the public and even many professionals.

Lacking evidence for causation, we tend to use the term *risk factors* for those commonly accepted conditions found through research to be closely linked to the occurrence of elder abuse. Unfortunately, there have been relatively few studies focused on elder abuse risk factors. Moreover, many existing studies are methodologically flawed, failing to use standardized definitions, control groups, and reliable and valid measures.

Risk Factor Applications

The inadequacies of elder abuse risk factor research should not be construed to mean that such investigations are regarded as useless or unimportant. Rather, knowledge of risk factors is seen as critical to problem detection, assessment, and prevention.

Understanding risk factors helps detect elder abuse by identifying conditions that may contribute to its occurrence. This means that whenever we uncover established elder abuse risk factors in circumstances involving older adults and trusted others, we should be watchful for specific examples or signs of the problem. Under the provisions of most state elder abuse reporting or adult protective service laws, examples and signs are the basis on which reports or referrals are made [2].

Risk factors also indicate the need for more thorough elder abuse assessment. It is only after completely evaluating the person and situation of victim and perpetrator that we can know what interventions are required and when. Finally, risk factors are key to elder abuse prevention. They offer a framework for determining what strategies (e.g., anger management, counseling, substance abuse treatment) may deter the reoccurrence of elder abuse or inhibit it from happening in the first place; for example, anger management, counseling, or substance abuse treatment.

Risk Factor Qualities

Risk factors increase the likelihood that elder abuse will occur. In addition, the greater the number of risk factors evident in a situation, the higher the possibility of abuse occurrence. Similarly, longer exposure to risk factors makes elder abuse more likely.

Some elder abuse research suggests that risk factors vary by form and setting. For instance, a pioneering examination of 328 elder abuse cases found different perpetrator and victim profiles for physical abuse, material abuse, and active neglect, among maltreatment forms studied. Physical abuse perpetrators were characterized by a history of mental illness, alcohol abuse, recent decline in mental and physical health status, increased dependency, and poor relations with the victim. Physical abuse victims tended to have poor emotional health, more independent functioning, and a stable social network.

In contrast, active neglect perpetrators found their victims a source of stress, and victims had deficits in memory, orientation, and performing daily living tasks. Material abuse perpetrators were alcoholic, lacked family support, were financially dependent but did not live with the victim, and experienced both long-term and recent financial problems. Their victims had difficulty with financial management and transportation as well as recent loss of social supports [3].

Elder abuse in institutional settings, like nursing homes, is distinguished from that in domestic settings, like single-family homes, in such ways as potential perpetrators and likely risk factors. More specifically, perpetrators in institutional settings include staff, visitors, and other residents; most perpetrators in domestic settings are family members. The National Center on Elder Abuse recently reviewed available studies to develop a list of elder abuse risk factors in residential care facilities. The following were among those named: no abuse prevention policy, inadequate staff education and training, insufficient staff screening, staff stress and burnout, staff shortages and high staff turnover, history of deficiencies and complaints, a closed structure with reactive problem-solving and little attention given to resident concerns, few visitors, and poor resident/staff interaction [4].

Some researchers have found that certain risk factors are particularly important for predicting elder abuse in institutional settings, such as stressful work conditions (largely resulting from staff shortages), staff burnout, staff viewing residents as childlike, staff frequently thinking about quitting their jobs, the combination of resident aggression or conflict, and poor staff training in managing challenging behaviors [5, 6].

Conceptual models exist that integrate elder abuse risk factors to better explain the problem. None have been rigorously tested. For example, Anetzberger proposes a model for domestic elder abuse where the problem is a function of characteristics on the part of the perpetrator primarily and characteristics of the victim secondarily. These come together and provide the etiology for abuse occurrence. Context is important in the model, initially as the vehicle for bringing the perpetrator and victim in contact and later for triggering the actual mistreatment [7].

The National Research Council proposes a model for institutional elder abuse. In it, risk factors begin in a sociocultural context (exemplified by the state regulatory environment and urban-rural location of the facility). These are combined with risk factors related to the social embeddedness of the facility in providing resident care (considering characteristics like supervision/staff ratios and average resident age) and those related to individual characteristics of employees or volunteers who provide resident care (including relevant work experience and stress) [8].

Elder Abuse Risk Factors

Risk factors for elder abuse can be found in characteristics of the perpetrator, victim, perpetrator/victim environment, and cultural milieu. Research is minimal on all four types of characteristics, but it is nearly absent on the last. Still, culture provides the basis for each of us becoming members of society, and specific groups within society. In the process, we learn about and adopt commonly accepted values, attitudes, and normative responses. Youth, individualism, and material acquisition are American values thought to contribute to elder abuse. Ageism, stereotyping of people with disabilities, and glorification of aggression are attitudes believed to foster prejudice, discrimination, and sometimes mistreatment of elderly and other vulnerable adults.

Perpetrator Risk Factors

Pathology can predispose individuals to be abusive through distortion of reality, inability to empathize,

lack of impulse control, and inability to handle frustration. Evidence for perpetrator pathology as an elder abuse risk factor exists for mental illness e.g., [9, 10], alcoholism e.g., [11, 12], and hostility e.g., [13, 14].

Dependency can be related to pathology in that persons with mental illness or alcoholism may have difficulty holding jobs and therefore come to rely on others for support. Dependent adults can feel resentment and powerlessness. This can result in abusive behavior as a means to compensate for or retaliate against perceived imbalances in resources and power. There is considerable evidence for perpetrator dependency as an elder abuse risk factor [15, 16]. However, two popular explanations for the problem largely have been discredited through research, namely caregiver stress and transgenerational abuse.

Victim Risk Factors

Only a couple of victim risk factors have held up to scrutiny. There is a substantial body of research identifying dementia as a victim risk factor [17, 18]. The effect of Alzheimer's disease and other dementias is: (i) to increase the vulnerability of sufferers through decreased functional capacity, rendering them dependent on others for care, not all of whom are willing or able to provide it and (ii) to limit the ability of sufferers to protect themselves through self-defense, escape, or sometimes even recognition of elder abuse when it happens.

Victim problem behaviors also represent a validated risk factor for elder abuse [19, 20]. Since persons with dementia can exhibit problem behaviors, the two risk factors can be related. Victim problem behaviors identified in the literature include being complaining, critical, demanding, disagreeable, passive, aggressive, or uncooperative. The evidence for other suggested victim risk factors, like gender or physical impairment, is either insufficient or contradictory.

Perpetrator/Victim Environment Risk Factors

While there is ample evidence for shared living arrangements [13, 15] and social isolation [21, 22] as elder abuse risk factors, there is considerably less evidence for other proposed environmental characteristics, like financial difficulties or family disharmony.

Elderly in Court

Older Adults as Witnesses in Court

Aging and Changes in Memory

There is no uniformly agreed upon definition of what age constitutes old age. Most gerontological research uses the threshold of 65 years (or sometimes 60 years), and this is also the threshold adopted in this entry. Certain aspects of memory performance decline with age, although not all parts of memory are equally affected [1]. One of the most important memory areas related to eyewitness performance is long-term episodic memory, which is particularly affected by the aging process [1].

Another relevant aspect of memory that declines with age is source–memory, or the ability to identify the source of a memory. In general, it becomes more difficult to remember the contexts in which a particular piece of information was learned and this can lead to source misattribution (i.e., misremembering where familiar information comes from, such as direct perception, suggestion, dreams, etc.). Compared to young adults, seniors have been shown to have impaired memory when having to decide if they know about a certain fact because they heard it or saw it [2] or if they heard a statement from one person as opposed to another. This confusion about which one of two people said something is especially evident if the sources are similar, such as both of them being women [3]. In the legal context, the source of a memory can be of importance in several ways.

In some cases it may be crucial to know which individual made a particular statement. In many cases, however, source memory is more important in a more indirect way: source misattribution is one on the avenues in which misinformation can taint the testimony of a witness. Witnesses to a crime or an accident may learn additional information about the observed incident by reading a related article in the local newspaper or by watching coverage of it in the news.

Witnesses may be questioned by interviewers who mistakenly introduce false information in some of their questions. If source monitoring is impaired, then witnesses may come to believe that the additional information stems from the event itself, as opposed to originating from the subsequent informational sources. Source misattributions are therefore important for the explanation of false memories and susceptibility to suggestions [4–6]. Mistakes in remembering in which exact circumstances a familiar looking person was encountered can also lead to the false identification of an innocent bystander to a crime as the perpetrator [7, 8].

Aging can also impair the ability to accurately recall the chronological order of events and actions. Older adults make more mistakes in the temporal ordering of actions than young adults [9, 10]. Similarly, spatial memory declines with age. Older adults have been found to be less good in describing the spatial layout of places visited than young adults [11]. Thus, in situations when it can be crucial to describe the layout of a crime scene or the temporal order of events, seniors may perform less accurately than young adults.

How many and which details a person remembers is affected by the retrieval format used, e.g., the types of questions asked of a witness to obtain a memory account. A witness can be asked to provide a free

recall account of what happened, answer open or specific questions (also known as *cued recall*, e.g., "What did the perpetrator look like?") or be presented with recognition questions (e.g., "Is this person the person who attacked you?"). Memory research has shown that age differences between younger and older witnesses are largest for free recall, smaller for cued recall, and smallest for recognition questions [1]. This distinction is important for eyewitness testimony: A witness statement usually contains some information obtained in free recall and cued recall. A person identification decision made in a lineup is a memory recognition task.

Older Adults' Person Identification Performance

As would be expected from the fact that person identification is a recognition task, and that recognition is less affected by age, older and younger adults do not differ very much in their rates of correctly identifying a target from a target-present lineup [12], i.e., a lineup where the suspect is indeed the perpetrator, although older adults are more affected by delays between exposure and the lineup [13] (*see* **Eyewitness Lineups: Identification from**). Reliable age differences, however, occur when the task is to identify a person from a lineup in which the actual perpetrator is not present, i.e., where the suspect is not the perpetrator of the alleged crime. Here older adults have higher false alarms rates, which means that they are more likely to choose a foil than young adults [14–16]. In situations in which the witness has looked through a mugbook that did not contain the perpetrator, and where the subsequent lineup contains a person seen in the mugbook but not the actual perpetrator, older adults are more likely than young adults to pick out this person previously encountered in the mugbook falsely as being the perpetrator [8].

Eyewitness Memory in Older Adults

When giving witness statements, older adults tend to give fewer details than young adults [17–19]. In particular, older adults seem to be less good in describing in free recall person-related details, such as what an offender looked like [18, 20]. For other details, age-related decreases in memory seem to occur later than the usual research cutoff age of 60 or 65 years: Witnesses over the age of 75 have been found to give fewer correct details for actions, objects, or the surroundings of an incident than those aged 74 and below [18].

When questioned, older adults also recall fewer correct details than young adults, both when questioned in techniques used in investigative interviews (e.g., Structured Interview or Cognitive Interview, see below) [18], or in simulated direct examinations and cross-examinations [19].

Suggestibility and Older Adults. Another issue impacted by aging may be suggestibility, also called *susceptibility to misinformation*. Most people can be influenced by misinformation, depending among other issues on one's memory of an event and the skill of the person trying to plant misinformation (*see* **Eyewitness: Suggestibility of**; **Interrogative Suggestibility**), but older adults may be more susceptible to misinformation than younger adults. Most research to date on suggestibility and the elderly has employed the standard misinformation paradigm, in which participants watch a film, receive misinformation about some details of the film a short time later (typically after 10–30-min intervals), and then, after another brief delay, they are tested for acceptance of the misinformation in a questioning phase. Results of these studies on seniors have been mixed.

While some researchers have reported higher rates of susceptibility to misinformation in older adults than in young adults [21–24], others have not reported reliable age differences [25, 26]. A study using a live event in which participants were actively involved [17] found that seniors were overall more suggestible than younger adults. However they were more susceptible for certain types of misinformation (central details, such as whether or not they had been touched during the event, or concerning actions they had performed themselves) but not for other types (e.g., peripheral details, such as whether a person they had interacted with had been wearing a skirt or trousers).

Another path to the investigation of interrogative suggestibility is the Gudjonsson Suggestibility Scale, a standardized assessment tool. An application of this to older adults demonstrated that while they were more suggestible than younger adults overall, they were more influenced by the suggestive wording of the questions than young adults, but not more easily moved to change their answers through social pressure [27]. These findings that older adults can be more suggestible than young adults become more

pertinent when one considers that older adults are less likely to use self-initiated remembering and thus need to be asked more questions than young adults to obtain a comparable amount of information [17, 18]. Whenever questions are asked in an interview, this opens the possibility that (unintentional) misinformation is introduced. Therefore, particular care needs to be taken when questioning older adults to ensure that no suggestive question or misinformation is introduced into the interview.

Improving the Testimony of Older Adults: the Cognitive Interview. Given that older witnesses provide fewer details in free recall and when questioned than young adults, efforts have been made to enhance their interviewing performance. The most promising to date is an application of the cognitive interview. The cognitive interview [28] relies on two main assumptions: that contextual reinstatement improves memory performance by increasing the accessibility of encoded information and that memories are encoded in a network of associations, which implies that they can be triggered by multiple cues.

The components of the original cognitive interview include: mental reinstatement of the context, complete reporting including details believed to be trivial, varied retrieval routes, and witness compatible questioning. Varied retrieval includes changes in retrieval order and perspective, e.g., starting at the beginning, then starting at the end, then reporting from the perspective of a bystander. Witness compatible questioning includes tailoring the interview questions to the mental representation of the witness instead of using the same standardized checklist for all witnesses. The cognitive interview is also sensitive to the fact that witnesses' resources are limited and therefore questions are not asked while the witness is still thinking about the last question.

Applications of the cognitive interview to the interviewing of older adults have shown substantial increases in the number of correct details reported when compared to standard interviews [18, 29], importantly without a concomitant increase in number of incorrect details. The increase in correct details is mainly due to increasing the details reported in the free recall part of the interview. This is an interesting finding because seniors do not usually do well on free recall tasks, which suggests that the cognitive interview provides the contextual scaffolding that facilitates free recall [30].

Moreover, as older witnesses remember more in free recall, they will have to be asked fewer questions, thus decreasing the likelihood of unintentionally exposing them to misinformation. The cognitive interview can even be successfully used to interview older adults who are cognitively impaired [31]. To date, there is very limited research investigating to what extent older persons with cognitive impairment, e.g., in early stages of Alzheimer's disease, can accurately report events. This is an important field in need of more attention because persons with cognitive impairments may be particularly likely to be subjected to maltreatment and abuse [32] (*see also* **Elder Abuse: Risk**).

Credibility of Older Witnesses

When keeping the performance of younger and older witnesses constant, e.g., in experimental mock-juror studies where participants read a fictitious witness statement and cross-examination presented to be either from a young or older witness, older adults are consistently rated as more honest than young witnesses. In such research, older male witnesses seem particularly highly regarded. The credibility assigned to older witness in such mock-juror studies has been shown to be related to what aging stereotypes jurors hold. Persons who have more favorable attitudes tend to rate older adults' credibility more highly than persons who have more ageist attitudes [33].

In reality, of course, older witnesses often perform less well than younger witnesses. Studies looking at the credibility of actual memory accounts given by younger and older witnesses found that older adults' statements were perceived to be less accurate and less credible than those of young adults [19]. However, credibility was not affected by the age of the witness itself but by the quality and characteristics of the statements. It has been shown for younger witnesses, that they are perceived as more credible if their accounts include a high amount of peripheral details in their descriptions of the observed crime [34] and when their statements are uttered with confidence. As seniors typically provide fewer peripheral details in their accounts, and as a group more frequently use negative qualifiers (e.g., "I am not sure"), it is plausible that this signals to mock jurors that older adults are comparatively less accurate witnesses.

In all these considerations, it is important to emphasize that not all persons are equally affected

by the aging process. Some maintain high levels of cognitive functioning until very old age, while others experience an earlier decline. Consequently, there is large variability in the memory performance for this age group. When assessing the performance of a particular older witness it is important to consider this person as an individual and not merely as a member of the group of "the elderly".

Elderly Offenders *see* Death Penalty and Age

Electrical Engineering

Introduction

Forensic electrical engineering is the practical application of electrical engineering knowledge to legal questions about electrical phenomena. Practical electrical engineering knowledge is obtained from experience in designing, installing, maintaining and repairing electrical devices, appliances, and equipment. Reports, demonstrations, depositions, and court testimony are used to explain electrical phenomena to insurers, attorneys, arbitrators, judges, and juries. The area of practice extends from software for computers to the generation and distribution of electrical power, which might be controlled by software, and to consumer products.

The electrical engineer explains how the electrical software, equipment, or device functions normally and why it malfunctioned, violated a copyright, or failed in this instance causing damage, financial loss, injury, or death. In some instances, the electrical engineer might be retained by a client to verify that electricity was not involved with the cause of a fire, damage, or injury. Quite frequently, electrical engineers must use mechanical, thermodynamic, and optical knowledge to answer questions since the generation, distribution, and utilization of electrical power involves mechanical components, which can produce heat and light.

History

The investigation of electrical phenomena began in Europe in the seventeenth century [1]. The first electrical investigators were called *electricians*. At the time electricity was believed to be fire, "fulmen fulminis" or fire of fire and lightning was fire from the sky, the wrath of God].[a] St Paul was struck by lightning in 33 AD while traveling to Damascus to suppress Christianity. On regaining his sight, St Paul was baptized and immediately began preaching Christian theology.[b] On July 2, 1505, lightning struck near a happy-go-lucky law student, Martin Luther. Fifteen days later, Martin Luther entered the Black Monastery in Erfurt, Germany [2]. Church bells often were inscribed with a Latin phrase, Fulgura frango, which when translated means, "I break up the lightning". A treatise on the subject by a medieval scholar titled "Proof that the ringing of bells during thunderstorms may be more dangerous than useful", found that over a 33-year period in Germany, a total of 386 lightning strikes on church towers killed 103 bell ringers [3, 4]. In 1767, a church in Venice storing 100 t of gunpowder was struck by lightning, 3000 people were killed and a large section of the city destroyed [5]. Benjamin Franklin perceived and proved that lightning is an electrical phenomenon. He devised the famous sentry box experiment in 1749, which clearly displayed the electrical nature of lightning [6]. When he reported his findings, the King of France, Louis XV, who was an

electrical fanatic, had a sentry box built in 1752, and subsequently Franklin's experimental findings were verified in Europe [7, 8]. Benjamin Franklin made on-site inspections of churches, which were struck by lightning, [9] wrote newspaper articles requesting information about lightning damage.[c] and read articles about lightning damage to churches to determine the effectiveness of bell ringing [10].[d] Franklin found that bell ringing during a thunderstorm is a very dangerous occupation. If metal wire was used to ring the bells, the lightning would vaporize it but not damage anything along its path but killed the bell ringer. However, if rope was used to ring the bells, the lightning would cause severe damage to the steeple but probably not kill the bell ringer. This is where Franklin got the idea to attach metal wire to his rod. Franklin rods were opposed by church clergy on their structures because it seemed a sacrilegious act and an expression of no confidence in the mercy of God in striking a sacred structure. However, a Franklin rod was installed on a building in Venice (Campanile of San Marco) that had been struck and severely damaged by lightning nine times from 1388 to 1762. Since the installation of a Franklin rod in 1766, it has not been damaged by lightning [3, 4]. Franklin inspected buildings protected with a Franklin rod, which resulted in Franklin writing the first specifications or standards improving lightning rods [11].

Electrical engineering emerged as a discipline in 1864 when the Scottish physicist and mathematician James Clerk Maxwell summarized the basic laws of electricity in mathematical form and predicted that radiation of electromagnetic energy would occur in a form that later became known as *radio waves*.

The first practical application of electricity was the telegraph, invented by Samuel B. F. Morse in 1837. However, there was not a great need for electrical engineers until the inventions of Alexander Graham Bell and Thomas A. Edison approximately 40 years later; Bell's telephone in 1876 and Edison's incandescent lamp in 1878 and the first central electric generating plant in New York in 1882. Overnight a large demand was created for men educated and trained to work with electricity [1]. During the 1890s, engineering schools all over the world added studies in electrical engineering, often as optional courses within the mechanical engineering field. Previously, the study of electricity was considered to be a subfield of physics. Academic departments of electrical engineering emerged around the turn of the century [12]. In 1883, Cornell University introduced the world's first course of study in electrical engineering and, in 1885, the University College, London, founded the first chair of electrical engineering in the United Kingdom [13]. The sudden explosion of the electrical industry generated a need for electrical experts to answer legal questions about electrical designs, patents, contracts, personal injury, and damage. The adversarial legal system permitted each party involved in litigation to retain their own electrical expert as opposed to other legal systems where the judge appoints the expert to assist with technical questions. In addition, the ability of attorneys in the United States to pursue litigation on a contingency basis and the subrogation laws of the United States increased the demand for forensic electrical engineers.

Electrical litigation started with patent disputes and Lewis Howard Latimer was probably the first electrical engineer to testify in a patent dispute [14]. It is possible that there were earlier trials where someone was qualified in electrical engineering, but without an appeal that there is no documentation.

Education, Training, and Certification

There is presently no formal program for a Bachelor of Science degree in forensic electrical engineering. In the United States, the basic educational requirement for a forensic electrical engineer is normally a Bachelor of Science degree in electrical engineering from an accredited university. A few universities in the United States offer graduate courses in forensic engineering. The University of Iowa has a Biomedical Engineering Program. The University of Texas at Tyler has "Advanced Topics in Engineering (introduction to forensic engineering)". The University of Colorado at Denver offers "Failure Analysis and Condition Assessment in Civil and Mechanical Engineering". Purdue University's Weldon School offers a course to seniors and graduate students titled "Medical Device Accidents and their Engineering Analysis".

In addition, the individual should be a licensed professional engineer since state laws in the United States require engineers who work independently to be licensed. The requirements for licensing differ among the states.

In Canada, the engineering students normally take their professional engineering test in the senior year of their educational program.

Typically, engineers get involved with forensic work by joining a consulting firm, which specializes in forensic engineering, or associating with practicing forensic engineers. The senior members of the consulting firm or practitioners provide the training needed by the degreed and experienced engineer in the aspects of forensic engineering.

In 1997, the National Academy of Forensic Engineers (NAFE) appointed a committee, the Forensic Engineering Curriculum (FEC) Committee, and supplied funding to develop guidelines for university courses in forensic engineering. The FEC Committee determined that any forensic engineering degree program should begin at the masters degree level because of the specialized nature of forensic engineering.

Education and training for forensic electrical engineers is also available through various technical, legal, and forensic societies. The Institute of Electrical and Electronic Engineers (IEEE), conducts seminars and lectures on electrical equipment and the problems associated with the equipment. NAFE has seminars twice a year where technical papers are presented about forensic engineering investigations. The academy also publishes a journal of the papers that were presented at the seminars. Many of the presentations and published papers involve electrical engineering. The American Academy of Forensic Sciences (AAFS) has an engineering section. The engineering section of AAFS presents papers about forensic engineering investigations at their annual meeting each February. The AAFS has workshops at their annual meeting and sometimes the workshops involve some aspects of electrical engineering.

Certification in forensic electrical engineering in the United States is provided by NAFE through the Council of Engineering and Scientific Specialty Boards. Subsequently, members of NAFE can refer to themselves as a Board Certified Diplomate in forensic engineering by NAFE, program accredited by Council of Engineering and Scientific Specialty Boards (CESB). Another certification program is through the International Institute of Forensic Engineering Sciences, Inc., (IIFES). The IIFES maintains its certification program through the Forensic Specialties Accreditation Board. Forensic engineers who meet the requirements of IIFES are awarded a Certificate of Qualification as a Diplomate, IIFES. They are then entitled to represent themselves as being board certified by the IIFES.

Societies, CPD's and Sections

The largest forensic engineering society is NAFE. NAFE has approximately 400 members and 52 are degreed electrical engineers. NAFE is a chartered affinity group of the National Society of Professional Engineers of the United States and all members are licensed/registered professional engineers. All members of NAFE must provide forms each year reflecting that they have accumulated 100 continuing professional development (CPD) credits during the past 5 years.

The AAFS established an engineering sciences section in 1981. The AAFS engineering sciences section has approximately 170 members and 20 members are electrical engineers.

Casework

Electrical engineers are asked to answer legal questions about electrical phenomena from charged particles to the appliances in our homes and the electrical system that supplies them with power. The questions might be asked verbally or in written statements by a client to determine if further investigation or litigation should be pursued. Most of the casework involves civil litigation and the majority of the clients are insurance companies and their attorneys. The engineer is contacted by telephone, email, and fax machine by claim/loss adjusters, attorneys, public defenders, manufacturers, private investigators, military investigators, law enforcement, and individuals who are handling a matter involving financial loss, violations of law, or personal injury/death. The matter is discussed with the potential client and the engineer informs them if they can provide any assistance in the matter. The client usually requires a curriculum vita (CV) (resume) to check if the engineering education, training, and work experience would qualify them to be declared an expert witness in a court of law involving the matter. Rate sheets (charges for services) are almost always requested. If the client decides to retain the engineer, a contract should be signed between them, which details what service the engineer will provide to the client: inspection, investigation, testing, analysis, reports, and/or testimony.

The subrogation laws in the United States permit insurance companies to recoup the money they paid for fire damage from individuals, companies, or manufacturers for improper/defective installation, use, or manufacture of a product. Subsequently, most of the forensic electrical engineer's casework involves fire investigation. Electrical engineers who investigate the cause of fires must also have training in fire investigation. Fire investigation training is necessary because to determine the cause of a fire, the individual must be able to locate the origin of the fire (where it started). Examination of the electrical components, if any, at the point of fire origin will usually reveal if electricity was involved with the fire's cause. Training in fire investigation can be obtained through the International Association of Arson Investigators (IAAI). The IAAI holds annual fire investigation training seminars. It has state chapters throughout the United States and in other countries, which conduct fire investigation training seminars.

Electrical injury and electrocution cases are normally large loss matters exceeding several million dollars but there are very few of them compared to the number of fires.

Engineers evaluate electrical damage to determine if it is covered by an insurance policy or which policy (fire insurance, boilermaker, or umbrella). If the verbal statement of the engineer is not sufficient to answer the legal technical questions, then a written report might be requested from the engineer to pursue the matter further. Normally, the report would include the scope of work to be performed, details of the investigation, any testing, research, analysis, and conclusions. The analysis might include an evaluation of different versions of events in the matter and their affect on the cause of the damage or injury. The majority of the cases settle after a report is submitted. However, a few go on to depositions where the engineer is asked questions under oath by the attorneys involved in litigating the case. Before the deposition, the engineer must educate his client attorney about electricity and/or fire investigation. The client should understand how electricity caused the injury, damage, or fire and what laws, codes, or standards apply to the case and if any were violated by any parties involved. At the deposition, the engineer is asked for their CV by the deposing attorney and they are questioned under oath about the CV to evaluate their qualifications to testify about the matter at hand. They are asked details about their case file, investigation, testing, and analysis. Hypothetical questions are asked to evaluate potentially different conclusions. Sometimes, an estimate of the percentage of reliability of the conclusions is asked of the engineer.

Very few cases go to trial because of the cost of presenting a case in court. Some cases go to trial because the various parties have experts with drastically different opinions, personal grievances, or ask the court to determine how the case should be settled. Before trial, the engineer might be asked to submit a list of casework, authored articles, depositions, and trial testimony. At trial, the engineer is asked about their education, training, and professional work experience by attorneys and sometimes judges to determine if they are qualified to give expert witness testimony at the trial and on what areas/subjects they can testify about. The judge determines if the engineer qualifies as an expert witness. If qualified, the engineer answers technical questions posed by his client attorney, opposing attorneys, and rarely the judge and jury to aid the jury and court in their deliberations. During questioning by his client, the engineer must educate the judge and jury about electricity, fire investigation, computer software, or whatever is the subject of the litigation. The normal operation of the electrical device should be explained and also how it malfunctioned in this instance causing the financial loss, injury, or death. Next, the engineer is questioned by the opposing attorneys who attempt to find errors in the expert's testimony.

An example electrical injury case involved the loss of arms and a liability of \$10–15 million. An electrical engineer was contacted by an independent adjuster retained by a supermarket company to assist him or her with investigating the cause of the injury. Normally, property owners in the United States are liable for electrical damage or injury on their property and the injury occurred on supermarket property. A group of children had been playing behind a closed supermarket where a 13 kV switch was located near a loading dock (Figure 1). The engineer was asked to determine why the injury occurred; if the electrical equipment was properly installed, maintained, or manufactured and if not, what parties were at fault. At the injury location, the engineer saw that the switch did not have a fence or additional enclosure around it, as required by electrical standards [15]. This indicates that the switch was improperly installed by the supermarket's contractors. The observation opening on the

Figure 1 Figure showing the front doors on the high-voltage disconnect switch. Arrow 1 indicates the missing cover over the observation window of the switch. Arrow 2 indicates a lock with a key broken off in it, which is shown in more detail in Figure 2. Arrow 3 indicates holes in the fuse compartment door, which is shown in more detail in Figure 3

front of the switch was missing a cover to keep water out, arrow 1 in Figure 1. The switch operating handle was in the closed position, arrow 1 in Figure 2. A key was broken off in a lock that was mechanically linked with the position of the switch, arrow 2 in Figure 2. Normally, the key can only be removed from the lock when the switch is in the open position. When the switch is open, the key is removed from the lock and utilized to unlock another lock, which is securing the lower door of the switch where fuses are located. Additional unsealed openings were found around the switch handle, arrow 3 in Figure 2. The switch's lower fuse compartment door had holes in it where a lock that was controlled by the broken key should have been located, arrow 3 in Figures 1 and 3. This indicates that the switch was not properly maintained by the supermarket. Subsequently, the fuse compartment of the switch could be opened and entered while the switch was energized with 13 kV. Evidence of burning, arcing, and melted metal was found at the top of the left fuse holder in the fuse compartment (Figure 4). This is where the child's right hand made contact with 13 kV. Fingerprints in metal were found on the left side of the fuse compartment opening (Figure 5). This is where the electrical current exited the boy's left hand. The electrical current flowed from the top of the fuse holder through the boy's arms to the side of the switch, which is grounded as required by electrical codes. This injury was caused by the improper design, installation, and maintenance of the high-voltage disconnect switch, which violated electrical codes and standards. It was not designed for outdoor use. The openings in its enclosure permitted water and debris to enter into the switch. A single-door design covering the fuse compartment and switch operating handle would have eliminated the problem with the missing interlock lock on the fuse compartment door. The fuse compartment is required to be secured from entry when the switch is closed. The switch was designed for installation in a locked electrical room. However, it was incorrectly listed in a utility company's book of acceptable switches for the location. A scheduled maintenance program would have detected the switch's deficiencies and corrected them. This case settled out of court without depositions or reports. The engineer educated the supermarket attorneys verbally and with printed documents about the improper installation, design, and maintenance of the switch and the codes/standards that were violated. The education and documents enabled the supermarket attorneys to bring their contractors and the utility company to the bargaining table and share in the liability for the injury.

An example of a fire case involves a severe residential fire with a large property loss. A fire investigator brought a box of items from the fire's area of origin to this engineer's office. The fire investigator asked the engineer to inspect and photograph the items to determine if they were involved with the cause of a fire. He also emailed photographs of the fire scene and his fire determination report to the engineer. Among the items was a severely heat-damaged steam generating tank (Figure 6). The steam generating tank was X-rayed (Figure 7). The X-ray showed that the sheath (exterior enclosure) of the unit's heating element was open (arrow 1 in Figure 7) and a thermal over-temperature device had blown apart (arrow 2 in Figure 7). In addition, the nichrome wire

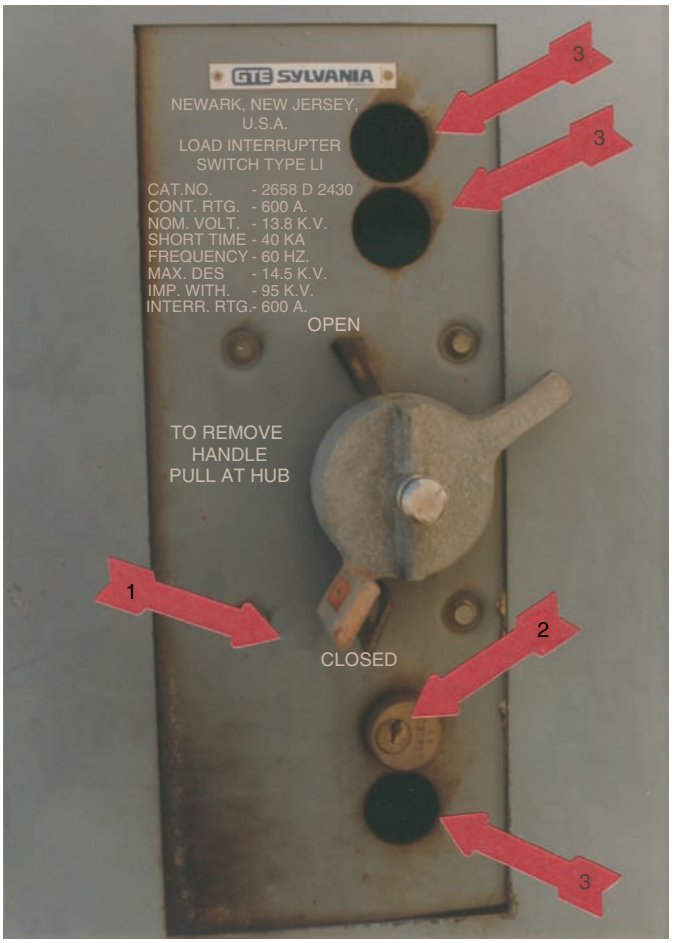

Figure 2 Figure showing the operating handle of the switch. Arrow 1 indicates that the switch is in the closed position. Arrow 2 indicates the broken key in the lock. Arrow 3 indicates unsealed openings

inside the heating element was separated and disintegrated in many locations (Figure 8). The nichrome wire is the device that generates heat inside the heating element when electric current passes through it. Nichrome wire is a nickel-base alloy, containing chromium and iron. Nichrome wire has a melting point of 1020–1452°C depending upon the chemical composition of the alloy [16]. The fire temperatures in a residential building normally do not exceed 800°C. Subsequently, the disintegration of the nichrome wire inside the heating element indicates that the heating element malfunctioned and caused the fire. The engineer verbally reported his conclusions about the inspection and X-rays to the fire investigator and the insurance company that retained him. An exemplar steam generating tank by the same manufacturer was purchased, inspected, and tested by the engineer. The exemplar was found to be defective in design and manufacture. An engineering report was requested and submitted with photographs and X-rays. The report stated that the subject steam generating tank was defective in design, manufacture, and caused the fire. The manufacturer retained experts with different opinions even after examining the evidence, X-rays, and exemplar. As a result, the engineer was deposed by the manufacturer's attorneys and he educated them about the appliance's defects. The case settled after the deposition.

Another case involved a large residential building that sustained fire damage while $500 000 worth of

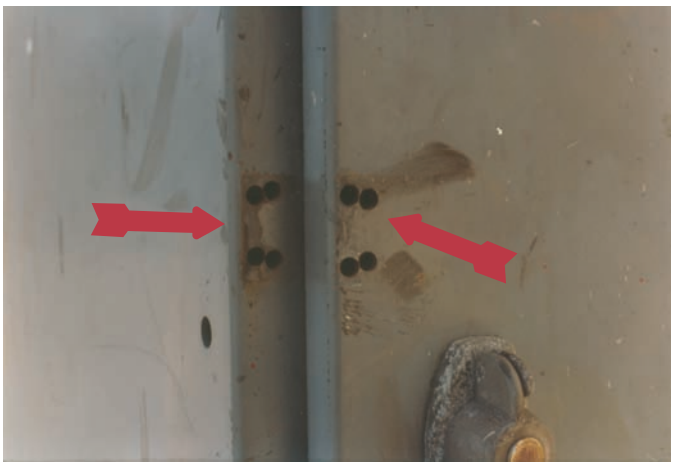

Figure 3 Close-up figure showing the holes in the door of the fuse compartment and frame of the switch, as indicated by the arrows in the Figure

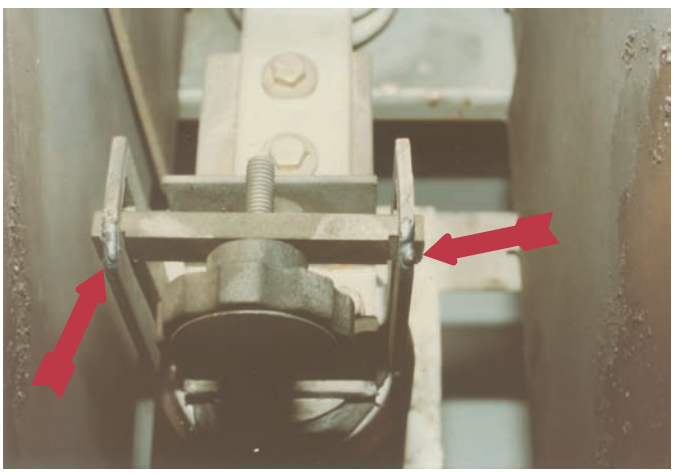

Figure 4 Close-up figure showing the melted metal at the top of the fuse holder, as indicated by the arrows in the Figure

renovations was being performed. An electrical engineer was retained to investigate the origin and cause of a fire along with a fire investigator and mechanical engineer for subrogation purposes. The building had experienced electrical problems and the fire was discovered just after the building's new fireplace was lit for the first time. The fire originated within the walls of the building where electrical wiring was located. The origin was in the concealed space above the new fireplace. Electrical wiring was located there to supply electrical power to an outlet on the right side of the fireplace. The wiring was solid copper and evidence of melting was found <2 cm apart on two wires (Figure 9). Melted copper between two electrical wires quite frequently indicates that the two wires short-circuited together. When copper wiring short circuits, it generates temperatures exceeding 1200°C with sufficient energy to ignite most common combustibles. However, the evidence of melting is normally at the same location along the length of the wire. Microscopic inspection of the melted areas found that they were bite marks (Figures 10 and 11). Subsequently, an animal bit the wiring and produced the short circuit, which ignited the building. The fire

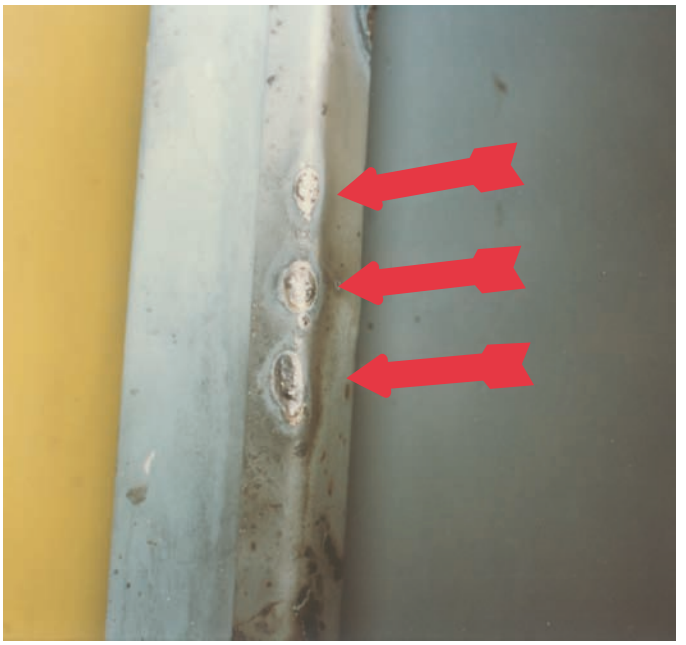

Figure 5 Figure showing fingerprints in metal, as indicated by the arrows in the Figure

Figure 6 Figure showing the bottom of the steam generating tank

was the result of the renovation contractor leaving openings to the interior of the walls unsecured during construction after electrical power was supplied to the building. The engineer determined the origin and cause of the fire and the party at fault, the renovation contractor. However, no litigation followed because the building owner had signed a contract with the renovator that eliminated their liability for damages that occurred during the renovation.

Another example of an electrical injury case involves an electrical explosion in an electrical distribution room that caused electrical injury and severe

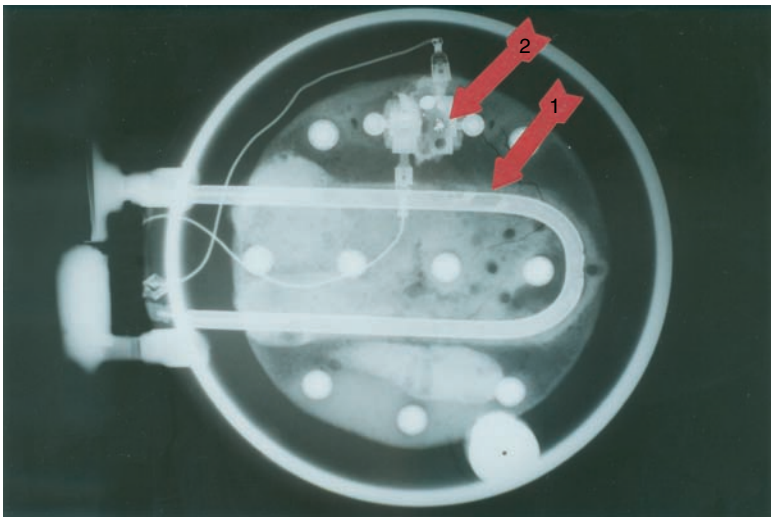

Figure 7 Figure showing an X-ray of the steam generating tank. Arrow 1 indicates an opening in the sheath of the heating element. Arrow 2 indicates a thermal control device

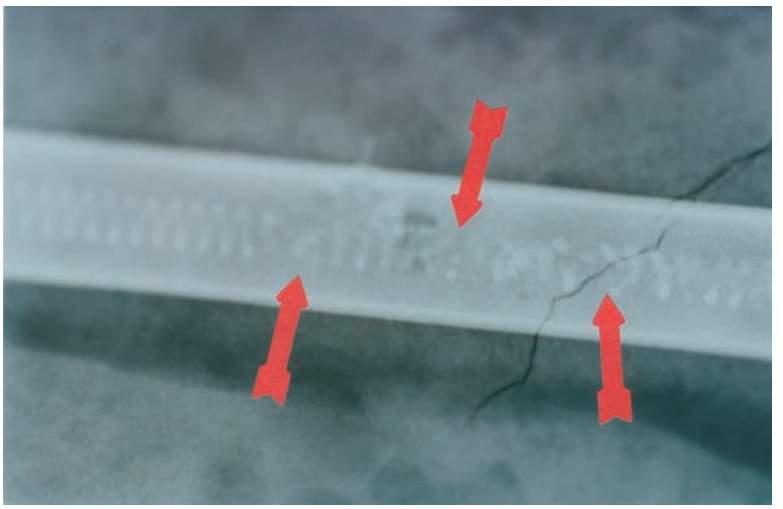

Figure 8 Close-up figure showing the nichrome wire inside the heating element, as indicated by the arrows in the Figure

property damage (Figure 12). The engineer was asked by a law firm to inspect the scene of the explosion, evidence retained from the scene and research documents to determine the cause of the explosion and the parties at fault for causing the personal injuries of workers. The oil within a 5000-V oil circuit breaker had exploded and ruptured its tank (Figure 13). The explosion occurred when the oil circuit breaker was closed after maintenance was performed on it. The maintenance personnel were only permitted 30 min to work on the circuit breaker. Their maintenance consisted of draining the oil out of the bottom of circuit breaker and pumping new oil in. However, proper maintenance on this type of oil circuit breaker requires a minimum of two men working 4 h. The oil should have been put back into the tank from the top of the tank after its interior was cleaned, inspected, and mechanically tested. Furthermore, the electrical

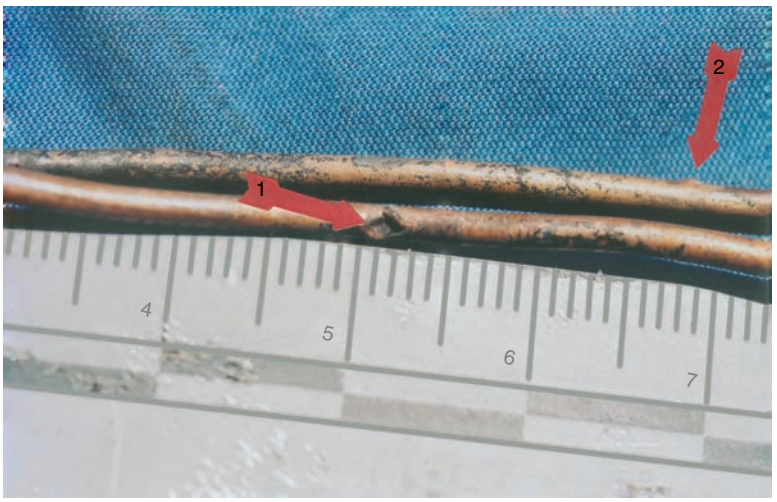

Figure 9 Figure showing copper wires with melted areas. Arrow 1 indicates a melted area shown in more detail in Figure 10. Arrow 2 indicates a melted area shown in more detail in Figure 11

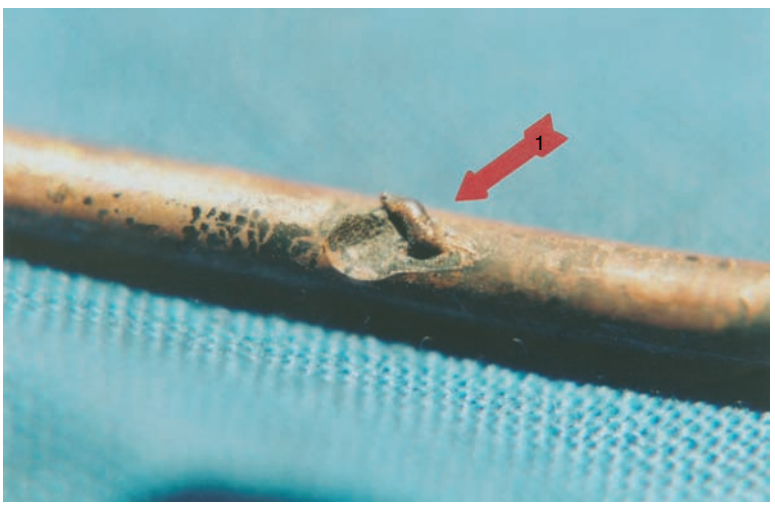

Figure 10 Close-up figure showing the melted area indicated by arrow 1 in Figure 9

distribution room should have been cleared of personnel before the circuit breaker was closed after maintenance. Consequentially, the property damage was caused by bad maintenance. The personnel injuries were the result of not following proper electrical protocol in closing the switch after maintenance without clearing the area of all unnecessary personnel. The engineer reported his conclusions to his attorney client who did not request a formal written report. Litigation against the maintenance people was started and during the discovery process the engineer was deposed by the maintenance attorneys. The engineer educated the maintenance attorneys while testifying about their own electrical protocol, which required the injury area to be cleared of all unnecessary personnel (the injured workers) before a high-voltage switch is closed after maintenance. After the deposition, the case settled out of court.

The last example involves a severe fire in a commercial building with a large property loss. The fire

Figure 11 Close-up figure showing the melted area indicated by arrow 2 in Figure 9

Figure 12 Figure showing where an explosion occurred in an electrical room

originated in an electrical distribution panel in a room of one of the commercial businesses in the building. An electrical engineer was retained by the insurance company who provided liability coverage to the tenant of the commercial business where the fire originated. The engineer was asked to determine the origin, cause, and parties at fault for the fire damage. The owner of the building had filed a million-dollar complaint against the tenant. Most of the contents of the fire building had been removed prior to this engineer's arrival at the fire scene except for the main circuit breaker, which protected the electrical conductors (wires) located within metal conduits (pipes) that feed electrical power to distribution panel previously located in the area of the fire's origin. The burn pattern in the area of fire origin indicated that the fire started in the ceiling area above the distribution panel where a conduit containing the service conductors feeding the panel was located. The service conductors were fused to the bottom inside of the conduit

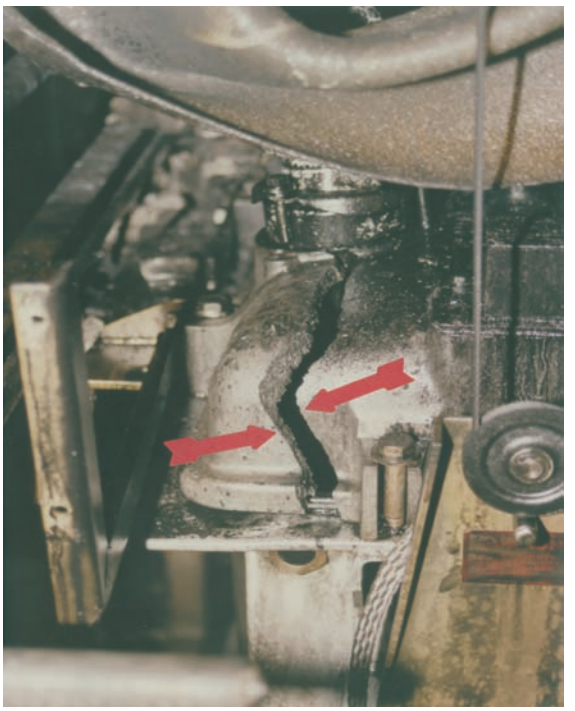

Figure 13 Figure showing where the tank of the circuit breaker ruptured

Figure 14 Figure showing the exterior of the circuit breaker

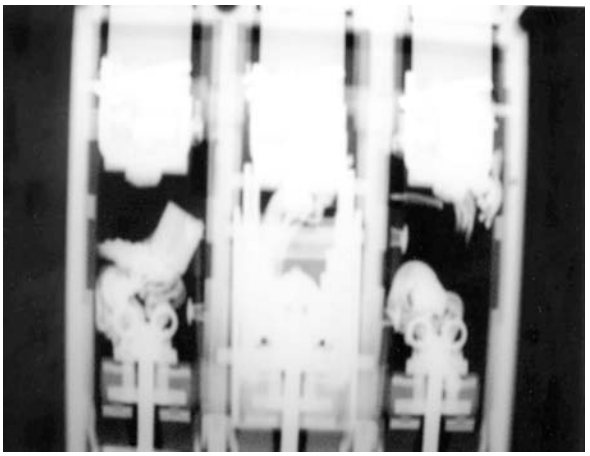

Figure 15 Figure showing the X-ray of the circuit breaker

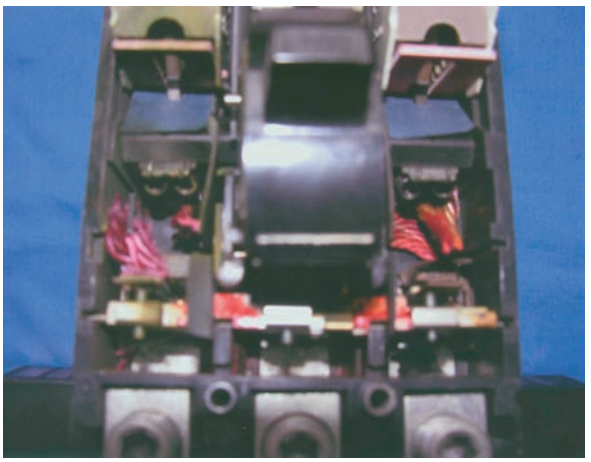

Figure 16 Figure showing the interior of the circuit breaker after disassembly

that was in contact with the structural wood components of the ceiling. The conductors were separated from the conduit to perform tests on the circuit. The tests indicated that the conductors had short-circuited to the interior of the conduit all the way back to the main circuit breaker. The main circuit breaker's operating handle was found in the closed position even though the conductors were not energized. Tests found no voltage present on the load terminals of the circuit breaker. Therefore, the local utility company was contacted to shut off power to the building so that the main circuit breaker could be removed from the main panelboard for further testing. The main circuit breaker had three phases and was rated at 200 A. No evidence of fire damage or overheating was found on the exterior of the circuit breaker (Figure 14). Preliminary tests of the circuit breaker indicated that two of the phases (circuits) inside the circuit breaker were open even when its operating handle was in the closed position. The circuit breaker was X-rayed. The X-ray showed that internal components of two phases of the circuit breaker had separated and melted (Figure 15). The engineer reported the results of the inspection, testing and X-rays to the insurance company adjuster. A report was requested with Figures and X-rays. The manufacturer of the defective circuit

Figure 17 Figure showing the internal components of an exemplar circuit breaker

breaker was put on notice of the financial loss. Subsequently, the circuit breaker was disassembled with representatives of its manufacturer present. The internal examination of the circuit breaker confirmed what the X-rays showed (Figure 16). An exemplar circuit breaker was disassembled to compare internal components. The components that melted and separated in the other circuit breaker were much lighter in color (Figure 17). The difference in color indicates that the separated components had overheated. The circuit breaker should have opened before its components melted and separated. A circuit breaker is "a device designed to open and close a circuit by nonautomatic means and to open the circuit automatically on a predetermined overcurrent without damage to itself when properly applied within its rating". The circuit breaker "is provided to open the circuit if the current reaches a value that will cause an excessive or dangerous temperature in conductors or conductor insulation" [17]. The purpose of the main circuit breaker is to open and disconnect electrical power from an electrical distribution panel and the circuit feeding it before the malfunction produces sufficient heat to ignite a fire in a building. Consequentially, the fire was caused by a defective main circuit breaker. The engineer answered the technical questions about the origin, cause, and party at fault for the fire damage, the circuit breaker manufacturer. The case was settled after disassembly of the circuit breaker with representatives of the circuit breaker manufacturer present, engineers, and attorneys.

Entomology

Introduction

Definition

Entomology is the study of insects and related arthropods. Forensic entomology is the use of such knowledge in legal investigations including cases of medicolegal, stored product or urban circumstances. Although entomological knowledge is often employed for investigations involving stored products (e.g., a grasshopper in a can of green beans, grain beetles in cereal) or urban damage (e.g., termite infestations), we focus on the aspects of entomology used in medicolegal investigations. Such investigations are broadly defined as felonious violent crimes that include murder, suicide and rape, but can also involve cases of extreme neglect and abuse. In most instances, forensically relevant inferences are made by the collection, identification, and study of arthropods associated with a decomposing body. The arthropods usually consist of the true flies and beetles, but may also include incidental organisms such as assassin bugs, cockroaches, bees, wasps, ants, spiders, mites, and lice, among others (Table 1).

History

Although forensic entomology has only recently seen increased interest and acceptance in the forensic sciences and in courts of law (since the early 1990s), the initial contributions of insects in legal investigations dates back to centuries and has an established history of routine use for about 150 years. Regular use of insects in criminal proceedings began in Europe in the later half of the nineteenth century with techniques that are similar to what are used today. The publication of better insect identification keys during the early to mid-1900s inspired interest in forensic entomology in North America, but its acceptance within the forensic community was meager until the early 1980s. It was at this time that there were publications of developmental rates and other biological aspects on forensically important species of flies by investigators such as R.D. Hall and B. Greenberg. Recent interest has been facilitated by a surge of research into the biology and ecology of forensically

Table 1 Decomposition stages of a body along with associated arthropods[a]

Stage of decomposition	Accumulated time[b] (days)	Common arthropods	Relative degree of PMI accuracy
Fresh			
Begins at the moment of death and ends with bloating caused by the breakdown and metabolism of proteins, lipids and carbohydrates.	0–3	Adult blow flies and eggs, muscid flies, yellow jackets, ants, daddy longlegs	Fair
Bloated			
Putrefication begins during this stage and trapped metabolic gases from anaerobic bacteria inflate the body.	4–7	Adult and larval blow flies, flesh flies, muscid flies, rove beetles, hister beetles, carrion beetles, ants, assassin bugs, yellow jackets	Good
Decay			
Gases rupture the abdomen and the body deflates. This stage is very odiferous.	8–18	Adult and larval blow flies, muscid flies, rove beetles, hister beetles, carrion beetles, dermestid beetles, scarab beetles, cockroaches, red-legged ham beetles	Best
Postdecay			
In dry habitats the remains are composed of dry skin, cartilage and bones. In wet habitats, the remains are wet and viscous as byproducts of decomposition.	19–30	Dermestid beetles, hister beetles, fungus beetles, springtails, mites, fungus gnats, fruit flies, cheese skipper flies, phorid flies	Fair
Dry			
Only bones, cartilage, hair and dry skin remain. Most odor is gone.	≥31	Dermestid beetles, ants, cheese skipper flies, sow bugs, solder flies, ground beetles	Poor

[a] The relative degree of PMI accuracy provides an estimated accuracy of entomological evidence between each stage of decomposition when a body can be discovered. A forensic entomologist will generally provide an estimated time range (e.g., 1–7 days) when death may have occurred, and the accuracy increases with a narrower time range

[b] Accumulated time estimated from studies on pig carcasses in southern Michigan during the summer and early autumn

important arthropods from around the world, and the use of arthropods in highly publicized cases bringing attention to the usefulness of "bugs" or "maggots" in criminal investigations. The entertainment industry also has publicized the use of arthropods in legal proceedings through popular TV programs (e.g., New Detectives, Cold Case Files, CSI).

Forensic entomology is now a recognized discipline of the American Academy of Forensic Sciences and has gained international acceptance with the American Board of Forensic Entomology (ABFE), the North American Forensic Entomological Association (NAFEA), and the European Association for Forensic Entomology (EAFE).

Background

Because insects and other arthropods have predictable life histories, habitats, known distributions, and developmental rates, the presence/absence and

size of specific species at a crime scene, such as a homicide, can provide important information about when, where, and even how a particular crime occurred. Insects and other arthropods play a natural role in the decomposition of carrion in the environment, consuming the decomposing organic material and recycling the energy and nutrients as part of their life cycle. When an organism dies, bacteria that were once held in equilibrium by the immune system immediately begin to digest the body's proteins, lipids and carbohydrates as energy sources, creating both gaseous and liquid byproducts that act as an olfactory cue (i.e., a smell) for colonization by multicellular organisms such as flies and beetles. In most instances the initial arthropod colonizers are adult blow flies that will feed and lay eggs (i.e., oviposition) on the remains. Within a few hours the decomposing body acts as a food source for newly hatched larvae, and they grow and develop through life stages at temperature-dependent rates. The presence of blow fly (Diptera: Calliphoridae) larvae attract roaming predators and parasites such as beetles, mites, ants, wasps, and spiders that then feed on or parasitize the eggs, larvae, or pupae of the flies. This is followed by other insect species that come to feed on previously eaten or conditioned (e.g., dry skin) remains in a predictable succession (sequence) of arthropod species that colonize and ultimately decompose the carrion to dry bones and hair. Some representative insect groups associated with carrion in nature are shown in Figures 1–4.

Forensic entomologists use data on insect development rates and the natural and predictable species succession to estimate the time of initial insect colonization. Because blow flies can oviposit within minutes to hours after death, this estimate of initial insect colonization is a reasonable surrogate of the amount of time since death, or what is known as the *postmortem interval* (*PMI*). However, many factors can influence oviposition, larval development rates and species succession, so only expert forensic entomologists should be consulted when insects are collected from a crime scene.

Assumptions of Entomology-Based PMI Estimates

On the basis of understanding the natural history of various insect species, a forensic entomologist

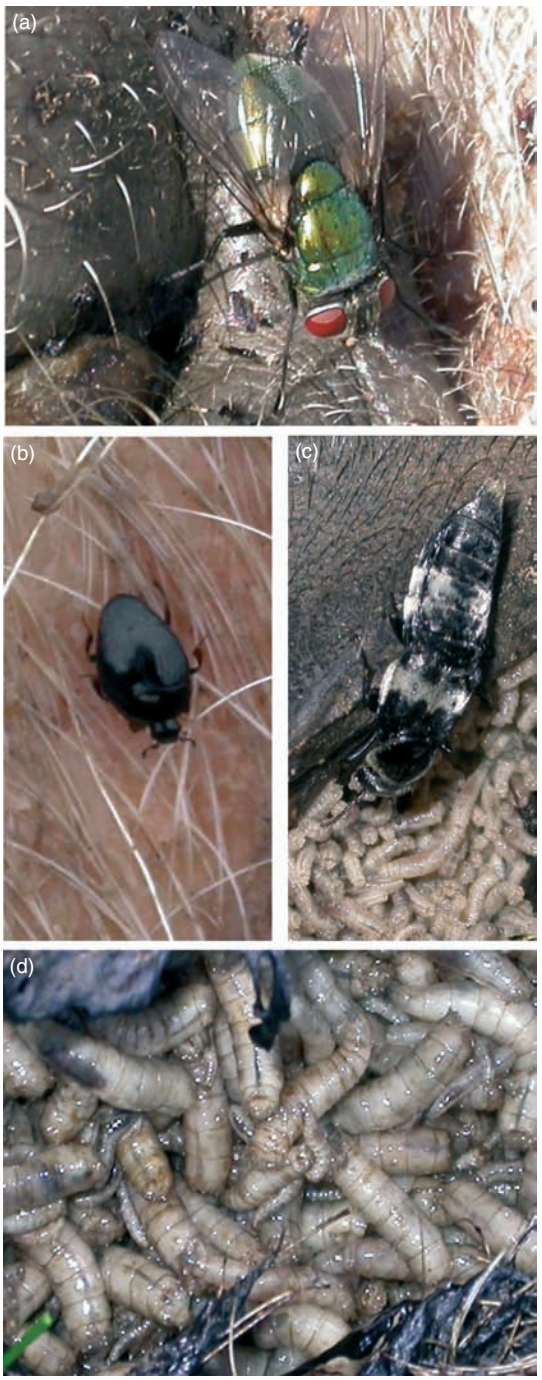

Figure 1 Representatives of some forensically important insects: (a) blow fly (Diptera: Calliphoridae); (b) histerid beetle (Coleoptera: Histeridae); (c) rove beetle (Coleoptera: Staphylinidae); and (d) blow fly maggots (Diptera: Calliphoridae)

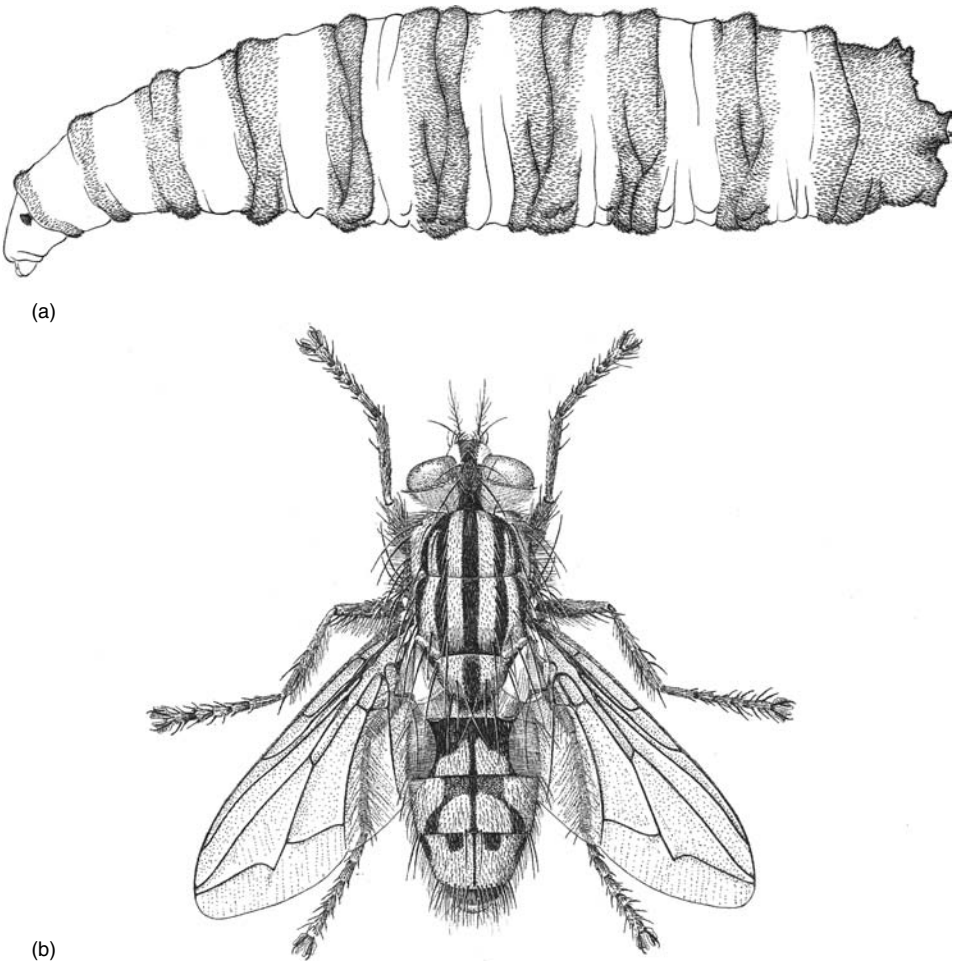

Figure 2 A flesh fly (Sarcophagidae): (a) larva and (b) adult [Reproduced from Gorman JR (ed.) (1987). *Insect and Mite Pests in Food: an Illustrated Key,* US Department of Agriculture, Handbook 655 [1].]

can make estimates of an entomology-based PMI, which represents a range of time for initial insect colonization. As with any forensic discipline there are basic assumptions that require evaluation when making determinations and inferences during a crime scene investigation. We provide several points here that are important to forensic entomology:

1. Oviposition usually does not take place at night. Most homicides occur at night, so there may be a delay in oviposition until the following morning.
2. Adult flies will generally oviposit as soon as they find a body. This is the general assumption that associates the PMI with initial insect colonization; however, any barrier to initial oviposition should be considered during an investigation.
3. Insect succession follows a predictable order. This is generally true, but can vary depending on the season, habitat and regional location, as well as other environmental conditions such as periods of extreme rainfall or drought, and whether the body is inside a house or outside exposed to the elements.
4. Ambient air temperature is the major variable influencing larval growth and development rates. Although temperature is the overriding factor affecting development, it does not always apply equally throughout the life cycle and

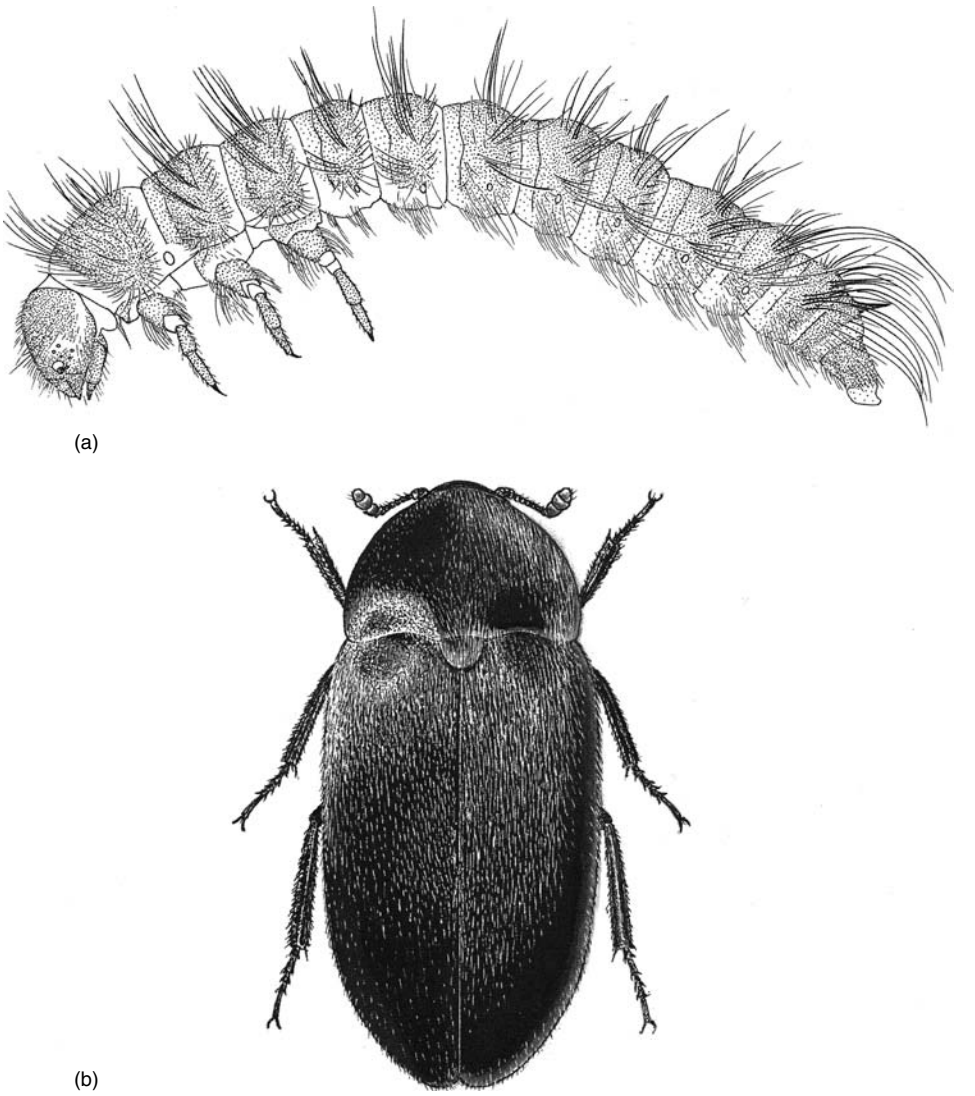

Figure 3 A dermestid beetle (Dermestidae): (a) larva and (b) adult [Reproduced from Gorman JR (ed.) (1987). *Insect and Mite Pests in Food: an Illustrated Key,* US Department of Agriculture, Handbook 655 [1].]

other variables can work in a synergistic fashion. When the larvae are in their early, small stages and when there are only a few individuals, ambient air temperature has its most profound effects on development. The effect becomes more variable as the larvae grow bigger and/or become more numerous. Hundreds to thousands of larvae can form masses (i.e., maggot masses) on a body (Figure 5). The thermogenic heat created by the metabolic and movement activities of the mass can raise the temperature of the mass and the body above the ambient temperatures. This effect can persist under much cooler ambient conditions and even when a body is placed into a refrigerator. Any larval masses should be noted, the size estimated and a temperature measurement made in one or two places within the mass. Other factors such as humidity, rainfall and sometimes chemicals or drugs consumed by the deceased

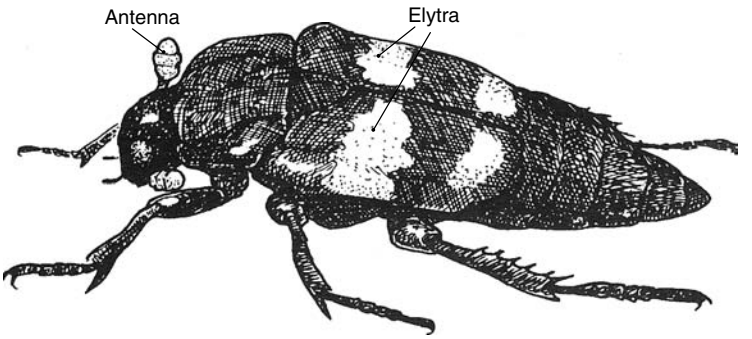

Figure 4 Adult carrion beetle (Silphidae) *Nicrophorus* sp. (20–25 mm in length) [Reproduced with permission from Catts and Haskell [2].]

Figure 5 A large mass of larvae (i.e., maggot mass) will sometimes form on a decomposing body, influencing the temperature at which they are developing. The white matter in this photo is the maggot mass

can influence development (see the following data).

5. Climate data from a weather station distant from a crime scene represents the ambient conditions of that scene. This is usually the weakest input to decision making in forensic entomology. Correlations between the crime scene and distant weather station data can vary substantially. Many variables can influence this relationship, including ground cover, topography, wind speed, and direction, and other microhabitat conditions that influence temperature conditions at a scene. It is recommended that crime scene temperature readings be taken for several days to weeks and compared to weather station data in order to check the validity of such assumptions; but this is not always done. Indoor crime scenes are much less variable compared to those found outdoors, and often a thermostat can be checked for ambient conditions.

Here we expand on these assumptions and discuss in greater detail the biology behind, and application of, using insect evidence for making entomology-based PMI estimates.

Entomological Succession

Ecological succession is defined as the predictable and sequential colonization and replacement of specific communities of organisms over time in, or on, an open area. This same principle is used in forensic

entomology with the open area being a body, and the communities represented by arthropods that are primarily insects. When an organism dies, it goes through five stages of decomposition that coincide with the activity of bacteria and insects (Table 1). The duration of each stage is directly related to the air temperature and the degree of insect activity associated with the body. While the length of each stage varies with temperature, the series of stages is very predictable, and a forensic entomologist can estimate a PMI based on the stage of decomposition, the insects present, and known temperature data.

Adult blow flies, flesh flies and other species are generally the first insects to arrive at a decomposing body, appearing within minutes or hours after death to lay eggs or live larvae in some instances (Figures 1 and 2). From a few hundreds to several thousands of eggs can be laid on a body and the resulting larvae are the most obvious and important group of insects, for they will eventually consume most of the decaying flesh. Larval activity, and thus decomposition, is greatest through the decay stage (Table 1). It is during this stage of decomposition that an entomologist can estimate the PMI with a high degree of confidence by evaluating the various larval developmental stages. The largest larvae are most important since they represent the earliest time of oviposition. After the decay stage, when most of the flesh is gone, changes in the decomposing remains and the associated insect fauna occur at a much slower rate, making the accuracy of the entomology-based PMI more variable. The later stages are dominated by dermestid and carrion beetles and other insects that feed on the remaining dried flesh, skin, and hair (Figures 3 and 4; Table 1).

Fly Life Cycle and Development

Life Cycle

The true flies (order Diptera) are the most important group of insects that are used in making entomology-based PMI estimates. In particular, two families of flies have evolved to specialize on carrion: blow flies (Calliphoridae: Figure 1a,d) and the flesh flies (Sarcophagidae: Figure 2). Blow flies are generally medium- to large-sized insects (usually <1 cm in length) with a metallic green or blue color and are often referred to as *greenbottle* and *bluebottle* flies (Figure 1a). Adult females are known to oviposit on a body immediately after death. Oviposition is primarily a daylight activity, and as such, may be delayed for several hours if death occurs at night. Eggs are generally equal to or <2 mm and are initially deposited around naturally moist open areas (mucous membranes) or orifices such as eyes, nose, ears, and mouth, but also are laid in and around wounds. A single adult female blow fly may lay up to several hundred eggs in a short period of time, and many females oviposit on the same body; the results can be thousands of larvae and the formation of larval masses, commonly referred to as *maggot masses* (Figure 5). Flesh flies are usually gray with black longitudinal stripes (Figure 2). Female flesh flies deposit small live larvae on a body in the same areas as blow flies. The larvae of flesh flies are usually far fewer in number compared to the more dense blow fly larvae. The larval body size of both types of flies can vary between 5 and 15 mm, depending on the species and developmental stage.

The life cycle of true flies is described as *holometabolous*, meaning there is a "complete change" in body form during growth and development (Figure 6). In this type of life cycle there is complete metamorphosis from the larvae to pupae, where the larvae are structurally different from both pupae and adults (Figure 6). In other life cycles, such as the hemimetabolous life cycle, the larvae resemble the adults throughout development; they are just smaller versions of the adults and there is no metamorphosis or pupal stage.

Whether deposited as eggs (blow flies) or as small larvae (flesh flies), there are three larval developmental life stages, or instars. During development the larva body size increases dramatically during each instar before molting into the next instar (Figure 6). The soft-bodied larvae feed on decaying flesh with hard, hook-like mouthparts and secrete enzymes that aid in digestion. As a larva progresses from the first, to the second and into the third instar, its size increases tenfold from continuous feeding. It is when the larvae have reached the third instar that most of the decomposing biomass is consumed leading to the beginning of the dry stage of decomposition (Table 1). At the end of the third instar, the larvae go through a brief stage of postfeeding, prepupal migration: the larvae move away from the decomposing remains for up to 10–30 m to burrow into soil or leaf litter to undergo metamorphosis. During this prepupal stage, the larval body begins to shorten and turn darker, while mobility is reduced.

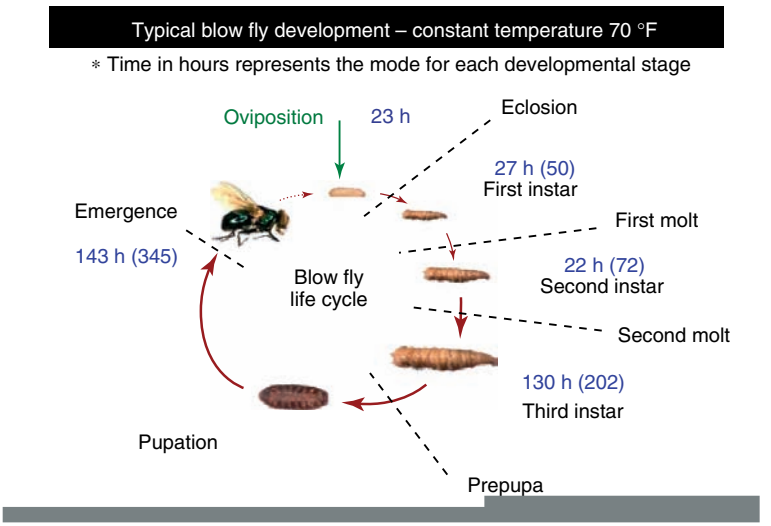

Figure 6 A schematic of the life cycle of a representative blow fly, indicating the approximate time necessary for each stage of development

These changes mark the beginning of metamorphosis into the pupal stage. It is the exoskeleton of the third instar that forms the outer hardened casing known as the *puparium*, and within this structure the pupa is formed (Figure 6). Inside each puparium a pupa slowly metamorphoses into an adult fly, which in several days will emerge as a flying adult, beginning the next life cycle.

Effects of Temperature on Development

Insects are poikilothermic, meaning that their body temperature is dependent on ambient temperature conditions of the macro- and microenvironment. Because of this growth and development are closely related to temperature: as ambient temperature increases so does the rate of development (Figure 7). This relationship holds for most ambient temperatures; however, development slows or ceases at extreme cold and hot temperatures (e.g., 2 °C and 100 °C, respectively) (Figure 7). These thermal thresholds are not universal for all fly species, but rather, they can vary between species and between geographically distant populations of the same species (e.g., temperate *vs.* tropical populations) (Figure 8). For instance in Figure 7, development was undetectable at 12 °C.

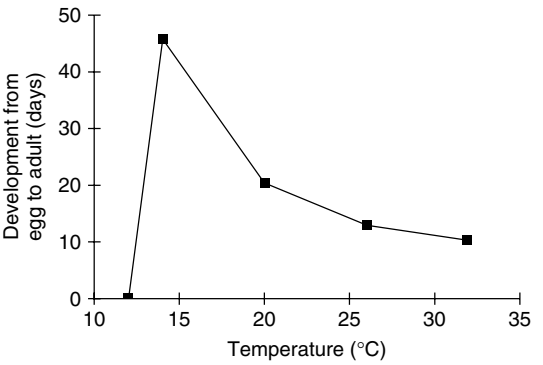

Figure 7 A representative relationship between blow fly development and temperature. Development is the time it takes to grow from egg to adult. Data are for laboratory reared *Phormia regina* and plotted from Table 1 of Nabity *et al.* [3]. At 12 °C there was no detectable development

Further, insect metabolism increases with temperature, therefore, feeding and the resulting decomposition increases throughout larval development. A body exposed to direct sunlight on a hot summer day may be reduced to bones in a little over a week or less, while an exposed body in the late autumn or winter may show little change for months. Because of this relationship between development and temperature, it is possible to predict how long it takes for an insect to develop from egg to adult by measuring temperature

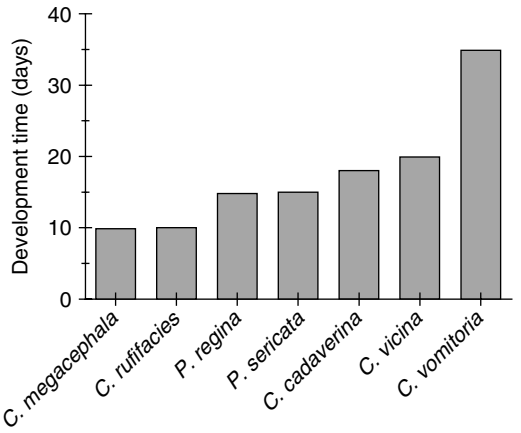

Figure 8 Development time for various blow fly species from different regions of the United States: two tropical species (*Chrysomya megacephala* and *Chrysomya ruffifacies*) reared at 28 °C; two summer species (*Phormia regina* and *Phaenicia sericata*) reared at 26.5 °C; and three cool-weather species (*Cynomyopsis cadaverina*, *Calliphora vicina* and *Calliphora vomitoria*) reared at 26.5 °C [Modified from Haskell *et al.* [4]]

over time and calculating species-specific accumulated thermal units.

Accumulated Degree-Days and Degree-Hours

Entomologists have carefully studied the development of many species of carrion-feeding flies, determining their thermal requirements for completing each stage of development from egg to adult (Figure 6). These thermal requirements are expressed in temperature-time units called *accumulated degree-days* (*ADD*) or *accumulated degree-hours* (*ADH*). It may be easier to think of ADD or ADH as the accumulation of heat units over time. A hot summer day will accumulate more hourly heat units compared to a cool autumn day. For instance, if a species of fly requires 400 degree-hours to reach the third instar, it may accumulate 100 of those on a single, warm summer day, while it may accumulate only 10 degree-hours on a cold autumn day. As an overly simplified example of ADD, if a fly species requires 200 degree-days to develop from eggs to pupae, it may acquire those in 10 days if the average daily temperature is 20 °C, or only 5 days if each averages 40 °C. In addition, there is always a species-specific threshold temperature where no development takes place (Figure 7), and below which adult flies are inactive. For most species, this threshold temperature is around 10 °C but can be as low as or lower than 4 °C, but varies substantially by species and geographic location. In general though, a body exposed to air temperatures below 10 °C will generally not be colonized by flies until the temperature rises.

An exception to this ambient temperature to developmental time relationship occurs when large numbers of second and third instars feed in a concentrated "maggot mass" (Figure 5), thereby generating additional heat within the mass that can influence activity and development. The activity of several hundred or thousand fly larvae in a small area can raise the temperature within this mass up to 30 °C above the ambient air temperature, and larval development may proceed at a much faster rate than might be expected at a given temperature. The masses become so hot that larvae sometimes need to move from the middle of the mass to the outside in order to cool. If a maggot mass is present on a body, a forensic entomologist may consider recording the temperature within the mass when computing an estimate of the entomology-based PMI.

Estimating an Entomology-Based PMI

A forensic entomologist can estimate the PMI by two methods. The first and usually more precise method is the development-driven PMI and involves identifying the species of flies (larvae and/or pupae) collected from the body at the time of discovery, determining the growth stage, and calculating how long it would take them to reach this stage being given the environmental temperatures at the scene. This provides information for making an estimate of fly age. Because adult flies will usually oviposit on a body within minutes or hours after death, knowing the age of the larvae gives a close approximation of the time of death.

In order to estimate an accurate PMI, the forensic entomologist should be able to identify the species present on the body; should be working with the oldest, and hopefully the largest larvae at the scene; must have access to nearby temperature records, and; must know the thermal requirement (i.e., ADD or ADH) of the identified species. Identification of

the fly larvae is difficult, but an entomologist can generally use several structures including the shape and structure of the spiracles (Figure 9), both of which are species-specific and change with instar stage. Once the species is identified and measured the ambient temperatures of the scene are acquired and annotated. Local temperature data usually comes from records of the nearest weather station; however, weather station temperatures may not always accurately reflect the local crime scene conditions. In these situations, scene temperatures are often compared to weather station data in order to assess their relationship and make any necessary corrections. From the temperature data and working backward from the time the body was discovered, an entomologist calculates the accumulated thermal units associated with the instar of the fly species collected at the scene. The entomology-based PMI is determined when the calculated scene-specific accumulated thermal units are compared to those of the same species developed under temperature controlled laboratory conditions.

The second method is the succession-driven PMI and involves examining the composition of the insect community on the body associated with the appropriate stage of decay (Table 1). This method is usually employed in cases of advanced decay, after most of the larvae have gone through metamorphosis and emerged as adults. By this time most of the flesh has been removed by larvae, so much of what remains is hair, skin, and bone. Changes in the insect community and the body itself during this stage occur very slowly, making estimates of the PMI much more variable. The entomologist uses the presence of various beetle species and other insects to estimate the PMI, and usually must present a possible time range rather than an exact date.

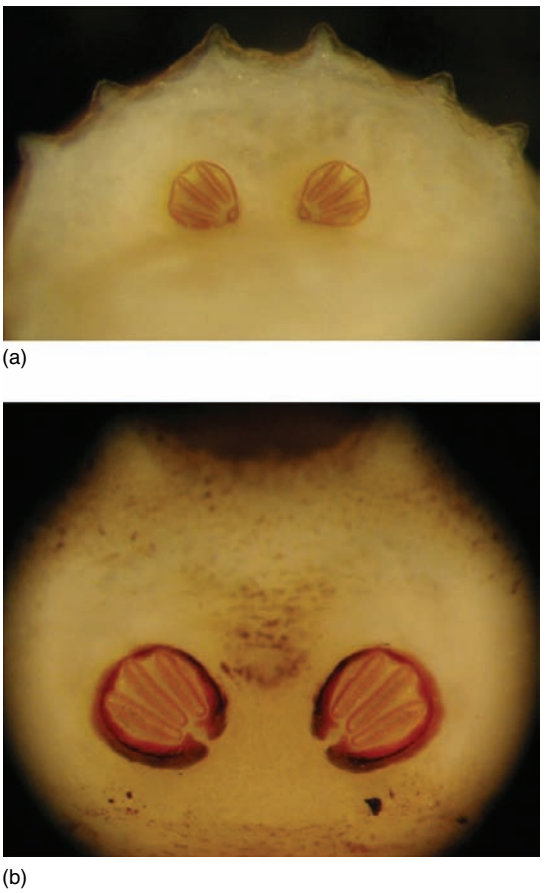

Figure 9 The posterior end of a third instar showing the structure of the spiracles for (a) *Phaenicia sericata* and (b) *Chrysomya rufifacies*. The spiracles are the respiratory openings for the larvae and are one of the most distinctive morphological features used to identify the species of fly, and aids in determining the developmental stage (instar). The shape and size of the posterior tubercles (fleshy projections) also assist in making identifications

Other Factors Affecting an Entomology-Based PMI

Any factor that makes a body inaccessible to insect colonization can affect the accuracy of estimating a PMI. Night (darkness) and cold temperatures, as well as rain, delay adult oviposition. In addition, factors that physically prevent insects from reaching a corpse can delay colonization for potentially long periods of time. Such factors include submergence under water, burial underground, concealment in sealed containers, caskets, or wrapping, and enclosure in a freezer, closed vehicle, or building. While these factors will often delay insect colonization, rarely will they totally prevent it. Flies are very adept at locating bodies, and will usually find access into a closed vehicle or building. A specific group of flies (Phoridae) have been found 1–2 m below the ground in association with coffined bodies, hence their common name "coffin-flies". Various studies have been conducted to determine how long such factors listed earlier will delay insect colonization, and the forensic entomologist accounts for such factors when estimating a PMI.

Collecting Entomological Evidence

Collecting at the Scene

When insects are found associated with a decomposing body a trained forensic entomologist should be called to collect specimens. If a forensic entomologist is not available, it is imperative that collections be made at the scene as soon as possible. If larvae are present on the body, the largest specimens should be collected, along with representatives of other sizes. The largest larvae are generally the oldest, and thus represent the earliest colonizers. The oldest larvae allow for the most accurate estimate of PMI. The investigator should search the surface surrounding the body for larvae crawling away to pupate, and also dig into the surrounding soil (up to 2–3 m away from the body) for fly puparia. If no larvae are visible, search the body, particularly around the eyes, ears, nose, and mouth for fly eggs. The eggs look like small grains of rice. Care should also be taken to collect insects from underneath the body once it has been removed. Detailed field notes such as climatic conditions, location and condition of the body (e.g., rainfall, full sun, shade, fog, position of the body, wounds, etc.), and visual observations should be made of any insect activity in and around the remains. All of this information can be important at a later time in the investigation. In addition, photographs and/or video of the crime scene should include close-ups of entomological evidence and any potential barriers to insect colonization.

Many times at a scene there will be numerous flying insects on and around the body. If flying insects are present over the body, an aerial sweep net can be used to collect fast flying or fast crawling adult insects. These specimens are then placed in a wide-mouth killing jar containing ethyl acetate and later pinned or placed in ethanol for subsequent identification by an entomologist.

Specimen Preservation

The sample of insects collected from the body itself should be placed in a vial or jar containing alcohol (ethanol or isopropyl) along with a label (written in pencil) that includes the following: case number, date, time, collector, the presence and location of a maggot mass, ambient temperature conditions and the location on the body where specimens were collected. It is preferred to have both a label inside the container and one adhered to the outside. If possible, larvae first should be killed in boiling water and then transferred to ethanol to prevent shrinkage in larval size. This is the most appropriate method to preserve larvae for the best identifications. However, this may not be practical, thus, specimens should be placed directly into alcohol. Larvae collected away from the body should be preserved separately, as should any fly puparia and this information should be noted on the label and a death scene form.

If possible, live specimens of eggs, larvae and puparia also should be collected. An entomologist may wish to rear these specimens to adults to aid in identification. Separately, eggs and larvae should be placed in a jar and transferred as soon as possible to an aluminum foil envelope containing a small amount of fresh beef liver. Puparia can be placed in a jar with some of the surrounding soil, vermiculite or sand. Live specimens should be kept in a warm (about room temperature) but not too hot location, where temperatures can be continuously recorded (e.g., about every two to three hours). All specimens, living and preserved, should be transferred to a qualified forensic entomologist as soon as possible for analysis. Copies of crime scene notes and photographs also should be provided.

Additional Value of Insects at Crime Scenes

While assisting in an investigation by estimating the PMI is the most common job of the forensic entomologist, insects at a crime scene also can reveal additional information important to an investigation. For instance, larvae and pupae can be analyzed for toxicological trace elements when more traditional sources such as blood and tissue samples are no longer available due to decomposition. Traces of cocaine and other drugs have been obtained from insects on a corpse, and have been used to determine the probable cause of death. In addition, research has shown that larvae feeding on tissue containing cocaine experience accelerated growth. The presence of unusually large larvae, or "super maggots" as they have been called, particularly those feeding around the nasal cavity, may indicate cocaine use by the deceased, and such specimens should be preserved for toxicological analysis.

The presence of larval activity on areas of the body other than the eyes, nose, ears, and mouth prior to the decay stage of decomposition (Table 1) may indicate possible trauma sites. Adult flies are attracted to wounds and will lay eggs in these areas. Larval activity in the female urogenital and anal areas during the early stages of decomposition may be indicative of rape.

Entomological analysis also can be useful in nonhomicide cases, particularly those dealing with neglect and accidental death due to bites or stings. Neglect can often be identified by the presence of larvae in living tissue, such as one might find in a nursing home for the elderly. Certain fly species lay eggs only in living tissue, and their presence on a body can indicate invasion while alive or prior to an immediate death.

Deaths resulting from the bites or stings of insects, spiders, and scorpions are fairly common. The marks left by these bites or stings are usually very small and may be overlooked during an investigation. For instance, death may be attributed to a heart attack rather than an accident, a conclusion that may be important for insurance purposes. A forensic entomologist, or a physician familiar with such cases, can often recognize evidence of bites and stings.

Acknowledgment

The authors would like to thank R. Kimbirauskas for the use of his photographs in Figures 1 and 6.

Environmental Science

Introduction

Forensic ecology is an emerging discipline concerned with complex threats to environmental systems and the human populations that depend on them. It provides evidence on environmental issues in civil, commercial, and criminal legal actions, and on compliance with environmental legal frameworks. There are three main areas in which ecologists are employed as experts.

Compliance Analysis

The increasing scale of development projects places a considerable demand for full compliance of projects and developments with the multiple legal frameworks and the ethical codes of practice of governments, international development agencies (IDAs) and professional consultancy firms. Paradoxically, despite the proliferation and increasing complexity of environmental regulatory frameworks, project preparation, and compliance analysis still rarely employ legal specialists. Consequently, the task of auditing compliance with all of these disparate codes has moved out of the sphere formerly controlled by the planners and engineers into the domain of the forensic ecologist.

Claim Management

Ecologists are employed by insurers assessing claims for environmental pollution damage. Marine salvage firms may obtain very significant bonuses if they can show that their work resulted in the removal of a significant threat of environmental damage, so the role of ecologists is central to both compiling and settling salvors' claims. The complexity of ecosystems and the pathways whereby pollutants travel through them and affect different plants and animals – sometimes thousands of miles away – requires special skills and experience to identify the full potential range of impacts of environmental contamination, and of the inevitable claims that even relatively minor local incidents may generate.

Acting for the Defense in Environmental Prosecutions

A third, less obvious area in which ecology is in increasing demand is assisting defendants faced with actions by regulators. Regulators are usually funded by public finance, and have comparatively greater access to scientific services than the defendant. Consequently, courts tend to assume that the prosecution has superior expertise. Defendants may have to cope with evidence that they find incomprehensible, and need independent expertise that enables them to understand the reliability and interpretation of the evidence against them.

The Role of Forensic Ecology

In the past, ecologists have taken only minor roles in legal actions and the resolution of criminal charges. But as environmental issues take center stage in the debate on climate change and sustainable management of endangered natural resources, legislation is proliferating at both national and international levels. A bewildering array of statutes, directives, conventions, agreements, and treaties is aimed at ensuring continued access to essential resources and environmental stability for the future; all need to be consistent in their approach and application (*see* **Alcohol: Behavioral and Medical Effects**).

The methods of strategic environmental assessment (SEA) [1] underpin the assessment of project compliance, and ecologists with an extensive knowledge of the dynamics of ecosystems are able to act as moderators in the process of harmonizing the environmental legal framework under which national and international policy-making and development operate.

This escalation of environmental legislation has not been matched by an adequate increase in forensic training capacity to improve the skills of the regulators' field staff. Prosecutors all too often rely upon inadequately prepared material and inadmissible or flawed evidence. The ecologist is required to identify anomalies in regulatory legislation, uncertainties over scientific issues, and a lack of enforcement capacity. Even if his or her skills are used to defend against such system weaknesses, the exposure of these defects help to ensure that, in the long run, the system is strengthened and justice served.

Dealing with issues in local pollution actions in the face of ill-informed or defective prosecution

evidence is a relatively simple matter, but the greatest risks of noncompliance are frequently caused by the most powerful corporate and institutional entities. When these offend or are about to do so, they can appear to enjoy immunity to all but the most sophisticated legal challenges. The ecologist may therefore be placed in the unusual position of not only providing evidence of an offense but of also deciding exactly how to use this information to bring about adequate restitution. This is particularly the case when the regulators themselves misbehave, and it is this aspect of forensic ecology that poses the greatest challenges, both professional and physical, to the ecologist working in the field of compliance auditing. In this article, it is described how unilateral direct action by the ecologist can be used to resolve particularly difficult issues of enforcement.

Principles

Beyond Reasonable Doubt, or on the Balance of Probability?

In many ecological assignments, the questions in issue relate to an incident that occurred months, or even years, before. In such cases, the reliability and provenance of environmental evidence may be weak; pollution cases can take years to come to trial, while the medical effects of an exposure to an environmental contaminant may emerge only decades later. Much of the primary evidence is long gone, and post-incident contamination or interference soon renders the interpretation of what residual data can be salvaged difficult, if not impossible (*see* **Interpretation: Legal Perspective**).

Although the regulators may have secured formal samples close to the time of the incident, the vital contextual information that turns evidence into understanding in court could well be irretrievably lost. Supporting evidence for a specific interpretation of the issues may even have been deliberately cherry-picked, and any that is inconvenient to the prosecution's case deliberately eliminated – this is by no means a rare occurrence. The ecologist has therefore to rely on data salvaged from obscure sources, often by untrained members of the public. The provenance and admissibility of such evidence is inevitably uncertain, and only useful as part of a collection of contextual evidence – material that is collectively consistent and unlikely to exist purely by chance.

It is often only possible to secure secondary circumstantial evidence about an old event, but if a wide enough range can be obtained, then the case can be presented on the basis of a coherent contextual analysis that could establish causation, but only on the basis of balance of probability. In practice, much of the workload of the ecologist is settled by out-of-court agreements. Large corporate organizations are often reluctant to see their deficiencies exposed publicly in the courts and the media, and prefer to settle privately rather than risk a formal guilty verdict being reached, thus setting a precedent that would be embarrassing, were it to be disclosed publicly.

In issues of severe human injury, however, a court is much more likely to require evidence that establishes the charges or claims beyond reasonable doubt. In practice, unless there is clear evidence of toxic damage from a very characteristic and unusual chemical, causation can be difficult to establish to this standard. This is especially so if the same or similar pathology occurs naturally in equivalent-sized populations, even if only sporadically. In such cases, the statistical approach of the epidemiologist must be relied on to estimate the probability of an excessive incidence of the condition, but this can offer only presumption evidence of a possible causative relationship. Unless it is supported by clear toxicological and pathological evidence, in such cases class actions are more likely to succeed than one dealing with damage to a single individual.

A Matter of Scale – Sampling the Ecosystem Rather than the Incident Location

In cases of unusual environmental contamination by toxic substances, the ecologist seeks to obtain as wide a range of corroborative evidence as possible. If the nature of the contamination is known or suspected, then it may be possible to predict what unusual medical or veterinary conditions are likely to be found close to the release location. But the situation is often reversed; symptoms of ecological, veterinary or medical damage may appear with no indication of their probable origin or causation. Such incidents should always be treated as ecological in scope, and not confined to purely medical investigations (*see* **Sampling Trace Evidence**).

Initially, evidence is collected from humans, animals, and the environment at or near to the location of the incident, in an attempt to pinpoint the source.

But sometimes it may be possible to collect more revealing samples farther from the site of an incident. Traces of release of a toxic substance from an unknown location may be transferred along food chains in an environment, becoming more concentrated as they move from one species to the next. It is often possible to detect high concentrations of otherwise unsuspected or undetectable contaminants in species at the summit of a food chain, or at the distal end of a linear environment – for example, in the estuary of a river.

Discovering such traces allows the ecologist to work back up the transfer pathway of the substance through the ecosystem, until evidence of the presence of the substance disappears. At that point, the entry to the environment is presumed to have occurred. Many estuarine and marine shellfish passively accumulate extraordinarily high concentrations of persistent organic contaminants in their flesh, especially oil fractions, polychlorinated biphenyls (PCBs), and pesticides. Concentrations of these fat-soluble compounds may be many times more than those that are present in the surrounding water or sediments [2].

The "Keumdong No 5" Oil Spill – Identifying the Source of Lethal Oil Contamination in Shellfish

After a small but remarkably lethal oil spill in Kwangyang Bay in South Korea, I collected samples of the dispersants that were used to clean oil from beaches, oil from tidal zone sediments, and smears of oil from the hulls of fishing boats soiled in the incident. Live shellfish were also obtained from the contaminated areas and the oil residues and shellfish tissues were analyzed at an iccredited forensic analytical laboratory. Using fast atom bombardment mass spectrometry (FABMS) and gas chromatography/mass spectrometry (GC/MS), detailed chemical descriptions of the oil-related contaminants present were obtained (*see* **Toxicology: Initial Testing**; **Confirmation Testing: Toxicology**).

The oil "fingerprints" from the shellfish corresponded with those from the oil residues, and revealed that the type of oil spilled was not a heavy fuel oil, as was claimed by the oil industry pollution claim managers. It was a much lighter fuel oil, with a higher concentration of those components that are able to cause oil narcosis and delayed death in shellfish. This information allowed the legal team acting for the fishermen to estimate the significance of the incident to the recorded shellfish mortalities, and present verifiable compensation claims to a Tribunal in London, and to the Seoul District Court 4 years later.

Ecological Processes – the Key to Forensic Investigation

The most important factor in understanding how an ecosystem works is an appreciation of the processes that operate in its normal, undisturbed or uncontaminated state. Only then it is possible to identify existing problems or predict future ones, and devise cost-appropriate mitigation strategies. Although modern development programs emphasize the importance of avoiding adverse impacts, some very large existing projects have evolved piecemeal over many years. The compliance of some (or even all) of the original proposal components may be defective according to current standards and procedures. When this happens the ecologist needs to be aware of both the underlying engineering constraints and of exactly how the ecosystem that is affected actually works, because this is the key to identifying least-cost but effective remedies.

Using Circumstantial Evidence to Direct Targeted Evidence Collection

Carefully targeted follow-up investigations can only be planned once the most likely locations for an effective data salvage operation have been suggested by the initially collected circumstantial evidence. If human victims are involved, the aim is to establish whether or not there is an unexpectedly large group of people with specific injuries that could have been caused by their exposure. Patterns of related effects may emerge, and these can be used to predict specific conditions that a monitoring program should concentrate upon. The aim is to use as wide a range of evidence as possible to ensure that nothing is missed that might persuade a court that a causative link exists between the incident and identifiable damage.

In some environmental contamination incidents the examination of exposed individuals is often seriously delayed; in others adverse medical conditions may develop only long after their initial exposure. In both cases, a high level of discrimination and vigilance is necessary to distinguish genuinely damaged individuals from those who may develop physical or

medical conditions that are similar to those that might naturally occur in the population as it ages.

The Camelford Poisoning – Watching for Delayed Alzheimer-Like Neurodegenerative Conditions. A classic illustration of the need for increased vigilance in pos-tincident monitoring is the severe contamination of the public water supply by aluminum sulfate in a quiet UK town in 1988. As a result of a mistaken delivery to the local water treatment works at Camelford, concentrations of aluminum in the town's water supplies reached 620 mg l^{-1}; this was 3100 times the permissible maximum in drinking water under both European community and British legislation. On entering the treated water supply, the chemical released sulfuric acid that turned the normally neutral water acidic. This corroded domestic copper plumbing systems, and the water in some hot water tanks contained several grams of copper per liter. Many of the 20,000 people exposed became extremely ill, and a large number of pets and livestock were either severely damaged or died (*see* **Reconstruction: Accident** and (**Poisons: Detection of Naturally Occurring Poisons**).

After the incident, the public sector health authorities refused to carry out any detailed clinical investigations on human victims of the poisoning. Although they knew that some individuals in the population would be "superabsorbers", they perversely claimed that aluminum cannot be absorbed in any significant quantity from the gut into the bloodstream, so no adverse medical effects could possibly occur. The possibility of a link between aluminum and Alzheimer's disease (AD) [3] led to public speculation about a possible epidemic of AD after the event, and this was vigorously denied by the health authorities.

The acute effects in the human population included severe arthritic-type pains in joints as well as eruptions of skin conditions. But these can, and do, occur normally in any population, and no definitive decision about their significance could be made. However, information on the sudden deaths of many pets and livestock in the area indicated that there could be potentially serious long-term medical risks to the human population.

Analyses of tissue samples taken from sows at a local pig farm revealed significant increases in aluminum loadings in some organs, and implied that severe aluminum-related medical conditions might develop in some of the human victims after a relatively long period. The effects of an exposure on animals may therefore provide an "early warning system" that can warn of possible future adverse effects in the human population when direct invasive medical examinations of human victims are either unethical or are obstructed by authorities [4].

Limitations of Ecological Evidence

Evidence presented in most pollution prosecution trials relies heavily on the chemical analysis of samples taken from the site of an incident. Biological sampling of populations tends to be less revealing despite the existence of techniques that can suggest the presence of polluting materials. This is because the abundance of species and individuals, and the complexity of community structures, naturally vary unpredictably in both space and time. Experts in the chemical and physical sciences are able to rely upon legally enforceable standard parameters which, if exceeded, are taken as firm evidence of contamination. No such standard populations exist for the ecologist to use as a legal baseline, so it is more difficult impossible to quantify biological changes caused by an incident with a high degree of certainty.

Practice

The Individual Expert versus the Institutional Laboratory

In the cases of environmental contamination brought quickly before a court, individual experts in chemical and physical analysis are usually members of teams working in public sector (and occasionally private) laboratories. In contrast, the ecologist working for the defense on such contamination incidents normally works alone, with much of his or her efforts directed to highlighting defects in the prosecution evidence. When it is necessary to obtain direct private sector evidence, the ecologist must arrange for samples to be taken by a specialist from an accredited analytical laboratory, to ensure that the resultant data are robust and reliable enough to be admissible as evidence. But this does not preclude the collection of sample evidence by less conventional methods.

In the Camelford incident, a water sample collected by a family was rejected by the water authority

responsible for the contamination of the water supply, but was eventually analyzed six months later by a BBC team making a documentary on the incident. The aluminum content of this sample, revealed by analysis at a public health laboratory, was far in excess of that in any sample taken officially by the authority, and forced the reluctant British government to set up the formal inquiry that the public had been demanding for 6 months. Part of the job of the ecologist is to seek out such hidden evidence, regardless of its type and location, and ensure that it is professionally assessed in case it proves critical to an otherwise hopeless case.

When carrying out compliance audits, ecologists rely on, or even manage, teams of experts in a wide range of social, environmental, and engineering disciplines. They collect the contextual data upon which an ecological analysis depends. There is no formal training in forensic ecology (which should not be confused with environmental forensics, for which there are established training courses available) – the rare specialist in the field tends to be an experienced loner who has drifted into the discipline after a varied and busy career as a team leader or environmental impact assessment (EIA) manager.

Ecological Techniques

Engineering and Hydraulic Modeling – Part of the Ecologist's Toolkit. Ecological systems are extremely complex, and identifying damage (or the threat of damage) to them demands considerable expertise and experience. For the forensic practitioner, the most important skill is understanding the core processes that govern the stability of the systems under examination. An innovative approach to field data collection is needed, to apply this experience to the collection and interpretation of evidence that may be elusive, obscure, or even initially quite incomprehensible.

A working understanding of civil engineering technology is essential, since identifying practical methods of damage avoidance or limitation demands an appreciation of what can, and what cannot, be done. In river systems, hydraulic modeling is emerging as a critical technique for assessing options, and familiarity with the strengths and weaknesses of the techniques employed by modelers often enables the ecologist to predict future risks to the environment that no other expert has been able to foresee (*see* **Computer Animation and Simulation Evidence**; **Reconstruction: Three Dimensional**).

Elegant Experimentation or Inspired Guesswork? Many standard ecological field research practices rely on repeated long-term studies involving complex statistical analysis. This is because ecological processes tend to be either cyclical or progressive, varying on a seasonal basis or over much longer periods as habitats pass through a succession of stages toward a stable climax community. In the case of compliance audits, this is an important consideration when assessing the potential risks of unacceptable future outcomes. But when the ecologist takes on a new assignment involving a severe environmental incident, many of the standard techniques have to be abandoned in favor of an idiosyncratic or innovative approach that may be required.

Working with Complexity Frequently, the most important questions to ask at the start of a mission are "How does this system work? What am I not seeing? Who has something to hide?" The ecologist needs to be able to predict impacts in not only the three spatial dimensions, but to extend predictions in time. Ecosystem processes operate on many different timescales, from the 30-min cycle of reproduction in many species of bacteria, to the millions of years of erosion and the movements of continental plates. So the results of an incident or intervention may become evident almost instantly, or may be delayed for centuries or even longer. The ecologist looks for disturbances in the rhythms of ecosystems that might imply a link with a past incident or intervention.

Ecological versus Political Boundaries – Complexity at its Most Formidable

A large part of the work load of the ecologist tends to revolve around project compliance auditing. Historically, this developed as one of the tools used in EIA. Since the mid-1970s, ecologists have been responsible for identifying environmental and social threats in every conceivable environment and social regime. This involves the correlation of disparate data across an often dauntingly wide range of disciplines. Because it is essential to devise solutions that reduce or avoid specific predictable social and environmental problems, the ecologist has to be aware of what is, and especially what is not, permissible. From this

has emerged the mantra that project development is limited not by what is technically feasible, but by what is legally permissible (*see* **Expert Opinion in Court: a Comparison of Approaches**).

But on occasion, a development project spans several national boundaries. Political policies, religious codes, and administrative regulations often differ widely, even across single borders, and the resolution of conflicting transboundary attitudes and approaches to environmental problems can present the ecologist with enormous challenges, demanding quite remarkable powers of concentration and flexibility in resolving issues in such locations. All too often, what may be accepted as scientific fact or political correctness in one country may be denied in an adjacent one. Increasing competing demands for water in rivers that cross national boundaries are frequently cited as the most probable cause of future "water wars". The migrating fish that travel across these boundaries regardless of political restrictions are the unwitting hostages to fortune in all of the world's great rivers, and many are now in imminent danger of extinction.

Eradicating the Fruit Fly in South America

An excellent example of transboundary political confusion was the Fruit Fly Eradication Project in South America. The larvae of the Malaysian Fruit Fly living in Carambola (Starfruit – *Averrhoa carambola*) were accidentally introduced into Guyana, Suriname, French Guiana, and a small area in northeastern Brazil. After a period when the Fly appeared to be relatively contained, and only occurred locally in orchards of exotic fruits, it suddenly developed the ability to use native fruits as larval food, threatening to colonize the entire Brazilian and adjacent rain forests. The resulting risk of a complete ban on exporting fruit from the entire continent because of its presence in commercial fruit would have been an economic catastrophe.

The most effective eradication technique available involved the destruction of the male flies, by luring them to chemical baits that attract only the male flies. The active ingredients were the pseudo pheromone methyl eugenol (a natural component of clove oil), and the pesticide malathion. Unfortunately, the project was bogged down in arguments over incompatible legislation in each of the four infested countries, as well as the laws of France (French Guiana is an external department of France), the European Union, and California. In addition any solution had to be compatible with the internal rules of the donor organization, based in Italy.

The resulting conflicting framework of six disparate legal codes, printed in four languages, threatened to prevent the project from being completed just as success was in sight. The tangled legal issues were resolved with an analysis of the legislation and the available options for compromise, and provided new toxicological risk assessments on both substances, allowing the eradication program to be resumed [5].

Statutory Environmental Audit Procedures

Many governments, and all leading IDAs, have standard procedures that dictate the methodology to be used in EIA and in the auditing of project compliance and performance. In recent years these have been augmented by techniques that extend this work considerably. Both nongovernmental organizations (NGOs) and individual ecologists are now involved in assessing issues relevant to the judicial process and in advising legal practitioners in personal injury, quantum of loss of assets and resources, and the provision of indemnity against environmental and other losses and claims.

Technical developments in the practical methodology of ecological analysis are rapidly adopted into the standard armory of skills used by ecologists. They enhance the efficacy of ecological services provided to project proponents, donors, lawyers, and insurers. They also help to minimize the need for compensation when projects fail to deal with regulatory constraints, or cause damage that could and should have been avoided.

Hydropower Conflicts in the Mekong Basin

In planning the expansion of hydropower in the Mekong Basin, it was realized that new hydropower schemes scattered almost randomly throughout the entire Mekong Basin would cause significant changes in the timing of floods on which migrating fish depend. The development program would place fish stocks in the main and tributary rivers under enormous environmental pressure, threatening the viability of the entire indigenous river and delta fisheries, worth an estimated US$2 billion a year (*see* **Learned Treatises as Evidence**).

By ranking the 39 proposed schemes according to their socioenvironmental impacts and their technical and economic reliability, and showing how hydraulic changes in the rivers affect the biological mechanism governing fish migration, it was then possible to predict the disruption that would be caused by the cumulative impacts of any specific combination of projects. This provided a basis for estimating the consequential costs for expensive mitigation options and reducing compensation claims.

"Kitchen Sink" Chemistry and Toxicology

In the real world of dirty environments and sometimes corrupt operators, it is frequently been necessary to collect whatever marginally relevant historical data or contaminated materials remained on site, and submit them to analysis in the hope that new insights could be obtained and new approaches to interpretation developed. When there has been a release of a toxic substance, such as when fish are killed by water pollution incidents or public drinking water supplies have been contaminated, "quick and dirty" experiments may need to be designed that help to clarify and answer the questions that were thrown up by the initial situation analysis (*see* **Toxicology: Initial Testing**).

Many contaminants have never been formally assessed for their toxicity, or may undergo unexpected reactions in the environment that may completely alter the interpretation of the event. Even if the ecologist does not have access to a sophisticated chemical analysis laboratory, or to a toxicological research facility, simple "kitchen sink" experiments may reveal crucial new facts from very simple procedures.

Blue Baths and Foaming Torrents – Resolving Difficult Problems with Simple Science

In the Camelford poisoning incident, investigators were baffled by unexplained reports that bathwater turned blue when it came into contact with soap. Extremely high concentrations of copper had unexpectedly appeared in the contaminated water, but none of the samples of water collected after the incident contained enough to produce this effect. In fact, although this was not appreciated at the time, the extreme acidity of the water supply caused domestic copper plumbing pipes and storage tanks to dissolve. The crucial question was simply, just how much copper does it take to produce a "blue bath"?

Small pieces of cotton cloth were soaked with different concentrations of copper sulfate solutions and soap solution, and compared the intensity of the colors that developed with that of blue-stained clothing retained for 12 years by a few local people. The concentration of copper needed – at least 2000 mg l^{-1} – was 100 times greater than the highest concentration detected by conventional analysis of supposedly contemporary water samples taken by public sector agencies. The officials had been too slow to respond to the incident, and had failed to detect the worst of the induced secondary contamination by the copper.

Both aluminum and copper are now regarded as possible environmental agents in the development of conditions similar to Alzheimer's disease and some forms of Parkinsonism. This simple "kitchen sink chemistry" had alerted our community to be vigilant for unusual neurological conditions amongst those who had complained of particularly severe effects of their exposure; 15 years after the event we began to see just such delayed medical developments (*see* **Postmortem Toxicology: Laboratory Analysis**).

Community Epidemiology – Evidence Collection by Members of the Community

When public sector authorities seem to be obstructing the understanding of an environmental incident, the new field of community epidemiology provides a powerful tool with which local communities can counter public sector subversion of evidence collection. Some of the most inspiring examples of forensic ecology have involved independent experts working with communities to collect highly sensitive data and releasing their data and conclusions to the media. On many occasions the resulting publicity has forced reluctant authorities to accept the evidence now in full public view, and carry out their statutory regulatory duties and enforcement responsibilities.

In this field, "communities" can be functional groups with a common interest, or conventional geographic communities. They generally develop spontaneously out of frustration that the regulatory or health authorities persistently refuse to admit that a problem exists. The stimulus is usually public frustration that the "Establishment" refuses to accept that there has been a significant event that has resulted in serious damage; the accusation that there has been an official "cover-up" is often correct, even if hard to prove.

A global association of airline crews established the "Aerotoxic Association" in London on June 18, 2007. Its aim was to force official recognition of the potentially lethal contamination of cabin air by tricresyl phosphate, originating from burnt oil leaking from jet engines. Members organized a covert program of collecting swab samples from aircraft cabins for a year, and this provided clear evidence of universal contamination of commercial aircraft by this dangerous organophosphate (*see* **Confirmation Testing: Toxicology**). The evidence was passed to the media, stimulating a series of television programs and newspaper articles exposing the risks to aircrew and public alike [6].

Problems

Corruption

A very common problem for the ecologist is that evidence of illegal activities may be deliberately suppressed, often by corrupt authorities and the regulators themselves. Some of the examples given earlier show how political or commercial vested interests can lead to the deliberate blocking of comprehensive studies. Researchers who receive funding from industry are also very vulnerable to the suppression of potentially damaging evidence, and if forced to face an inquiry they may be accompanied by "minders", to make sure that no compromising material is disclosed.

The Future

Forensic ecology is at an early stage in its development, but it promises to become increasingly important in conflict reduction and environmental dispute resolution. Already their skills in compliance auditing make ecologists crucial specialists in project management and incident investigation. They are in increasing demand as team leaders, supplanting the role traditionally occupied by civil engineers, but they are also in demand for investigating serious incidents and the assessment of the quantum of damage in some of the most spectacular contamination incidents such as the Exxon Valdez oil spill in Alaska and the catastrophic reactor meltdowns at Chernobyl and Three Mile Island.

Universities are increasingly aware of the need for trained specialists in fields such as wildlife and marine forensics, but entry to the ecological field is still reliant on the migration of experienced field specialists into the less disciplined and often openly aggressive arena of adversarial law enforcement, international conflicts in access to depleting natural resources, and the increasing involvement of organized crime in toxic waste disposal. Few traditional ecologists realize that their skills are appropriate in the forensic environment. But as environmental conflicts intensify and regulatory frameworks proliferate, the shortage of skilled experts in this field will force universities to develop courses to provide the expertise demanded by an increasingly environmentally aware international, indeed, global legislature.

Enzymes

Enzymes are biomolecules, most commonly proteins, that catalyze biochemical reactions in the body. Catalysts are substances that facilitate specific chemical reactions, but which are not themselves consumed or changed in those reactions. Usually these reactions involve the conversion of a molecule from its substrate form to its product form. Enzymes are extremely selective for their substrates and only catalyze specific reactions. The set of enzymes available to a cell determines the metabolic pathways that can occur within that cell.

Enzyme activity can be affected by other molecules that act as either activators or inhibitors. Some enzymes also require nonprotein molecules called *cofactors* to be bound in order to promote enzyme activity. Cofactors can be either inorganic (e.g., metal ions) or organic compounds (e.g., heme). Temperature is also an important regulator of enzyme activity with most reactions having an optimal temperature range. Excess temperature can also denature enzyme structure, thereby reducing or preventing its activity.

There are many enzymes that have a critical influence on the forensic biology process. Some naturally occur in the template material available for testing, whereas others are introduced by forensic scientists to drive specific reactions in the laboratory (a selection of relevant enzymes are mentioned in Table 1).

Table 1 Enzyme classes and examples of their use in forensic biology

Enzyme	Properties	Importance to forensic biology process
Nucleases	These enzymes are capable of cleaving the phosphodiester bonds between the nucleotide subunits of nucleic acids, such as DNA	Endogenous nucleases can cleave the DNA in the cell rendering it unable to be analyzed. Some DNA isolation methods (such as the Chelex 100™ resin) function by attempting to disable the nuclease activity through heat and chelation of the inorganic cofactor required for nuclease activity (Mg^{2+})
DNA polymerases	A DNA polymerase enzyme catalyzes the addition of doexynucleotides during DNA replication. This thermostable DNA polymerase carries the name of its bacterial host, *Thermus aquaticus*	Taq DNA polymerase is able to withstand high temperatures and has an optimal temperature for activity of ~72 °C. This property makes it suitable for use in the PCR to catalyze the addition of nucleotides during the final extension step
Proteinases	A proteinase enzyme cleaves peptide bonds in proteins, destroying their tertiary structure. Proteinase K is a serine pronteinase originally isolated from fungus.	Proteinase K is commonly used in DNA extraction techniques to digest cellular protein, particularly those in cell membranes, thereby promoting cell lysis
Acid phosphatase	A phosphatase enzyme cleaves phosphate groups from other molecules and is active around pH 4.9–5.5	Pancreatic acid phosphatase is present in high concentrations in seminal fluid. The presence of acid phosphatase is used as a presumptive indicator of semen. The test is simple, rapid, and sensitive and is a cornerstone test in forensic bioscreening
α-Amylase	An amylase enzyme digests long-chain hydrocarbons. The α-amylase enzyme hydrolyzes α-(1,4) glycosidic bonds of glucose polymers such as glycogen or starch	α-Amylase is present in high concentrations in saliva and is used as a presumptive test for this body fluid. The common test is applied through reaction with dyed starch substrates (e.g. Phadebas test). In the presence of amylase the starch is digested and the dye released into solution

Error Rates in Forensic Methods

Introducing Error in the Forensic Process

Errors committed during forensic examinations can be the result of a myriad of situations and involve individuals other than laboratory examiners.

The procedures at crime scenes are of special concern regarding acts of omission or commission.

Acts of omission include failing to

- protect the scene from contamination (*see* **Crime Scene Investigation**; **Crime Scene Management**);
- record the scene (*see* **Rape Trauma Syndrome**; **Crime Scene Photography: US Perspective**);
- collect the evidence (*see* **Evidence Collection and Preservation: Casting**); and
- properly package the evidence (*see* **Packaging and Transport**).

Acts of commission include:

- allowing access to untrained personnel;
- introducing potentially contaminating material e.g., *via* clothes or equipment; and
- moving DNA around the scene on people or equipment (e.g., fingerprint brushes).

Analytical Error

In analysis, there are numerous error types. In an ideal testing system, there would be no errors. However, most testing regimes have some level of error associated with them. These error rates, and if possible how to identify and mitigate them, should be measured as part of the validation process of the test method.

Errors can be binary, off/on, yes/no, true/false classification errors, or errors whose magnitude may vary with the amount of material being tested or be a systemic bias in the system.

Binary errors are of two types.

Type 1 Error

This is more usefully, probably, and usually called a "*false positive*" error. In a Type 1 error, a material that should be classed as "negative" produces a "positive" result. For example, crime scene examiners may use a presumptive test for blood (see Km test), which also produces a positive result with some fruit juices. In such instances, of course it is not possible to know the error "rate", but simply the types of material that may produce an erroneous result can be identified.

Type 2 Error

This is the corollary of the false positive error: a false negative. A false negative result is produced when the material under test contains the analyte being sought, but fails to identify it.

Using Controls

It is a normal scientific practice to ensure that methods are working properly by running simultaneous tests on materials that are known to contain the analyte (known as a positive control sample) and that

do not (known as a "negative control" or, in some chemical tests, a "reagent blank").

Type 1 and Type 2 errors inform another two important parameters of testing; the specificity and sensitivity of the test. These errors are primarily qualitative; i.e., whether the material has some quality (such as being blood) or not. There are more sophisticated errors that occur in quantitative analysis (*see* **Case Assessment and Interpretation**).

Other Types of Error

The measurement of error is usually performed for the purpose of determining the reliability of a result. This area can be particularly confusing to the nonscientist, as many terms, such as "reliability", have a very specific meaning when used in a scientific context. In scientific parlance, there are various terms that have been developed to define the variation that may be seen when quantitatively testing things. In considering the reliability of a test result, it is important to know and understand these parameters, which should have been derived during the validation of the procedure. Each of these parameters can be a source of error.

Many laboratories have quality assurance systems that require recording of all errors, howsoever they have been caused. Some laboratories partake in schemes that involve the testing of materials of known provenance as a test of the laboratories' system. These proficiency tests may be "blind" or "declared". In blind trials, the laboratory staffs are ostensibly unaware that the sample is a test, although this can frequently be fairly easy for the staff to spot. In a declared trial, the staffs are aware that they are being tested. The former are considered better measures of laboratory performance although it can be difficult or impossible to ensure truly blind trials with some evidence types.

These proficiency tests have occasionally been cited as evidence of the reliability of the laboratory or system. For such purposes, it is important to consider the type of recorded error and when it occurred. One of the main reasons that a laboratory will undertake such exercises is to ensure that they provide reliable results. Nonconformances, as they are called, are identified as part of the normal practices of most laboratories and are specifically documented and dealt with in almost every form of laboratory accreditation. These records should be maintained and available. Clearly, if an error has been identified and dealt with, then it is inappropriate to use the precorrective action error rate as a measure of the post-correction system. To fully understand laboratory error rates, a consideration of not only the overall rate but also the rate for individual methods, equipment, and staff is required.

Measurement of Error

An additional complication in the use of error rates is the fact that a rate is one unit divided by another (e.g., miles per gallon and dollars per test). An error rate could be expressed as, *inter alia*, per test, per person, per sample, and per laboratory (*see* **Sampling and Estimation of Quantities**). The choice of the appropriate rate depends on the purpose for which the information is being used. The fact that one analyst is a poor performer does not necessarily reflect the reliability of the test, method, team, laboratory, or organization.

Another consideration is whether any error in the multitude of processes that occur in a modern laboratory is manifest in the final report. If an analytical process has a checking process, for example, the inclusion of positive and negative controls, or the manual checking of results, this minimizes or eliminates the risk that these errors will not be detected in the formation of an opinion or evaluation. In that event, the error rate for the process may be irrelevant with respect to that opinion.

A sophisticated analysis is normally required to understand the factors affecting a specific case.

Error Rate Calculation

Thus, the words "error rates" also have multiple meanings. The term can denote the statistical likelihood that a value calculated on the basis of multiple repeated occurrences of data collected in a databank corresponds to its "true" value in a particular instance.

In the law, the words "error rate" have acquired a special meaning in those jurisdictions that follow the *Daubert* (*see* ***Daubert v. Merrell Dow Pharmaceuticals***) rules on admissibility of expert testimony.[a] In the *Daubert* decision, the US Supreme Court delineated a number of different factors by which trial judges are asked to decide whether proffered

expert testimony will qualify as "scientific knowledge" shown to be sufficiently reliable to be admitted at trial.

One of these factors is whether the results of the underlying theory, technique, or methodology have been subjected to an error rate determination. The Court stated: " ... Additionally, in the case of a particular technique, the court ordinarily should consider the known or potential rate of error." [1]

Conclusion

In the hundreds of decisions following *Daubert*, the courts have been at pains to elucidate exactly what the Supreme Court's opinion requires in this and in other regards. Judge Alex Kozinski of the Ninth Circuit Court of Appeal whose decision in the same case while sitting on the intermediate appellate court was reversed by the later statement of Supreme Court, when discussing the *Daubert* decision at a legal conference, stated "In addition, you have to consider the error rate ... What is the error rate? I have no idea what this means but there it is." [2]

Ethics: Codes of Conduct for Expert Witnesses

Introduction

It is universally understood that, in the practice of their professions, forensic scientists are required to refrain from unethical practices, but what is "unethical" is often difficult to determine. By what standard is the ethical nature of one's conduct to be measured? The very first source of information of what is considered unacceptable professional behavior is the code of ethics of the professional association to which one belongs. Most forensic membership groups maintain a code of ethics [1]. Since many scientists belong to more than one society, the person's conduct may be governed by several different codes of ethics that may not necessarily look similar. All of them, however, make engaging in ethical conduct a requirement of belonging to the association and provide sanctions for violating the professional standards of conduct.

In addition to defining unprofessional conduct, codes of ethics also typically contain procedural mechanisms whereby purported unethical conduct is to be investigated and, if appropriate, sanctioned. Such sanctions can run the gamut from a mere reprimand to expulsion from membership in the organization. This may, at times, be accompanied with loss of license, accreditation, or board certification. Since the law in common law countries tends to view membership in a professional association as a valuable property right, the mechanisms whereby a person is stripped of that right must comport with procedural safeguards against abusive and otherwise improper exercise of the power to sanction. Because of the great variety of mechanisms, this article does not concern itself with the "due process" aspects of procedures that seek to enforce the ethical injunctions imposed upon an association's membership. This article is confined to a general overview of what conduct may be regarded unethical.

The conflicts between the codes of various groups are at times *de minimis*, but one must, nevertheless, remain sensitive to the fact that wide differences in approaches to ethics can exist. Some scientists who must possess a license to practice their profession granted by governmental authorities in some countries – i.e., medical doctors, dentists, psychiatrists,

psychologists, etc. – may see their licenses jeopardized if found to have been sanctioned for unethical professional behavior.

Professionals may also belong to specialty boards with different ethical codes, such as that of the generalist group,[a] as well as the codes of ethics promulgated by specialty boards. The same is true of the members of virtually every specialty group within the forensic sciences.

Finally, it should be remembered that, in addition to the sanctions that can be imposed by a professional society upon its own members, there is a "common law" of ethical conduct as well. Violating these common law prohibitions against unethical conduct, usually involving professional conduct that includes deception, fraud, overreaching, perjury, or behavior merely considered to be dishonest or inequitable, whereby either the public or society, in general, is injured – as by engaging in "negligent" professional conduct – may expose a forensic scientist to civil legal sequelae in damage actions as well as potential criminal liability for perjury or fraud. These are sanctions that professional societies cannot impose. Even the expert witness who does not belong to an organization that has a mandatory code of conduct may be subject to such legal actions. Potential liability of this sort falls within the area of "professional malpractice" for either intentional or unintentional (negligent) conduct – tortious conduct – as defined by applicable law.[b]

Defining Ethics

The existing ethics provisions in forensic science vary greatly in how the terms "ethics" or "unethical conduct" are defined. Some list specific prohibitions, others frame ethical principles in terms of aspirations. How these rules can be applied in specific fact settings is not always clear. Outside the legal profession, most professional societies do not publish compilations of ethics complaints that were decided by its boards. Additionally, while general ethical principles may be listed, the manner in which ethics codes have been applied in illustrative cases may remain obscure to the membership.

In general, the professional codes of conduct devote much more space to outlining the procedure to be followed when an accusation of questionable ethics has been made, than to the definition of ethics itself. Perhaps that is understandable because notions of fair play and clear advance notice of what conduct is complained of, require provisions that outline the process of *enforcing* codes in more elaborate terms. The notion of "due process" that pervades the forensic sciences, because of its close connection to civil and criminal litigation, of necessity requires it to exemplify fairness in the application of its rules of conduct to its members.

Defining Prohibited Conduct

The definition of what constitutes unacceptable expert behavior is stated, in some ethics codes, only in general terms. Other codes go into great detail about the type of conduct that it requires of its members. Perhaps the majority of codes of conduct define ethics in terms of prohibitions. An example of the broad general approach is that of the American Academy of Forensic Sciences (AAFS), which contains just four general prohibitions:

> "a. Every member ... shall refrain from exercising professional or personal conduct adverse to the best interests and purposes of the Academy. The objectives stated in the Preamble to these By-Laws include: promoting education for and research in the forensic sciences, encourage the study, improving the practice, elevating the standards and advancing the cause of the forensic sciences;
> "b. No member or affiliate ... shall materially misrepresent his or her education, training, experience, area of expertise, or membership status within the Academy.
> "c. No member or affiliate ... shall materially misrepresent data or scientific principles upon which his or her conclusion or professional opinion is based;
> "d. No member or affiliate ... shall issue public statements that appear to represent the position of the Academy without specific authority first obtained from the Board of Directors".[c]

It is understandable that required conduct provisions of a society such as the AAFS, which gathers under its umbrella members who are engaged in a wide variety of different disciplines, be fairly general. It is impossible to describe specific instances of prohibited conduct when the organization contains a broad spectrum of specialties, each of which may also be subject to ethics codes within its own specialty.

An example of a code of professional conduct that is more explicit in terms of prohibited professional

behavior is the American Board of Criminalistics (ABC) Rules of Professional Conduct which, in Article IV.5.d of the bylaws, enumerate 18 specific mandatory rules of behavior that its members "shall" obey. Unlike the AAFS code, it enjoins members to report to its Board any violation of the rules by another applicant or diplomate.[d] The ABC rules place a great emphasis on impartiality and integrity when dealing with evidence,[e] and prohibit members from using "techniques and methods that are known to be inaccurate and/or unreliable".[f] Considering that users of a technique will invariably advocate its reliability, there may, nevertheless, be an important segment within a profession that frowns upon use of some methods of analysis, which they consider to lack reliability. One wonders how controversies on those issues can ever be effectively resolved.

Defining Ethical "Aspirations"

Rather than defining the prohibited conduct, the approach within some professions is to define appropriate professional conduct in terms of the aspirations toward which its members should strive. The Code of Conduct of The Forensic Science Society in the United Kingdom is an example. It states that members have a duty to

> "- . . . conduct themselves honourably in the practice of their profession
> - promote to the utmost of their power the interests of the Society * * *
> - have special regard at all times to the public interest and to the maintenance of the highest standards or competence and integrity * * *
> - only undertake any forensic activity commensurate with and in the field within which they are registered or accredited by the Society".[g]

Some groups eschew categorizing any specific instances of unprofessional conduct or the categorization of "standards" of behavior. An example of such a group is the American Psychological Association (APA), which describes the "Ethical Principles of Psychologists and Code of Conduct" into five rather wordy aspirations, wherein a full paragraph of text each is devoted to Beneficence and Nonmaleficence; Fidelity and Responsibility; Integrity; Justice: and Respect for People's Rights and Dignity. The APA code then elaborates on these aspirations in more than a dozen pages of ethical standards stated in broad, generalized concepts.[h]

While flexibility in terms of expected professional aspirations are the norm in the behavioral sciences, similar approaches are taken also in some organizations that deal with the physical or comparative sciences. The International Association for Identification (IAI) Code of Ethics is not worded in terms of prohibited conduct but is, instead, worded in the form of a personal pledge of good behavior that its members publicly affirm. Its true "code" of prohibited conduct then follows as "Standards of Professional Conduct".[i]

Similarly, the code of ethics of the Northwest Association of Forensic Scientists[a] lists series of ethical considerations relating to five different categories: those relating to the scientific method, to opinions and conclusions, to aspects of court presentation, to the general practice of forensics, and to the profession.

The importance of a thorough familiarity with a profession's ethics rules is particularly crucial because potential legal sequelae may follow from proven unethical conduct. When legal actions for damages are brought against forensic scientists based on either negligent or willful conduct, or when a prosecution for criminal conduct is initiated, whether the activity that is the subject of the complaint is considered "ethical" or in accord with "professional standards" may well be taken by courts as depending on what conduct the applicable professional society expects of its members.

Fact Settings Presenting Potential Ethical Problems

Fact settings in professional practice that may involve ethical problems fall within certain categories. While clear authority for each fact setting may be difficult to provide, the experience of persons serving on ethics committees may serve as a guide.

A first type, and perhaps the most frequent complaint lodged against experts is in regard to inaccuracies in the way they represent their training, education, and experience. Misrepresentation of this sort may occur in statements made in a public forum (in speeches, on websites, or in correspondence), or in drafting curriculum vitae that are disseminated to potential clients and courts. If the inaccuracies simply amount to exaggeration that can be justified as "puffing," the perceived inaccuracy will not necessarily be considered an unethical practice. More often, the assertions are made in support of establishing

the expert's competence and qualifications in depositions or in court testimony. If the misrepresentation is deemed significant and occurs at a time the expert is giving sworn information to a court, whether in a deposition or testimony, the expert may also be subject to criminal prosecution for perjury, or in damages in a civil suit by parties injured or aggrieved as a result of willful misstatement of one's background and experience [2].

Examples of misstatements that are normally considered material and significant would be to assert having received credentials (diplomas, academic degrees, board certifications, and honors), which were not, in fact, obtained. In this same category, fall claims of membership or of a category of membership status for which the expert has not been qualified.

A second category of ethical complaints, and one that is more fraught with enforcement difficulties, encompasses assertions that a person was incompetent when he engaged in a certain examination. In many disciplines, it may be disputed whether a particular methodology leads to reliable or repeatable results. When a method is fairly novel, there exists a danger in prematurely using an unproven method as the basis for expert opinions in court. Influential people in a discipline may assert that the method was not properly validated and that, consequently, reliance on test results produced by such methods is evidence of incompetency. Because of the difficulty of defining "competency," some associations refrain from entertaining complaints based on incompetency altogether, especially if the organization has fairly rigorous standards for admission to membership and the person complained of has met these criteria.

Lack of established reliability or inability to establish method validation has become a more frequently litigated issue in courts as a result of court decisions and other legal provisions, which place restrictions on opinion testimony based on unreliable processes or technologies[j].

A third category of potential problems has to do with fraud and deceit in such areas as misrepresenting data examined, results obtained, or in testifying to conclusions that are not supported by the examinations conducted. While fraud and deceit typically connote willful conduct, certain acts of omission may be placed in this same category – allegations that a person did not use recommended or standard methods which the profession recognizes as valid and routine for a specific purpose.

Finally, there exists a category of potential ethical conflicts that do not fall within the above categories, such as those arising from conflicts of interest or violation of confidentiality rules. Alleged unethical conduct in these areas often depends on existing law on conflicts of interest and confidentiality in the jurisdiction where the conduct arose.

Sanctions Against Experts for Unethical Conduct

Most, but not all, ethics codes provide for a gamut of potential consequences that befall a member found to have violated its ethical provisions. The sanctions range from measures that may be seen by the public as a simple "slap on the wrist," such as a reprimand (whether oral or in writing), to the more serious ones, which encompass public censure, suspension of membership for a stated period of time, or expulsion. Where applicable, the most severe sentence of expulsion may also be accompanied by a revocation of credentials or professional certifications.

The imposition of severe sentences against professionals such as membership suspension or expulsion can be imposed only if a procedural code exists which affords due process to the accused member. Due process typically requires notice of the specific charges brought, presentation of evidence at a hearing at which the accused is permitted to attend, confront the charges against him, and present evidence to rebut them. It also typically requires the complaining association to carry the burden of proving that the violation occurred, though the quantum of proof is by no means uniform.

In some codes, the quantum of required proof of unprofessional conduct must be "beyond a reasonable doubt," though, more typically, ethics provisions require that unprofessional conduct be established by either the greater weight of the evidence or, at most, by clear and convincing evidence. Some ethics codes permit the member against whom the complaint is filed to be assisted by legal counsel at the hearing. Some codes also make provisions for a right to appeal an ethics board decision to the entire membership of the organization.

Since the imposition of a severe sanction may impair the ability of the member to engage in his profession, especially when an expulsion also has the

effect of revoking the member's certification, courts whose power was thereafter invoked by the expelled member have insisted that the procedure, whereby the expulsion was effectuated, comported with due process of law. In deciding such lawsuits, when the procedural aspects of the ethics codes were found to satisfy notions of fairness and fair play, courts tend to be deferential to the professional society's factual determination of unprofessional conduct.

Conclusion

If professional societies intend to retain the power to sanction conduct of their members that is deemed unethical, the rules of professional conduct must be described with particularity so as to provide adequate notice to its members of the type of conduct that is deemed unacceptable. The process by which violations of the codes of professional conduct are to be enforced must also comport with basic notions of fair play and due process.

End Notes

[a.] For example, Medical examiners will belong to generalist countrywide, state or local medical societies, such as the American Medical Association (AMA), and further be subject the professional rules of conduct of the National Association of Medical Examiners (NAME), the American Board of Forensic Pathology, and the Pathology-Biology Section of the American Academy of Forensic Sciences.

[b.] See, in this regard the related article on Malpractice of Experts.

[c.] The Code of Ethics and Conduct is contained in Article II of the group's Bylaws. See, 2007 DIRECTORY OF MEMBERS AND AFFILIATES – AMERICAN ACADEMY OF FORENSIC SCIENCES, p. 222. The version printed herein was as modified at the Annual Meeting of the membership in Washington, D.C. on February 20, 2008. It will be noted that subsection a. appears to be a catch-all provision that may be difficult to enforce for lack of specificity. Both subsections b. and c. deal with misrepresentations, but the addition of the word "material" may also make it difficult to know in advance when a misrepresentation might not rise to the level of materiality.

[d.] http://www.criminalistics.org (accessed on, 2008).

[e.] Subsections 3–5 require members to treat objects of potential evidential value with care so as to ensure their integrity, provide appropriate technical analysis while following the necessary standards and controls.

[f.] Subsection 6. Emphasis is placed elsewhere on the duty not to "exaggerate, embellish or otherwise misrepresent qualifications," (sub. 11) and "maintain an attitude of independence and impartiality in order to ensure an unbiased analysis of the evidence" (in sub. 14).

[g.] http://www.forensic-science-society.org.uk (accessed on, 2008) See also the provisions of The International Institute of Forensic Engineering Sciences, Inc. (IIFES), which, in defining its Rules of Professional Conduct, lists 11 aspirations in positive terms rather than in prohibitions. The 11 provisions are: "1. Be aware of ones [sic.] own professional and technical qualifications in dealing with each case, and address only those factors that are within ones [sic.] own expertise and competence. Seek the assistance of other qualified experts whenever necessary. "2. Treat ones [sic.] own personal integrity with great respect, and never do or say anything that might compromise that personal integrity. This entails not only saying the truth art all times, but also giving due weight to all pertinent observations and facts. "3. Treat all information from a client, agency, or any other exclusive source with the confidentiality required. "4. Treat every object or specimen of potential evidential value with the case and control necessary to preserve its integrity. "5. Utilize the appropriate standards and controls in conducting examinations and analysis. "6. Render opinions and conclusions strictly in accordance with the evidence in the case and only to the extent justified by that evidence. "7. Maintain an attitude of independence and impartiality in order to ensure an unbiased analysis and presentation of the evidence. "8. Carry out the duties of this profession in such a manner as to inspire the confidence of the public. "9. Respect ones [sic.] peers in this profession and regard them with the same standards that one holds for oneself. "10. Report to the IIFES board any violation of these rules by any other person who is accredited by the board. "11. Refuse to accept, on a contingency fee basis, any assignment involving opinions, conclusions, or expert testimony intended for use in arbitration and/or litigation." See, http://www.iifes.org/ethics.htm (Last visited, Feb. 11, 2008).

[h.] The current version of the Ethics Code of the American Psychological Association went into effect on June 1, (2003) See, http://www.apa.org/ethics/code

2002.html; To the same effect, though not as wordy, are the Ethical Guidelines for the Practice of Forensic Psychiatry of the American Academy of Psychiatry & the Law. See, http://www.aapl.org/ethics.htm (accessed on 2008).

[i] The Code of Ethics of the International Association for Identification is printed on page 1 of the 2008 IAI Membership Directory. It provides: "As a member of the International Association for Identification, and being actively engaged in the profession of Scientific Identification and Investigation, I dedicate myself to the efficient and scientific administration thereof in the interest of Justice and the betterment of Law Enforcement". "To cooperate and others in the profession, promote improvement through research, and disseminate such advancement in my effort to make more effective the analysis of the expert". "To employ my technical knowledge factually, with zeal and determination, to protect the ethical standards of the profession of Scientific Identification and Investigation". "I humbly accept my responsibility to Public Trust and seek Divine guidance that I may keep inviolate the Profession of Law Enforcement." This "Code of Ethics" is then followed, on page 2, by a series of nineteen specific instances of mandatory conduct that are titled "Standards of Professional Conduct".

Evidence: Rules of

There exist compilations of rules, codified in statutes, court decisions, or other legal literature, that determine how courts operate, what types of evidence tribunals may consider in reaching decisions, and how other aspects of the litigation process are conducted. Most of these law rules are highly technical and are not particularly of interest to forensic experts. Some legal evidentiary terms, however, interface with expert testimony so often or in such significant ways that forensic examiners who are likely to have contact with the courts should be aware of their meaning, importance, and applicability.

The rules that pertain particularly to expert opinion testimony are discussed in this Encyclopedia in many different articles. The length of each article varies with the importance or complexity of its subject matter and the frequency of its interface with expert testimony. Thus, forensic experts can consult the articles listed below covering rules of evidentiary law on the following:

Evidence Collection and Preservation: Casting

Casting – The First Steps

Whether it is a tire track, footwear, or tool mark impressions, the first step is to take photographs, including a scale (Figure 1). That way should something go awry during the casting process, the crime scene investigator (CSI) will at least have the

Figure 1 Scale photograph of footwear impression

ability to produce a full-size scale photograph of the impression.

Once photographs have been taken, the casting can begin. With the introduction of dental stone as a casting material, Bodziak [1] rightly states that the compound can be poured directly into the indented impression. If the impression is on even a slight slope, a frame or form should be placed around the impression. This could be a commercially produced frame for the purpose. Some CSIs prefer to use a section of flexible plastic lawn or path edging (Figure 2). If neither is available, cardboard is a good substitute. Whichever system is used, press the frame into the ground to ensure no liquid compound can escape. On uneven ground use some soil to block gaps at the bottom of frame.

A fine spray of shellac paint or hairspray should be applied to the impression [2] as a fixative. The CSI must apply this carefully and allow it to form a haze over the impression by spraying horizontally downwind. Never spray it directly on to the impression, to avoid damaging the fine details. In addition, practice in the United Kingdom and recommended by Bodziak [1] is the use of a release agent. This allows the soil to come away from the cast easier. Release agents can be frying pan sprays, WD40® or even a baby powder in a puff spray.

Casting the Impression

The best compound to use when casting impressions in soft earth is Class I dental stone [3], a gypsum powder product. Different gypsum compounds have different properties and the results can vary depending on the product used. Generally a water-to-powder ratio of around 40 parts water to 100 parts powder will provide the correct consistency and strength [3].

Water can be added to a premeasured bag of dental stone or use a plastic bowl to provide a suitable mixture of the powder and water. The gypsum industry recommends that the powder is added to the

Figure 2 Form constructed from lawn edging

water; hence, using a bowl is a better method for the less experienced CSI.

Pour a measured amount of water into the bowl and add some powder. Continue to stir the mixture, while adding the water. During the mixing process, one may see the mixture darken around the edge and appear much thinner. This is caused by water separating out from the mixture. The mixture must be well combined as separation will adversely affect the cast. It is important that the CSI make enough of the mix to pour into the impression and surrounding area in one operation. Attempting to add a further mixture may result in a loss of evidence and a broken cast. It is better to have a surplus of the mixture. The dental stone is relatively inexpensive.

Practitioners will differ on the consistency of the mixture; some describe it as similar to double cream or thick emulsion paint. When pouring the mixture from either a bag or a bowl, the CSI should hold the mixture as close to the ground as possible and pour it slowly into the impression (Figure 3). When complete, the liquid cast should be gently tamped down with a small stick. This will knock out most of the air bubbles that may have formed. To give the finished cast some extra strength, one can also add a small section of wire mesh. Small twigs are an effective substitute for the mesh, although the CSI should exercise care as the wood may expand causing the cast to crack while drying (Figure 4).

Drying time depends on the air temperature. In relatively warm weather, the time needed for drying can be 20–30 min, increasing time as the temperature decreases. Mixing gypsum and water produces an exothermic reaction. As the mixture sets, the heat generated is apparent when placing a hand over the cast. As it sets the gloss may fade and the cast will become matte in appearance. As the mixture begins to set, it is good practice to etch identification markings onto the top of the cast. These will vary according to agency protocols and standard operating procedures.

Impressions Covered by Water

During inclement weather, impressions, especially tire tracks, may be found in standing water. Bodziak [1] advises that the CSI should not drain the water from the impression area. Any items floating on the water but not touching the impression should be removed.

Place a frame or dam around the impression. The technician must be careful that they do not damage the impression by placing them too close to the impression itself. Bodziak [1] recommends about 2-in. separation (5 cm) as a minimum.

Sift the powder into the water until it has covered the impression to a depth of about 1 in. (2.5 cm) and

Figure 3 Dental stone mix being poured into impression

Figure 4 Strengthening the cast

then mix enough compound to cover the framed area to a depth of 2 in. (5 cm). The cast should be left for a minimum of 1 h.

Recovering the Cast

To remove the cast, once it has set, it is best to use a small trowel to ensure the CSI can release some earth from around and under the cast. This will prevent any thin parts of the cast from breaking. When recovered, the CSI should not attempt to remove any of the soil from the footwear impression (Figure 5). The cast needs to be air dried for about 48 h [3]. The soil will be removed by the examiner at the laboratory. This also allows the CSI to have a soil sample from exactly where the tire of footwear impression was.

Figure 5 Recovering the cast

This may provide additional valuable evidence in some cases.

Place the cast soil side upwards in a suitable box (*see* **Packaging and Transport**).

Casting in Snow

Footwear and tire impressions in snow can be problematic as attempting to photograph impressions will be extremely difficult because light may reflect off the snow. In addition, mixing any material used as a casting agent creates an exothermic reaction that can destroy the detail of the impression.

To overcome this, a fine coat of matte black spray paint should be applied gently over the impression prior to photography. Where this is unavailable, some CSIs gently sprinkle some black powder over the impression. Both the methods increase the contrast, enabling a better photograph to be produced.

Prior to casting, a product called "Snow Print Wax™" is gently sprayed on the snow. This is a spray wax solution that creates a thin membrane on the surface and reduces the effects of the exothermic reaction on the snow.

When casting only little water is added to the powder to start the reaction and this is then supplemented by the addition of snow, which melts but reduces the temperature rise.

Once set, the resultant cast can be removed and packaged in the same manner as one cast in soil.

Casting Instrument Marks

Instrument marks, commonly referred to as *tool marks* are cast in a similar way.

Prior to casting, a photograph is taken showing the position of the mark. Then a close-up photograph of the mark with a scale.

Casting materials vary greatly but they are normally proprietary silicone-based casting compounds of the flexible type used by dentists when providing dentures.

When cured, they can be peeled away from the mark or impression. Prior to removal, it is good practice to show the vertical position of the mark by means of an arrow, indicating whether this is pointing up or down.

The resultant cast is then placed between two sheets of acetate or plastic to prevent damage. This should be sealed all around with adhesive tape and details written on the plastic sheet and on the attached chain of custody document (*see* **Crime Scene Documentation**).

Evidence Evaluation *see* Bayesian Networks, Case Assessment and Interpretation

Evidence Interpretation: a Logical Approach

Introduction

A criminal trial is suffused with uncertainty, and everyday court language reflects this: words such as *probability, likelihood, likely, unlikely* are regularly invoked, as well as phrases such as *balance of probabilities, beyond reasonable doubt, can't exclude the possibility of*, etc. among others. It is important for us to gain a good understanding of the role of the scientist in all this. No one pretends that a jury reasons logically, and few lawyers and judges have a grasp of the logic of forensic inference to match that of Professor Kaye (**Interpretation: Legal Perspective**). However, here we are concerned with the role of the forensic scientist, and it seems desirable that if scientists must reason in the face of uncertainty, then they should do so within a robust framework of logic.

This article describes such a framework. It would hardly be compatible with a scientific viewpoint to claim that it is the only framework that could ever exist, but at the time of writing it is the one that the overwhelming majority of students of evidence interpretation espouse.

Many people equate inference with statistics, but that is a mistake. Statistics is about data and we do not discuss data analysis in this article. We will be concerned with probability.

In the following section we give a brief discussion of the nature of probability. We then go on to look at how a fundamental theorem of probability theory – Bayes' theorem – provides a model for inference in the context of a criminal trial. We then see how this approach leads to the formulation of three principles of interpretation. We discuss issues of how probabilities can be addressed – with or without data. It is necessary to talk about a common fallacy encountered in the courts – the prosecutor's fallacy. And finally, we discuss the presentation of evidence at the court.

Probability

Three Examples

Consider the following statement:

> The card revealed when I cut this deck of playing cards will be a spade.

This seems a fairly simple statement[a] – but is it true? Well, the answer to that depends on a number of things. You would, presumably, like to know whether or not this is a conventional deck of cards; whether it has been prepared in any particular way – e.g., by shuffling; whether the person making the statement has any facility for party tricks; and so on. If you are told that it is indeed a conventional deck, that it has been shuffled, and that there is no question of a trick, then you might feel that the probability of the statement being true is one quarter.

Now consider:

> England will beat Switzerland in their next soccer match.

This is another simple statement (again making some assumptions about the knowledge of the reader), but, again, deciding on whether it is true or not depends on many things. Indeed, on the days leading up to the match the popular press will furnish you with masses of information about the previous encounters between the sides, the composition of the teams, the recent form of individual team members, the expected strategies of the two sides, and so on. Sporting pundits will make varying predictions and, no doubt, individual fans will be swayed by emotive issues such as national pride. Hence, resolving your uncertainty with regard to the truth of this second statement is far more difficult than it was for the first. Indeed, we should not be at all surprised when different people

express different probabilities. If, in turn, you wish to make your own rational assessment (perhaps because you are considering a small wager on the outcome!), then you will be more swayed by those who appear to be knowledgeable, rather than those who are more inspired by emotion.

Finally, consider the following:

The defendant murdered Mr Y.

This is a statement made by a prosecuting counsel to you, a juror in a criminal trial. Is the statement true? You might form an initial view from the physical appearance of the man in the dock: physiognomy, clothing, body language, etc. The prosecutor calls witnesses to show how the defendant threatened to shoot Mr Y with his shotgun, how Mr Y was indeed shot by a shotgun, how the defendant initially confessed to the police but later retracted, and so on. The defense attorney leads evidence from witnesses to the effect that Mr Y did not actually own a shotgun, he was maltreated by the investigators, he was 30 miles away at a prayer meeting at the time of the incident, and so on. Subject to the direction of the judge, each of these items of evidence will have a bearing on your uncertainty with regard to the truth of the prosecutor's statement.

Basic Concepts

The first thing to notice about the three examples these is that each of them may or may not be true. The extent to which you believe each of the three to be true depends on many things. Let us consider them one at a time.

There are many differences in detail between the three examples but there are some important common elements. First, in each case we consider a *proposition* that may, or may not, be true. Next, your uncertainty about its truth is influenced by what you know, what you are told, and how effectively you employ the information that is available to you. These ideas stimulate a form of mathematical notation that we will use throughout this article. For a particular proposition, we write:

$$\Pr(H|I)$$

where Pr denotes probability, H is the proposition whose truth is uncertain,[b]| is shorthand for "given", and I represents everything that we know, or assume, that is relevant to the truth of H.

Our shorthand notation is convenient because in the space of a few letters we summarize:

The probability that the proposition H is true given everything that we know that is relevant.

A few remarks about the nature of probability are desirable here. First, probability is a means of encapsulating our uncertainty about the truth of a proposition. Second, we have emphasized that our probability for the truth of a proposition depends entirely upon what we know (or assume). Probability is then conditional. Third, it necessarily follows that probability is *personal*; apart from relatively simple situations – such as tossing coins, rolling dice, etc. – different people considering the same proposition will have different levels of knowledge.

Laws of Probability

There is a rigorous body of mathematical theory that shows that provided that probability is constrained to obey certain laws, then it is the most effective means of dealing with uncertainty.

The first law states that probabilities must lie between 0 and 1. The other two laws deal with addition and multiplication of probabilities. There are so many excellent texts that explain probability theory that we give no more detail here. References in the forensic field include Aitken and Taroni [1] and Evett and Weir [2].

There is one aspect of probability theory that we do need to explain here – the concept of odds. The odds in favor of a proposition being true are given by the probability of it being true divided by the probability of it being false. In mathematical terms,

$$O(H|I) = \frac{\Pr(H|I)}{\Pr(\overline{H}|I)} \qquad (1)$$

where $\overline{H}$ denotes "the proposition H is false".

Inference in a Criminal Trial

The analysis that we discuss in this section is perfectly general, but it will help if we present it in the form of an example.

Eyewitnesses, outside a nightclub, saw two men fighting and grappling with each other. Eventually, one of the two men drew a knife and fatally stabbed the other. The man with the knife ran from the scene. After interviewing eyewitnesses and taking account

of all that was known about the circumstances of the crime, police arrested a suspect shortly after the incident. The suspect denied all knowledge of the crime and said that he had never been in the company of the deceased individual. In this example, we consider the interpretation of the results of the examination of the clothing of the deceased and the suspect for fibers. A number of fibers were found on the clothing of the suspect that matched samples from the upper clothing of the deceased; and fibers were found on the clothing of the deceased that matched samples from the clothing of the suspect.[c] We consider the case at court; we refer to the deceased as the "victim" and the suspect as the "defendant".

The defendant has pleaded not guilty to the charge of murder and the jury hears evidence about the circumstances of the incident from the eyewitnesses and from the investigators. We will summarize all of this nonscientific evidence by I. The prosecution position is that the following proposition is true:

H_p: the defendant is the person who stabbed the victim.

The defense position will, of course, be completely different from this. The defense proposition will depend to a considerable extent on what, if anything, the defendant wishes to say in his own defense. For the sake of the present discussion, the defense proposition will be taken to be:

H_d: the defendant had nothing to do with the incident.

The evidence of the eyewitnesses, investigators, and what the defendant himself says, if he chooses to give evidence, will together influence the jurors' uncertainty in relation to the two propositions. We do not study this process, which is undoubtedly extremely complex. We content ourselves with recognizing that the jurors' belief may be expressed in terms of odds. Because our interest is in considering the impact of the scientific evidence, we call these the *prior odds* and, using our notation, we can write them as follows:

$$\text{Prior odds} = \frac{\Pr(H_p|I)}{\Pr(H_d|I)} \tag{2}$$

Now the scientist gives evidence with regard to the results of the examination for fibers – we summarize this evidence by E – and we are interested in what effect this has on the jurors' belief with regard to the truth of H_p and H_d. We express this as the *posterior odds*:

$$\text{Posterior odds} = \frac{\Pr(H_p|E, I)}{\Pr(H_d|E, I)} \tag{3}$$

Hence, we recognize that the jurors' uncertainty has changed because it is now *conditioned* by more evidence than was available before the scientist presented his results. This notion of updating uncertainty in the light of new evidence is not just confined to the court of law – it is an integral part of everyday life and there is a standard result of probability theory that enables us to write out a formal, logical relationship between the prior and posterior odds. It is called *Bayes' theorem* and, in the present situation, it states that in odds form:

$$\frac{\Pr(H_p|E, I)}{\Pr(H_d|E, I)} = \frac{\Pr(E|H_p, I)}{\Pr(E|H_d, I)} \cdot \frac{\Pr(H_p|I)}{\Pr(H_d|I)} \tag{4}$$

Nonmathematical readers may, by now, be feeling somewhat apprehensive – but be reassured that (i) there will be little more in the way of demands on your patience in this article and (ii) the insights that come from this somewhat forbidding expression are profound, yet very simple. Let us unpick it slowly.

The equation tells us that the posterior odds can be derived from the prior odds if we multiply them by a ratio (the middle ratio in the equation). This ratio has a special name that will be recurring throughout this encyclopedia; hence, it will be worth spending some time in grasping it. It is known (for reasons that we do not need to go into) as the *likelihood ratio* and practically everybody denotes this by its short form – LR. It is worth writing it out:

$$LR = \frac{\Pr(E|H_p, I)}{\Pr(E|H_d, I)} \tag{5}$$

Hence, our forbidding bit of mathematics may be written in words as follows:

The *posterior odds* are equal to the *prior odds* multiplied by the LR.

Now, one reaction to this is that it is a pretty unrealistic model for the way in which real-world jurors behave. Indeed, that would appear to be the case. In *R v Denis J Adams* [3], defense attempted to encourage the jurors to assign probabilities to all of the relevant aspects of the nonscientific evidence: something that proved to be an uncomfortably complicated process. To cut a long story short, the Appeal Court took a firm line against this kind of approach to nonscientific evidence, and quite rightly so. But what we are looking

for here is not something to model the jurors' thinking – but that of the *scientist* and the insights that follow from this analysis have profound implications for scientific evidence.

This is what the jury considers (however imperfectly):

$\Pr(H_p|E, I)$: the probability that the prosecution proposition is true, given the scientific evidence and all the other evidence;
$\Pr(H_d|E, I)$: the probability that the defense proposition is true, given the scientific evidence and all the other evidence.

This is what the scientist must consider:

$\Pr(E|H_p, I)$: the probability of the scientific evidence, given that the prosecution proposition is true and given all the other evidence;
$\Pr(E|H_d, I)$: the probability of the scientific evidence, given that the defense proposition is true and given all the other evidence.

Let us consider these two questions in the example that we have outlined. The model directs that the scientist should address two questions:

$\Pr(E|H_p, I)$: "what is the probability that I would find a number of matching fibers if the defendant was the man who stabbed the victim, given the circumstances of the incident?"
$\Pr(E|H_p, I)$: "what is the probability that I would find a number of matching fibers if the defendant had nothing to do with the incident, given the circumstances of the incident?"

We do not consider in this article the issues that the scientist must consider to address these questions. A few remarks are desirable, however. We have been deliberately vague in talking about "a number of" matching fibers: in practice, the scientist would know the number, at least to a broad order of magnitude. In relation to the first of the two probabilities – the numerator of the LR – the scientist needs to take into account the circumstances of the incident as far as they relate to the nature and extent of contact between the examined garments if the prosecution proposition were true (transfer), and the time interval between the incident and the taking of the exhibits for examination (persistence). In relation to the second probability – the denominator of the LR – the scientist will refer to whatever data are available relating to the presence of fibers of a given type on the clothing of persons who are unconnected with particular criminal incidents. The circumstances of the case are relevant when the scientist considers the issue of the extent to which the data are representative of the conditions that pertain in this particular case.

Three Principles of Interpretation

The analysis we have presented here suggests three principles that a scientist should adhere to when interpreting evidence.

1. Scientific evidence must be interpreted within a framework of circumstances.
We have seen that the conditioning of the probabilities that constitute the LR includes I, which summarizes the nonscientific evidence. Much of this, of course, will not have a bearing on the scientific evidence but it is essential to recognize those aspects that do. In the example that we have discussed, there are aspects of I that influence the scientist's deliberations relating to transfer and persistence and also any background data that might be relevant to the probability of finding matching fibers on the clothing of the defendant were the defense proposition true.

As another example, evidence about the ethnic appearance, if known, of a person who left DNA at a crime scene is highly relevant to the choice of a database for interpreting a matching DNA profile.

We have seen much confusion among scientists as to the extent of the I information impacting on the assessment of the evidence (see [4] for example). The forensic scientist should be made aware only of the relevant information (nature of the alleged activities, timing, nature of the garments and surfaces, etc.) that may impact on his/her expectations as to the forensic material recovered and the comparative results obtained. Other information regarding the case that will impact on the decision of the ultimate issue should neither be considered nor assessed by the forensic scientist.

2. Scientific evidence can only be interpreted by considering two[d] propositions.
As we have seen, it is necessary for the scientist to address the probability of the evidence, given both the prosecution and defense propositions. In more complex cases, such as where there are multiple defendants, there may be more than two: these are much more difficult to deal with because the simple

form of Bayes' theorem that we have used here is only applicable when there are two propositions. We do not discuss such cases here, but content ourselves with observing that whatever the conditions the scientist cannot present a balanced interpretation unless both the prosecution and defense positions are considered.

3. It is necessary for the scientist to address questions of the kind "what is the probability of the evidence, given the proposition?"

Whereas the jury necessarily addresses questions of the kind "what is the probability of the prosecution proposition given the evidence?" and "what is the probability of the defense proposition given the evidence?", we have seen that the scientist must consider the probability of the evidence, given the prosecution proposition and the probability of the evidence given the defense proposition. The ratio of the answers to these two questions – the LR – is of crucial importance.

Statistics and Qualitative Opinions

A common reaction to the foregoing treatment is "that's all very well, but it doesn't work in my area of forensic science because we don't have any data to assign the probabilities that are required." But this is a misconception that arises from a confusion between probability and statistics. Certainly, if data are available to the scientist, then the logical approach leads to the effective and proper use of those data and, no doubt, we can cite DNA profiling as a field where an enormous work has been done on the proper use of DNA statistics. But the data are secondary: the logic of inference comes first, data come second. The strength of the logical approach is that it helps the scientist to identify the most appropriate *questions*. If we have data, then we may be able to provide quantitative answers to those questions. If there are no data, or if the data that are available defy simple analysis, then qualitative answers can provide powerful guidance to courts of law. A fine example of this is the field of documents examination and insightful illustrations, which are given in the chapter by Steve Day in this encyclopedia (*see* **Handwriting and Signatures, Interpretation of Comparison Results**).

There is a growing concern expressed in the literature when forensic findings are expressed by qualitative opinion and not substantiated by statistical numbers [5]. Opposing systematically human judgment to statistical value translates a misconception of the nature of science [6]. There is nothing wrong in applying informed judgment and expressing opinions in the form of qualified opinions such as in the following examples (still in relation to our above fiber case):

- The probability of observing such a number of fibers having been transferred, persisted, and recovered under the alleged conditions is high.
- It is very rare to observe this type and number of fibers, recovered by mere coincidence on the garments of a victim.
- The findings are what I would expect to find if the defendant had nothing to do with the incident, given the circumstances of the incident.

Such qualitative opinions amount to subjective probabilities [7] based on the training and experience of the examiners. As long as they are addressing relevant questions (as defined above) and that there are mechanisms in place to assess the reliability of them (either by a calibration with known data or through collaborative or proficiency tests), they have a crucial role to play in the interpretation of evidence.

The Case Assessment and Interpretation approach

In 1991 the Forensic Science Service (FSS) became a government agency: still a government department, still a nonprofit-making service, but with a strong emphasis on being run on business-like lines. One of the early developments was to introduce direct charging for casework, and so the FSS came to be financed purely through the sale of its services. An immediate consequence of this was that the costs of forensic science were no longer invisible to operational police officers – who were now referred to by the FSS as "customers". The aim of direct charging was to enable customers to make better decisions based on a greater sense of value for money. In the mid-1990s a project was initiated within the FSS to achieve improvement in value for money by encouraging greater participation on the part of the customer in decisions about what work was done in the laboratory. The Case Assessment and

Interpretation (CAI) model was developed with the objective:

> To enable decisions to be made which will deliver a value for money service meeting the needs of our direct customers and the Criminal Justice System.

Several FSS scientists participated in the CAI project and a number of them are contributors to this encyclopedia. The most important aspects of the work were published in a series of papers [8–12]; they included some key advances in thinking about evidence interpretation, which we now briefly discuss.

The Hierarchy of Propositions

Consider the following pairs of propositions:

H_p: the glass fragments came from window X.
H_d: the glass fragments came from some other broken glass object.

H_p: the semen came from Mr B.
H_d: the semen came from some other man.

H_p: the blood on Mr C's clothing came from Mr Z.
H_d: the blood on Mr C's clothing came from an unknown person.

These three have an important feature in common in that each pair relates to the *source* of some recovered material. These are examples of *source level* propositions and they represent level I in what the CAI project defined as the *hierarchy of propositions*. With the advent of more sensitive DNA techniques, it has become necessary to propose a further level, called *sublevel 1*, or *subsource level* [13] in the form of:

H_p: the DNA profile obtained is that of Mr Z.
H_d: the DNA profile obtained is that of an unknown person.

If we assume that a full, unmixed DNA profile (at 10 loci, for example) is obtained in some of the above cases, then the LR at subsource level will be in the order of a billion, assuming that the unknown contributor is unrelated to the suspected contributor and that no laboratory error has occurred. The LR, in such a case, will simply be the inverse of the match probability (*see* **Short Tandem Repeats: Interpretation**). To progress from the subsource to the source level, in addition to the match probability, we will need to consider uncertainties surrounding the relationship between the DNA profile obtained and the underlying body fluid assumed. It will depend on the type of presumptive tests conducted in an attempt to identify the body fluid, their specificity and sensitivity, the microscopic examination carried out, the efficiency of obtaining DNA profiles from targeted fluids, etc.

Consider the next set of examples:

H_p: Mr A is the man who smashed window X.
H_d: Mr A was not present when window X was smashed.

H_p: Mr B had sexual intercourse with Ms Y.
H_d: Ms Y had sexual intercourse some man other than Mr Y.

H_p: Mr C is the man who kicked Mr Z in the head.
H_d: Mr C was not present when Mr Z was kicked in the head.

Each of these three pairs relates to *activities* and they represent level II of the hierarchy. As with source level propositions, these will be addressed on the basis of the observations, measurements, and analysis that the scientist has carried out. But addressing propositions at the activity level, in general, requires more background information than for those at source level. In particular, the scientist will need to address issues of evidential transfer and persistence; and more may be needed in the way of background surveys. In relation to the first pair, for example, access to data on glass found on the clothing of people unconnected with particular crimes is highly desirable: much more can be read on issues relating to activity level propositions in glass cases (*see* **Glass Evidence: Bayesian Approach to**).

Now consider the following:

H_p: Mr A committed the burglary.
H_d: Mr A had nothing to do with the burglary.

H_p: Mr B raped Ms Y.
H_d: some other man raped Ms Y.

H_p: Mr C assaulted Mr Z.
H_d: Mr C had nothing to do with the assault on Mr Z.

These represent the highest level – level III – of the hierarchy and can be termed *offense level*

propositions. If the scientist can address propositions at this level, and this will depend to a large extent on the amount of information that is available to him/her, then he/she will be providing the jury with the greatest possible assistance in their task. Retreating from offense level propositions down the hierarchy leaves more of the interpretative issues to the jury.

Preassessment

The CAI project did much to develop the notion of preassessing a case in order that there should be a meaningful discussion between scientist and investigator with a view to optimizing value for money. The scientist is encouraged to consider what propositions may be addressed *before* attempting any examination and considering what magnitude of the LR might be expected if the prosecution proposition were true or if the defense proposition were true. This process is described in more detail, with a worked example elsewhere (*see* **Case Assessment and Interpretation**).

Structure of Statements

The three principles of interpretation lead naturally to a structure for a formal statement for use in criminal proceedings [12]. We concentrate here on the section having interpretative elements (leaving aside *technical issues* and *examination and results* sections).

Framework of circumstances
The scientist will have been provided with information about the circumstances of the alleged crime, the suspect, and what the suspect says about the incident. These circumstances will have been directly relevant to the formulation of the propositions that have been addressed and also to the interpretation of the observations that have been made. It is therefore important that the framework of circumstances, as understood by the scientist at the time of writing the statement, should be clearly expressed in the statement. Of course, it is necessary to recognize that the circumstances are rarely based on incontrovertible facts, but depend on evidence from other witnesses; as such, they may change as the case approaches trial. It is necessary then for the scientist to point this out and to emphasize that in the event of changing circumstances it may be necessary for him to revise his opinion.

Purpose
This would normally be a short section that explains the reasons for carrying out whatever scientific examination was undertaken.

Interpretation
This involves a clear statement of the propositions (and their level in the hierarchy) that are addressed and an assessment of the extent to which the findings are explained or not under one or other of the propositions.

Conclusion
The conclusion must help to address the questions raised in the purpose and should be expressed following the principles of interpretation. The statements must then be focused on the assessment of the findings in the light of the relevant propositions at hand. That implies the concept of various degrees of "support" for one proposition versus others depending on the magnitude of the LR.

To ease communication with the criminal justice system and especially when qualified opinions dominate the assessment of the LR, scientists may want to express their findings using a verbal scale of strength. For example, a common scale is summarized in Table 1.

The table is given for LRs in excess of 1, which therefore represent support for the prosecution proposition. The scale works in a directly comparable way for LRs less than 1, when the evidence represents support for the defense proposition. Such a verbal scale reflects a consensus on the correspondence between LRs and verbal equivalents describing the degree of support for one proposition versus another.

Table 1 Common scale showing the relationship between verbal equivalent and range of likelihood ratios (here for LRs in excess of 1)

Likelihood ratio	Verbal equivalent
>1–10	Limited evidence to support
10–100	Moderate evidence to support
100–1000	Moderately strong evidence to support
1000–10 000	Strong evidence to support
>10 000	Very strong evidence to support

We feel strongly that the scale should reflect the logical framework for interpreting evidence and encapsulate the concept of support for propositions. Any other verbal scales using terms such "possible", "probable", or "very likely" when referring the propositions at hand are logically flawed and ought to be avoided.

The Transposed Conditional

Dubbed "the prosecutor's fallacy" by Thompson and Schumann [14], this common error may conveniently be illustrated by an example from DNA profiling. Assume that the genotype of a crime sample is the same as that of a defendant; then the scientist's evidence might include a sentence of the kind "the probability of observing this genotype if the crime sample came from someone else is one in a million". The prosecutor's fallacy is to say "the probability that the crime sample came from someone else is one in a million". It is easy for the layman to confuse these two statements – and journalists do it all of the time – but, armed with the rigor of the previous sections, we can see the problem. The scientist is making a statement about the denominator of the LR: $\Pr(E|H_{\mathrm{d}}, I) = 10^{-6}$. The lawyer is making a statement about the posterior probability of the defense proposition: $\Pr(H_{\mathrm{d}}|E, I) = 10^{-6}$. The interchange between E and H_{d} is why this is known more widely among statisticians as *the fallacy of the transposed conditional*.

In spite of rulings in the British Central court of Criminal Appeal, particularly in *R v Doheny and Adams* [15], there is little doubt that the fallacy is not widely understood. In particular, consider the following extract from another Appeal Court judgment (*R v Bates* [16]), set down some 10 years after *Doheny and Adams*:

> Data drawn from empirical research is available to enable analysts to calculate the statistical likelihood of any person within the population having a particular allele at a particular locus. Using that data it is possible to estimate the *statistical likelihood that a particular sample of DNA originated from the person whose profile is being used for comparison*. This is usually referred to as the "*match probability*". (Italicized for emphasis.)

Moving away from DNA into fields where weight of evidence cannot be quantified, it has been common practice for experts to express opinions of the kind "the questioned handwriting was probably written by the suspect." We can now see that this kind of opinion is, in effect, a transposed conditional and is not logically sustainable.

Identity and the Logical Approach

Interpretation of some evidence types – most notably fingerprints, footwear, and toolmarks – are characterized by a willingness among experts to express categorical opinions of identity of source. The issues of identity, uniqueness, and individualization are discussed in **Identification and Individualization**; for the present we content ourselves by remarking that it is hard to reconcile such opinions with the logical approach to evidence evaluation. Typically, a conclusion of individualization amounts to claiming an infinite LR. Such an extreme value is difficult to justify satisfactorily [17].

In British Courts at present we have a paradoxical situation. The judgment in *Doheny and Adams* said, in relation to a DNA expert witness [15]:

> He will properly explain to the Jury the nature of the match [. . .] between the DNA in the crime stain and the DNA . . . from the Defendant. He will properly, on the basis of empirical statistical data, give the Jury the random occurrence ratio – the frequency with which the matching DNA characteristics are likely to be found in the population at large [. . .].
>
> The scientist should not be asked his opinion on the likelihood that it was the Defendant who left the crime stain [. . .].

This, as we have seen, was a response to the prosecutor's fallacy, which had occurred in both of the original trials and, although its wording could be considerably improved, it is difficult to take exception to what their lordships said. This judgment means that a DNA scientist may not give an opinion as to whether or not a defendant left a crime stain. We have seen from the logical model that this is right – the scientist should address the probability of the evidence given the proposition, and not the probability of the proposition given the evidence.

However, in relation to a fingerprint comparison, it has been accepted in courts throughout the world for some 100 years that it is perfectly reasonable for a fingerprint expert to give an opinion of the form "in my opinion, this mark was made by that person."

That is undoubtedly an opinion about the truth of a proposition.

Conclusion

Understanding the basic concept of probabilities is essential in developing a logical framework for interpreting forensic findings in court. The breadth of probabilistic knowledge required to tackle and understand these issues is reasonable (within the capability of any scientist or member of the judiciary) and allows us to identify clearly the role of the forensic scientist in the interpretation process.

We hope that the above section will allow scientists to identify clearly the nature of answers they are inclined to bring to the decision maker and how these assessments may be dependent on the circumstances of the case and the level of the propositions addressed. Having a clear underpinning logic is a decisive mechanism that creates greater transparency in the way scientific findings are presented in the court.

End Notes

[a.] It seems that every statement we make invokes some assumptions. Here, of course, we are assuming that the reader knows what a deck of playing cards is and is familiar with the idea of cutting the deck.
[b.] We use H for "proposition" because P is so often associated with "probability". I might be seen as standing for "information" in its broadest sense.
[c.] Of course, in a real case, the scientist would also search the clothing of the deceased to see if there were any fibers that match the clothing of the suspect. However, to keep the example simple, we will consider just the one direction of transfer.
[d.] In certain circumstances, there may be more than two – the point is that there cannot be only one proposition.

Evil: Illusion of

> The belief in a supernatural source of evil is not necessary; men alone are quite capable of every wickedness.
>
> -Joseph Conrad

> Nature has no morality. She makes no distinction between good and evil.
>
> -Anatole France

Interest in "evil" is growing. The psychological and psychiatric literature has reflected increasing attention to the concept of "evil" over the past two decades. While most of the relevant publications are from the field of social psychology, there has also been a growing interest in the fields of psychiatry and forensic mental health. Articles by prominent forensic psychiatrists have debated the issue of whether forensic psychiatrists should "define" and testify about evil [1, 2]. Nevertheless, attempts by behavioral science to define evil as though it were an objective and quantifiable concept will be inherently flawed. Because evil is a subjective moral concept with inextricable ties to religious thought, it cannot be measured by psychiatric science. Moreover, there does not appear to be any significant need to define or use the term *evil*, as forensic mental health already has working concepts describing deviant behavior that is harmful to others. This article will address why evil is an entirely subjective, nonscientific concept. Relevant historical issues will be discussed, as well as the apparent surge of interest in evil by forensic clinicians. The need to accept the term *evil* into the forensic mental health lexicon will be examined, as well as the potential costs of doing so.

The Illusion of "Evil"

Evil is an entirely subjective concept created by *Homo sapiens*. Evil cannot be detected or measured in nature or the universe. Primitive cultures believed that natural calamities were manifestations of evil. It was in this way that humanity first began to personify adverse circumstances or tragedy so that they could attempt to master attendant anxiety. Yet in all of evolutionary theory and natural selection, there is no designation for evil [3]. The relentless, brutal manner of natural selection may dispose us to a belief in so-called natural evil, while the reality is that this is nothing more than our own subjective interpretation and projections. Further, our own interpretations will invariably be ambiguous, culture-bound, and likely to evolve over time. The "evils" of the past are often today's sources of literary amusement.
