The word "evil" has very ancient origins. It is "emotionally loaded, morally judgmental, full of brimstone and fire" [4]. When evil is used to label an individual, it has a strongly damning consequence. The word "evil" inescapably invokes religious and mythological mind-sets, which were responsible for it's origination [5]. It summons the supernatural, the mystic, and the esoteric. Labeling someone as evil suggests that they are "beyond redemption". Concluding that someone is evil also suggests that they are permanently beyond human understanding, a sentiment which is contrary to scientific principles. A question about the material universe may be currently beyond our understanding, but saying it is permanently outside of our grasp suggests the issue lies in the realm of the supernatural. Perhaps the most objective conclusion one could reach about "evil" is that it is a term associated with considerable linguistic ambiguity, and has variable meanings to different people [6].

At best, a term such as "evil" is mere subjective abstraction [7]. Further confounding the concept of evil is the conundrum: Evil from whose perspective? The victim's perspective? The perpetrator? Laypersons? All will be different, and all will simply consist of that individual's subjective conception of how evil is defined. Biases and distortions can be expected to flourish. While the victim's perspective is essential

for the *moral* evaluation of evil acts, it is ruinous for a causal understanding of them [8]. Ultimately, viewing evil as a distinct or quantifiable concept is an illusion. The real causes of violent or harmful behavior will always be different from the way people think of evil. This phenomenon has been called the *myth of pure evil*. According to the myth of pure evil, "the face of evil is no one's real face – it is always a false image that is imposed or projected on the opponent (p.62)" [8]. In contrast, what is not illusory is our history of feeling justified in committing atrocities against individuals who are labeled as "evil". Herein lies one of the strongest cautions against embracing a subjective moral concept as though it were a scientific concept.

To the best of our current and limited knowledge, what leads people to commit acts of intentional harm involves a complex interaction of biological, psychological, and social forces in concert with situational variables. One set of factors affects and is affected by the others, and cannot likely stand on its own. Behavioral science has made efforts to objectively study each of these factors, mostly in a reductionistic approach. In contrast, it is important to consider whether accepting an emotionally laden and morally judgmental term like evil will advance our understanding of deviant or violent behavior. We must also consider whether forensic mental health professionals will be able to remove the biased moral connotations of the term, particularly in the courtroom, so that ethical and objective testimony is proffered. This will be a difficult, if not impossible challenge, given the inherent predisposition of some courts, as noted by Gilligan:

> "There were times in the courtroom and prisons in which I did my work when I felt as though I had somehow been transported . . . back into the Middle Ages, when people still thought that evil (like its mythical embodiment and namesake, the devil) was an objective thing that actually existed independently of our subjective feelings and thoughts, rather than a word we all to often use to rationalize, justify, and conceal, from ourselves and others, our own violence toward those we hate and wish to punish." (p.14) [9]

Learning from History: The Witches Hammer

In biblical times, mental illness was often seen as evidence of demonic forces and thus, the opposite of what was "good". During the middle ages, progress in medical science was severely squelched by the Christian church. During the Renaissance period, an obsession with evil in the form of witches became prominent. The official "practice guidelines" on detecting witches, the *Malleus Maleficarum* (1486), assisted Inquisitors in finding evil lurking amidst women, the socially disenfranchised and the mentally ill [10].

The witch-hunting of the fifteenth and sixteenth centuries serves as a fascinating, sobering example of an "official recognition of a hitherto unknown form of deviance" [11]. Once the crime of witchcraft was officially recognized, serious problems developed in terms of providing "proof" and legal restraints to the hysteria. The powerful legal and religious emphasis on the reality of witchcraft helped to reinforce the legitimacy of the trials, in addition to the public's belief that there was "evil" afoot. It has been theorized that the English government's systematic efforts for dealing with witchcraft served as a form of repressive deviance-management. In addition, one of the benefits to church and state of the witch-hunting hysteria was that it effectively shifted public attention away from growing demands for more equitable redistribution of wealth [12].

In retrospect, "evil" (in form of witches) was nothing more than what the English legal system claimed that it was. Those who were found to be witches were often ill-equipped and powerless to fend off this creative label of deviance. Once the definition of witchcraft was officially accepted, very little could be done to prevent or limit the system's abuse of the term. As a result, large populations of "deviant" witches were discovered, particularly among vulnerable lower-class groups. This in turn, fostered the growth of an "industry" revolving around the detection, prosecution, and punishment of witches. The industry included the proliferation of "rackets", and entrepreneurs seeking to profit from its operation [13]. The development of a profit-making "deviance" industry was perpetuated in cyclic fashion. The more rigorous the detection efforts, the higher the rates of deviance appeared to be, which then justified the use of more extreme measures of detection. However, forces other than economic had vested interests in defining and controlling deviance. Political, religious, and psychological interests have also been cited as playing significant roles [13]. One of lessons from the witchcraft hysteria in England is that once a definition of "evil" has been officially

sanctioned, the potential for abuse becomes virtually unlimited.

While the example of witchcraft is an entirely invented form of deviance, it is the process of stigmatization and repressive control that merits present-day consideration. It requires little stretch of the imagination to consider how more modern notions of "evil" might be creatively imputed to those who are unable to ward off its powerful moralistic connotations. Indeed, it is hubris to conclude that we are beyond such societal dynamics today. Given the right setting and circumstances, a regressive return to a variety of analogous behaviors is distinctly within our repertoire of responses. Consider the example of present-day Russia. The unstable environment of post-Soviet society has been characterized by drastic social changes and societal insecurity. A therapist working in a boarding school for teens reported a startling return to the practices of various superstitions and witch persecution [14]. The witch persecution was described as providing a socially sanctioned outlet for repressed anger, anxiety, and frustration. Exposing a witch among their peers helped them to explain daily misfortunes, and reaffirmed the boundaries between good and bad parts of the group.

When considering the present-day implications of legitimizing evil as forensic science concept, it should be noted in the present day and age, over 40% of Americans believe in demons, devils, and other superstitious concepts [13]. Beliefs in "evil" as an objective force can be observed among many ordinary citizens. For example, individuals are quite ready to believe that Hitler's personality or aura of "evil" can spread into his sweater, causing them to refuse to wear it [15, 16]. This is but one example of the tendency toward magical thinking in which material objects come to be seen as symbolic representations. Indeed, the distinction for many between the laws of magical thinking and reality is dangerously ambiguous [17].

Forensic Interest in "Evil": The Recurrence of an Illusion

Over the past two decades, an explicit emphasis on evil has been developed by several respected social psychologists [9, 18–21]. However, even in these scientific contexts, the term is used inconsistently. More importantly, use of the term does not escape vagueness and biased connotations. Over the past several decades, there have been quite reasonable advances in the areas of neuroscience, psychology, and sociology that begin to address, in a scientific manner, the problem of violent and/or deviant behavior. Thus, one may be inclined to wonder why some forensic mental health professionals are "raising the spectre of some demonic force at work", despite its regressive implications [22]. Indeed, might it not be irresponsible, given the fixed connotations of the term, its implications of untreatability and, dare I say it – the need for extermination? Then why do we find ourselves conjuring evil and summoning demons?

Both the legal and forensic mental health literature inform us that we are in the midst of a "punitive era" of criminal justice [23, 24]. Rehabilitative efforts have been pruned away like so much dead wood. The number of incarcerated individuals in this country at the end of 2005 reached a record high at approximately 2.2 million [25], and there are no signs that this trend will reverse itself. Keeping the prevailing emphasis on punishment in mind, it is possible to discern *some* of the hypothetical "pressures" on forensic mental health professionals, *vis-à-vis* the justice system, to identify and root out "evil". It has been suggested that the United States may be in the midst of a "moral panic", where radical measures are seen as reasonable and reassuring options [26, 27]. This is of little surprise during a period in which the "politics of crime" have been driven by fear inducing appeals to "common sense" punitiveness [28]. Such appeals have the allure of reducing the complex to a simple battle between good and evil. Thus, anxieties about "moral relativism" are concretely allayed.

In times of trouble, societies tend to stiffen and enforce conformity. Typically, strenuous efforts are made to root out the elements of "sin" and "vice". Encouraged by leadership, society is transformed into metaphorical "Spartan fist", as it prepares to steel itself against threat or chaos [29]. Fear and anxiety further drive the contraction of societal attitudes, and a return to earlier, more familiar practices. In such times, if an illusion of a "handle" by which to control a problem is produced, it is often grasped with intensity and passion. At the base of such a handle, it is not uncommon to find the illusion of an "evil" enemy. When threats to safety and survival become a prominent feature in society, the attendant terror is managed by reinforcing well-worn cultural values. The uncertainty produced by existential anxiety is mastered by reifying a system (or individual) which promises

order and permanence [30]. Thus, the latent meaning underneath confronting the "problem of evil" is the fundamental "struggle to make meaning out of a universe that appears cruel and wicked" [31]. However, the gain of coping with existential anxiety in this way must be carefully balanced against the loss that comes with abandoning some measure of rationalism.

The Need to Keep "Evil" Obscured

Part of the drive to catalog and illustrate evil may be a growing awareness that its face is rather ordinary, and provides no prospective cues for recognition. From Eichmann to a long list of serial killers, the phrase "terrifyingly normal" is sometimes used. The absence of a "look" or a mark of Cain is highly disturbing to most. It momentarily turns a rational, ordered view of the world on its head. How can someone who appears normal commit such deeds? A journalist covering the Jeffrey Dahmer trial could not get over how ordinary Dahmer appeared, remarking that "there was nothing to him" [32]. It would seem that we need to give evil a face. If we can somehow learn to recognize it, we may be able to bring it under our control. Otherwise, we will continually be threatened by unknown forces cloaked in the guise of normality. "Moral monsters", unbranded by physical stigmata, will be able to commit atrocities undetected [33].

Giving evil a distinct face also gratifies us by putting distance between us and the "others", lending certainty to the idea that we are worlds apart in our differences. Thus, there is a "social virtue" to outlining the face of evil – society is exonerated and bears no responsibility. When a bright line separating good from evil has been identified, society may "take comfort in the illusion that such a line constrains crossovers in either direction" [34]. But the desire to know the "face of evil" is in *direct* conflict with our desire to keep it partially obscured. This is necessary for keeping it the repository of noxious projections. It has been commonly observed that "humanizing" a monster "makes him less compelling as the embodiment of evil" [35]. In other words, very clear view of evil's face undermines the effectiveness of projection. The "celebrity status" of serial killers in American culture reflects precisely such contradictory desires [36]. The public is repulsed by their deviance, yet attracted by the vicarious thrill and tension. It is the tension between the killer's outer normalcy and inner deviance that elicits the fascination. Finally, there is the inevitable, comforting denouement that the killer is an "alien" aberration, whose detection has made society a much safer place. This societal morality play requires "powerful" evildoers, as society appears uninterested in the "mundane", ubiquitous purveyors of violence [34]. Crimes must be truly deviant or monstrous for them to be easily disavowed.

The claim that "We do not want to look at evil" [37] is difficult to refute for obvious reasons. Further, the tendency to keep evil obscured is consistent with lay notions that evil is *beyond* comprehension, and that those who commit evil acts lie *outside* the demarcation of being human [38]. Thus, the psychological need to keep the "face of evil" at least partially obscured will present yet another impasse to any serious scientific attempts to "standardize" or quantify evil. While attempting to study human cruelty under the auspices of a morally judgmental term may ease the investigator's subjective discomfort, it will do little to permit unbiased observations.

"Evil" in the Courtroom

It is not difficult to imagine a scenario in which the results of a legal adjudication of "evil" include discrimination against poor or disadvantaged individuals. Strong emotional and psychological forces are at play, particularly during capital trials, which are potentially biasing. It is well-known that much more than legal fact is communicated in the courtroom, and that this "much more" has a direct and powerful effect on a jury's punishment decision. For example, a defendant's *appearance* significantly influenced whether jurors imposed the death sentence [39]. Thus, one may be inclined to wonder: If jurors are unable to discount the physical appearance of a defendant in their deliberations, what is the likelihood that they will remain objective when a word steeped in religious morality is introduced by "experts" as an allegedly "scientific" construct?

When testifying about forensic mental health issues in court, it is not uncommon for the expert to encounter issues of moral conflict. A very helpful guideline for dealing with such a dilemma is to make use of the "touchstone" of asking oneself "what the ideal forensic *pathologist* would do in a similar situation" [40]. This ultimately has the effect of focusing one's testimony on the technical matters of forensic mental health. At the same time, it steers one clear of biased inferences or impressions. When the expert

strays too far from the touchstone of forensic scientist, she delves even deeper into the problem of the fact–value distinction [41]. It is difficult to argue that mental health professionals are not constantly making value judgments, either implicitly or explicitly. However, as an expert witness one must take care not to move away from clinical science, and toward illusory moral concepts, where the line between fact and value becomes hopelessly blurred.

Here it must be acknowledged that even certain clinical terms have, in fact, come to be associated with moral judgments. Diagnoses such as psychopath, personality disorder, and conduct disorder may be used by some as more of a moral judgment than a clinical diagnosis [42]. Rather than take this as proof that such practice is acceptable, forensic mental health professionals should remain cautious about the ease with which we inject our moral judgments into situations where they are not called for. It is critical that attempts via forensic mental health to understand such behavior be accompanied by a vigilant suppression of moral judgment. Achieving a state of absolute moral neutrality may indeed be unrealistic; nevertheless, "the *ideal* of being value-free is important because values prevent one from seeing the facts (p.386)" [9].

"Evil" Unnecessary

Forensic mental health already has working concepts describing deviant behavior. Certainly, these concepts and related nomenclature are not without their imperfections. However, none of them have blatantly recognizable origins in notions of religious morality. Efforts to understand violent human behavior have already provided us with steps toward an initial objective approach. Forensic mental health theories supported by research and case studies abound on topics such as malignant narcissism, psychopathy, sexual sadism, and serial sexual homicide [43–47]. From the biological perspective, although deviant or violent behavior is not well understood, genetic and neurochemical studies are beginning to proliferate [48, 49]. Studies on the neurobiology of maternal and pair bonding are being used to understand the origins of human violence [50]. Although still in the very early stages, neuroimaging studies have suggested dysfunction in certain neural systems of violent and psychopathic individuals [40, 51]. Tangible neuropsychiatric deficits have been found among serial and sexual murderers, individuals considered by many to represent the extreme of human cruelty and narcissism [52–54].

Thus, forensic mental health already has a tradition of at least attempting to avoid moralistic bias by focusing on concepts such as violence, aggression, or sexual disorders. Terms with value-laden or pejorative connotations are either limited or avoided. This is a tradition that places value on the struggle for neutrality and objectivity. One potential result of using terms that have a tendency to shut down objective thought is that the complexity and sophistication of scientific dialogue may be reduced. Additionally, sensationalized terms may serve to distract from underlying problems that are too difficult or complicated to acknowledge. Many violent crimes involve significant social issues that cannot be reduced to a dichotomous equation of "good vs. evil". Providing a finding of "evil" or "not evil", reduces the likelihood that more complex issues will receive consideration.

The Cost of Legitimizing an Illusion

> "When the natural consequences of a deed are no longer "natural," but thought of as caused by the conceptual specters of superstition ... then the presupposition of knowledge has been destroyed – *then the greatest crime against humanity has been committed*."[55]
>
> - Friedrich Nietzsche

Substantial skepticism already exists in the courts about the reliability of mental disease evidence [56]. Doubts about the objective reality of mental illnesses are less likely to be resolved by the courts, should forensic mental health pursue scientific answers under the shadow of a religious concept. There would also be the added risk that forensic expert witnesses might veer further into a moral and quasi-religious morass. It is the path of least resistance to find the offensive party "evil", and thus beyond the need for further understanding. The matter is settled, and no one need dispute or question the presence of evilness. As one nationally known criminal justice expert put it, "Some people are just evil" [49].

In essence, a finding of "evil" is an expedient substitute for thought [57]. But the business of dismissing someone as evil is really too easy, and "merely begs the question of how they became that way" in the first place [42]. Lay concepts of evil often fuse with the professional ethics of

mental illness, and threaten to confound each other's ideologies [58]. There remains a deeply ingrained societal prejudice that persons with mental illness are "ticking time bombs, ready to explode into violence" [59]. A significant portion of the lay public requires little persuasion to associate mental illness with mystical and potentially evil forces. Arguably, this association is strengthened by Hollywood movie portrayals of mental illness (e.g., *The Exorcist*), which perpetuate the myth that evil and mental illness are overlapping, related phenomena [60]. Thus, the primitive association between mental disorder and moral depravity has yet to be completely dissolved. The archaic myth that it is ultimately evil which gives birth to mental disease lingers in the shadows and waits to be resurrected.

In addition to the potential for further stigmatization of mental illness, legitimizing evil as a forensic mental health concept will have serious detrimental effects on forensic clinical practice. Sobering evidence of this comes from a study of forensic psychiatric nurses' approaches to treatment on a high-security psychiatric hospital in the United Kingdom [48]. Nurses were given a series of vignettes describing themes such as child killing, serial rape, and interpersonal violence. The nurses' discourse in semistructured interviews was analyzed, and compared to data collected from actual care plans of forensic patients on the nurses' wards. When a patient was judged to be "evil", staff abandoned medical discourse and reverted lay notions of badness.

Further, "evil" patients were viewed as being beyond help, which was then reflected in their care plans. The authors stressed that forensic psychiatric services may be actively limited in the face of socialized values and lay concepts of evil. The semantics of lay discourse proved to be of more than academic interest, particularly where forensic terminology is translated into practice and treatment. Those forensic patients who were labeled as evil by nursing staff were, in effect, excluded from the usual medical, symptom-centered approach [61]. In other words, *a finding of "evil" caused a withdrawal of treatment.* The implications of using the term *evil* as a form of punitive sanctions by the staff are being considered in future research. It is this worrisome effect – the withdrawal of treatment efforts – that should be among the strongest objections to the use of the term *evil* in forensic mental health. Given the implications of these early studies on forensic treatment efforts, it may be difficult to reconcile the use of the term *evil* with Hippocratic ethics or the medical ideal of *primum non nocere.*

Withdrawal of treatment is not the only possible outcome of declaring someone evil. Consider a scenario in which a defendant has been "scientifically" determined to be "evil". If it is a capital trial, he will either be given the death penalty (presumably if rated "high" in evilness) or life imprisonment (perhaps if rated as only moderately evil). Already, the specter of the witches' hammer has been resurrected – an essentially moral judgment has been cloaked in science in order to put someone to death. While in prison, on or off death row, the label of "evil" will doubtlessly stick. In a correctional setting, inmates and staff are only too aware of charges and findings in disturbing cases. Thus, it is not difficult to imagine a scenario in which "evil" inmates will be targeted for a special brand of hysteria-induced harassment and denial of services. To doubt that this could occur is to be unaware of the way in which sex offenders are severely harassed in prisons today. If the humanitarian aspects of this scenario are insufficient, there is also the troubling adverse economic outcome to consider. When the "evil" inmate is no longer able to tolerate steady doses of harassment and other forms of sadistic projection, he will ultimately seek escape through suicide. Some of these cases will result in costly litigation for corrections, and ultimately for taxpayers.

Views of evil as the adversary of good work well for increasing hostilities between rival nations, ethnic groups, and other social units [2]. Having strong beliefs in an active and tangible evil (i.e., "Satan") is significantly correlated with intolerance toward others [62], thus setting the stage for aggressive tensions. In addition, depicting an enemy as evil helps to foster an obligation to oppose and dispose of him. Because he is evil, there is little need to concern oneself with his health, welfare, or gaining a better understanding of him. All of this can be done free of guilt, for those who are "evil" bring about their own "just desserts". Perhaps the most self-satisfying achievement of perpetuating the myth of evil is that it allows us to be reassured of our own "goodness". It confers a moral superiority that is itself a setup for perpetrating all manner of atrocities. Most importantly, none of this does anything appreciable to stop people from committing terrible violence against others.

Finally, another untoward effect of legitimizing, and perhaps sensationalizing evil is the risk that it will present an attractive identity to those who feel disenfranchised by society. Poor social bonding has been found to increase the chances that adolescents will bond with deviant peers and adopt similar identities [63]. Vulnerable adolescents who have endured abusive developmental experiences have been observed to identify themselves as "evil", and search for identity in satanic cults [64]. Should evil be legitimized, particularly with the assistance of media sensationalism, there is the chance that it will serve as an orienting influence for the generally dissatisfied.

Conclusions

"Evil" can never be scientifically defined because (i) it is an illusory moral concept, (ii) it does not exist in nature, and (iii) its origins and connotations are inextricably linked to religion and mythology. The term *evil* will be very unlikely to escape religious and unscientific biases that reach back over the millennia. Any attempt to study violent or deviant behavior under this rubric will be fraught with bias and moralistic judgments. Embracing the term *evil* as though it were a legitimate scientific concept will contribute to the stigma of mental illness, diminish the credibility of the forensic clinicians, and corrupt forensic treatment efforts.

Preoccupation with evil has always been a part of human affairs. Indeed, the notion of "good vs. evil" has served as a catalyst for many positive human achievements. However, the field of forensic mental health should not succumb to a manner of thought that is regressive and distinctly unscientific. While further defining evil within the fields of philosophy or theology may provide greater precision for discourse on ethics, this purpose does not proclaim itself evidenced-based science or suitable for expert testimony. The fact that no philosophical, religious, or ethical debate over the past several thousand years has conclusively "defined" evil must inform us of something. Well-designed studies which help us to understand, and ultimately prevent violent, harmful, and deviant behaviors are sorely needed. In contrast, efforts to legitimize moral judgments by forensic scientists who should strive for moral neutrality should be avoided. Should forensic mental health accept the view of evil as an objective, quantifiable concept, a sacrifice of rational thought for expediency will have been made. The price of this sacrifice is likely to involve an insidious creep toward shutting down scientific thought and toward illusory moral judgments.

Examination of Fibers and Textiles

Introduction

Edmond Locard had already postulated in the early twentieth century that an exchange of fragmentary evidence takes place at the scene when two or more items come in contact [1]. Looking at textiles in more detail helps to confirm this statement from the point of view of fibers. Textiles and clothes are constructed of tiny fibers. These fibers and their fragments readily break free from the textile surface and are left behind making contact with another textile or a different item. On the basis of this principle [2–4], fibers from scenes can be recovered and compared with target garments to identify possible links between scenes or between persons. To probe the role of fibers in trace evidence, this article reviews the following:

recovery of fiber evidence including issues related to contamination;
fiber/textile analysis;
textile intelligence work.

Recovery of Fiber Evidence

Textile fibers are mostly tiny particles that are invisible to the unaided eye. Therefore special precautions must be taken to recover the fibers.

At the time of trace recovery at the scene, it is not always possible to predict the type of evidence that is relevant to that specific case. The strategy of how to progress with the case depends on the surrounding information; therefore, it is vital to get as much information as possible. Only in this way is it possible to get a fairly good idea of where the case-relevant fibers can be expected to be present. The taping of an item or body is an appropriate means to recover textile fibers or possibly other micro traces. Altering objects or moving the objects or the victim before taping should be avoided as far as possible. This is due to the type of evidence involved, since all micro traces, including fibers, are extremely sensitive to movement. Items collected at the scene for trace recovery in the laboratory should be handled to the minimal extent possible to prevent loss or contamination. They also need to be packaged and

sealed in a way that prevents contamination or loss and minimizes alterations. The material needs to be labeled in such a way that it is absolutely clear by whom, when, and where exactly the material was recovered. If movement or any other changes cannot be avoided, it is necessary to document these in detail.

To prevent contamination in the laboratory, it is important to recover traces from victims, offenders, or other people involved, using different rooms and via different personnel. The collection of reference samples from the immediate surrounding of the scene, from living areas, and other surroundings of victims and offenders, and the clothes involved, are as important as the trace recovery itself.

Techniques of Recovery

Picking-off fibers from a surface or a sharp edge is a suitable method for visible textile traces (e.g., fiber tufts). It is also a suitable means to recover fibers under a low-power microscope from smaller surfaces where other traces are present (e.g., blood or fingerprints) and where a tape lifting might destroy other evidence. *Tape lifting* is a highly recommended technique because it involves a detailed and overall collection of the fiber population on a surface [5]. *Additive tape lifting* is a procedure in which a defined area or zone is taped with the multiple use of only one tape. It represents, to a certain extent, the fiber distribution in a defined area if the chosen area for the multiple tape lifting is relatively small. Another highly specialised technique for an exhaustive collection of fibers and also other trace evidence is *1 : 1 taping*. The technique offers more comprehensive information since one tape is used only once, and recovered fibers can be associated with a defined spot on a surface; this allows a detailed mapping of fibers. It is mainly used in high profile cases (e.g., murder), whereby information about density, position, and distribution of certain fiber types can be obtained [6].

For all tape lifting techniques, it is essential to choose a clear tape with glue that will not affect the fibers over time.

There are other different techniques available like combing [7], vacuuming, and scraping, which are just briefly mentioned here. These techniques are suitable only for certain aspects of fiber recovery. The type of fibre recovery to be used has to be decided individually and depends on the situation at the scene. Special situations might require creative techniques for fiber recovery.

Textile Fibers

The analysis of fibers and fiber fragments requires special measures to adapt routine industrial methods for forensic analytical purposes.

Single textile fibers are the microscopic building materials of clothing and other textile products. Huge numbers of these tiny fibers are carefully constructed to form a thread or fabric. In many different ways, they are "built in" and therefore show a number of different characteristics. Single fibers can occur as staple fibers (fibers of a more or less defined length) or filaments (fibers of indefinite length). Besides morphological features, the most important characteristic of fibers is color. During production and during wear and tear, a textile and its fibers are exposed to different extraneous influences. These influences may alter, damage, and fragment the fibers and its color, and influence the shedding abilities of the textile. In combination with the intensity of contact and the donor qualities of a garment, this dictates the number, distribution, and appearance of fibers on the surface of contact.

Classification of Textile Fibers

Fiber classification starts with two basic groups – *natural* and *manmade fibers*. The first group comes about in nature and refers to the origin of the material. The second group does not occur naturally and contains only manufactured fibers. The term *classification* refers to the production process.

There are numerous classification systems available, which differ slightly from each other [8, 9]. For fiber identification purposes in forensic applications, generic names and their subtypes should be used.

For the forensic analyst, it might be essential to identify even the generic subtype of a fiber in order to verify a match or to gain further information about production and use.

Generic names and codes are used according to regulations of the International Organization for Standardization (ISO), the German Institute for Standardization Deutsches Institut für Normung (DIN) and The International Bureau for the Standardization of Man-Made Fibres (BISFA).

Care must be taken not to mix up generic names and brand names of fibers. The latter only refer to fiber products of certain companies.

Natural Fibers. Natural fibers are split into three main groups (animal, vegetable, and mineral), which are divided into subgroups according to the origin of the fiber material [10, 11]. Natural fibers are listed below in Table 1.

Man-made Fibers. Man-made fibers are split into two groups – organic and inorganic fibers, which are divided into subgroups depending on the origin [12, 13].

Table 1 Natural fibers

Type	Group -Generic name examples	Code

According to ISO 2076 and BISFA

High-performance fibers with added values have surfaced in the market and more will show up in the near future. "Smart Clothes" and "Intelligent Textiles" are catch phrases but these textiles are highly specialized products that are a challenge for the forensic textile expert. The identification of nanoparticles and nanocomposites, especially, is a task for the forensic scientist, since these particles are at the limit of perception in brightfield microscopy.

New developments in this area need more refined techniques to identify these specialized textiles and fiber types and also offer possibilities to enhance textile intelligence work. The question for the near future is how to develop refined procedures to identify these specialized textiles and fiber types in cases where routine examinations are not conclusive.

Fiber Analysis

The methods of fiber analysis are divided into microscopy, analysis by other instrumentation, which is very often carried out with the additional help of a microscope, and microchemical techniques for analysis.

The norm, as with other trace evidence types, is to characterise the donor fiber type and then use the most discriminating techniques to check whether the recovered fibers match. The microscope will always be the first tool as the level of discrimination is very high.

The range of tests may be limited by the size of the recovered fibers. Most instrumental techniques in common use in fiber examination are discussed below.

Microscopy

Microscopy is the basis for all further examination of fibers. It is a highly discriminative technique with regard to the morphological features of fibers. The microscopy of textile fibers allows identification and discrimination of the physical characteristics (morphological features) of natural and manufactured fibers. It also allows discrimination of the different optical characteristics.

The discriminative power of microscopy makes it the starting point of every case of fiber examination [14, 15].

Essential for all microscopic investigation is the correct set up of the microscope.

The adjustment of all brightfield microscopes for Köhler illumination should be a basic routine. Calibration and performance checks need to be carried out on a regular basis for the different microscopic systems in use.

Generally, the longitudinal view of fibers or fiber fragments is observed, but sometimes the additional examination of cross-sectional shapes is required to gather further information (e.g., regarding fibers structures, delustrants, and pigment particles).

Low-Power Microscopy (Reflected Light Stereomicroscopy). In general, fiber investigation starts with the examination of tape lifts or smaller items under a low-power microscope (*see* **Microscopy: Low Power**; **Microscopy: Light Microscopes**). The length, outer shape, and general behavior, which partly are due to the production process, can be detected. Color and color distribution already play an important role in detecting differences or similarities. Fibers showing notable differences from the known sample will be eliminated from further investigation

at this stage. Visually similar fibers need to be marked on the tape lifts. The position of a specific fiber on a tape lift is thus documented. For further detailed examination, the marked fibers need to be removed from the tapes. The removal of fibers is carried out with the help of a low-power microscope to prevent loss.

Subsequently, fibers should be mounted on microscope slides. The choice of mounting media differs from laboratory to laboratory, but it should certainly meet the requirements that known and recovered fibers are mounted in the same media; fibers should be so mounted that they can be removed from the slides without any damaging effects.

Brightfield Microscopy. The microscopic examination of textile fibers provides a nondestructive means to describe the morphological features and helps to discriminate fibers. Natural fibers can be distinguished on the basis of their characteristic features. Manmade fibers offer also a wide range of different morphological features (e.g., diameter, cross-sectional shape, delustrant particles, channels or voids, inclusions, and pigments) to help in distinguishing them. Besides morphological features, the type of coloration (e.g., print and type of print, spin dye, fiber dye, yarn or fabric dye), can be determined using brightfield microscopy.

Some information may already have been obtained under a low-power microscope but further information can be obtained only with the help of a brightfield microscope (*see* **Microscopy: High Power**; **Microscopy: Light Microscopes**).

Polarized Light Microscopy. Examination between crossed polars can prove helpful in identifying the fiber type. With natural fibers, polarized light is a helpful means to identify mercerized cotton or wool. Polarized light also helps to perceive morphological features more clearly (e.g., crossover marks in silk) under certain circumstances. Otherwise, polarized light does not play a dominant role in the identification of natural fibers. Regarding the nature of synthetic fibers, the alleged polymer type can be detected via optical characteristics by using polarized light [16]. An authentic collection of fiber types is useful to differentiate the material. Otherwise, a table showing the behavior of most generic types should be consulted. For confirmation and further detailed classification into fiber subtypes, other methods need to be employed (*see* **Microscopy: Light Microscopes**).

Polarized light microscopy also offers the possibility to observe whether dichroism is present in a fiber; this is observed when the fiber is orientated at different angles.

In combination with a hot stage, polarized light is also a helpful means to determine softening range and melting point of a fiber more easily for further classification [17].

Fluorescence Microscopy. Fibers fluoresce when excited by light of a shorter wavelength and emit energy usually at a longer wavelength. Therefore combinations of excitation and barrier filters are used for fluorescence microscopy [18, 19]. Generally, a range of broadband excitation filters is needed to cover the UV, blue and green ranges. A good light source is required to produce sufficient results (*see* **Microscopy: Light Microscopes**).

Besides the presence or absence of fluorescence, the color and intensity should also be noted.

Variations may occur already within the known material. Therefore it is essential to choose a wide range of fiber material from a potential source to make sure that all the variations are detected.

Fluorescence may arise from the fibers themselves or from additives (e.g., dye, washing powder, and optical brighteners).

Microspectrophotometers (MSP), Diode Array Detectors (DAD), or Charged Coupled Devices (CCD) can be equipped to measure emission fluorescence spectra (see below). Spectra might also prove helpful if needed.

Scanning Electron Microscopy/Energy Dispersive X-Ray (SEM/EDX). A very fine beam of electrons is focused on a fiber sample. From the interaction of electrons with the molecular composition of the fibers, a pseudo three-dimensional image is produced; this represents the unique elements present in the fiber. Magnification up to 250 000 times is possible [20, 21] (*see* **Microscopy: Scanning Electron Microscopy**).

Scanning electron microscopy (SEM) is a helpful tool for further morphological characterisation of fiber surfaces. It is a useful means for the detail examination of wool or hair scales. Besides the detailed examination of fiber characteristics, it provides the possibility to detect debris on the surface. Furthermore, the fiber edges may show specific characteristics originating from cuts (knife, scissor) or tears. The

easy characterisation of fiber cross sections is also a possible benefit of this technique [22].

Scanning electron microscopy/energy dispersive X-ray (SEM/EDX) may be used for the identification of pigments and delustrants or other additives used as flame retardants (e.g., halogens, antimony, and phosphorus). Moreover, it is possible to apply this method for the identification of other additives used in production, chemical residues, or debris on the surface of the fiber.

Other Microscopic Techniques. Besides the microscopic basic methods described, other techniques may be of further help and are used for fiber discrimination mostly by determination of the refractive index. Birefringence, interference microscopy, and dispersion staining offer a range of possible examination techniques that might add to the discriminative power in fiber examination, but these are not discussed in further detail since they are not routine techniques in every laboratory. The use of different methods highly depends on the specific equipment of each laboratory and its availability on the market.

Analysis by Other Instrumentation

UV/VIS Spectroscopy. Color is one of the most important characteristics to distinguish fibers. MSP, DAD- and CCD-spectroscopy offer highly discriminating methods for comparison and analysis [23].

Dyes are conjugated systems of excitable electrons and both principles explained beneath offer a method of measuring the interaction of the radiation with the fiber sample [24]. The region used for fiber spectroscopy is the UV/VIS (ultraviolet/visible) region. Usually a range from 240–760 nm is covered. If spectroscopy is restricted to the visible range, differences in dye components may be undetected. For UV/VIS detection, fibers need to be mounted on a quartz slide with a fluorescent-free media.

Generally, there are two different methods for UV/VIS spectroscopy available.

The first one is used with MSP where a step monochromator allows only a defined area of light (with a certain bandwidth) to pass through the sample at a time (2-nm steps are often used). In general, the light source used is an Xenon Short Arc Lamp (XBO) lamp. After passing the fiber sample a Photo Multiplier Tube (PMT) detects the signals and transfers the photons of the light into electrical energy. Creating spectra step by step is a time-consuming but exact process when the equipments setup works correctly.

The second method is used with a DAD or CCD spectrometer where a single beam of light passes the optical path and the sample simultaneously and is split for detection only after passing the sample. This is called multichannel spectroscopy and all results are detected simultaneously. The resolution for detection depends critically on the number of diodes used in a DAD or CCD system. Older systems sometimes lacked a sufficient number of diodes with a small bandwidth. Newer systems, meanwhile, offer a high number of diodes so that the quality of spectra is comparable to MSP. The method is less time consuming and equally exact if the setup works correctly. Applied to these systems, a deuterium/halogen combination has proven to produce good results.

With both methods, spectra can be taken either in absorption or transmittance. Most systems offer software to switch spectra between absorption and transmission. The first derivative of the absorbance spectra should also be taken into account for evaluation. First derivative spectra sometimes prove to be helpful for the interpretation of spectra with a broad and featureless appearance [25].

In addition, fluorescence emission spectra can be measured if fluorescence is observed and systems are suitably equipped.

FTIR Spectroscopy. IR microscopes coupled with a Fourier Transform Infrared (FTIR) spectrometer, covering the wavelength of about 4000–600 cm^{-1}, can be used to determine the composition of single fibers. Spectra can be obtained using transmittance or reflectance methods (*see* **Microscopy: FTIR**).

As with a DAD or CCD spectrometer, all wavelengths pass through the optical path and the sample simultaneously, and the light is only split for detection after passing the sample. This is called *multichannel spectroscopy* where all results are detected simultaneously. The resolution for detection depends extremely on the number of diodes used in an FTIR system. Older systems sometimes lacked a sufficient number of diodes with a small bandwidth. Newer systems, meanwhile, offer a high number of diodes so that the resolution and quality of spectra is satisfying.

With the help of the microscope it is possible to define very small areas for analysis on single fiber or fiber fragments and it is even possible to determine the different materials of core/sheath fibers after flattening the fibers slightly.

FTIR spectroscopy can be used either for the purpose of identification or comparison of fibers [26]. It is a technique that allows the identification of the polymeric composition of the fibers and it is even possible to determine the subtypes of the fibers, in addition to the generic classes [27, 28].

Optical information, melting point determination, or solubility tests cannot always give satisfactory information regarding the fiber subtypes, therefore FTIR might be used as an additional tool to get further information or as a replacement for other techniques.

It is to be noted that, despite the potential of gaining additional information regarding the fiber composition, FTIR spectroscopy can never be used as a replacement for microscopic examination! Microscopic examination is the basis for all further analytical work.

A very important step for using FTIR as a tool for further examination and information is the preparation of the fiber material. To prevent loss, it is suggested that a low-power microscope is used for preparation purposes. To get satisfactory results, some of the fibers need to be flattened before spectra can be taken. This needs some experience and training because the flattening of fibers might produce interference fringes if too much pressure is applied. Diamond cells are often used for this purpose. With attenuated total reflection (ATR) and microinternal reflection two surface techniques are available which are also used for FTIR spectroscopy. The sample is in close contact with the crystal but for the same reasons as above, it is also essential not to apply too much pressure. A variation of other techniques is available and probably useful for special purposes.

Regarding the use of libraries, it is highly recommended to produce in-house spectra libraries for a specific instrument, using known reference material of a reliable source.

Raman Spectroscopy. Raman spectroscopy (named after Sir C. V. Raman) involves the detection of the inelastic scattering of light depending on the vibrational energy level of molecular nonpolar bonds. Recently, various instruments, with different lasers for excitation, have become available for analysis. Different lasers for excitation are necessary to choose the lasers most suitable to gather sufficient information. Therefore the instrument should be equipped with different lasers covering the range from Ultraviolet (UV) to Near Infrared (NIR). Usually, instruments are fitted with three or four lasers for excitation, a sensitive CCD detector is required [29]. Additionally, a light microscope of good quality is essential for fiber examination [30].

Spectra are generally taken in the range $1800-200\,cm^{-1}$. The fibers should be mounted on an aluminum foil that can be fixed on a glass slide. The technique is not widely used as a routine method in fiber analysis, its predominant focus being on the detection of the major dye components [31] and under certain circumstances it may offer valuable information regarding the detection and/or comparison of fiber dyes. However, it must be taken into account that there is a detection limit for minute dye components.

Raman spectroscopy cannot be used as an alternative for UV/VIS spectroscopy. It is a technique that might prove useful in conjunction with UV/VIS spectroscopy and can play a complementary role.

The discrimination power depends on the substrate, the dye, the intensity of the dye, the sensitivity of the instrument, the choice of lasers used for excitation, and the careful interpretation of results. Fluorescence of fibers has an effect on the results too.

The interpretation of results is crucial since small relative intensity differences seem to have an impact. The dye identification on single fibers proves to be difficult at present since no comprehensive spectral libraries of commercial dyes are available in the market. Another difficulty is the limit of detection for minute dye components.

A subgroup within the European Fibres Group (EFG) evaluates the use of Raman to analyze the dye components on single fibers. Projects are ongoing and helpful information is being gathered [32].

Other Instrumentation. There is a wide range of other analytical techniques available. These techniques are used occasionally, depending on circumstances. Pyrolysis–Gas chromatography mass spectroscopy (GC(MS)) and Pyrolysis–Mass Spectrometry are two techniques that are briefly mentioned [33]; these are destructive analytical methods. In general, these are sensitive methods for identification by comparison but the applicability for fiber examination depends highly on the amount of substrate present in a case. This is also true for high performance liquid chromatography (HPLC) [34], which

is also a fast and sensitive technique for dye analysis. The basis for HPLC analysis of fiber dyes is the use of standard dyes for verification.

Numerous other analytical techniques showed up in fiber examination and vanished again, or only single prototypes of the instruments were on the market (e.g., laser microprobe mass analysis (LAMMA)). Specific instrumentation might prove helpful for certain applications but, at present, there is no other instrumentation or technique used in routine case work. Therefore these instruments and applications are not discussed.

Microchemical Techniques for Analysis

Thin Layer Chromatography. Thin layer chromatography (TLC) is one method to detect additional dye components. TLC might add valuable information to visible spectroscopy and is often used if UV spectroscopy is not possible, but since the method is destructive, it should be used only after all other possible paths of examination are exhausted. Prior to TLC analysis, it is necessary to determine the generic class of fibers [35] and the dye class [36]. Depending on the generic class of the fibers and the dye class, it is more or less difficult to extract the dye. Especially, reactive dyes on wool cause problems to extract the dye [37]. It is necessary to choose specific extraction solutions to remove the dye. This can be achieved with the help of dye extraction/classification schemes.

Generally, it has to be noted that it is easier to get sufficient information from single fibers when the dye is dark and a sufficient amount of dye can be extracted. When single fibers only show a very light coloring, most likely more then one fiber is necessary to gain sufficient results.

TLC of optical brighteners and other fluorescent agents proves to be extremely difficult and might cause problems, therefore extreme care must be taken if the method is applied. Under visible and ultraviolet light bands, positions and colors can be detected and documented. In general, TLC results tend to fade. Therefore the plates should be documented immediately (e.g., via photo documentation) to prevent the loss of results. To avoid fading processes, the TLC plates should be stored accordingly.

Solubility Tests. Solubility testing is a destructive method that was often used in the beginning of forensic fiber analysis. Solubility tests provide reliable information regarding the composition of material in terms of generic classes and even of subtypes in some cases [38]. There are several schemes available that are of interest for fiber identification or the analysis of other fiber or dye characteristics [39].

Using specific solvents the effects can be observed more easily under a microscope. Small fragments of the fiber can be used for the different steps of identification.

Although the techniques used in fiber examination are not unique, their application in the fiber area is very specialized and therefore good laboratory systems and training schemes are needed to ensure reliable results. The European Fibres Group (EFG) within the European Network of Forensic Science Institutes (ENFSI) is an excellent platform to exchange information and learn from each other. Organizing suitable collaborative exercises [40] poses particular challenges in fiber work. EFG has organized one such exercise every year since 1994.

Fibers and Textiles Intelligence Work

Textile investigation in forensics covers a wide range of different aspects. Samples range from very small and "invisible" textile traces to those that cannot be detected without the help of a microscope to whole pieces of textiles or clothing, which may offer clues for the investigation.

All information fibers and textile examination can offer that supports the investigator in the investigative process is described as fiber and textile intelligence work and can also be used to enhance the evidential value of the findings. Fiber and textile examination can play a key role in police investigations and can be used as an investigative tool if the forensic scientist and the investigator work in close contact. The continuous exchange of objective information between both sides is a necessary method to increase the efficiency and evidential value of examinations.

Textile Contact Traces and Their Advantages

Textile microtraces in forensic investigation are very often related to contact traces in the best sense of Locard's exchange principle, that is, that which may occur during the contact of one or more textiles with

a person or another item/textile. Therefore, traces can be found in the contact areas between two or more people or objects. The number of transferred fibers depends on intensity and shedding abilities of the donor garment. Additionally, the number of recovered fibers depends on the recipient's surface qualities and on the activities and changes taking place between the times of contact and recovery of the garment.

This characteristic is useful in setting time limits on interactions to be examined. For example, DNA may provide a useful link between a wearer and a balaclava. Fiber links in the hair combing of the suspected wearer suggests recent contact. The literature has many references to target fiber studies [41, 42] and survey data that have been carried out to help assess the significance of matching fibers [24, 43, 44].

Fiber findings can be used as investigative lead, to link garments to a scenario or to the living areas where they originate from. Contact traces in a certain context might also enable the examiner to put them into a relative time frame within a scenario and to enlighten the interactions at the scene (e.g., in the case of car accidents). Furthermore, it is possible to link different crime scenes via the combination of fiber populations found at the scenes. Fiber examination can be a powerful tool if carried out with adequate care to avoid other contamination.

Nonpermanent Contact Traces. This sort of contact causes a nonpermanent reflection of a textile contact, and fiber traces are transient. During the interaction of two or more different textiles/objects, particles originating from these textiles/objects may be transferred (primary transfer). It is most likely that fibers on the surface of a donor garment, which originate from other textile sources, are also transferred in a close symbiosis with the primary transferred fibers (secondary transfer). Mostly, those surface fibers originate from the immediate surrounding of the person wearing the donor garment.

Without available comparison material, directly or primary transferred fibers may be used as valuable lead for further comparison with the living area or certain textiles of a suspect [45]. They are easy to perceive if they are prominent either by number, color or distribution. The technique of using populations or collectives of these prominent fibers as an investigative lead is also known as the *Leitspur Principle* [46, 47] and depends on an extremely detailed fibers recovery and even more detailed information about the case. This is a very labor-intensive examination and is not routinely performed in all laboratories and not suitable for every type of casework.

The donor garment is the intermediate between a suspect's living area and the case-related contact traces and represents the living area of the owner via its surface fibers. These so called secondary fibers occur always in the near vicinity of primary contact traces on the recipient and the combination of primary and secondary fibers in the supposed contact area heightens the evidential value of findings enormously.

The position of fiber findings also can play a prominent role. A detailed trace recovery not only allows to state a contact between two items/textiles it is also possible to link the findings to an alleged scenario. In addition fibers offer the opportunity to link different crime scenes via found fiber populations and the combination of different fiber types and colors heightens the evidential value enormously. Under defined conditions, it is possible to link a person via fiber examination to a certain area at the scene and subsequently to a certain event within a relative time frame (e.g., via 1 : 1 taping in murder cases or via fiber fusion marks in car accidents).

Textile microtraces are not visible to the unaided eye. The invention of taping techniques in the early 1950s meant a revolution in trace recovery. It is now the method of choice in Europe and is very effective in the collection of surface fibers. The use of 1 : 1 taping in murder cases is a time-consuming but high-end technique that offers the opportunity to locate the exact position of the found fibers on a taped surface. Fiber mapping enables the forensic scientist to evaluate the findings and connect them to the crime scenario and the actions taking place on the scene. For this method, it is necessary to place each tape only once for tape lifting. This kind of extensive trace recovery is very useful in cases in which no significant change of the crime scenario took place and trace alterations or a loss of traces were prevented. Cases of murder with the immediate trace recovery on the scene are ideal for the technique of 1 : 1 taping.

The technique applied in murder cases allows to distinguish fiber collectives on a victim by evaluating

the fibers by distribution, density, and number, which, in consequence, offers the opportunity to associate them to case-relevant activities.

A zonal approach [48] might be less time consuming and might offer enough information in some cases, but with this additive method, fiber distribution schemes are not as detailed as for 1 : 1 taping. Questions regarding the interactions at the scene probably cannot be answered in great detail via a zonal mapping, whereas, a 1 : 1 distribution chart enables the examiner to visualize the detailed imprint of the contact. The contact transfers have to be regarded as an imprint of the events taking place on the scene.

As the fiber transfer mainly takes place in the intense contact areas between victim and offender the advantages can be seen in the possibility of the exact location of the fiber's position on a body and/or an object. This way, a fiber map can be produced and the findings can be related to the scenario and the alleged activities on the scene. It is of eminent value to compare the findings with the results of other evidence. As an example, the correlation of information coming from different sources like forensic medicine and fiber investigation (e.g., broken ribs in correlation with fiber findings in the specific area) is of added value in the interpretation of results. An additive collection of fibers would not enable the forensic expert to interpret the findings in the same way.

The foreign fibers found on a textile or another object may assist the examiner and also the investigator in identifying the textile source of the trace evidence [49]. The more detailed the trace recovery is at the scene and the less the situation is untouched and unaltered, the more evidence can be gathered to gain as much information as possible.

In case of 1 : 1 taping (e.g., in murder cases) single fibers can be traced back to a certain location on the victim. This offers the possibility for a fiber mapping that helps to evaluate whether the found fibers not only match but are in correspondence with the position of a suspect's clothes and accordingly fit into the alleged scenario or not. It is a powerful tool to link the fibers found by way of assessing the scenario and building a chain of plausibility that might stay within the fibers' discipline or even might involve other disciplines.

Car accidents offer another approach to link nonpermanent fibers on a surface to a certain incident. Under routine conditions, an airbag sits secured and folded in its compartment and it only inflates during a crash of relatively high energy. This way, a massive fiber transfer can only occur at the time of an accident and might lead very quickly to the person driving the car at the time of the accident. Again, the number, distribution, and relative position of fibers from different worn garments can be detected by using a very detailed recovery technique.

Permanent Fixed Contact Traces. Textile fibers can also occur as permanently fixed traces. This offers the opportunity to find traces a long time after the actual crime or incident took place. Those traces can be detected, for example, as fiber fusion marks in car accidents and may help state the contact between a car and a person involved in an accident and/or to state the position of a person in a car at the time of the accident [50, 51]. This type of trace evidence enables also the reconstruction of individual positions of different people inside a car during a crash.

Textile fusion marks are traces that develop in combination with high kinetic energy. A car crash, for example, is an incident involving a very high energy that enables the plastic surface of a car interior or exterior to melt and to fasten the fibers from a textile at the very moment of the accident. Very often, the direction of the forces can be observed via the position and direction of the fibers in the molten plastic. Under these circumstances, the fiber findings can be related to the case scenario again. This is especially important and helpful in cases where the potential driver of a damaged car is also the authorized owner and/or user of the car. Other then loose fibers on the surface of the car seats, fiber fusion marks can relate a garment of the official user to the accident.

This kind of trace evidence is very resistant against change after the incident and trace recovery can take place a long time after the accident took place. An important factor that has to be taken into account is the influence of UV light on single fibers, especially when fusion marks are located on the car exterior. Another aspect that needs consideration is the thermal influence on fibers [52].

The advantage of this kind of evidence is, in general, the restricted number of persons and often, the limited number of textiles involved, which allows this trace to be highly valued. The cross transfer

of fibers and plastic fusion marks can also be observed in certain cases and allows a very specific interpretation.

Damage

Information about the type of damage can be gained by examining a textiles surface, especially the edges of damaged areas. This way, it is possible to determine the type of damage (mechanical, thermal, or chemical/biological) and its origin [53]. Cuts (slash cuts, stab cuts, scissors cuts, and punctures) [54], tears, shot holes, abrasion, and heat marks, bite marks, degradation effects [55], and effects from wear and tear can be detected. This way, valuable clues for the investigator can be offered by the examiner (e.g., the type of weapon or tool responsible).

Damages in textiles or clothes result often from a device. In other cases, damages are due to interactions between the offender and the victim and result in tears. To determine the cause of the damage the entire outward appearance (e.g., shape and effects of stretching), dimensions (size, length, diameter, etc.) course of the damage (e.g., vertical, horizontal, diagonal, and zigzag) need examination. The surface of a fabric, and the edges of threads and fibers offer additional and more detailed information.

By investigating these damages very carefully, sometimes, the scientist is able to draw conclusions about the crime, the scenario and the subsequent order of actions taking place on the scene. This is very often only possible if other trace evidence is taken into account (e.g., textile damages and blood stains, textile damages and soil) and an overall investigation and interpretation is accomplished.

The textile fiber examiner may have to consult other experts to reach a conclusion when considering other types of trace evidence.

Physical fits of two textile parts in question allow a definite conclusion that these two parts of a textile originate from the same source. Physical matches indicate that the two or more pieces of material belonged to a continuous piece of textile. If no physical match is possible, a complete fiber and textile comparison, including construction (as far as possible) is the basis for further conclusions. In addition, the foreign fibers from different textiles surfaces can be considered to corroborate the other findings.

Reconstruction of Textiles and Further Information

The reconstruction of textiles helps to assess the clothing of a victim at the time of the crime, which might lead to an identification of a person. Accessories, zippers, buttons, labels, and seams are very often the remains that are encountered. These residues of a textile offer the opportunity to identify a certain textile and its model characteristics. Textile imprints left at a scene can help provide information about a textile source and knots might indicate an occupation if special techniques are applied.

Textile labels might also offer valuable information concerning the manufacturer, the type of garment, the number of garments produced, the time frame of production, and the distribution of textiles and clothes in certain countries or areas [56]. If a number of textiles is left behind, labels enable the textile examiner to identify the origin of the textiles and arising from this, possibly the region or country of a person involved.

Video Imaging

In addition, video imaging (comparison between video images and textiles or garments) can play an important role in forensic textile investigation and offers the possibility to gain information about the worn clothes via patterns and logos and offers the possibility for an individual characterization of textiles. Video imaging is the comparison of images and textiles or garments. The images may occur from bank robberies or other scenarios where images related to a crime were taken at the scene. Very often, the physical appearance of a person is not clearly seen on such images. The comparison of textile characteristics from the clothes to be seen can be of important value.

Clothes depend on different influences due to design, construction, and manufacture. Textiles and clothes are influenced and characterized at large by numerous influences during production, which enable the forensic scientist to individually characterize a certain garment [57].

Visible details like the general cut (e.g., arms, bodies, and collars) are responsible for the appearance of a textile. The observation of a textile cut can only give some information about a certain type of clothing and is the basis for all further investigation and comparison.

Certain characteristics can arise by chance in patterned clothes due to production. In general, the patterned fabrics are not designed to fit a certain part of a garment. Resulting from this, a completely unintentionally combination of textile pattern parts results. In different clothes from the same type and model, numerous variations of the general theme can be observed and lead to an individualization of the textiles.

During sewing procedures, unintentionally formed folds and creases can occur. The characteristics of the chosen textile materials can increase these effects. This offers also a possibility to individualize a certain textile, if unintended.

Clothes are characterized by the effects from wear and tear. Folds and crimps and color abrasion, for example, offer a lot of characteristics to individualize a textile.

Another possibility to individualize a textile can be observed when the basic textile underwent intentional or unintentional changes (e.g., different buttons, addition of applications, wrong colored seam material, and additional seams). Through these alterations, a single object is also individually characterized.

A basis for this type of investigation is a wide knowledge of garment production and side effects on garments. In general, every garment has the potential to be individualized, but this is dependent on the quality of the provided images and the possibility to visualize certain details on the images and compare them to the original garment. Conclusions can be drawn if a garment seen on an image is comparable to the garment from an individual.

Every textile, in general, has the potential to be individualized – this is certainly due to the quality of the provided images and the resulting abilities to visualize certain details from the images and relate them to the original textile [58].

Conclusion

Fiber and textile examination rely heavily on the basic analysis of fibers. Fiber persistence and population studies already underline the value of findings at this point of investigation.

In combination with other disciplines, fibers can close missing links in the sequence of events, and despite being generally not visible to the unaided eye, offer lots of valuable information. In addition to pure fibers analysis, there is much more the examiner has to offer that might help the investigator in the process of investigation or in heightening the evidential value of findings. Fiber and textile analysis together with intelligence-led information can be thus used as powerful tool [59].

Expert Opinion: Appeal v. Trial

When Does the Presentation of Expert Testimony Occur

The presentation of expert testimony in court is (*see* **Expert Opinion in Court: a Comparison of Approaches**; **Expert Opinion: United States**; **Expert Opinion: United Kingdom, Canada, and Australia**;) ordinarily restricted to the giving of evidence at trials. Seldom is expert testimony needed when the losing party appeals the decision of the trial court to a tribunal with appellate power. In order to explore the differences between various juridical approaches, two different jurisdictional systems are examined. They are (i) the process followed in the United States of America and (ii) that in use in the United Kingdom.

The United States of America

The American system of trial and appeals procedure is still very much based on the common law model (*see* **Adversary Systems of Justice**) that developed in England centuries ago, modified only insofar as US constitutional requirements of the Bill of Rights have mandated some alteration. It permits the taking of appropriate and admissible expert testimony at the trial, and at certain postconviction proceedings. No expert testimony, indeed, no lay evidence either, is admitted in appellate proceedings.

The bulwark of the system of justice, in particular that of criminal justice, is that all factual disputes are to be settled at the trial. The common law jury (*see* **Jury Instructions on Expert Testimony**) system, which retains its validity for civil as well as criminal trials, is the place where all factual disputes are to be settled. In theory, if not in absolute terms, nothing is permitted to interfere with the jury's fact-finding authority. Therefore, experts may testify only at trials, and not on appeal.

In the United States, plaintiff as well as defendant in a civil dispute has a right to appeal the determination of the trial. In criminal cases, however, an appeal can be taken only by a defendant following conviction. Where the jury returns a verdict of not guilty, the prosecution cannot appeal even if flagrant

jury error can be shown to have occurred. The constitutional protection against being placed in jeopardy twice for the same act makes impossible prosecutor appeals from not guilty verdicts.

There are some rare situations where prosecution appeals are possible from adverse rulings on pretrial motions excluding evidence, if a statutory provision authorizes such appeals. In the absence of such statutory authority, the common law reigns supreme and appeals can only be taken by an accused who has been convicted.

When a convicted person appeals (the appellant), the only issues before the appellate court will be matters of law. All factual disagreements in the evidence as presented by either the prosecution or the defense will be deemed to have been resolved by the jury. When the defendant appeals, he or she will prepare a petition for appeal, wherein all legal arguments for reversal of the judgment of conviction must be enumerated. Defendant's counsel will also secure the printing of the verbatim transcript of so much of the trial testimony and argument as is deemed to be appropriate for a proper consideration of the issues on appeal. Ordinarily, no argument can be made by the appellant that the jury erred in its fact finding.

Following the preparation of the petition for appeal, each party will file briefs with the reviewing tribunal, which may also schedule arguments where each side may orally argue its position. At these oral arguments, only counsels speak. No witness, lay or expert, is permitted to give testimony on appeal.

The United States also adheres to a fairly strict "waiver" of rights concept. This means that if a convicted person knows of any reason why a trial court is committing error during the trial, the accused is required to object to the error during the trial. If that is not done, the point is deemed waived forever. If the reviewing tribunal, after briefing and oral argument, hands down a decision to the effect that nothing prejudicial to the defendant has happened at trial, the judgment of conviction will be affirmed.

If legal errors were committed, the conviction will be reversed and the case will typically be remanded for a new trial. In rare cases, the appellate tribunal may find that the evidentiary record is so defective that it cannot, as a matter of law, support a judgment of conviction. If that is the case, an outright reversal without retrial will be mandated and the accused is ordered to be released.

Upon reversal and remand, the court will treat the earlier conviction as if it had never occurred. At the subsequent new trial before a different jury, if a jury trial is selected, all the evidence presented at the first trial, including expert testimony, can now again be presented, including additional evidence that has been discovered since the end of the first trial.

In order to enable higher courts to correct egregious errors in court decisions and prevent injustices from occurring, especially when newly discovered evidence of potential innocence that was not available at the first trial has been discovered, there exist separate statutory postconviction remedies in the United States that permit further review even after a conviction has already been affirmed by a reviewing court on direct appeal.

To initiate such a postconviction action, the defendant files a petition for a writ of habeas corpus in a state or federal trial or appellate court. Such a petition asserts that the petitioner is being unlawfully detained and requests release and/or retrial. If, upon a study of the petition itself, the judge believes that it likely has merit, a hearing on the specific issues that are properly cognizable on habeas corpus will be scheduled. At such a hearing, expert or lay testimony on the newly discovered evidence may be heard.

If, at the conclusion of the habeas corpus hearing, the judge is convinced that there is no ground supporting the convicted person's petition, the habeas petition will be dismissed. If the judge decides the petition was well founded, the petition for habeas corpus will be granted and the conviction reversed and remanded for a new trial. The prosecution may also appeal the granting of the writ before retrial can be held.

The United Kingdom

In the United Kingdom, the use of expert testimony (*see* **Expert Opinion: United Kingdom, Canada, and Australia**) at trial proceeds generally in the same manner as in the United States. When it comes to the appellate process, some notable differences can be observed.

While the United Kingdom's system has the same common law origin as that of the United States, there has been a more extensive change in the UK posttrial procedure than is the case in the United States. In

accord with common law traditions, before 1907, the legal system of England and Wales allowed appeals to be made on issues of law only. Such an appeal was perfected by the filing of a writ of error and the reservation of legal questions. Issues of fact could not be relitigated on appeal, because an appeal against a conviction would undermine the role of the jury. Thus, as in the United States, expert testimony was typically admitted at trials, but not during appellate proceedings.

The enactment of the Criminal Appeal Act in 1907 (amended several times subsequently) essentially safeguarded the traditional common law role of the trial jury, but gave the new Court of Criminal Appeal powers that allowed it to rectify certain miscarriages of justice. According to this act, an appeal could be granted on any ground of fact, or mixed fact and law. If the Court of Appeal allowed an appeal against the conviction on the ground the conviction was "unsafe", the conviction could be set aside and a new trial ordered.

The Act's extension through the passage of the Criminal Justice Act of 1988 gave the court discretion under its Section 23 to do whatever in its judgment was necessary and expedient in the interests of justice. As a result of this further enactment, Section 23(1) permits the bringing of new evidence before the Court of Criminal Appeal. Such evidence may include real, documentary, and oral testimony before the court. The law provides that "To that end it may order the production of a document or other object or the attendance or examination of a witness, whether on request or of its own motion, and may receive evidence not adduced at trial".

Unlike in the United States of America, in the United Kingdom, expert testimony may be freely presented before the Court of Criminal Appeal and the common law prohibition restricting criminal appeals solely to legal issues has been removed.

R. v. Pendleton [2002] 1 W.L.R. 72, a decision of the House of Lords, settled some significant legal issues as a result of these appellate process changes in the United Kingdom. In paragraph 17 of the opinion, it began by stressing that the central role of the jury in a trial by indictment was to be maintained:

> "Trial by jury does not mean trial by jury in the first instance and trial by judges of the Court of Appeal in the second. The Court of Appeal is entrusted with a power of review to guard against the possibility of injustice but it is a power to be exercised with caution, mindful that the Court of Appeal is not privy to the jury's deliberation and must not intrude into territory which properly belongs to the jury".

Whether a retrial was desirable is an issue the reviewing court determined should not be reached until, on the evidence presented in the Court of Appeal, the earlier conviction was deemed to be "unsafe". If so, the statutory duty of the court requires it to allow an appeal and to quash the conviction. A mere risk that a conviction was unsafe, however, does not suffice; the appellant (the convicted person) has the burden to persuade the Court of Appeal that the conviction is, in fact, unsafe. If, exercising its own judgment, the Court of Appeal finds that the evidence supports a finding that the conviction was unsafe, only then can the issue of whether a retrial is to occur be reached.

Expert Opinion: United States

American courts have admitted expert testimony for nearly two centuries. Before binding court precedents or legislation existed regulating such admission, the decision to permit a person to offer opinion testimony was made under poorly articulated common law principles. Essentially, this meant that if the trial judge believed the witness's expertise was believable, and available information showed he was at least marginally qualified, the witness would be permitted to offer opinion evidence.

The first important legal development occurred when, in 1923, the Court of Appeals for the District of Columbia handed down its relatively brief, but extremely significant, decision in the case of *Frye v. United States,* 193 F. 1013 (D.C. Cir. 1923) (*see* ***Frye v. United States*** for the facts and full text of this brief, though still significant, precedent-setting court opinion) [1]. In the *Frye* case, the court created what became known as the *general acceptance* test, requiring the specialized subject matter of the evidence to have been generally accepted as reliable in the field to which it belongs.

Since neither Congress nor the US Supreme Court had enacted rules on the subject, each federal circuit court of appeals was free to decide what the admissibility test ought to be in its own jurisdiction. Individual state courts, too, were free to adopt their own rule of admissibility. Perhaps by default of other workable models, *Frye*'s "general acceptance test" became, over the years, the polestar that generally guided admissibility decisions of all types of expert opinion testimony in criminal cases, in state and federal American courts.

In 1975, Congress, for the first time, enacted legislation dealing with a wide variety of evidential issues when it passed the Federal Rules of Evidence. Rule 702 had applicability to expert witnesses in civil and criminal cases. The Rule, as it currently exists, provides the following:

> "If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise, if (1) the testimony is based upon sufficient facts or data, (2) the testimony is the product of reliable principles and methods, and (3) the witness has applied the principles and methods reliably to the facts of the case".

The language that follows "if (1) . . . " was added after the Supreme Court's decision in *Daubert*, next to be discussed.

Following 1975, state and federal courts were divided alike on whether the passage of the Rules of Evidence, which were also adopted as state rules in a number of American states, signified that *Frye* was no longer the controlling precedent. Most of the courts that faced this issue concluded that *Frye* retained its validity, though a minority of jurisdictions fashioned rules that hinged the admissibility decision on "mere relevance" – whether the evidence, if believed, was more likely to be helpful than not.

Frye also had never become widely used as a guide for admitting expert evidence in civil cases until the next significant legal development, which occurred in 1993, when the United States Supreme Court applied Federal Rule of Evidence 702 (on expert witnesses) in an important civil case. The decision was *Daubert v. Merrell Dow Pharmaceuticals*, 509 U.S. 579 (1993), and the Court overturned federal precedent of more than half a century by replacing the "general acceptance test" with a loose standard that conditioned admissibility of challenged expert opinion testimony on its reliability [2]. The Court also articulated a series of guidelines for lower courts to use in making the reliability decision (s*ee* ***Daubert v. Merrell Dow Pharmaceuticals*** for a discussion of the facts in *Daubert* and the record trial courts are

expected to create in deciding whether a particular technique was shown to be reliable or not).

The *Daubert* opinion revolutionized the way in which courts had to think before admitting challenged expert opinion evidence. The meaning of the Court's new test remains fiercely debated by academicians. Perhaps that was inevitable since *Daubert* sought to fashion a test for admissibility in a way that attempted to combine irreconcilable principles. Proceeding from the thought that the reliability of expert evidence had to depend on whether it rested on genuinely "scientific" principles, the Court then seemed to embrace two incompatible philosophies of science. On one hand, it seemed to embrace Karl Popper's "falsifiability" test, and, on the other hand, it sought to accommodate Carl Hempel's "verification" approach to validity. These two philosophies are incompatible. The result: *Daubert* is an opinion that lacks the very thing it sought to require of expert testimony: scientific validity. No wonder courts and legal commentators have been at odds to apply or explain *Daubert* since 1993. The Supreme Court was quite clear, however, in stating that the new approach was less restrictive than *Frye*'s principle, which it saw as too conservative.

A whole host of new issues surfaced in the wake of *Daubert*. Since the Court had fashioned its rule in terms of "scientific" expert testimony, the question soon arose whether it would also apply to nonscientific, experience-based expert evidence. In applying *Daubert* in such cases, lower courts came to inconsistent results, as they did in attempting to unravel whether a discipline's endeavors were based on "science".

Those questions were resolved in 1999 when the US Supreme Court handed down another momentous decision in *Kumho Tire v. Carmichael*, 526 U.S. 137 (1999), another civil case (*see* ***Kumho Tire v. Carmichael*** for a discussion of its facts and holding) [3]. Recognizing that *Daubert's* rationale was based on an interpretation of Federal Rule of Evidence 702, which rule lumps all types of expert opinion testimony in the same category, the Court said that the *Daubert* principle, which required proof of reliability, applied to all forms of expert evidence, though the Court recognized that it might not be possible to literally apply each of the *Daubert* factors to all forms of experience-based opinion evidence. In recognition, the *Kumho Tire* Court reiterated its admonishment of *Daubert* that the 1993 decision offered flexible guidelines, instead of rigorous litmus tests, for courts to apply.

There are perhaps more court decisions in the United States dealing with the admissibility of forensic evidence in the years that followed 1993, than there were in all the years preceding *Daubert.* The interpretations of courts given to the Supreme Court precedents, often inconsistent with one another, continue to appear monthly in the American jurisprudential literature.

Expert Opinion: Ultimate Issue

see Ultimate Issue Evidence by Experts

Expert Opinion: United Kingdom, Canada, and Australia

England, Wales, and Scotland

The role of the expert in UK courts is to assist the court itself in deciding the reliability of evidence. There is no such thing as a claimant's or a defendant's expert and, by Rule 35.3 of the Civil Procedure Rules 1998 [1], it is the duty of the expert to assist the court on matters within their expertise. This duty overrides any contractual obligation that may have been formed between the expert and the party instructing and paying them.

It is the court that decides the validity of the expert witness and it is not necessary, in most cases, that the person called is formally qualified. In *R v. Silverlock* [1894] 2 QB 766 [3], an amateur graphologist was allowed to act as an expert on handwriting and a number of cases since have maintained the position that expert status can be obtained by personal experience as well as by formal training. The decision in *Liddle v. Middleton* [1894] 2 QB 766 [4] would seem to agree that the expert need only have expertise beyond that of a layman, not that the expert be qualified beyond that of a layman.

In the civil courts, the admissibility of expert evidence is governed by section 3 of the Civil Evidence Act 1972 and rules of the court [2]. "An expert was only qualified to give evidence that was relevant if his knowledge and expertise was beyond that of the layman and such evidence had to relate to a factual issue in the case".

There has long been some difficulty in determining which matters require an expert opinion but, in general, where the evidence to be given is outside the experience of the court, there is a *prima facie* requirement for an expert. If indeed an expert is required, then evidence of a nonexpert is not admissible. *R v. Inch* (1989) 91 Cr App R 51 [8].

Where the tribunal of fact has sufficient knowledge and understanding of the subject, it is not necessary to call an expert and this renders expert testimony inadmissible, *R v. Turner* [1975] QB 834 [6]. It is also the case that an expert's views on subjects within the understanding of the tribunal are inadmissible as explained poignantly by Lawton LJ:

> "The fact that an expert witness has impressive scientific qualifications does not by that fact alone make his opinion on matters of human nature and behaviour within the limits of normality any more helpful than that of the jurors but there is a danger that they may think it does."

By Rule 24 Criminal Procedure Rules in criminal trials the evidence of the expert must be, as soon as practicable, furnished to the other side along with the expert's observations, calculations, and other procedures. Failure to do so will render expert opinion inadmissible.

One further feature of the expert evidence is that an expert may rely on information, which in other circumstances, would be regarded as hearsay. A scientific expert may, for instance, rely on publications in journals, databases, and textbooks as source material for the opinions they give in evidence. *R v. Abadom* [1983] 1 WLR 126 [7].

An expert cannot be asked to state an opinion on the ultimate issue (guilt or innocence). *R v. Holmes* [1953] 1 WLR 686 [5]. The ultimate issue is a question for the jury, but it has been said that so long as the question is worded differently it may be allowed. *R v. Stockwell* (1993) 97 Cr App R 260 [9].

Australia

In Australia, the common law rules on evidence have been largely superseded by the Evidence Act 1995, although some residual use of common law remains in some state jurisdictions. Under section 56 of The Evidence Act, expert testimony is only admissible where it is relevant. The "Opinion Rule" under section 76 of the Act states that

> "Evidence of an opinion is not admissible to prove the existence of a fact about the existence of which the opinion was expressed."

The Evidence Act 1995 makes provision for exceptions to this rule where the evidence is given by experts by section 79 of the Act.

> "If a person has specialised knowledge based on the persons training, study or experience, the opinion rule does not apply to evidence of an opinion of that person that is wholly or substantially based on that knowledge."

The meaning and scope of this provision can be found in the ruling of Justice Heydon in *Makita (Australia) Pty Ltd. v. Sprowles* (2001) 52 NSWLR 705 [11].

This equates with the position in the United Kingdom where, in general terms, opinion evidence is not admissible unless the person tendering it demonstrate that he have this specialized knowledge. It is to be noted in this codified version of the rule that no formal qualifications are required and that "study and experience" have as much bearing as training. There is no specific definition of what is meant by "specialized knowledge" and it largely coincides with the position in the United Kingdom that the knowledge must be beyond the experience of ordinary people.

In civil cases, in Australia, the Uniform Civil Procedure Rule 2005 provide the code of conduct for experts and, as in the United Kingdom, the position is clear as to the role of the expert in that they are there ostensibly to assist in the decision making of the court rather than as an advocate for either party. The expert in Australia is not a hired gun.

Canada

The Canadian Courts traditionally followed the position established in the United Kingdom that expert evidence was admissible if the evidence assisted the court in reaching a decision. The admissibility relating to reliability and quality was assessed by the judge and, in 1994, the Supreme Court of Canada decided that the standard was too low. The Supreme Court stated that while the judge was appropriately the "gatekeeper" for expert evidence that novel science should be subjected to special scrutiny, *R v. J.-L J* [2000] 2 SCR 600 [10]. This position placed the Canadian courts in a similar position to that in the United States and courts there are now encouraged to use the US model known as the *Daubert* test of reliability, *William Daubert et al. v. Merrell Dow Pharmaceuticals Inc.* 509 U.S. 579 (1993) [12] (*see* **Expert Opinion: United States**). Courts in Canada following *R v. J.-L J* may strike out expert witness evidence if it does not come up to scrutiny under the *Daubert* test.

BARRY TURNER

Expert Opinion in Court: a Comparison of Approaches

Before commencing on a jurisdiction-by-jurisdiction examination of the systems for employing expert testimony, a brief look at the main jurisprudential traditions lays a proper foundation for the subject matter.

There are many commentaries on the differences between traditions of legal systems of Europe, the United States, and elsewhere. Most juridical systems fall into one of two groups, each exhibiting distinct legal philosophies and characteristics. On one hand, there is the tradition employed in the English-speaking world, which is typically described as the Anglo–Saxon jurisprudence, commonly referred to as employing an *adversarial approach*. On the other hand, there is the civil law system that is based on the Napoleonic Code, which in turn was modified from

the Roman Law model. The civil law system is often called the *inquisitorial* or *investigative system*.

An effective comparison of the two main legal philosophies is fraught with difficulties. Both systems share some terminology, but the terms used have significantly different meanings in each. The rules of how the tribunals function, what the roles of various law professionals are, and how decisions are made, including the uses of juries and panels of judges, also differ between these two systems.

The inquisitorial system is broadly based on a search for the truth and is structured around an exhaustive analysis of the evidence by a specialist judge or, as this official is called in the French legal system, the *juge d'instruction* or *examining magistrate*. One who is familiar with the inquisitorial system might be tempted to compare the examining magistrate to the prosecutor of the American system, but such comparison is inappropriate. An examining magistrate is a member of the judicial branch, whereas a prosecutor is typically in the service of the executive branch.

The adversarial system is grounded on a system of rules of evidence designed to limit the "factual" evidence that may be presented to the court. The purpose of these rules of evidence is to avoid injecting into the lay jury's fact-finding process, any proof that is of little relevance to resolving disputed issues. Further, judges in adversarial system jurisdictions have the ability to also exclude evidence of doubtful reliability or that would unfairly prejudice the jury to an accused in a criminal case. This does not occur in civil law systems where all evidence is effectively analyzed by the examining magistrate, although it must be added that the examining magistrate does not have any role to play in any subsequent trial.

In the adversary system, questions of fact are decided by a jury, or, if no jury is present (called a *bench* trial), by the judge. In a jury trial, the judge decides the issues of law and instructs the jurors in the legal principles that they must apply to the facts, as they have found them to be established by evidence that has been presented. The most common type of evidence that is excluded from the trier of fact in adversary system courts is evidence of bad character. The rationale behind excluding, what in many cases can be directly relevant evidence, is that the evidence of the bad character of the accused may have a prejudicial effect on the minds of jurors that outweighs its probative value, thus leading to a verdict based on prejudice rather than "fact". Counsel for the accused would, at the Voir Dire, which is the preliminary hearing before the court and conducted without a jury, make an application (or present a "motion") that certain evidence should not be admitted. In England and Wales, the rules on bad character evidence established for over 100 years in the Criminal Evidence Act of 1898, have now been fundamentally altered by the passage of the Criminal Justice Act of 2003, which increased the circumstances where evidence of character is admissible despite its potential prejudicial effect.

Other evidence that has increasingly come under scrutiny for exclusion is autoptic or forensic evidence. The use of forensic evidence is of powerful probative value, but it can also be inherently misleading in that the reliability of scientific evidence often falls below the trier of fact's faith in it. In recent years, a number of high profile cases regarding expert testimony have drawn attention to the often fallible nature of such evidence. Forensic evidence is now much more likely to be questioned at the Voir Dire as to not only its relevance but also its accuracy.

One common misconception held in the adversarial world is that, in civil law systems, the accused is "guilty until proved innocent". That is incorrect. All European civil law systems are intimately tied to the European Convention on Human Rights, which recognizes the presumption of innocence. The misconception is fueled by a lack of understanding of the processes of the courts in the civil law system, and also to some extent on the subtleties of translation of legal language. In this regard, the French text of the European Convention of Human Rights at Article Six reads as follows:

> "Toute personne accusée d'une infraction est presumée innocente jusqu'à ce que sa culpabilité ai été établie."

The article refers to the defendant's presumption of innocence, which persists until the facts *establish* his guilt. This compares to the English text where the presumption of innocence remains until guilt is *proved* according to law. It is in the arrival at *proof* or *establishment* that the systems differ. The English text presumes that the "proof" is obtained during a trial and that *proved according to law* refers to a verdict arrived at after the trier of fact has examined all evidence adduced before the court. The French version talks of guilt being "established". This means

that a *prima facie* case of guilt can be demonstrated in advance of the trial by the evidence accumulated in the *dossier* during the inquiry by the examining magistrate. The purpose of the trial in the French civil law system is to allow the trier of fact to judge the accused as a person against the material in the *dossier* or case file. Any lack of *prima facie* evidence will almost certainly result in the case not reaching trial.

In reality, the two systems do not exist in opposition or in isolation. There is a great deal of overlap or convergence, and the assessment of factual evidence in both differs more in style than substance. The judges in the adversarial system now often play a more "inquiring" role, while in some civil law systems, such as Italy, there is a move toward adversarial-type cross examination of witnesses. In Australia, in particular, ostensibly an adversarial jurisdiction, there is a major debate as to the evolution toward a more active and inquisitorial participatory role played by judges.

In Britain, the Crown Prosecution Service has a role, which could be compared to that of an examining magistrate, in that a Crown Prosecutor will examine evidence for relevance and probative value and will apply an "evidence test" before the case can be brought to the bar. In practical terms, the Crown Prosecution Service will not send a case to trial unless the totality of the evidence, what in France would be a *dossier*, contains sufficient evidence to make a guilty verdict, at least, very likely. While there is still the possibility for evidence to be skillfully unraveled or silenced by a sharp defense counsel at the actual trial, there will be in existence at the opening of the trial a situation that, to all intent and purposes, could be equated to the *prima facie* case seen in the civil law process.

As to the position regarding expertise of witnesses, there will be opportunities prior to the trial for this to be examined, and if a case for ureliability or the underlying science or technology or inapplicability of its conclusions to the disputed facts can be made, such evidence may be ruled inadmissible. While the partially codified system established by the *Frye* and *Daubert* rulings in the United States are not directly applicable in the majority of adversarial courts, and do not apply at all in the inquisitorial system, comparable mechanisms for exploring issues related to forensic evidence use are present in all jurisdictions.

Nonexpert, or lay witnesses testifying in courts that follow the Anglo-Saxon model – the "adversary system" – are permitted, with some exceptions, to testify only to perceptions made with the senses: hearing, sight, and smell. Under court rules that decide what evidence is admissible, such witnesses are prohibited from offering opinions on the significance of their observations and perceptions, if knowledge of the perceptions alone will give the fact finder sufficient information to resolve the disputed facts. If the sense perceptions of a witness alone do not alert the fact finder to their significance in the case at bar, a witness who qualifies as an expert may be permitted to explain the meaning of the factual testimony and also testify to the conclusions that the expert has drawn from those facts or data.

An expert is a person who, by education, training, knowledge, or experience has gained a special skill, ability, or knowledge in a field and who is, by virtue of that status, permitted by a court to offer opinion testimony. Thus, in the application of forensic science to the purposes of the law, being an "expert" is not a job title, but rather the designation of a type of witness and the form that his testimony may take.

Admissibility of expert opinion testimony requires, as a foundation for the testimony, that there be a showing that the witness is qualified in the particular field in which he proposes to testify. In the Anglo–Saxon system of justice, the determination whether a proffered witness qualifies as an expert is a question of law for the trial judge to decide.

Courts worldwide have traditionally possessed a great deal of latitude in deciding (1) whether a discipline is a proper one for the offering of expert testimony and (2) whether the witness before the tribunal is qualified as an expert. It is in the United States that courts have developed, during the twentieth century, a series of specialized rules that purport to regulate the judge's exercise of discretion in making an admissibility decision on expert opinions. These legal developments have been studied, and are followed, in many other countries as well. It is common, today, to see Canadian, United Kingdom, or even continental European courts dealing with novel forensic issues to refer to United States court precedents relating to these topics. Therefore, it is important for forensic scientists everywhere to be familiar with these tests of admissibility.

Expert Opinion in Court: Civil Law Jurisdictions (France, Germany, Italy, and Spain)

Jurisdictions: Regulatory Similarities and Differences

While civil law jurisdictions differ from country to country in the manner in which they regulate the participation of experts in litigation, they also share many procedural characteristics. The discussion of the approaches in the following five countries can be taken as representative of both the similarities and differences in the utilization of expert evidence.

France

The purpose of the expert witness in France in the inquisitorial system of justice is ostensibly the same as in other jurisdictions. They are there to effectively explain matters, which are beyond the experience of the triers of fact, and to help them in their decision making. As in other legal systems, the expert is considered to possess knowledge outside the range of the layman.

The inquisitorial system differs from that of the common law adversarial jurisdictions in that the trial commences following an exhaustive analysis of evidence during the investigation by a judicial official referred to as the *juge d'instruction* (examining magistrate). This is the process followed when serious crimes are investigated. In less serious cases, evidence of the offences will be gathered and assessed by the law enforcement agencies under the guidance of a *procureur* or state prosecutor. The evidence is subjected to analysis and is examined as to its relevance and admissibility. The decision-making processes are guided by a search for proof of what is asserted and while the legal burden lies with the party affirming rather than the party denying, as in common law jurisdictions there may be a greater reliance on presumptions to support the assertions. It may not always be necessary for witnesses to discharge the burden of proof.

There are a number of facts that may be presumed. They may be assumed because of their inherent probabilities (*presumptio judicis*). In such a case, the judges, using their own intellect and knowledge, determine the probability of a fact being true. There are presumptions of law where the law presumes unless evidence to the contrary is proved (*presumptio juris*) and presumptions required by law, where the law disallows any attempt to prove the contrary. In the common law tradition, this would be the irrebuttable presumption (*presumptio juris et de jure*).

In civil procedure, the evidence is presented to the court in the form of a *dossier* or file, which contains all the material collected to form the basis of the judgment. This material gathered in the investigatory stage of the process includes all the evidence in the form of summaries of oral testimony, expert reports,

and pleadings of the parties. This is also the case in criminal trials as in commercial and administrative cases. The expert's report is there to assist the trier of fact in his decision making.

The French procedural codes allow for the adducing of oral testimony, but it is unusual to do so except in criminal cases, where an expert may be required to give such testimony in court. Ordinarily, though, the judges will rely on written submissions. Expert evidence may be requested by either of the parties to the case or requested directly by the judge. The expert will provide the court with a provisional report, which may be later amended into a final report, for inclusion in the dossier once it has been amended by reference to facts or legal necessities. Where expert evidence is requested by either of the parties, it may be contested by other evidence. In the case of a court-appointed expert, the evidence is considered to be conclusive and is not open to challenge.

The position of the expert in France underwent a significant change in 2004 with the adoption of statute no. 2004-130 of 11 February 2004 and its subsequent implementing regulations, no. 2004-1463 of 23 December 2004.

This legislation impacted upon two different areas of the status of the expert. In the first instance, it was designed to codify the conditions for registration as a court expert and secondly examined practical matters dealing with the courts' ability to exercise quality control when appointing experts.

Experts are now usually appointed from official lists but the judge retains the discretion to appoint any person he considers to be the best person.

The expert is registered on a list for the area in which he lives or works and may also be listed on the final appeal court list (*Cour de Cassation*). These provisions do not apply in the administrative courts.

Under the old statute no. 71-498 of 29 June 1971 and its implementing regulations no. 74-1184 of 31 December 1974, there was no "quality control" or adequate monitoring of the abilities of experts. It was the 2004 statute that introduced these measures.

Germany

While German courts are not strictly civil courts in structure or function, they more easily lend themselves to this philosophy than to the one pertaining to adversarial courts.

In the German criminal process, the function of a witness is to prove factual evidence, which may be relevant for a conviction. Witnesses may be asked to provide evidence on matters they have personal knowledge of or even their observations on matters. This is a striking difference to the role of a witness in the adversarial system where conjecture and speculation is inadmissible and opinion evidence is confined to expert testimony to the greatest extent. The witness in the German criminal justice system has duties codified in the *Strafprozeßordnung* (*StPO or* Code of Criminal Procedure). He is obliged to appear in court before the public prosecutor, must give evidence under oath and must tell the truth subject to the purpose of the examination. Giving false testimony is punishable under the Code of Criminal Procedure. The law on requiring the appearance of witnesses is much broader than that employed in common law courts, but a potential witness has a range of circumstances under which he may refuse to give evidence.

In Germany, the *Sachverständige* or expert witness is appointed by the court under §§ *et seq* 72 StPO. They are, as in most systems, required when some evidence needs explaining to the court because the subject material or content is beyond its understanding. The expert's duty is similar to that of the lay expert and, in their case, has a duty to prove facts and circumstances by reference to their particular expertise. As in other jurisdictions, the expert is allowed to make reference to scientific or other scholarly protocols in order to carry out the necessary research or experimentation, and may refer to published material in the area of expertise. As with ordinary witnesses, the expert can refuse to give evidence or to provide an opinion. Experts in German courts can be refused leave to give their evidence on the grounds of prejudice where prejudicial effect may outweigh the probative value of the expert opinion. This prevents the expert from overly influencing the final decision and reserves the ultimate issue to the trier of fact.

Under the *Zivilprozeßordnung ZPO* (Code of Civil Process), the expert's role is to provide the court with a nonpartisan assessment of the facts at issue based on their expertise on the subject matter. While the expert's opinion is classed as formal evidence by §§ 402 *et seq* ZPO and will be assessed as to its merit by the judge in making an ultimate decision, the evidence is not binding on the court. The court may

take into account all evidence submitted by all parties and witnesses and retains the discretion in finding the facts, including those that are the subject of the expert's evidence. The expert is not to be understood to be a substitute for the court's decision-making powers. Appointment by the court of an expert has, as its primary purpose, to allow the court access to a person who possesses specialist knowledge. Such appointment does not constitute a delegation of the court's decision-making duty on the ultimate issue.

Experts are appointed by the courts or they may be appointed by consent of the parties. Where evidence is adduced by an expert appointed by one party only, it is seen simply as an assertion by that party and does not possess any special merit. Expert evidence can be the domain of a public authority as well as individuals. In the case of an individual, the evidence may be regarded as "expert" or documentary. The opinions of a public authority are always considered as expert opinions, as is the opinion of a body of experts such as those working for a forensic or medicolegal institute. § *et seq* 404 ZPO requires that, where available, public authority experts are to be given priority.

German courts have a preference for expert testimony to be in the form of a report but they may be called to give oral testimony where required.

The courts may not interfere with or interpret partially the expert's evidence, since the expert is neutral in the proceedings. However, under § 404a ZPO, the court is allowed to define the parameters within which the evidence may be adduced and does, of course, retain final decision on whether an expert may or may not give evidence. Experts may be rejected on grounds of bias or prejudice and may not testify, if they are connected with either of the parties by § 41 and 42 ZPO.

Italy

The expert in Italy can be called to give technical advice to either the judge or the parties. They give their evidence during the inquisitorial stage of the proceedings.

There are two kinds of experts in civil proceedings. The parties may appoint experts to assist them or the judge may appoint an expert as an assistant of the judge. In the latter role, the expert will be directed by the judge to engage in an analysis of material where the litigation requires specialized knowledge or expertise. Experts are commissioned by the judge to carry out inquiries and to present to the judge the report, clarifying any technical issues on which the judge needed assistance. When testifying the judge will delineate specific questions, which will be answered in the experts report.

The expert remains in an advisory role rather than as a witness proper. Their purpose is to provide a report on technical evidence to assist in the analysis of the evidence where, without special expertise, the evidence would be difficult to understand. The report provided by the expert is not binding on the judicial decisions.

The court-appointed expert, although strictly an officer of the court rather than a witness, gives evidence under oath.

When the court appoints an expert, the parties may appoint their own experts to assist them in understanding the court-appointed expert's report. Experts retained by the parties may also file a report allowing them to comment or criticize the court-appointed expert's findings. It is unnecessary for the parties to require the court to formally appoint their experts and all they need to do is give notice to the court clerks.

Under Article 61 of the Italian Code of Civil Procedure, the court-appointed expert must be chosen from a register categorizing the specific scientific, technical, or professional expertise of prospective appointees. Each of the courts has its own list known as an *Albo dei Periti* and the individuals on it are managed by the President of the Court.

Strict rules apply to ensure a court-appointed expert is impartial and unconnected in any way with any of the parties. Similarly, the expert may not be involved in any other proceedings, which would, by their nature, involve a conflict of interest or litigation on the same issue. The Supreme Court has stated that the expert is guaranteed neutral because they are appointed in the capacity of assistant to the judge who is naturally neutral in the proceedings. The Supreme Court stressed this position by also referring to a court-appointed expert's discretion permitting him to abstain or object under the provisions of the Italian Code of Civil Procedure.

Although an expert has discretion to abstain from the appointment, a solid foundation for doing so must exist, such as conflict of interest or unsuitability for the inquiries necessary. It is then up to the judge to decide whether the abstention will be accepted.

After a court-appointed expert has been designated, the parties may still object to the court-appointed expert if they have reason to believe the expert lacks impartiality or that a conflict of interest is present.

The Netherlands

In Netherlands, the expert witness opinion is initially considered a part of the court inquiry rather than as *prima facie* evidence of fact. This does not exclude the expert's evidence being eventually admitted as evidence of fact but acts to protect the reservation of the ultimate issue as remaining in the exclusive domain of the trier of fact. However, if a court decides to disregard an expert's evidence, it must incorporate the reasons for doing so, into the final judgment.

By the Netherlands Code of Civil Procedure, experts may be appointed either at the request of the parties or on the court's own initiative. The court enjoys considerable discretion in the appointment of an expert and, where the judge believes that his or her own expertise is sufficient to an understanding of the evidence, he may refuse leave to appoint. This follows the standard pattern seen in many jurisdictions where unnecessary experts may be seen as actually prejudicial to the proceedings similar to the position held in the English case of *R v. Turner* [1975] QB 834. Where a court decides to appoint an expert, it is by interlocutory proceedings.

When the court agrees to the appointment of experts, the parties may choose from a list of potential experts. The court will then exercise its discretion again and appoints one suitable to both parties. This is also done by interlocutory order, which delineates the matters that the expert is to comment on. The interlocutory nature of this appointment and the appointment itself are not open to appeal by the parties.

Upon acceptance of the appointment, the expert is required to carry out an impartial analysis of the evidence. Changes to the rules from 1 January 2002 allows for the hearing of noncourt appointed experts with agreement of the court. In order to maintain equality of arms where this is permitted, the other party may also call a nonappointed expert.

The interlocutory orders direct the expert to produce an opinion in writing and to prepare for further oral examination, if the court needs clarification on anything contained within the written report. Where an expert is required to supplement the report with oral testimony, the court registrar will make a written record of the testimony. Under these circumstances, the first report is treated as a draft, which the parties may accept, rebut, or ask for further and better particulars. The expert will then issue a final report to which the parties may respond.

Parties to proceedings may themselves ask for a preliminary expert report. This may be used to assist them in formulating their case. Since this takes place prior to the commencement of proceedings, the court has no discretion. However, the court may dismiss such a request for a preliminary report where it can be shown that to allow it would involve an abuse of process or waiver of rights.

Spain

In Spain, evidence of experts is categorized by regulation, which came into force on 8 January 2001, as opinion offered by a person with special scientific or other specialized knowledge, not commonly understood by laypersons. The expert's contribution to the trial process is advisory and is designed that the court may be helped to understand complex issues in order to evaluate their value as evidence or relevant facts.

Experts may be appointed by the judge or by the parties. In the case of party-appointed experts, they are referred to as *expert witnesses* (*testigos expertos*). Experts appointed by the judge are described as judicial experts (*perito judicial*). There are fundamental legal differences between the two types of expert; these affect the way they are nominated (*nombramiento*) in the first instance and the way they may participate (*participación*) in the proceedings.

Experts for the Parties

Both parties may instruct an appropriate expert with the special scientific or technical knowledge required to assist the judge in understanding the relevance of issues to the dispute. In Spain, as in many other jurisdictions, formal qualifications are not necessary to establish expertise; however, in many areas, it is likely that a lack of formal qualifications such as degrees in scientific subjects may reduce the credibility of any evidence given. Judges are more likely to give weight to an expert's evidence where they are in possession of formal qualifications. From the perspective of the parties, they may also need to consider

the experts' experience in evaluating complex scientific issues within the context of judicial evidence.

Experts may be discredited within the proceedings or disqualified where conflicts of interest are discovered. Either party may raise opposition to the expert called by the other where their participation would materially affect the neutrality required in the litigation process. If a party intends to object to the nomination of an expert, it must be done before the hearings of the preliminary directions. The objecting party has the burden to show evidence that the expert is unsuitable.

The expert will produce a report, which must be filed accompanying the preliminary documents. This will be the statement of case or statement in defense. Only exceptionally will it be permitted to file the expert report after the parties serve their respective documentation. In such cases, the party is required to inform the judge that it intends to adduce expert evidence after commencement of proceedings. This may be the case where an expert report is required following examination of the contents of the statement of case or statement of defense. There are time limitations on the introduction of evidence after commencement of the proceedings.

Where the judge has given leave to an expert witness, following a request in the preliminary documents, they may participate in the trial by answering questions of the parties in order to fully explain their opinions. In the alternative, they may simply give an opinion on one single issue or may be required to expand on their explanation. They may also expect to have their opinions subjected to criticism. The judge may also ask questions of the expert witness but may not require them to expand on the statements in their preliminary submissions. There is no legal direction on cross examination of expert witnesses but it will be allowed on request.

The expert's fees will be paid by the party losing the litigation and these form part of the judicial assessment of costs.

The Judicial Expert

The parties may request that the judge nominate an expert, which they must do in their preliminary submissions. If the judge consents, then this nomination should take place within five days of the request.

The parties are invited to agree on experts taken from available lists or they may even draw straws to settle the nomination. The experts are to be found on various lists of professionals, academics, and institutional experts. Unlike the parties' expert witnesses, judicial experts must possess a recognized academic degree or appropriate professional qualification demonstrating specialized knowledge in the area from which the opinion is sought. Inevitably, this results in the judicial expert having greater credibility than experts called by the parties.

Once appointed, the parties have no control over the expert and they are advised to be diligent in selecting an appropriate person from the lists. The expert will apply his own understanding of the frequently complex issues and is under no obligation to take instruction from the parties.

Judges may object to the nominations of an expert. They may also object where there is a conflict, such as a professional relationship between one party and the judicial expert. It is possible to object to the expert either at the preliminary nomination stage or during the trial. The judicial expert's participation in the trial constitutes the production of a written opinion within a period determined by the judge. It is often the cases that the report is not complete within the time frame, and cases often need relisting.

The judicial expert appears at the trial when requested by the parties. Another notable difference between this judicial expert and experts appointed by the parties is that the judicial expert may be requested by the judge to expand on his or her original report.

The cost of the judicial expert is usually borne by the losing party but the judges have discretion to vary this and, where no specific direction is made, it is borne equally by the parties.

Expert Witness: Who Is?

In adversary systems (*see* **Adversary Systems of Justice**), that is, jurisdictions that follow the Anglo-Saxon model (United Kingdom, Commonwealth countries, Canada, and the United States), an expert is a witness who possesses those qualifications that permits him to offer to the court not only observational information but also formulate opinions and draw conclusions on the basis of an examination of forensic data using knowledge 'beyond that of the average juror' (*see* **Expert Opinion: United States**). Thus, being an expert is not an occupational title, but rather a special category of witness in legal proceedings who is permitted to offer information to the court that ordinary fact witnesses are not permitted to express.

> ''The opinion expressed by an expert witness in any branch of technical science depends for its effect for on, inter alia, his qualifications, skill and experience in that science. If it appears to be based on sufficiency of research directed accurately and relevantly to a particular issue and to be so supported as to convince a court of its fundamental soundness and applicability to the particular issue, a court is entitled, although not obliged, to accept it even if unsupported by any corroborative expert opinion." (Davie v Magistrates of Edinburgh, 1953, SLT 54; 1953 SC 34.)

Qualifying the Witness Is the First Step

To be considered an expert authorized to offer opinion testimony to a judicial tribunal, the witness must first be examined as to his qualifications. This involves demonstrating that the witness possesses the special abilities to engage in the work pertinent to a relevant forensic discipline. The witness's abilities may have been obtained through formal and/or informal study, work-related experience, pursuit of continuing education programs designed to maintain and advance one's skill and knowledge, and the participation in professional societies (*see* **Federal Rule of Evidence 702**).

When a particular discipline or profession has specific academic or licensing requirements, possessing the necessary diplomas or degrees, in addition to the required certification if such is the norm, are all factors that the court will take into consideration in determining of the witness qualifies as an expert. Although many bodies have been created to enhance or endorse experts' professional qualifications, most courts will reserve to themselves the decision as to who or what will qualify as an expert or expertise (*see* **General Acceptance Test for Novel Expert Evidence**; ***Kumho Tire v. Carmichael***).

The Judge Decides When Witness Is Expert

When, after the preliminary qualifying process, the trial judge becomes convinced that a witness satisfies the legal requirements of skill and knowledge, the witness will be recognized as an expert. Whether a proffered witness is qualified is a legal decision for a judge to make. The judge has a great deal of discretion in making this decision and, on appeal, will not be reversed on the basis of a finding that a witness either was or was not qualified as an expert, unless a serious abuse of discretion is shown to have occurred.

Once a witness has been qualified to give expert testimony, his qualifications may still be challenged by the opposing litigant during cross-examination (*see* **Direct Examination of Experts**, **Cross-Examination of Experts**). The background and qualification of the witness affect his credibility. The believability of any witness, including that of an expert witness, remains an issue that the jury must determine. The jurors will indeed be instructed in the law to that effect (*see* **Jury Instructions on Expert Testimony**).

The extent of qualifications required for a particular specialty is highly dependent on those required for entry and advancement in each chosen forensic profession.[a]

Expert Witnesses: Selection and Investigation of Credentials

Introduction

Expert testimony is increasingly important to attorneys. The field of scientific interpretation of evidence and its portrayal in popular media has progressed to the point that expert testimony at trial is not only commonly accepted by judge and jury alike, but expected [1]. This article addresses the factors that influence the selection of an expert, including the importance of investigating the expert's credentials and making an informed assessment of the credibility and expertise that the expert's qualifications will project to a judge and jurors.

While this article is written from a US perspective, many of the issues discussed here are applicable to expert witness testimony worldwide. This article will not, however, address the legal standards for the admissibility of expert testimony [2], or attorneys' ethics in dealing with experts [3].

Selecting an Expert

Many variables should be considered in selecting an expert witness, including the expert's availability, cost, experience, and reputation. When an expert serves as a consultant or in the pretrial phases of litigation, the criteria for selecting that expert may be limited to the expert's competency in the field. As a trial witness, however, the expert's integrity, charisma, and overall effectiveness as a witness must also be considered.

Thus, consideration should be given not only to the expert's formal training but also to the expert's personality, demeanor, and capacity to organize, express, and interpret complex concepts for the jury. The weight accorded to the expert's opinion by the judge or jury will be determined in large part by the expert's perceived character, objectivity, and impartiality.

Of course, the quality of the expert's credentials remains an important factor to consider as well.

A thorough evaluation of an expert should take into account such matters as (i) the membership requirements of the associations to which the expert belongs; (ii) how the expert's credentials compare to those of the opposing expert; (iii) whether the journals in which the expert's articles appear are held in high regard in the field; and (iv) whether the conclusions in those articles were subject to peer review. Studies of jurors' perceptions of experts can be particularly helpful in guiding this evaluation.

Care should always be taken to verify the credentials of one's own expert, as well as those of an adversary's expert, for although it is unlikely that an expert has faked credentials, it is not unheard of. Indeed, experts have come under increased scrutiny in recent years for fabricating or inflating their qualifications.

Qualifications

The court must determine whether a proffered witness is qualified to testify as an expert, and that determination will not be overturned except in the case of an abuse of discretion [4].[a] Federal Rule of Evidence 702 states that a witness may qualify as an expert on the basis of knowledge, skill, training, experience, or education. An expert witness must possess only one of these traits for the judge to find the expert qualified to give an opinion. In making this evaluation, the judge may consider the expert's educational background, work experience, publications, awards, teaching, speaking, or other professional engagements, prior expert witness testimony, and membership in professional associations.

Often, the expert may have to educate the attorney proffering the expert regarding the significance of particular experience, achievements, and certifications to ensure that they are appropriately emphasized to the judge. An expert must be prepared to explain board certification and licensure requirements to the judge in detail.

Experience as an Expert Witness

Experience and training are often more significant than academic background and are accorded more weight by jurors, according to a jury study evaluating fingerprint experts [5]. However, experience as an expert witness, by itself, does not qualify someone as an expert in later cases. For example, in *Bogosian v. Mercedes-Benz of North America Inc.* [6], the court rejected the opinion of a witness who had testified as an expert 126 times. Another court noted that, "it would be absurd to conclude that one can become an expert by accumulating experience in testifying" [7]. Conversely, a lack of previous experience as an expert witness does not disqualify one from testifying as an expert [8].

Education and Training

An expert may be qualified on the basis of academic credentials, including the expert's undergraduate, graduate, and postgraduate work. An expert's academic credentials should only be issued by accredited educational institutions and programs [9], because the proliferation of the Internet, while laudable for so many reasons, has also rekindled the old-fashioned diploma mill. One such business, Deplomas 4U, once provided bachelors, masters, MBA, or PhD degrees in its customers' field of choice; advertisements assured that no one would be turned down and that there would be no bothersome tests, classes, books, or interviews.

An expert should continuously perform research and publish in the expert's field, preferably in peer-reviewed publications. Teaching experience is another of the qualifications that judges will evaluate: all forms of teaching – regular, speciality, guest lecturing, visiting professorships, continuing education, and short courses – weigh in as credentials. An expert should also keep up to date with developments in his or her field of expertise by reading the current literature, enrolling in continuing education seminars, joining professional societies, and attending professional meetings.

Membership in Professional Associations

A study published by the US Department of Justice in 1987 found that jurors perceived those fingerprint experts who belonged to professional associations to be more credible than other experts, and presumed experts would belong to such groups.[a] It is therefore important for an expert to remain active and participate in professional societies; the expert's credibility is diminished if the expert has not recently attended a professional meeting. Professional associations that only require annual dues payment to become a member are not as prestigious as associations that are

joined by special invitation only, by approval of special referees, or by passing an examination.

Thus, an expert should be selective about which professional associations to join. The *Wall Street Journal* once noted that the American College of Forensic Examiners (ACFE), for example, had "mail-order" credentialing, for which applicants needed to pay a fee and pass an ethics exam; there were no examinations for board certifications in various specialties during ACFE's "waiver of examination" periods – all one needed to do was verify possession of 200 "experience points" and send in a fee [10].

A 2001 *New York Times* article discussed the case of a doctor who was board-certified in forensic medicine by the ACFE's sister organization, the American Board of Forensic Medicine (ABFM), while serving time in prison for the manslaughter of his wife [11]. In his application, he stated that he had never been convicted of a felony and that he was on sabbatical from his job. The business address he provided was that of a state prison. After learning of the doctor's conviction from the *Times* reporter, the ABFM stated that it would strip the doctor of his membership.

One expert, Dr. Steve K. D. Eichel, exposed the ease with which some organizations grant questionable credentials by obtaining board certification by the American Psychotherapy Association for his cat Zoe [12]. Despite the fact that Dr. Eichel planted numerous hints about Zoe's true identity in the curriculum vitae he sent to credentialing bodies, Zoe's tale was not publicly exposed until a reporter requested an interview with Dr. Zoe D. Katze regarding an article on hypnosis: "Dr. Katze" was listed on the American Association of Professional Hypnotherapists' website.

Increased Scrutiny of Experts

Experts have come under increased scrutiny for either fabricating or inflating their qualifications. For instance, in *State v. Ruybal* [13], the state's expert – an FBI agent who specialized in forensic serology – stated that he held a master's degree in biology when in fact he held only a bachelor's degree. Upon further examination, it was discovered that the expert had falsified other reports and lied under oath concerning tests in another case.

In Florida, in 1998, a person who had been testifying as an expert in toxicology for three years for both the prosecution and defense in criminal cases was prosecuted for perjury for testifying with fraudulent credentials [14]. The expert claimed to possess masters and doctorate degrees from Florida Atlantic University, but when a prosecutor sought to confirm the claims, he discovered that the registrar's office had no record of the expert attending or receiving a degree from the university. In fact, the university did not even offer a PhD in the program from which the expert claimed to graduate. The expert had also distributed a copy of his purported master's degree dated 1971 and signed by "Lawton Chiles, Governor" Unfortunately, Chiles was a US Senator in 1971, and did not serve as Florida's governor until 1991. The "expert" eventually pled guilty to three counts of second-degree perjury (one count for each first-degree murder case in which the expert testified as a defense witness), and received a three-year prison sentence.

In addition to perjury prosecutions for false qualifications, some jurisdictions also prosecute for academic fraud. For example, in Florida, a person who misrepresents association with, or academic standing at, a postsecondary educational institution is guilty of a first-degree misdemeanor [15].

In another case, a Harvard medical professor was sued for trademark infringement for falsely claiming to be board-certified by the American Board of Psychiatry and Neurology (ABPN) in five trials [16]. The board sought to seize the expert's witness fees and treble damages, but the court denied that relief because it believed the expert was unlikely to infringe in the future.

In *In re Vioxx Products* [17], the court granted the plaintiff a new trial in her product liability action when it was discovered that the pharmaceutical company's cardiology expert had misrepresented his credentials by testifying that he was board certified in internal medicine and cardiovascular disease when in fact those certifications had expired.

Courts have also overturned convictions where the experts testified outside their field of expertise. For example, in *Gilliam v. State* [18], the court held that the medical examiner was not qualified as an expert in shoe-pattern analysis; therefore, it was error for the trial court to allow her to testify that the defendant's sneaker left marks on the decedent's body.

There is evidence to suggest that, since the US Supreme Court's decisions in *Daubert* [19], and *Kuhmo Tire Co.* [20], courts have been more willing

to exclude expert testimony. The Federal Judicial Center compared a 1998 survey of 303 federal judges with a 1991 survey [21]. In 1998, 41% of the judges claimed to have excluded expert testimony, whereas only 25% of the judges did so in 1991. A 2001 RAND study similarly concluded that judges were becoming more vigilant gatekeepers; for example, in the US Third Circuit Court of Appeals, the exclusion rate in products liability cases rose from 53 to 70% [22]. This contradicts most of the reported case law following *Daubert*, which seems to indicate that the exclusion of expert testimony remains the exception, not the rule [23].

Weight of the Evidence

Once a judge decides that an expert may testify, the jury must then decide the weight to accord the expert's opinion. Expert witnesses and attorneys should be aware of the studies regarding jurors' perceptions of expert witnesses, which have shown that jurors give great weight to expert testimony, and reveal jurors' evaluations of the experts' qualifications, appearance, demeanor, and communication skills.

In 1978, Rich Tanton published a study in the *Journal of Forensic Sciences* in which he found that jurors held stereotypical views of experts [24]. For example, the male expert was expected to be 44 years old, upper-middle class, white, neat, intelligent, wearing a dark suit, and glasses, professional, calm, and serious; the female expert was expected to be white, 37 years old, dressed conservatively, neat, pleasant, and honest.

In 1984, Saks and Wissler conducted a telephone survey of potential jurors [25], in which respondents were asked the following: (i) whether they would believe testimony from the experts; (ii) whether they perceive the testimony to be honest; and (iii) whether they perceive the witnesses from different fields to have adequate experience to testify. The study concluded that physicians, chemists, and firearms experts ranked the highest in believability, honesty, and experience. Next-highest ranked were accountants, psychiatrists, psychologists, and eyewitnesses. Lowest-ranked were police officers, handwriting experts, and polygraph examiners.

Dr. Joseph Peterson conducted three studies on forensic evidence and the courts from 1984 to 1987. His studies concluded that jurors accorded great weight to expert testimony and found that in criminal cases in which expert witnesses testified for the prosecution, jurors were more likely to render guilty verdicts [26–28].

In 1992, the *National Law Journal* conducted a survey of jurors and their views of the jury system, and concluded that jurors were influenced by expert witnesses and accorded their opinions great weight [29]. In the civil and criminal cases surveyed, 89% of the jurors thought the experts were believable, and 71% said the experts' testimony made a difference in their verdict.

A 1994 study of preconceived notions of experts consisted of an extensive survey of American lawyers, judges, jurors, and expert witnesses [30]. It revealed that the characteristics of experts that were most important to jurors in determining the experts' credibility were (i) the expert's willingness to draw firm conclusions and (ii) the expert's ability to convey technical information in plain language that a layperson could understand.

Another study concluded that an expert's believability is linked to the expert's qualifications, familiarity with the facts of the case, good reasoning, and perceived impartiality [31]. Jurors were also influenced by independent research that corresponded with the expert's opinion.

A 1997 study of jurors' perceptions of expert witnesses in death penalty cases by Scott F. Sundby found that defenses based solely on expert testimony are likely to fail, but defenses that integrate expert testimony with persuasive lay testimony are more likely to prevail [32].

A 1998 *National Law Journal*/DecisionQuest Study exposed jurors as a more skeptical, cynical group [33]. Among the findings, the study concluded that 50% of those surveyed thought that expert witnesses say only what they are paid to say; 33% did not believe police testimony; and 75% said they would set aside what a judge says the law requires and reach a verdict the jurors felt was right.

A 2001 study demonstrated that mock jurors almost always sided with court-appointed experts except when the experts' opinion favored corporate defendants [34].

A 2007 study concluded that using expert testimony to counter the prosecution's expert in criminal cases caused jurors to be skeptical of all expert testimony, rather than simply sensitizing them to flaws in the prosecution expert's testimony [35]. In fact,

jurors rendered more guilty verdicts when they heard defense expert testimony than when they did not. This study throws into question the Supreme Court's assumption in *Daubert* that opposing expert testimony effectively safeguards against "junk" science in the courtroom.

Increasing awareness of errant experts and exonerations of the wrongly accused has influenced how jurors perceive scientific evidence. For example, background beliefs about the possibility of laboratory errors and intentional tampering affect the weight jurors afford a DNA report [36], and jurors with such beliefs gave probability estimates less weight. A separate poll regarding forensic fraud and its impact on potential jurors found that 32% think wrongful convictions happen frequently; 23% said that wrongful convictions are rarely an accident [37].

Today, 40% of the US jury pool consists of "Generation X" and "Generation Y" jurors. GenXers were born between 1966 and 1981; Generation Y members, or "Millennials" as they are sometimes known, were born after 1981.

In order to communicate most effectively with these generations of jurors, it is important to understand defining experiences that have influenced their lives. GenXers grew up with the television as a babysitter, no institutional stability, high divorce rates, gangs, and the specter of acquired immunodeficiency syndrome (AIDS). They grew up fending for themselves and therefore tend to be cautious, skeptical, and practical; they do not readily trust institutions and show little deference to authority. Generation X is also the first generation to grow up computer-literate; therefore, GenXers are media-and technology-savvy and expect to be entertained in the courtroom [38].

Millennials were also raised with cable television, high-speed internet, and increasingly elaborate and complex video games, and consider such phenomena as mobile phones, instant text messaging, and the 24-hour news cycle as natural parts of everyday life [39]. As a result, they expect "all information available all the time in a constant and instant stream," yet have increasingly short attention spans [40]. Millennials are accustomed to getting their information visually, graphically, and in 10–30s sound bites. Unlike GenXers, Millennials tended to grow up in an over-scheduled, heavily structured environment with "helicopter" parents who hovered about, guiding and supervising the Millennials' social and educational development. As a result, Millennials tend to be less independent than their GenX counterparts, and expect more personalized attention.

Experts must understand that effective communication with these jurors requires organized content, and the effective use of visual presentation techniques including, whenever possible, demonstrative exhibits that incorporate large, user-friendly data presentation monitors and systems for use both by the court and individual jurors, as well as interactive electronic timelines and e-documents that allow jurors to feel they are in control of and have access to all information regarding the facts of the trial. Data also suggests that when testifying to these jurors, experts should attempt to associate themselves with a more collaborative, personalized role such as a teacher, rather than a more hierarchal and impersonal profession such as a scientist [41].

National Law Journal/DecisionQuest juror outlook surveys confirm these conclusions distinguishing jurors from Generations X and Y from past generations [42]. For example, while 64% of jurors overall believe the police tell the truth when they testify, only 51% of jurors aged 18–24 years old share that belief. 60% overall and 72% of those aged 18–25 viewed presentations using videos, simulations, and computers positively.

Conclusion

Expert testimony will continue to play an important role in the future. Expert witnesses have been facing increased scrutiny in the US and worldwide. For more effective expert testimony, lawyers and experts must be aware of the factors that the courts will evaluate in order to determine whether an expert is qualified or not, as well as jurors' changing perceptions of experts.

Explosions: Scene Investigation

Improvised Explosive Devices

Improvised explosive devices (IEDs) or "homemade" bombs have been thrust upon the world stage of international terrorism and brought into our homes through daily newscasts.

An IED is essentially a combination of components not originally designed to be combined with each other; some explosives and some not, which when combined, form an improvised device that has a capability of violently exploding. In its simplest form, an IED consists of a main charge explosive and a fusing or initiation system that provides the stimulus to cause the explosive to detonate. Some IEDs have a few components while the others have many. As such, the number and type of components fabricated into an IED are generally dependant upon a number of factors. The first is how and where the device is to be used. It may have a timing mechanism built into the initiation system to afford a time-delayed initiation of the explosive. Examples of timing-mechanism components found after a bombing are shown in Figures 1 and 2. Usually the builder "hides" this type of device to prevent its discovery prior to explosion. There are several additional factors that affect the construction of an IED, including the following:

- the ingenuity of the builder;
- the skill of the builder;
- access to nonexplosive components; and
- access to explosives.

Although usually extensively fragmented, most of the components, other than the actual explosives, at least partially survive the explosion of the IED. This very basic point of component survivability is not apparent when the bomb explodes and most people incorrectly believe that nothing can or does survive. However, it is a fact that bomb components do survive an explosion and the recovery of those fragmented components constitutes the processes commonly referred to as *Bombing Crime Scene* or *Postblast Investigation*. Figures 3 and 4 show the postblast remains of two pipe bombs: one that was held together with threaded caps and the other held together by welded metal plates. Figure 5 depicts the fragmented remains of electrical detonators recovered following their use to initiate high explosives.

Bomb scene investigation involves a series of challenges to the investigator, which require not only basic crime scene investigation skills but also knowledge in a number of specialized disciplines. These disciplines include the following:

- explosion dynamics;
- identification features of main charge explosives and the accessories used to initiate them (detonators, detonation cord, safety fuse, shock tube, etc.);
- pre- and postblast identification features of nonexplosive components used to fabricate the IED;
- understanding of the capabilities of the laboratory with regard to the types of examinations that can

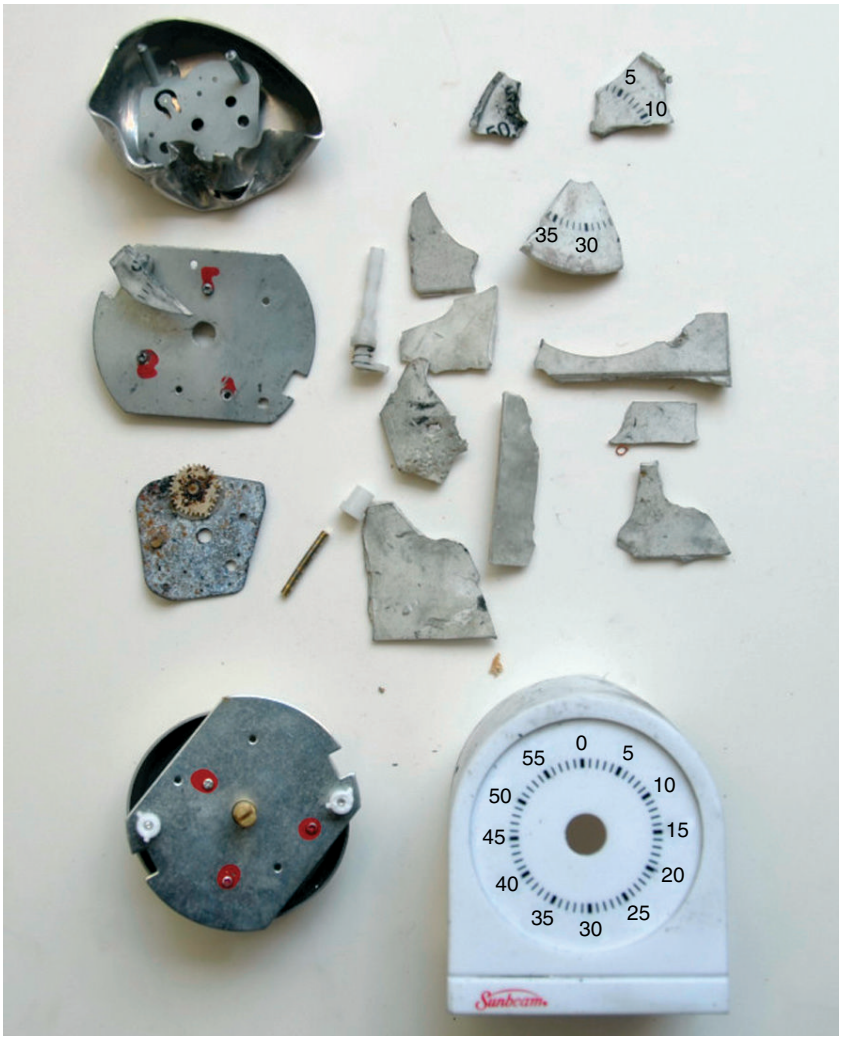

Figure 1 Fragments of a mechanical timing device compared with undamaged components

be conducted on the debris collected from the blast scene (*see* **Explosion Debris: Laboratory Analysis of**); and

- understanding and the identification of features associated with military explosive ordnance.

Additionally, the postblast investigator should be aware of the types of and the indicators of weapons of mass destruction (WMD), specifically, chemical, biological, and nuclear materials. This is especially important in understanding that the explosion of an IED may be a precursor to the delivery of WMD material.

The investigation into a reported explosion involves two stages: the scene investigation and the field investigation. The scene investigation involves site documentation and collection of postblast debris and components. The field investigation is that part of the investigation that is separate from the actual scene.

Scene Investigation

The following investigative steps are used to determine whether an explosion scene actually exists and

Figure 2 Remains of a mechanical clock used as a timing device, found after a bomb blast

Figure 3 Pipe bomb fragments. This bomb was constructed with a pipe nipple and two threaded end caps to form an enclosure for the explosive

then, the identification, collection, and documentation of bomb components:

- initial response;
- evaluation of the explosion scene;
- entering the scene;
- documentation of the scene;
- where to find evidence;
- how to find evidence;
- final survey; and
- release of scene [1].

The initial response to a reported incident may or may not include a postblast investigator or a bomb

Figure 4 Pipe bomb fragments. This pipe bomb was constructed with a pipe nipple and two welded end plates that formed an enclosure for the explosive

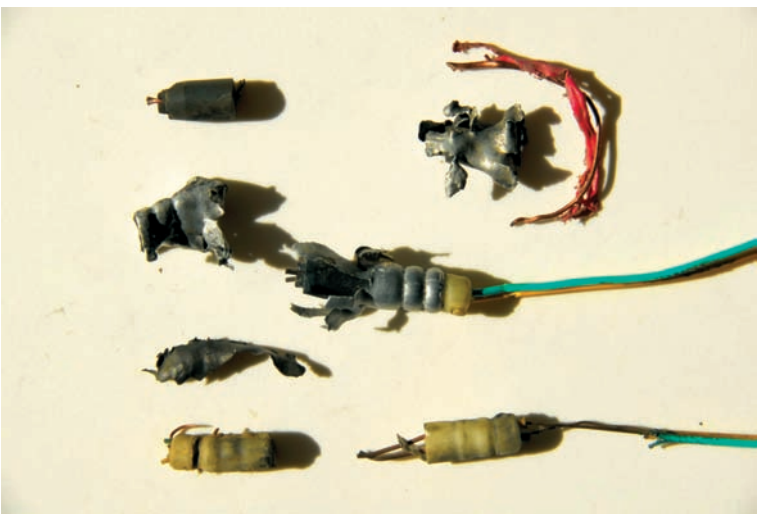

Figure 5 Fragmented remains of electrical detonators recovered following their use to initiate high explosives

technician, but it certainly includes the response by a uniformed police officer. The first responding officer evaluates whether an explosion has occurred and the degree of additional resources (additional police, fire fighters, and/or medical support) required. Should there be indications of an explosion, it is not the duty of the first responding officer to make a cause determination of the explosion, only that the scene "appears" to be from the result of an explosion. The actual cause determination is made later by the postblast investigator, which may be in conjunction with a bomb technician. It is the responsibility of the first responders, regardless of the cause of the explosion, to immediately assess the safety of the scene, establish exclusion perimeters around the scene, remove personnel from the scene, and assist medical support personnel in the removal and care of the injured.

The safety assessment should include an evaluation of the following list of possible explosion scene hazards:

- blood-borne pathogens;
- metal-glass debris;
- fire;
- structural integrity;
- utilities, especially electrical;
- hazardous materials; and
- secondary explosive devices, if the incident was caused by a bomb.

The evaluation of the explosion scene is conducted by an investigator knowledgeable to make the determination of whether the explosion was caused by the *detonation* of an explosive (a chemical compound or mixture of chemicals designed to explode), the detonation or *deflagration* of a diffuse fuel explosion consistent with air explosion involving a gas (e.g., natural gas or propane) or vapors from pooled flammable liquids or dusts, or some other source. Detonations are explosions in which the combustion zone propagates at a rate in excess of the speed of sound, while a deflagration's combustion zone propagates at a rate less than the speed of sound [2]. Mechanical explosions, such as those caused by ruptures of boilers or other pressure vessels, are usually not difficult to recognize. The following is a list of characteristics that an investigator may use to help distinguish between an event caused by an explosive material and an event involving the deflagration or detonation of a diffuse fuel Table 1.

The evaluation of the scene that is formed by the explosion of an IED requires additional steps to ensure that the scene is safely secured and that potential evidence is protected until it can be collected. These steps include locating the seat of the explosion or crater, and from that conclusion the demarcation of more specific inner and outer perimeters. Once this is accomplished, an evidence collection command post should be established. The person in charge of the evidence command post should document all personnel entering and leaving the scene, establish evidence documentation procedures, determine the level of investigative assistance required to locate the evidence, and obtain the legal authority required to search and collect evidence. This involves determining whether a consent to search is sufficient or a search warrant is required. Additionally, at this time, the principal scene investigator assembles the post-blast investigative team that has the responsibility of locating and securing the bomb remains.

Table 1 Investigative Characteristics of Explosion Scenes

Explosive material	Gas, vapor, or dust [3]
Crater	No crater
Localized damage	Entire walls blown out
Defined epicenter	No epicenter
Presence of bomb components	No bomb components
Explosives or residues present	No explosives present
No gas, vapor, or dust fuels on site	Gas, vapor, or dust fuel on site
Location of incident	Location of incident
Witness statements	Witness statements

The number of team members depends on the size and complexity of the scene, but can be from as few as one to dozens of investigators. Their team members play the following roles [4]:

- team leader;
- bomb disposal technician;
- photographer and assistant;
- evidence recovery personnel (searchers);
- evidence custodian;
- sketch artist; and
- specialists (e.g., chemist and structural engineer).

Additionally, the types of evidence collection equipment and supplies vary depending on the complexity of the scene. At a minimum, the team requires various types of containers (plastic and nylon bags of many sizes, metal cans), paper, writing instruments for evidence documentation, evidence labels, rulers and measuring tapes, hand tools, sifting screens, and residue collections kits.

Prior to the actual investigation of the bombing scene, it should be clearly understood by all involved that the investigative process has at least three main goals. First, to establish a legal basis that an explosion of malicious intent occurred. Second, to investigate the scene to recover IED components. And third, to link a subject with the bomb scene and/or the fabrication of the bomb. All three tasks

must be accomplished in a manner that is of sufficient integrity and credibility that the evidence developed is acceptable in a court of law.

Establishing malicious intent is not a trivial exercise in many cases. While it is always necessary to eliminate the possibility of an accidental explosion, scenes like the one shown in Figure 6, where a government building was destroyed by an exterior blast, leave little doubt about the malice of the bomber. Establishing the cause of aircraft explosions (particularly those that explode over water) is far more difficult. TWA flight 800 is an example of an explosion determined to have been caused by the ignition of jet fuel in the center fuel tank by what is believed to have been an electrical spark from deteriorated wiring. (There are still some skeptics.) The evidence that proved Pan American Flight 103 was the victim of a malicious act was postblast components, including a tiny fragment of a circuit board from the electronic timer, shown in Figure 7. It was possible to trace the source of the timer and determine that the timer was custom manufactured for Libya.

Upon entering the scene to conduct the investigation and collection of evidence, one of the first responsibilities is to begin the process of documenting the explosion scene. The documentation involves three separate forms that are used to supplement and not replace one over the other. These are as follows:

- written notes and logs;
- sketches and diagrams; and
- photographs [5].

Figure 6 The Alfred P. Murrah Federal Building destroyed by American terrorists Timothy McVeigh and Terry Nichols on April 19, 1995

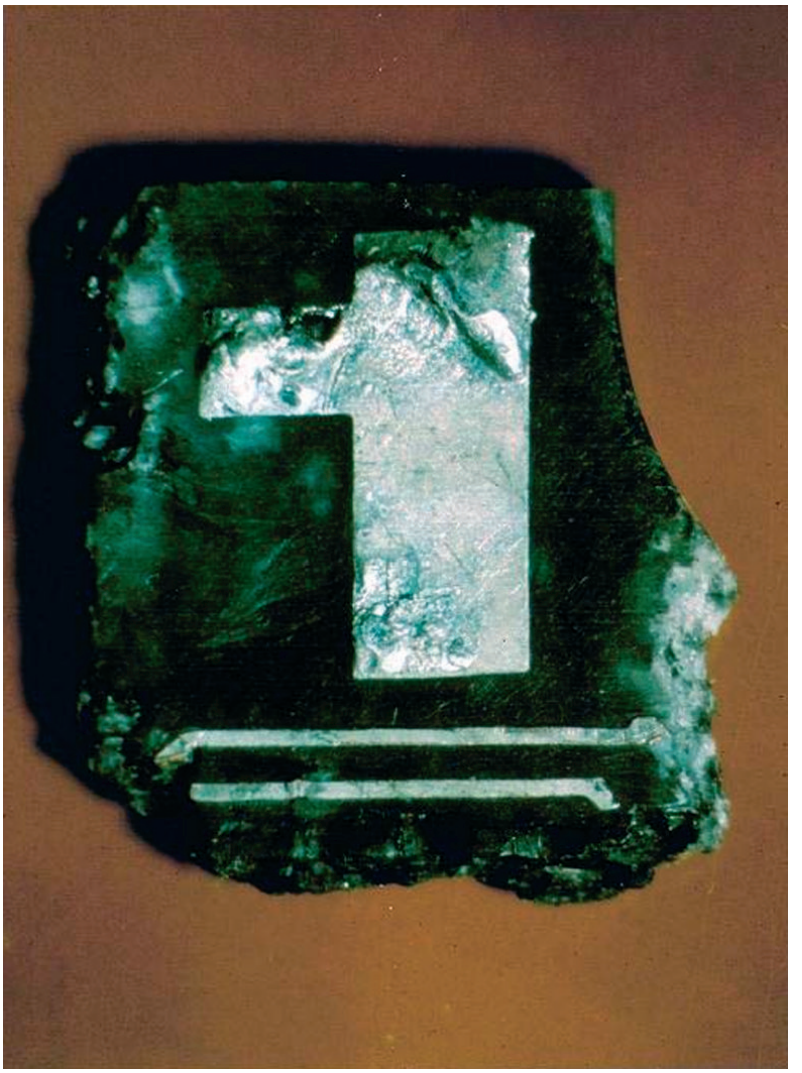

Figure 7 Small section of a circuit board that was part of the MST 13 electronic timer for the bomb that destroyed Pan American Flight 103 over Lockerbie, Scotland on December 21, 1988

These types of documentation provide a written and visual record of all the actions and conclusions of the investigative team, a systematic depiction of the scene, and the inventory and collection of evidence. Additionally, the investigators continually monitor the scene for any previously unidentified hazards, reevaluate the scene perimeters to determine whether they are appropriate and begin their efforts to locate evidence.

Once inside the scene, the investigative team needs to determine where to search for evidence. There are three general areas that contain evidence from the explosion. These are [6] as follows:

- the target of the bomb;
- victims of the bombing; and
- areas outside of the immediate target.

Obviously, the target of the bombing is the area that was impacted by the blast of the explosion. Depending on the quantity and type of explosive used, the target can be small (such as a postal

box) or quite large such as an office building. Within the target, evidence can usually be found in the crater or epicenter of the explosion and in the area and materials immediately surrounding the crater. Depending on where the explosion took place, the materials around the crater may be household furniture, vehicle components, building materials, and earthen materials. These materials are referred to as *witness materials*. The bodies of bombing victims, particularly those that were close to the blast, are excellent receptors of bomb debris. As such, all victims should be examined for the presence of bomb components, both construction components and explosive residues. The third area of search should be outside of the epicenter of the explosion. The areas usually are the places where bomb components have been projected away from the immediate scene along flight paths that can be identified by careful examination of the scene with an understanding of explosion dynamics.

Once a determination has been made regarding where to look for evidence of the bombing, the investigators need to determine how they search for evidence. The physical search for evidence can involve four types of organized methods. These are as follows [7]:

- explosive residue swabbing;
- organized search;
- sifting; and
- vacuuming.

Swabbing is a systematic collection procedure used to collect organic and inorganic residues of explosives resulting from the explosion of the main charge explosive. It is best used on nonporous items too large to be taken to the laboratory. The swabs are taken at the scene, entered into evidence, and then shipped to the laboratory with the other items of evidence recovered from the scene.

The organized search typically employs one of three types of search patterns: grid, line (or strip), and the spiral search. These patterns can be used independently or in conjunction with each other and involve the visual search of a given area for bomb debris. Of these patterns, the grid offers the most reliable method for locating evidence.

Evidence screening or sifting involves the separation of evidence from background materials by the use of a set of screens. These screens, much like those used on archaeological sites, have been found to be very useful when searching for evidence among soil, sand, or finally divided materials.

The last method is vacuuming that is used on porous surfaces too large to send to the laboratory for examination. This method can not only recover explosive residues but also minute bomb components that may be embedded in carpets, floors, and bomb fabrication workbenches. Vacuuming should be conducted after the bomb scene has been cleared of the larger debris and items of evidence; therefore, it should be the final search conducted.

Once evidence has been located, it needs to be collected and packaged in order to afford sufficient protection for it to be transported to the laboratory or used in any subsequent use in legal proceedings. The usual means is by "bagging and tagging". This operation provides a seamless chain of custody for each item recovered at the scene until final disposition. The "bagging" refers to the placement of the evidence into the appropriate type of container that protects it from being contaminated, altered, or lost. "Tagging" is the process of marking each evidence container with the required information that identifies where the evidence was found, by whom, the date it was found, and an inventory of the container by a numerical description that, in turn, corresponds to the evidence log. Guidance on the appropriate means of labeling evidence may be found in ASTM E1459, *Guide for Physical Evidence Labeling and Related Documentation* [8] and the Federal Bureau of Investigation, *Handbook of Forensic Services* [9].

The following is a listing of the types of evidence that may be found at the bomb scene and the type of container that is recommended for its collection Table 2:

Following the collection of the evidence and scene documentation, a *final survey* should be conducted prior to leaving the scene. The final survey is a review of all aspects of the scene investigation to ensure that the objectives of the investigative team have been met, and that all identifiable evidence has been collected, packaged, marked, inventoried, and entered into the evidence log. One of the last acts of scene documentation should be to depict the postinspection appearance through photography. This provides a visual record regarding the appearance of the scene after the scene investigation, should any questions arise as to the appropriateness of the

Table 2 Recommended Evidence Collection Containers

Type of evidence	Type of container
Components not requiring residue testing	Polyethylene zip-top bag
Materials requiring residue testing	Nylon zip-top or heat sealed bag
Material requiring residue testing	Metal can or glass container
Liquids, unconsumed explosives	Metal can or glass container
Unconsumed low explosives	Antistatic polyethylene bag
Dried clothing or cloth containing blood	Paper or Tyvek® bag

collection process and what the investigators did or did not do at the scene [10].

Finally, the team leader releases the scene to an authorized entity, if available, such as the property owner or public health official. In many instances, this may not be possible because of the victim's injuries or death. In the case where no actual person is available to take "custody", all reasonable efforts should be made to secure the scene prior to departure.

Following the completion of the scene investigation, the next phase of the postblast investigation process begins, the field investigation. The field investigation endeavors to establish a link between the person(s) responsible for the bombing and the evidence recovered from the bomb scene by establishing who had the motive, opportunity, and the means to commit the bombing.

To provide answers to these questions, various lines of investigation need to be considered. Depending on the circumstances of the bombing incident, these include detailed interviews of personnel associated with the following:

1. the neighborhood of the bombing for witnesses who may have observed suspicious activity prior to the bombing;
2. medical treatment facilities for the recovery of evidence from victims;
3. the first responders for what they saw upon arrival at the bomb scene and what the victims may have told them;
4. victim – subject associates and relatives for information that would lead to establishing an actual subject; and
5. review of logical sources of the components of the bomb in attempts to associate the bomb builder with the purchase of the components used to construct the IED. Retail outlets where bomb components are often purchased include hardware or home improvement stores, electrical supply houses, hobby shops, sporting goods stores, distributors of low and high explosives, farm supply stores, drug stores, mail order, and internet suppliers of componentry [11].

In conclusion, it is the responsibility of the postblast investigator and the investigative team to conduct as thorough and imaginative scene investigation as possible to determine and document the actual cause of the explosion and, if it is determined to have been the result of a criminal act, to assist the search for the person(s) responsible by locating, collecting, and securing the physical evidence.

JAMES T. THURMAN

Explosion Debris: Laboratory Analysis of

Introduction

In the United Kingdom, the United States, and most other countries, very strict regulations apply to the possession, storage, and handling of explosives. Apart from the stringent legal requirements for appropriate licenses for handling explosives, safety dictates that examination of explosives items should only be undertaken in properly equipped facilities by trained personnel.

Explosions, like dogs, are things that we all think we can recognize even if we find it hard to give a precise definition. Most people's perception of an explosion is formed from seeing special effects in cinema films and television programs. This has serious deficiencies. Typically, an explosion is characterized by a violent and exceedingly rapid release of energy, often accompanied by a bright flash of light. Nearby objects may be destroyed, damaged, or moved. For the forensic investigator presented with evidence from the scene of an event, the following questions need to be addressed:

- Does the evidence from the scene show that an explosion took place?
- If it was an explosion, what sort?
- Dispersed or condensed phase?
- Detonation or deflagration?
- Was it a deliberate act (a crime) or an accident?
- Does the evidence link to a suspect?

In addition, will be the following questions:

- What was the material of the bomb?
- How large was it?

At the Scene

If evidence collection is bungled at the scene, nothing done at the laboratory can fix it. Moreover, expert viewing of the scene can often establish whether, in fact, it was an explosion and indicate the order of magnitude and the general type of explosion, i.e., detonation or deflagration. Such observations can often enable subsequent laboratory examinations to be more efficiently and effectively focused. Ideally, the scientist would attend every scene. However, in many circumstances this is impractical or superfluous. If the scientist cannot attend the scene, if at all possible, a comprehensive account of the scene and circumstances, including, not merely descriptive text, but plans and photographs, should be provided.

Different approaches to investigate the scene of an explosion may be adopted depending on the local circumstances. For example, if an explosion scene is remote from the laboratory, it may be necessary to undertake more of the sifting and searching of potential evidential material at the scene. In the extreme, it may be necessary to deploy portable laboratory facilities. In more favorable circumstances, it may be practicable to undertake only limited searching of material at the scene, transporting potentially interesting material back to the laboratory for detailed forensic examination under controlled conditions. Investigation of the Bali bombing in 2002 is a good example of the dilemma faced by the forensic units. Teams were deployed from a number of nations, including Australia, the United Kingdom, and the United States. The Australians set up a clean room in a local hotel for on-site analysis and at the same time split samples in three ways for on-site analysis and analyses at the forensic laboratories in Australia and the United Kingdom.

Given the large quantities of debris that may contain material of potential evidential significance at the scene of an explosion, the investigation can be expedited by a degree of screening at the scene. A number of instruments have been designed for field use. Examples, as of 2008, are the hand-held ion mobility spectrometers (IMSs), e.g., Smiths, GE, Implant Science, or hand-held detectors based on other technologies, e.g., Nomadics Fido, Scintrex EVD-3500, Fido PaxPoint, Smith Travel IR, and Ahura Raman [1]. There are also colorimetric tests, which are acceptable presumptive tests, but destructive in nature, which can preclude subsequent confirmation in the laboratory. The use of field instrumentation at the scene may introduce difficult issues of calibration, maintenance, reliability, and quality assurance. Field conditions make the control of contamination and cross-contamination particularly challenging. It is essential that properly documented logs be kept to demonstrate the controls, which have been applied at the scene and ensure the subsequent integrity of evidence. Field analyses, in general, lack selectivity and are prone to contamination; thus, results should always be

checked under the rigorous conditions of the accredited laboratory. Unfortunately, analysis of a sample in the field often precludes further laboratory examination since the sample has effectively been destroyed. The risk that dirt may mask explosive traces in the absence of a laboratory cleanup treatment should not be overlooked when reviewing the results of field analyses; false negatives can occur in such circumstances. Another factor that needs to be considered is that there are often a number of social and economic pressures to return a bomb scene back to normal as quickly as possible. Although the recovery of evidence should not be compromised by these pressures, the possible benefits of using field instrumentation at the scene need to be carefully weighed up against the possible disadvantages, including time and resource implications.

The material of potential evidential value at an explosion scene can amount to a substantial quantity, sometimes measured in tons from large explosions. Dealing with such situations efficiently demands a well-designed and well-planned system. The scene investigator should have available large nylon and plastic bags and sheeting capable of safely containing large items, e.g., door and window frames, light fixtures, street furniture, ducting, and even automobiles. In addition, he needs collection containers for small items and a kit for swabbing immovable objects. The investigator should also be equipped with a supply of dustpans and brooms and a vacuum cleaner with replaceable filters and bags. Items, which obviously contain biological materials, such as blood-stained clothing, should be packaged separately with appropriate warning labels.

The items used to collect and package evidence must be verified as explosive-free prior to use. This may be achieved either by quality assurance before use or by the examination of unused control samples in parallel with the relevant evidential items. In the case of swabs, this may involve prior preparation and analysis at a forensic laboratory. For plastic packaging materials, dustpans, and brooms, this may involve use of new materials at every scene. Packaging and transport of evidential material is an important issue; without preplanning inappropriate makeshift containers such as unused garbage bins are likely to be used. Unfortunately, such containers once filled are too heavy and unwieldy for convenient handling. In the United Kingdom, a system has been developed using a standardized type of rectangular plastic box holding about 351 of debris and having a lid that can be sealed with an evidence tag. Many thousands of such debris collection boxes are deposited at strategic locations around the country ready for use by police officers charged with management of bomb scenes. Once filled the boxes are returned to the laboratory for examination. The potential evidential material should be divided into separate streams before it is sent to the laboratory. The basic division depends on the type of laboratory examinations expected. Swabs and objects for trace analysis require special packaging to prevent contamination, while items for physical examination only or bulk material to be searched for bomb fragments require only basic packaging to preserve evidential integrity and chain-of-custody. Given that it is not always readily apparent which items have the best potential for the recovery of explosives traces, it is wise to err on the side of caution in choosing the type of packaging to be employed.

A general misconception is that everything in the immediate vicinity of an explosion is completely destroyed. This is incorrect. Explosions shatter and scatter. The size of the fragments and the degree of dispersion depends on the nature of the items being fragmented and also on the proximity, size, and violence of the explosion. Thus, big powerful explosions tend to produce smaller fragments; and conversely, small weak explosions tend to leave larger fragments at or near the center (seat) of the explosion. Depending on the bomb design and explosive train, explosive material is spalled (thrown) from the outer surface of the bomb and projected clear of the high pressure, high temperature zone at the explosion seat [2–4]. In a well-built explosive device, it is only the spalled explosive material that is likely to survive detonation. Fortunately, most improvised explosive devices (IEDs) are far from ideal in either design or construction. Consequently, it is not uncommon to find visible explosive residue. This is especially true in the cases where a low explosive, e.g., black powder, smokeless powder, or a pyrotechnic has been employed.

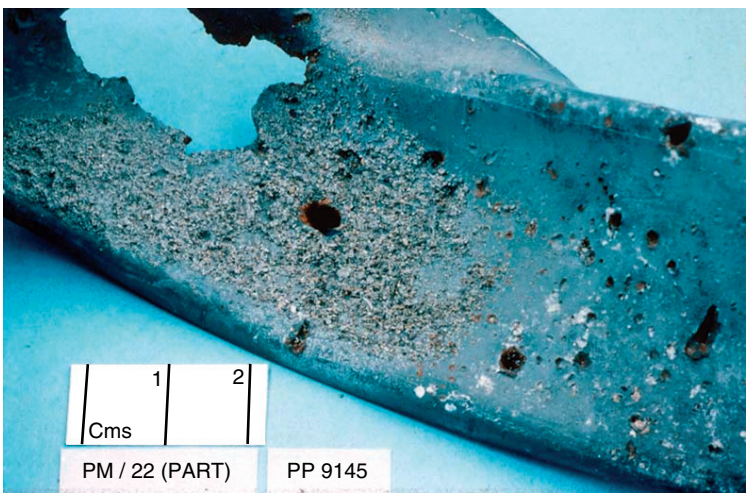
The first step of the explosion scene investigator is to locate the seat of the explosion, i.e., the place where the explosive device was placed. This location will usually be marked by a crater. The presence of a crater is good evidence that a condensed-phase (concentrated in one small area) explosive was used. If no crater is found, further investigation is needed.

This may point toward a dispersed-phase explosion, such as a natural gas explosion. The type of explosion, i.e., dispersed phase or condensed phase, is likely to be quite relevant to the question: crime or accident? Accidents caused by leakage of fuel gases and the subsequent explosion of gas–air mixtures are not uncommon, although the possibility of deliberate act, rather than accident, still needs to be eliminated. A condensed-phase explosion, in the absence of legitimate storage of explosives or volatile and reactive chemicals, is much more likely to indicate a criminal act. Dispersed-phase events, such as gas–air explosions, tend to produce low pressures and moderate effects over a large area without any clear origin. In contrast, condensed-phase explosions usually give very severe damage at the original position of the explosive (the "seat"), with a rapid decrease in effect with distance. The size of the crater and the distance from it at which damage is found are the normal ways that the size of the bomb is judged, although it should be noted that damage can be quite asymmetric. In some cases, information obtained from a suspect or from the suspected bomb factory may be the best indication of the amount of material used to create the bomb, e.g., the 1993 World Trade Center bombing.

Sampling in or near the crater often yields useful chemical and physical evidence. Unfortunately, the crater is often full of water due to breakage of sewer or water lines and fire-fighting activities. Surfaces near the seat of an explosion can be good sources of chemical residues from explosions. The most promising are those surfaces that exhibit some degree of visible disturbance from the effects of the explosion, for example, sooting, pitting, cratering, bluing, or gas wash. Figure 1 shows an explosively damaged metal strut from the scene of the bomb attack on the London Stock Exchange on July 20, 1990. The metal has been twisted out of its original shape, and the surface is peppered by tiny craters.

In our experience, metal surfaces often are a good place to find explosive residue; however, porous media and soil samples should not be overlooked. Particularly volatile residues, such as accelerants used in arson or triacetone triperoxide (TATP), a homemade initiating explosive, are often quickly lost from smooth surfaces but can be found embedded in porous surfaces. Of course, swabbing of porous surfaces is not generally fruitful; such evidence is best collected and returned to the laboratory. In addition, experimental trials with very large bombs showed that some explosive residues were deposited from the smoke cloud formed after an explosion; thus, residue collection may also be more promising downwind of the explosion seat for very large events [5–7].

Although small items of debris are readily collected, it is worth considering the value of large items of explosive debris. Large items retained should be identified as to location and then bagged and transported to the laboratory for examination. For



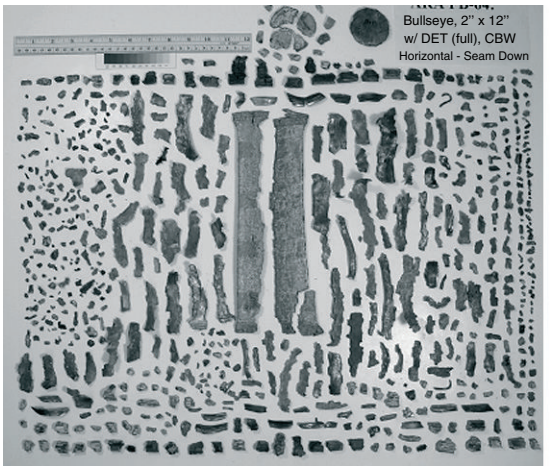


Figure 1 Explosively damaged metal strut from the bomb attack on the London Stock Exchange on July 20, 1990

(a)

example, in the case of an explosion inside a building fixtures and furnishings can act as useful witness pieces, potentially collecting bomb casing fragments and chemical residues depending on their position. Figure 2 illustrates the difference in a pipe bomb filled with black powder, a low explosive, and a smokeless powder capable of detonating. Note the difference not only in the number and size of fragments but in the manner in which the edges fractured. A complete discussion can be found in references [8–11].

In the case of an explosion in a street, nearby motor vehicles are potentially fruitful sources of evidence. Although there are numerous makes and models of motorcars, in practice, many of the basic components are standardized and shared among manufacturers. The condition and position of motor vehicles at the scene should be carefully documented. Subsequent reference to a car damage chart, such as that shown in Figure 3, can help estimate the approximate scaled distance of the car from the seat of the explosion. Since "scaled distance" is the distance divided by the cube root of the mass of the charge, using this chart in combination with the distance the car was from the seat of the explosion allows approximation of the size of the explosive charge. Great caution should be exercised in estimating charge sizes. Allowance must be made for the numerous unknown and unknowable factors involved in a bombing incident, and only rough order of magnitude estimates of charge size should be produced. In addition, motor vehicles can act as both excellent collectors of explosives residues and fragment interceptors at a bomb scene. It is common to find useful fragments of the bomb mechanism or container embedded in nearby vehicles. In addition to searching the bodywork and upholstery, the tires should be removed and examined for possible evidential fragments. Consideration should be given to sampling the exterior surfaces of vehicle facing the blast, either at the scene or back at the laboratory.

A particularly difficult concept to convey to scene responders, as opposed to laboratory investigators, is the need for background sampling. Determination of traces of nitrates in evidence is often a meaningless result, given that nitrates are ubiquitous in modern society [12, 13], but determination of particularly high levels of nitrates may be significant, particularly if taking into account the presence of other significant species such as ammonium, potassium, or uronium. It should be noted that for components of low explosives, the presence of invisible traces is rarely significant on their own due to their prevalence in the general environment. In these cases, the scientists would typically be looking for bulk (i.e., visible) quantities of unconsumed material or their combustion products. An example comes from the World Trade Center bombing in New York in

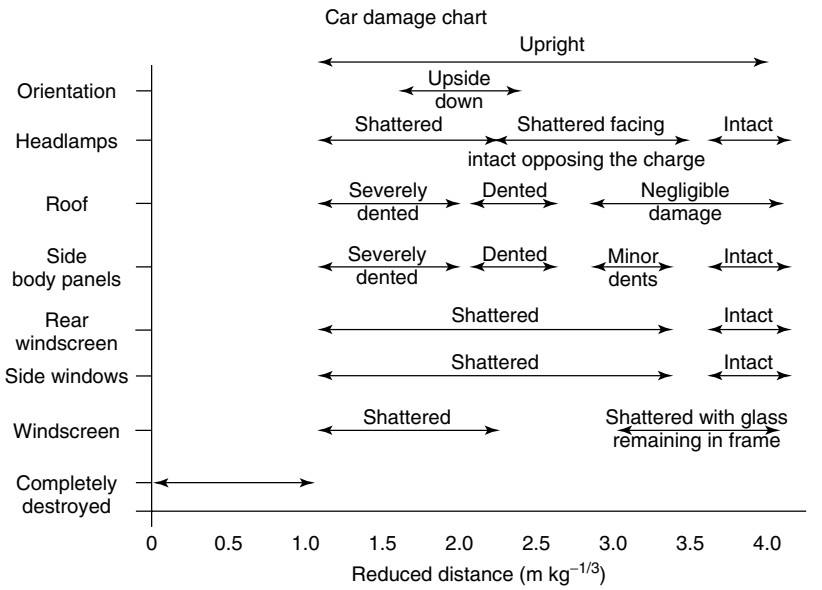

Figure 3 Car damage chart

February 1993. In that case identification of urea residue at the scene was of no evidential value, given that bags of urea were stored in the building for deicing of slippery ramps. The determination that urea nitrate was the main charge in that bombing came from examination of the contents of a storage locker rented by the perpetrators. Their purchase records and the marks on the floor indicating missing barrels led to the inference of the type and amount of material used. That being said, the presence of invisible traces of components of inorganic explosives may still have some evidential value from postexplosion scenes when taking into account other associative evidence such as the physical damage, other materials recovered, the combination of species, and the background environment.

In the Laboratory

There are several types of evidence that arrive at the forensic explosive laboratory: postexplosion scene debris, including fragments of possible device, fixed objects at the scene, and cars, parked or moving. The handling of large volumes of debris and large pieces of debris requires much preplanning. Sorting, cataloguing, and storing will require extensive efforts.

For items recovered from a premises search, whether the search is for a clandestine bomb-making labortatory or for evidence that the location had been used to store explosives, chemical analysis will be the main activity required. Even though the materials may appear to be in their original container, their chemical composition will need to be confirmed. Unlabeled materials, waste bins, and liquid mixtures may be particularly hazardous for the scene investigator. Hand-held detection devices may or may not provide the guidance needed for safe disposal of unlabeled chemicals. Rapid analysis of these becomes critical. Investigators will look to the laboratory forensic scientist to provide potential leads concerning where materials were obtained and even where the perpetrator(s) came from.

Samples from a suspect's person or property: his hands, his clothes, and his car – will again call for chemical analyses and may strongly influence court decisions as to whether a suspect should be remanded in custody, or granted bail, pending trial.

Physical Examination

Bins of debris from the scene of a large explosion can easily overwhelm a forensic laboratory. The first task of the forensic scientist is to select what to process first. Often, rain- or fire-fighting efforts at the scene of an explosion have left the debris wet, and, consequently, the first step in examination of

debris is to dry it. One approach that has been found satisfactory is a provision for a large room equipped with a dehumidifier. Material to be dried is spread out on a large clean plastic sheet on the floor and left overnight to dry. This makes subsequent processing of the material much easier.

Most explosives possess low vapor pressures (Table 1). Thus, if the debris is kept cool and dry the explosive will remain on the residue for years. A notable exception is the peroxide explosive TATP, which is extremely volatile and this can make its recovery more challenging. If this explosive is suspected or if there is sufficient evidence, some of the evidence should be tightly sealed until analysis, and analysis should be as soon as possible. The decomposition of 2, 4, 6-trinitrotoluene (TNT) in soil has been examined, and although it does decompose with time due to biological activity, some TNT remains detectable [14, 15]. Explosives lying between these two extremes in vapor pressure (TATP and TNT) in Table 1 may be in danger of disappearing over time. Cooled, sealed, and dry storage of debris is the only way to preserve evidence. Explosives traces can persist for much longer on adsorbent substrates and there are examples of traces of nitroglycerine (NG) being recovered after months or even years [16–18].

Table 1 Explosive properties including vapor pressure[a]

	Molecular weight	Melting point °C	Vapor pressure Pa at 25 °C
HMX	296	280 d	4×10^{-7} [b]

Biological residue, such as blood-soaked garments, will also require immediate appropriate handling. In particular, biohazard materials must be packaged separately from other evidence and appropriately labeled and sealed. To minimize decay, such items are likely to need drying before being packaged; however, this needs to be balanced against the possible loss of volatile explosive traces. Refrigerated storage is likely to be advantageous in some circumstances. Staff handling biohazard materials require an ongoing medical surveillance program. This should include vaccination against such diseases as hepatitis and others as advised by the supervising medical practitioner. Referring to Figure 4, it will be obvious from the investigator's dress that the evidence must be protected from him and him from the evidence.

In the case of large explosions, the laboratory investigator is often under tremendous pressure to produce a result: was it an explosive? If so what was used? It is imperative to resist a premature judgment that such pressure attempts to elicit; however, in any case, the investigator will want to examine the most potentially fruitful evidence first. Forensic trace analysis is time consuming and costly. In the event that large volumes of potential trace evidence need to be screened to select the most promising items for analysis, one technique which has been used at times in the United Kingdom has been to segregate items in sealed nylon bags, warm these in an oven, and then sniff the vapor inside with a portable explosives detector. This technique, somewhat reminiscent of arson debris identification, can enable the best items to be selected and given priority for analysis. However, it should be realized that the most portable explosive detectors are configured for detection of a limited set of explosives, and there is a risk of missing compounds outside this select group.

Explosion debris can range from invisible traces of explosive, fragments of the bomb mechanism, bomb damaged vehicles such as motorcars, street furniture, and many tons of building rubble as well as

unexploded, disrupted, or partially exploded bombs. The laboratory system must be able to cater for all these disparate types of evidence. Sorting is tedious, time consuming, filthy, and potentially hazardous to health; however, in our experience, in roughly 40% of the cases, a useful object was uncovered.

For bulk material, visual examination is the first step. This is aimed at establishing if an explosion actually occurred and identifying evidential material from the immediate proximity of the explosion. Next, the debris is sieved through a series of screens to remove dust (typically about 25% of the mass) and divided into a set of different size fractions of 3, 6, and 12 mm. Practical experience has shown that it is slightly easier to search debris which is all of a similar size. What is being sought is that which does not belong; thus, elimination of the size variable makes the task slightly more manageable. The sieved material is spread out a little at a time on a well-illuminated search bench. First, it is swept with a magnet to pick out any magnetic material; then, it is searched by eye. Having a choice of lighting and different colored backgrounds for the search benches can be of significant practical help in this task (Figure 4). Staff engaged in such searching should be carefully monitored and given frequent short breaks to ensure that concentration is maintained. Training and skills revalidation should include searching presalted mock debris to ensure that a high proportion of test items are recovered. Health and safety issues need to be carefully controlled. Bomb debris may contain sharp items such as broken glass, dangerous materials such as asbestos, and biohazards, such as body fluids, body parts, and sewage.

Recovery of fragments of the bomb mechanism and container often provides valuable investigative leads and evidence. For example, if it transpires that a bomb was carried in a distinctive kind of bag, then witnesses can be asked if they saw such a bag and surveillance camera tapes can be reviewed to see if the bag can be identified. Recovery of fragments of the bomb mechanism, e.g., parts of a timer, can be exceptionally useful to investigators; and such evidence often provides links to the person or persons responsible. In addition, it is often possible to recover fragments of metal, plastic, or textiles that were close to the seat of the event. Such items must be examined for characteristic damage indicative of proximity to a detonation. Thus, metal and plastic fragments may exhibit what is known as *gas wash* caused by the scouring action of the very hot fast moving gases close to an explosion. In addition, surfaces may show craters caused by the impact of tiny particles of the unreacted explosive; these are typically visible under a low power microscope. Some synthetic textiles may also show characteristic effects, for example, the formation of "toffee apples" on the ends of fibers which have been exposed to the hot high velocity gases from a nearby explosion. The scale of the surface disturbances, such as cratering and pitting, can range from that clearly visible to the naked eye, as illustrated in Figure 1, to effects which require either a low power lens or a microscope. The scanning electron microscope (SEM) is particularly valuable for this type of examination because it provides not only a wide range of magnification but also a much

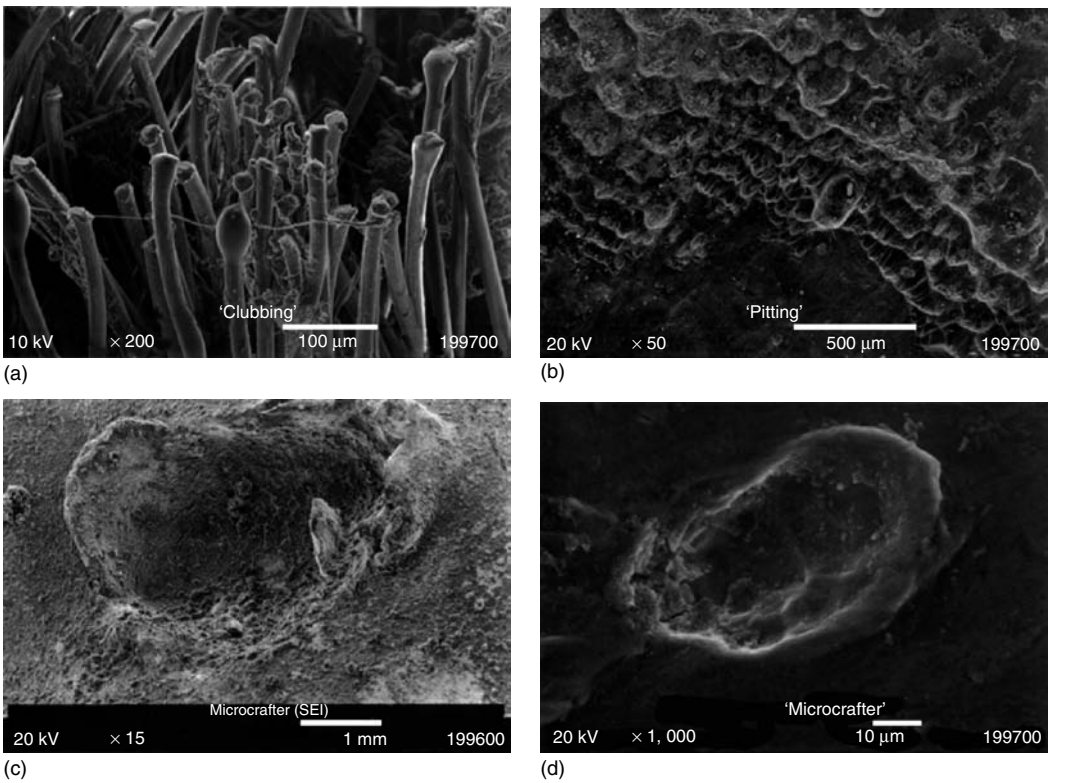
Figure 4 Drying cabinet for wet evidence (a); screening evidence (b); and examining evidence on colored background (c)

greater depth of field than a conventional optical microscope operating at the same power. Figure 5 shows SEM pictures of some explosive damage effects. The top left micrograph shows clubbing on nylon fibers; the other three show effects at different scales on aluminum alloy. The nature of such explosive damage to surfaces will depend on the target material as well as the nature and proximity of the explosion. The forensic scientist may well choose to generate reference photographs to illustrate the point being made in a particular case.

A bomb, typically, consists of an initiating system (detonator, match, squib, and flash bulb), a main charge, perhaps a booster, and a container. Timers may also be found, but these are not essential, e.g., suicide bomb, victim activated bomb, and tripwire bombs (Figure 6). Examination of unexploded or disrupted bombs involves identification of all these components. Moreover, these physical components can also be a rich source of trace evidence, for example, fingerprints, fibers, and DNA [27, 28] as well as toolmarks. Visual examination of any detonator and comparison against reference collections will often allow its identification. Detonators should never be broken down or opened to examine their internal components except in facilities which have been specially designed for the purpose. Such operations are extremely dangerous.

Chemical Analysis

Often the forensic scientist will have some background information which enables him to partly short circuit the full analytical scheme required for complete unknowns. As a simple example, recovered



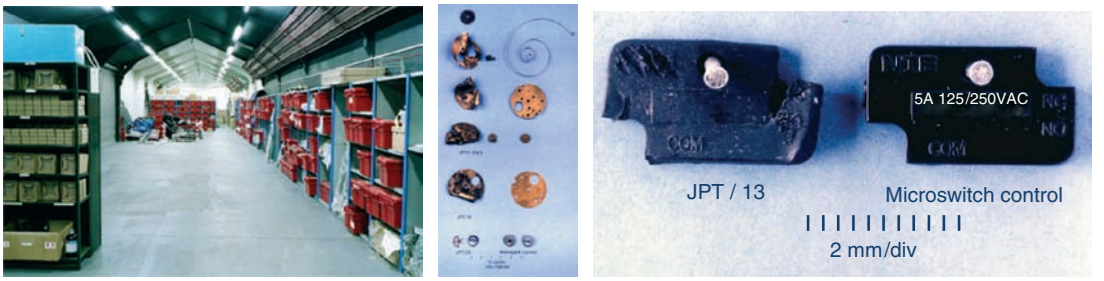


Figure 5 SEM pictures of some explosive damage effects Visual examination of bomb debris can also be supplemented by detailed photography to document the evidence. Photography of bomb debris can be technically challenging; for example, photographing features on soot blackened surfaces needs careful lighting if the necessary degree of contrast and extreme dynamic range is to be achieved in the final image

(a) (b) (c)

Figure 6 Storage of explosive debris in bins (a) and components (b and c)

material may already have a label giving its identity. In such a case, it would be reasonable to start by only doing the tests needed to confirm, or not, the correctness of the label. In other cases, the nature may be fairly obvious to the trained eye. For instance, an exploded pipe bomb with large amounts of residue may well suggest the use of a propellant or pyrotechnic and the visual appearance of the residue may be sufficiently distinctive that it can be recognized. In such circumstances, an abbreviated analysis scheme may suffice. Significant residue is often obtained from pipe bombs filled with low explosives because such materials require confinement for the reaction to proceed; and when the confining vessel bursts, the confinement is lost. Unconsumed particles can often be recovered by sweeping around the seat of the explosion. These particles can often be recognized by visual comparison with standard materials.

Bulk explosive, i.e., quantities visible to the naked eye should be collected and subjected to chemical analysis to establish their composition. This can then be compared with data in the reference libraries and, when possible, to reference samples. The approach to chemical analysis of residue varies from laboratory to laboratory. As might be expected, the analytical approach depends on information known about the sample, instrumentation available, and laboratory tradition. A consortium of North American forensic examiners, under the organization of Technical Working Group in Fire and Explosives (TWGFEX), published a list of suggested instrumental methods for identifying bulk explosives, including gas chromatography (GC)/mass selective (MS); liquid chromatography (LC)/MS; infrared (IR); energy dispersive X-ray (EDX); and Raman, GC/thermal energy analyzer (TEA), GC, LC/TEA, ion chromatography (IC), capillary electrophoresis (CE), thin layer chromatography (TLC), polarized light microscopy (PLM), spot test, and flame and burn tests [29].

Examination of intact explosive (visible residue or bulk) starts with a flame test to determine if the material is, indeed, energetic. This is a simple test to do and requires only a few milligrams of explosives. However, it is imperative that *only* a few milligrams be used and that the test be done a safe distance from the bulk of the material or any other explosive. Laboratories equipped with a differential scanning calorimeter (DSC) may find it useful to scan the sample. Not only will this indicate whether or not the sample is energetic, but it will provide information as to how energetic and whether it melts. For those familiar with the DSC trace of explosives, it may even provide a tentative identification (Table 2). The next examination for intact explosive is usually determining the elements present using EDX. This is particularly useful for identifying black powder and fuel-oxidizer or pyrotechnic mixtures. EDX can be a stand-alone instrument or attached to a SEM. An SEM provides a better depth of field than a traditional optical microscope. The SEM can be used to detect the presence of most elements of interest, although it is not usually suitable for determination of oxygen or nitrogen and lighter elements. SEM gives a starting point for subsequent chemical analysis. Furthermore, the combination of visual and element mapping is particularly powerful. For example, if EDX has detected the presence of aluminum, it is unclear whether that aluminum is in the elemental state or in a salt. SEM will clearly make that distinction. Furthermore, when an element map is performed by the SEM, it will be obvious whether the aluminum is dispersed or discrete. SEM or, indeed, optical

Table 2 Table of DSC peaks and IR spectrum

	Density ($g\,cm^{-3}$)	Exotherm maximum ($^{\circ}C$ at 20 $^{\circ}C\,min^{-1}$)	Average DSC exo heat (cal. g^{-1})	Major infrared peaks (cm^{-1}) by ATR				
				CH, OH, NH	Peak 1	Peak 2	Peak 3	Peak 4	Ranking of intensity

HMTD	1.6	166	700	3000, 2950	1360	1220	940	880	4, 2, 1, 3

microscopy will reveal whether the sample is heterogeneous or homogeneous. Inorganic elements, such as aluminum, magnesium, sulfur, barium, strontium, etc., can be confirmed and quantified by spectroscopic methods: inductively coupled plasma (ICP) emission, flame atomic absorption spectroscopy (AAS), or x-ray fluorescence [30–36].

Often the next step, with visible amounts of explosive, is IR spectroscopy. The nitro groups (NO_2) of most military explosives, the nitrate (NO_3^-) of ammonium nitrate (AN) or black powder mixtures, and the chlorates (ClO_3^-) of pyrotechnics are clearly visible in an uncluttered region of the IR spectrum. Thus, the single IR scan may allow classification of the material as organic or inorganic and possibly even a tentative identification of the explosive [37–39]. Table 2 lists the principal peaks observed in the IR spectrum of explosives commonly used illicitly. These spectra were collected using a portable, attenuated total reflectance (ATR) IR. (We have safely used ATR IR on explosives and even primary explosives; however, samples were always small and pressure was applied slowly.) This technique offers the advantage that the only IR peaks observed are attributable to the sample; no solvent or mulling material appears in the spectrum. The appendix shows the IR collected in their entirety, along with the corresponding Raman spectrum. The Raman spectrum can be used on white materials, but it should not be used on dark colored energetic materials as it may heat them too hot for safety. Because of safety problems, it is difficult to completely free the peroxide explosives hexamethylene triperoxide diamine (HMTD) and TATP from final traces of water and solvent used in their preparation. Thus, the presence of impurities can cause the appearance of the spectra to vary with the method of preparation. We include spectra of various different preparations of diacetone diperoxide (DADP), HMTD, and TATP in the appendix to illustrate the point.

After the entire sample has been examined, an attempt is made to separate the sample into organic and inorganic fractions. This is done by differential solubilities: inorganics are water soluble; organics dissolve in nonaqueous solvent. If trace samples (invisible explosive) are being examined, this is the point where relevance to their examination begins. Figure 7 shows the scheme used by the UK Forensic Explosives Laboratory for separation, cleanup, and recovery of traces of common organic and inorganic explosives.

Although this scheme is good for the recovery of the conventional explosives shown it is not satisfactory for the recovery of the peroxide explosives such as TATP, DADP, and HMTD.

Aqueous solutions are examined for the anions NO_3^-, NO_2^-, Cl^-, ClO_4^-, ClO_3^-, Br^-, PO_4^{2-}, F^-, SO_4^-, and SCN^- and cations Na^+, NH_4^+, Ba^{+2}, Sr^{+2}, K^+, Mg^{+2}, and Ca^{+2} of interest by IC or CE

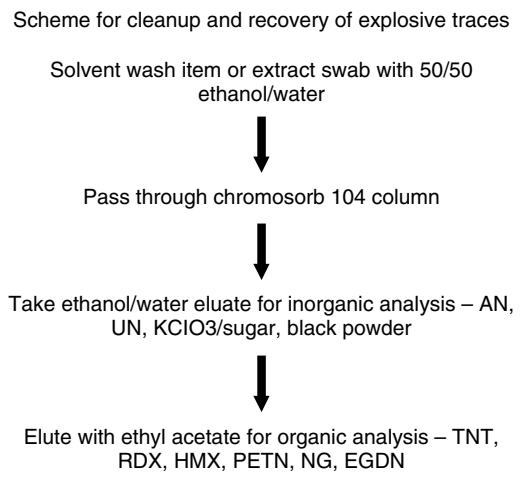

Figure 7 Scheme for separating trace explosives at the UK Forensic Explosive Laboratory

(Figure 8) [40–42], or colorimetric tests. Colorimetric tests are well established but not as sensitive or as definitive as chromatographic methods [43, 44]. Nevertheless, colorimetric tests are good for tentative field identification and commercial field kits, e.g., explosive test kit (ETK), are sold [45].

A number of homemade explosives are based on urea nitrate or on AN with a fuel. It should be noted that determination of the presence of nitrate and ammonium or nitrate and urea are insufficient to prove the presence of these specific compounds, as opposed to their component ions, which may be associated with a different species. Evidence as to these specific compounds can be found in the IR spectrum [39], X-ray diffraction, LC/MS, or PLM [46]. The order of analysis (organic versus inorganic) may be guided by field intelligence or observations made to this point.

Organic explosives (hexogen (RDX), TNT, pentaerythritol tetranitrate (PETN), NG, ethylene

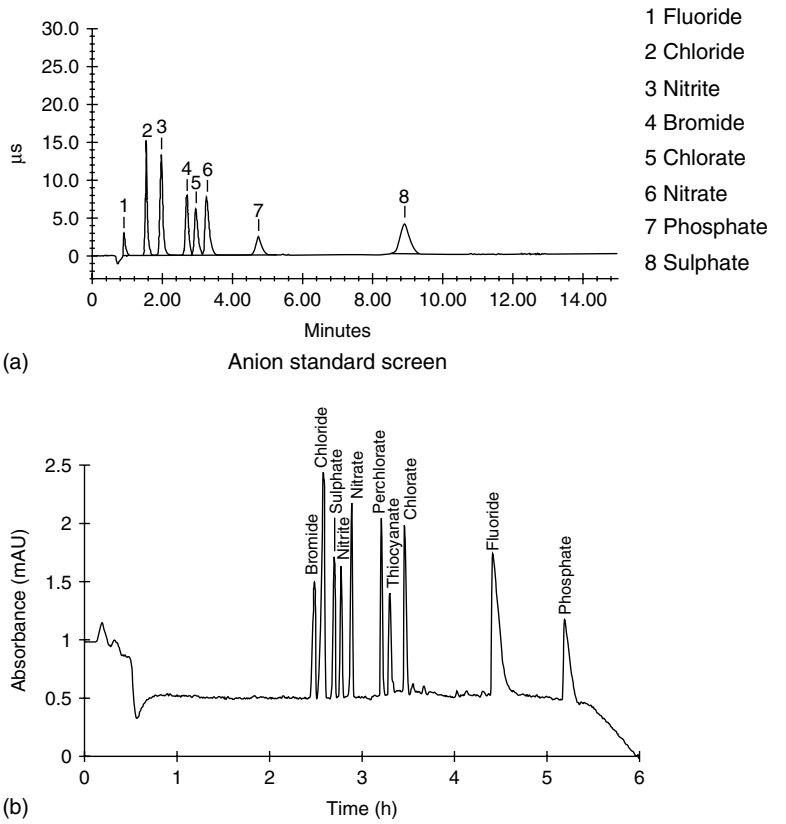

Figure 8 Ion chromatograph (a) and capillary electrophoresis (b) of anions

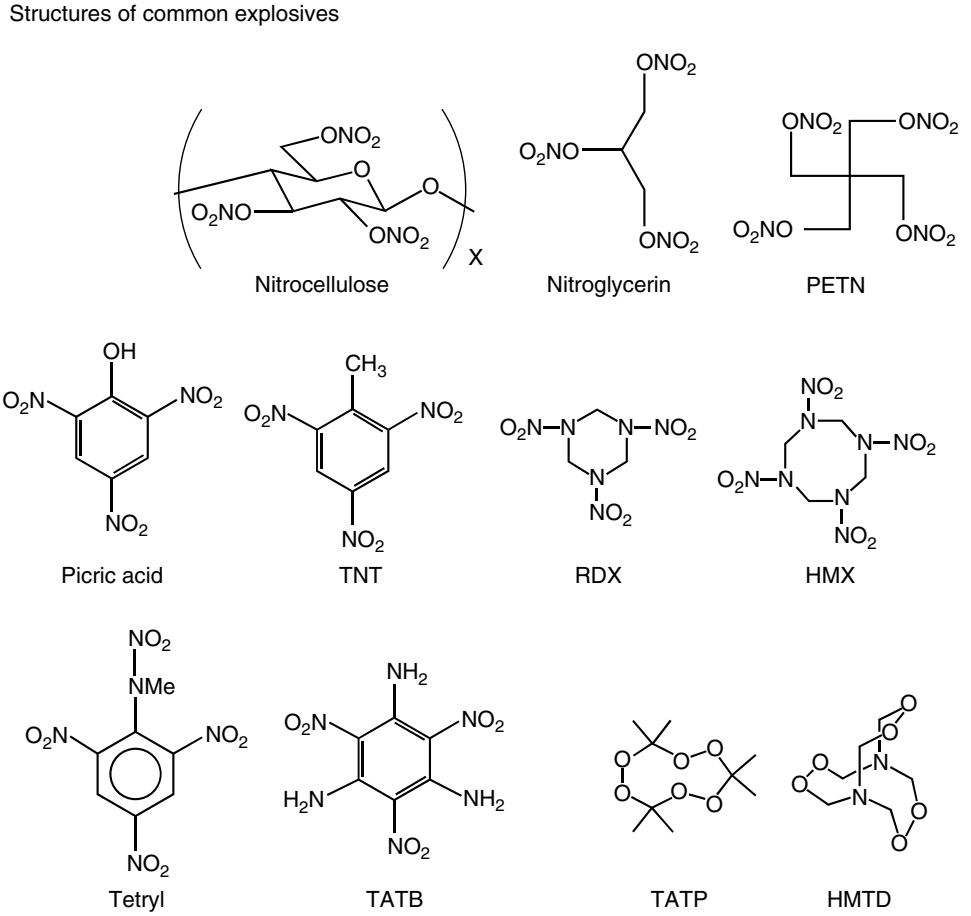

Figure 9 Structures of common explosives

glycol dinitrate (EGDN), octogen (HMX), and TATP, HMTD) can be identified by GC, LC, or TLC. Figure 9 shows the chemical structures of some of the common explosives. The availability of instrumentation, specifically GC or LC with MS detectors, has largely replaced the use of TLC, although it is still a valuable technique for screening and for meeting identification criteria requirements. TLC is a well established method for compound identification with surprisingly good sensitivity. The reader interested in this technique can consult Tables 3 and 4 and the suggested references [33, 47–49]. Although R_f values (ratio of distance traveled by analyte to solvent) are given for various explosives, the reader is advised to use this simply as guidance when developing his own library.

An organic solvent is used to extract swabs or physical samples to determine if the traces of organic explosives can be found. Various solvents could be used. In addition to the ethanol/water scheme described above in Figure 7, we have also found that HPLC-grade acetonitrile is well suited to extract the swabs and physical objects. Swabs can be immersed in solvent in sealed containers and vigorously shaken or sonicated with minimum volume of acetonitrile. After some minutes the solvent can be removed and filtered via a syringe filter, e.g., Millex-FG filter unit (0.20 μm, PTFE membrane for the removal of fine particles from organic solvents). Swabs should be rinsed or reextracted with solvent. It is often convenient to concentrate the solvent to less than 1 ml by blowing a stream of dry prepurified nitrogen

Table 3 Solvents for TLC

System	Eluent composition	(%) Volume	Comments
1	Toluene	100	NG and PETN not resolved
2	Petroleum ether 40–60 °C	40	NG and PETN resolved. RDX and HMX have low R_f's
	Petroleum ether 60–80 °C	40	
	Ethyl acetate	20	
3	Chloroform	90	RDX, HMX, and NC all resolved. Especially good for HMX in presence of high RDX
	Methanol	10	
4	Toluene	90	Recommended general screen. NG, PETN, RDX, HMX, and NC all resolved
	Ethyl acetate	10	

Table 4 TLC R_f values for explosives

Explosive	R_f in solvent system				Behavior under ultraviolet light	Color after spraying with NaOH solution and heating	Griess test color
	1	2	3	4			
NC	0.00	0.00	0.00	0.00	No effect	No effect	Magenta
HMX	0.01	0.02	0.25	0.06	Absorbs	No effect	Magenta

TNT	0.74	0.52	0.93	0.88	Absorbs	Brown	Magenta

gas by or through the solvent extracts. This solvent concentrate is adjusted to an exact volume (e.g., 1 ml) [50].

A reference standard should be prepared containing the explosive species for which the test is screened (RDX, TNT, PETN, NG, EGDN, and HMX). Standard commercial solutions are available. When preparing reference standards for use in a trace analysis laboratory, it is good practice to only use mixed standards so that any contamination of samples by laboratory standards is immediately obvious from the improbable mixture of compounds detected. An electron capture detector (ECD) is one of the most sensitive detectors that can be coupled with GC. A TEA detector is also extremely sensitive to explosives, but it is less versatile being selective only for nitro-containing explosives (although this can also be an advantage). If the detector used is flame ionization (flame ionization detector (FID)), ECD, or TEA, (i.e., not MS), then a positive match to a particular explosive requires that the retention time of the sample from the explosion scene must match that of the standard, and this match must be confirmed using at least one, if not two, different chromatograph columns.

With TEA or ECD it is not unreasonable to expect limits of explosive detection in the parts per billion (ppb) range. Most mass spectrometers are less sensitive than ECD or TEA; however, the technique is constantly improving. A number of good gas chromatographic columns are sold. We have found that shortening the column to 15 m or less improves detection, depending upon the film thickness and temperature program. DB-1 or DB-5 or RTX-200 capillary columns have given fine results, as have BP-1, BP-5, BP-20, and CPSIL-19. Mass spectroscopy offers the advantage of a second mode of identification. MS fragmentation patterns may be collected and stored as part of the library of the instrument; a few can be found

on the National Institute of Standards and Testing) (NIST) and on the University of Rhode Island websites (http://expdb.chm.uri.edu). GC-ECD identification protocols are found on environmental protection agency (EPA) method 8095, "Explosives by GC [51]".

Choice of GC or LC may depend on availability, volatility of sample, and amount of sample [52]. Explosives such as PETN, tetryl (CE), HMTD, and HMX can be difficult to identify by GC. These explosives are prone to decomposition either in the inlet or on column. This makes the choice of inlet and column temperatures as well as column length and type critical. Unless these parameters are optimized the parent peak may not be observed. For these particular explosives LC/MS may be more suitable. Until his death in May 2008, Yinon published many papers discussing identification of explosives by mass spectroscopy [33, 34, 53].

The peroxide explosive TATP can readily be identified by MS assuming that necessary care has been taken during the recovery and packaging of the explosion debris. Figure 10 shows the mass spectrum of TATP obtained on a bench-top GC/MS, and Figure 11 shows the mass spectrum of the other common peroxide explosive, HMTD, obtained on the same instrument. Because analytical techniques for handling TATP are relatively new, an exemplar method is given below and in references [22, 54–60]. Analytical methods for analysis of other homemade explosives are in the references: HMTD [58–60], urea nitrate [61–65], AN [66–69], ammonium perchlorate (AP) [40–43], and conventional explosives [52, 70–77].

Figure 12 is a chromatogram of a mixed TATP and DADP standard in acetonitrile analyzed on the GC-ECD. A Hewlett Packard 5890 Series II GC-ECD was equipped with a fused silica DB1 column (J & W Scientific $-8\,\text{m} \times 0.53\,\text{mm}$ i.d. $\times\ 0.5\mu\text{m}\ d_f$). The injection port temperature was set at 175 °C (2 : 1 split) with an injection volume of 1 μ. The carrier gas was ultra high purity (UHP) hydrogen (6.6 ml min^{-1} measured at 65 °C) and the makeup gas was UHP nitrogen (45 ml min^{-1}), with a detector temperature of 300 °C. The oven temperature program was as follows: 65 °C for 2 min, 20 °C min^{-1} to 250 °C with a 2-min final hold. The peak for TATP had a retention time of 2.49 min and the limit of detection was circa 0.01 ppm. The peak for DADP had a retention time of 0.57 min and the limit of detection was also circa 0.01 ppm. The TATP peak consisted of two fully resolved peaks,

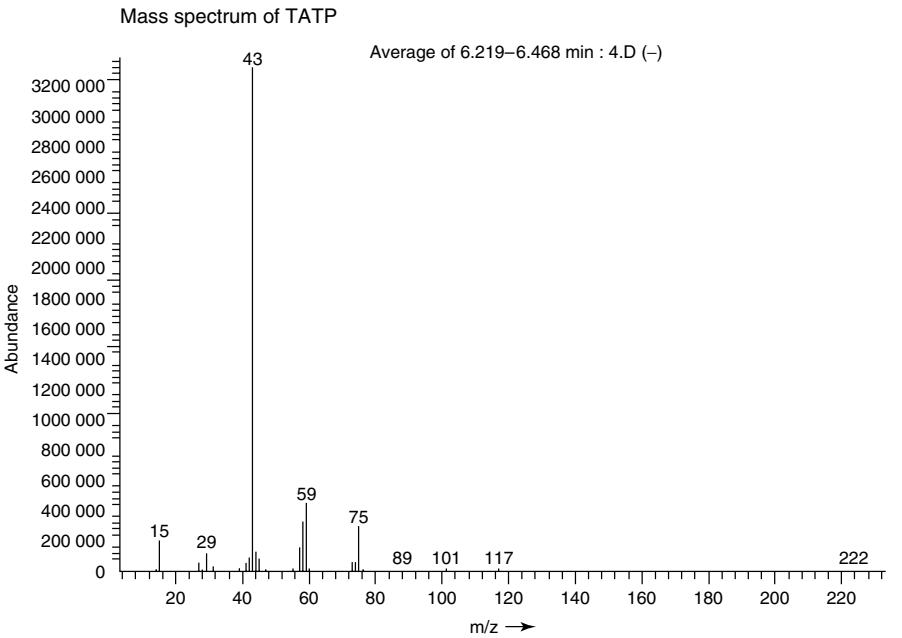

Figure 10 Mass spectrum of TATP

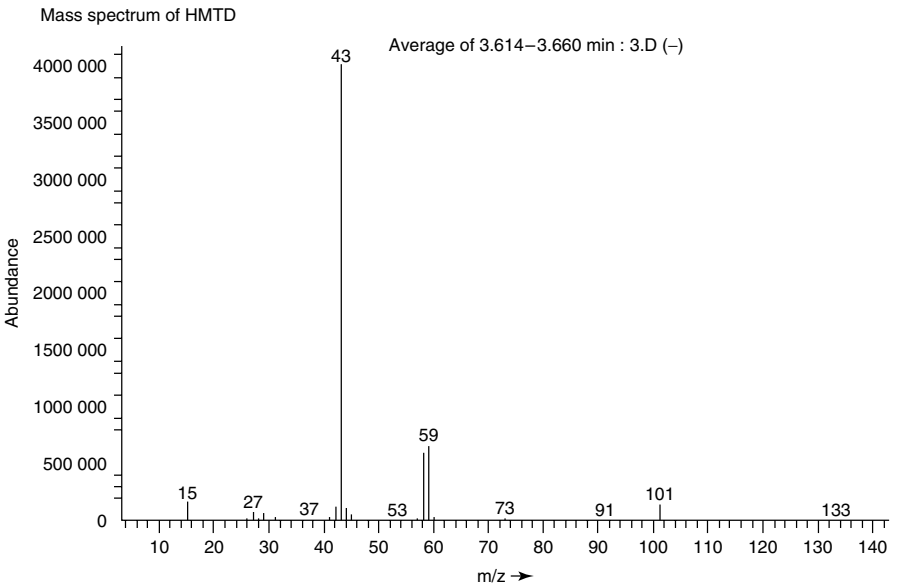

Figure 11 Mass spectrum of HMTD

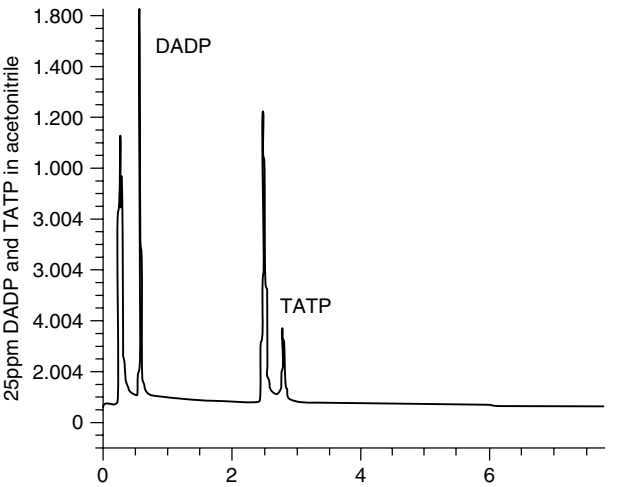

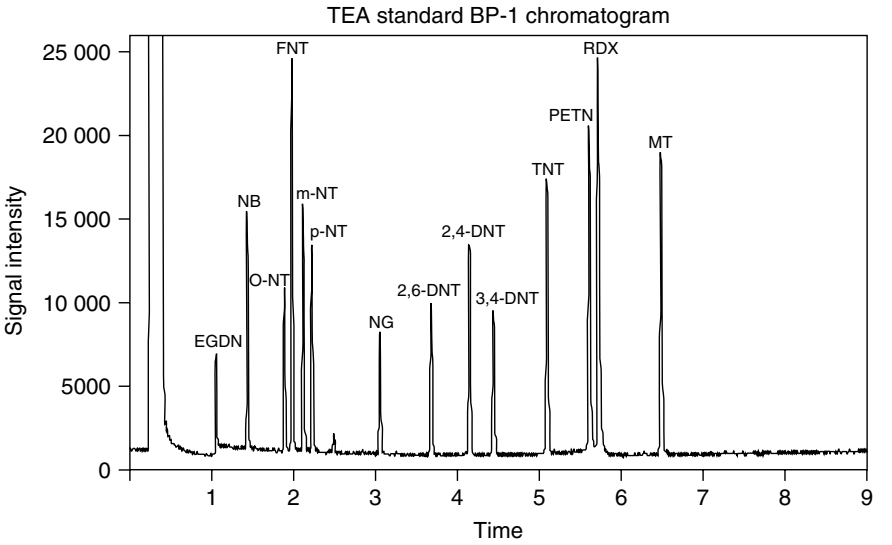

Figure 12 GC-ECD of 25 ppm DADP and TATP in acetonitrile

although on other chromatographic columns the second peak might appear as a shoulder. Both peaks had the same mass spectrum and have been shown in scientific literature to be two stable conformers of the nine-membered TATP ring. The larger peak corresponds to the conformation with the more stable symmetry (D_3) and the smaller peak corresponds to the conformation with the less stable symmetry (C_2). These kinetically stable conformers can interconvert through a high barrier, in the gas phase.

Typical chromatograms for conventional explosives are shown in Figures 13 and 14. The former shows a GC-TEA analysis of trace amounts, while the latter shows the use of GC-FID for analysis of bulk quantities.

SGE type 12QC2/BP1 0.22 mm 12-m polyimide clad silica, 0.22 mm i.d., 0.33 mm o.d., coated with bonded dimethylsiloxane 0.25 μm film thickness

The Questions and the Court

Was it a Bomb?

If military explosives or peroxide explosives such as TATP and HMTD were identified among the explosive debris and if this corresponds with the other observations and evidence recovered, then the answer is probably "yes" providing the explosion was not at a location where explosives would normally be found, e.g., an explosive factory or storage facility and providing all sources of contamination were eliminated. Potential sources of contamination at the scene are the bomb squad and law enforcement who may have attended previous incidents. Contamination at the scene can be avoided by insisting on disposable materials and fresh outer garments. Written procedures, tight controls, and an access log should be enforced at scenes to avoid claims of contamination. In the absence of relevant environmental survey data, background samples should be taken "near" the scene to look for ambient contamination. In the laboratory, working in bulk explosives environments prior to carrying out trace work should be avoided. The laboratory environment should be controlled and monitored. We have found the best way to prevent contamination is to overdress with disposable outerwear, including hair net and booties [78]. The work environment should be screened prior to handling scene samples. In running chromatographs or similar analytical tools, appropriate control samples, both blanks and spiked samples, should be added.

Finding trace levels of explosives needs to be set in context for investigators and the Court. For example, finding trace levels of TNT on a person could be highly significant. However, the possibility of an innocent source must be considered and evaluated. Thus, a trace of TNT on a soldier probably has a very different significance than a trace on a member of the general public. The investigator needs to take into account the location where the trace was found, whether there were potential sources of the explosives in the vicinity, whether the compounds in question are widely used commercially or industrially or, indeed, occur naturally in the environment. Finding chlorate traces at the seat of explosion could be highly significant; however, it must be remembered that chlorate and sodium chlorate, in particular, are used as weedkiller in some countries so that this potential source must be considered and eliminated if significance is to be attached to the finding. Perchlorate is generally uncommon in United Kingdom and United States public environments though one would expect it to be much more common in Chile where it occurs naturally. However, even in the United Kingdom and United States perchlorates are widely used in fireworks and rocket propellants, and traces have been found in both the cow's milk and mother's milk [13, 41, 42]. If significance is to be attached to traces of perchlorate, potential sources of innocent contamination must be considered.

Environmental surveys are particularly valuable as this enables the levels found in evidential samples to be compared with those found in the general public environment. Clearly, the greater amount of explosive in an evidential sample compared to the background samples, the higher the likely significance.

If the Explosion was a Bomb, who did it?

If a suspect is apprehended, it is good evidence if traces of the material found on the bomb can be found on the suspect's person. Timothy McVey (the Oklahoma City bomber) had traces of PETN on his tee shirt. Ahmad Ressam, the would-be millennium bomber, had acid holes in his jeans. Trace explosive residue should be sought on hands, clothing, jewelry, and glasses. The template pieces of glasses and watch bands often collect residue that trip up the bomber as well as the forensic scientist trying to prevent contamination. We have found that some explosives stay in hair for days, even after washing. That explosive can be collected by entwining clean swabbing material in the teeth of a comb and combing that through hair. Favorite head wear, e.g., baseball caps or hair bands, often become contaminated [79, 80]. Nonetheless, explosive trace evidence alone would not usually be considered sufficient to prove guilt; generally courts would look for other corroborative evidence. A jigsaw of many pieces all fitting together to produce a consistent picture is more

reliable than a single item of apparently conclusive evidence which might later prove to have some undetected flaw.

Scene investigators will likely be the ones to take samples from the suspect's vehicle or premise. Contamination can be avoided if the laboratory investigator prepares clean swabbing, vacuuming, and other collection tools. Laboratories with large, clean garage bays can request that the scene investigators simply wrap vehicles in plastic sheet and take to laboratory for careful sampling. The importance of avoiding contamination and instituting a rigorous protocol for quality control cannot be overemphasized if evidence is to be acceptable in a court of law [78, 81–83].

It may be many years before a case goes to court. Meticulous notes should be taken, and the scientist should sign and date them and either have a cross-check signature or an effective laboratory quality assurance system. Since evidence may be required in court years after the event, the critical pieces of evidence should be resealed and labeled and stored according to laboratory protocol.

In court, the forensic scientist will be asked if he identified a device. Optimally, he should be able to identify the components of the device, the explosive(s) used, the means of initiation, and the container and to discuss its construction. He may be asked whether it was an actual explosive device or an elaborate hoax. This will lead to a discussion of whether the device could have functioned and with what effect. Presumably the investigator has been able to identify the explosive or pyrotechnic content of the bomb. However, in some cases, e.g., smokeless powder, he may only be able to say that it was single-base or double-base and was or was not consistent with the powder found in the defendant's premises. In other cases, particularly those involving high explosives, it may not always be possible to positively identify traces of the actual explosive(s) used or all of the components of the device. In such cases, the forensic scientist may be able to make an assessment regarding the type of explosive used and the construction of the device by the nature of the damage, both at the scene and on individual fragments, together with other associative evidence. These observations and assessments can also be considered against materials found at a defendant's premises, etc.

It is important to determine if there has been a history of similar devices. The Unabomber eventually started marking his devices with the initials "FC" (standing for freedom club) so that he would be sure to be credited. However, his completely homemade devices were already so unique that even after a hiatus of many years, his devices were easily recognized. Today, at the federal bureau of investigation (FBI) there is a multiagency group devoted to characterizing the IEDs coming of Iraq.

In the case of the break-up of a so-called bomb factory, the investigator requires considerable care and objectivity. He needs to look at the whole picture, and not just the chemicals found. What hardware was found in that location? Was it timers, clocks, batteries, or matches? These are common electronics and may not be sufficient evidence of a crime. The investigator should look for evidence of manufacture, e.g., mixing bowls with traces of a homemade explosive, clocks with attached wiring, collections of explosives literature, or plans. If a bomb has already exploded, it will be important to look for correlations between unused items and remains found at bomb scenes.

Summary

Reliable laboratory analysis requires much preparation and training before the explosion has even occurred. Scene and laboratory investigators need to communicate as to how and where the sampling will be performed. Laboratory protocols for analysis should be written and tested. The laboratory, itself, should be checked for possible explosive contamination. And, of course, the investigators themselves need sufficient training and experience, which may be obtained to some extent, e.g., by practicing on mock materials so that when the actual even occurs, all will be in readiness.

Appendix

Infrared and Raman spectra of commonly abused explosives are shown in Figures A1–A27.

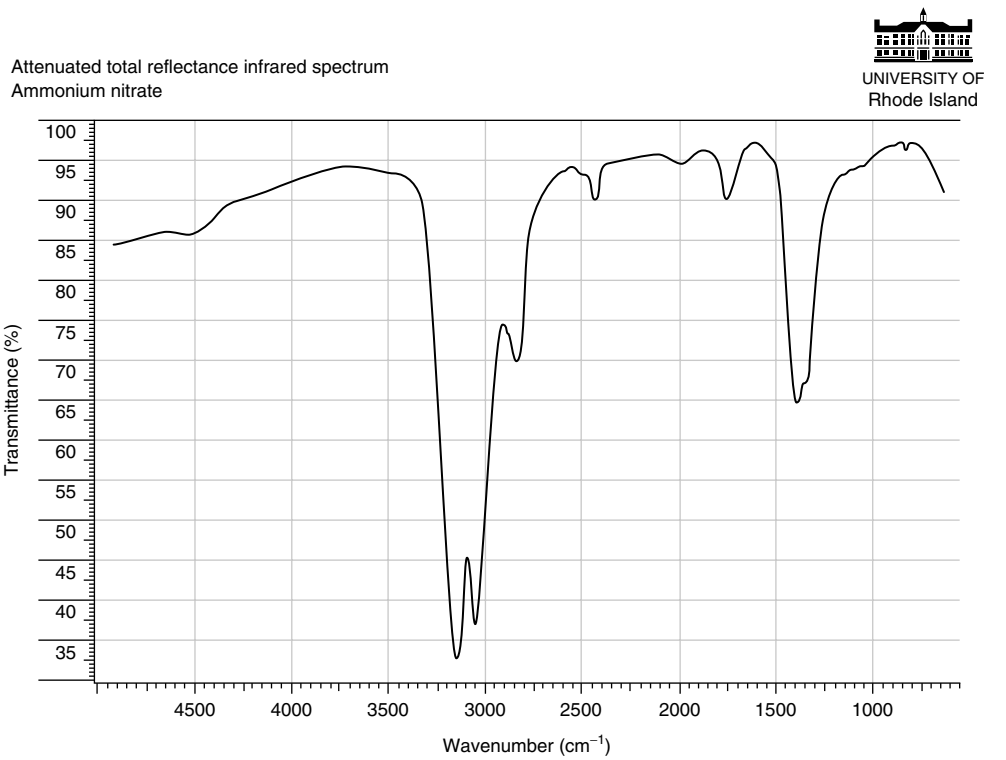

Figure A1 Infrared spectrum of ammonium nitrate (AN)

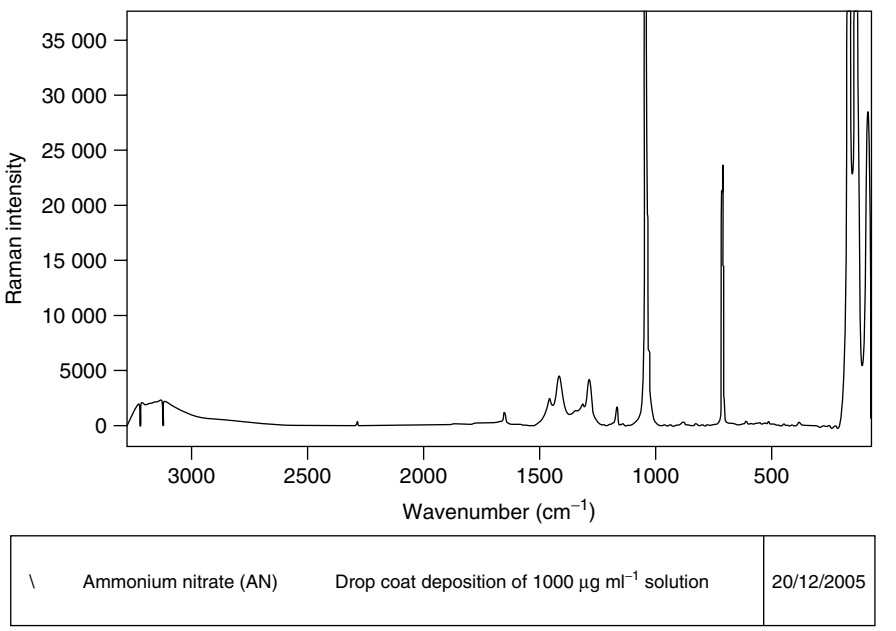

Figure A2 Raman spectrum of AN

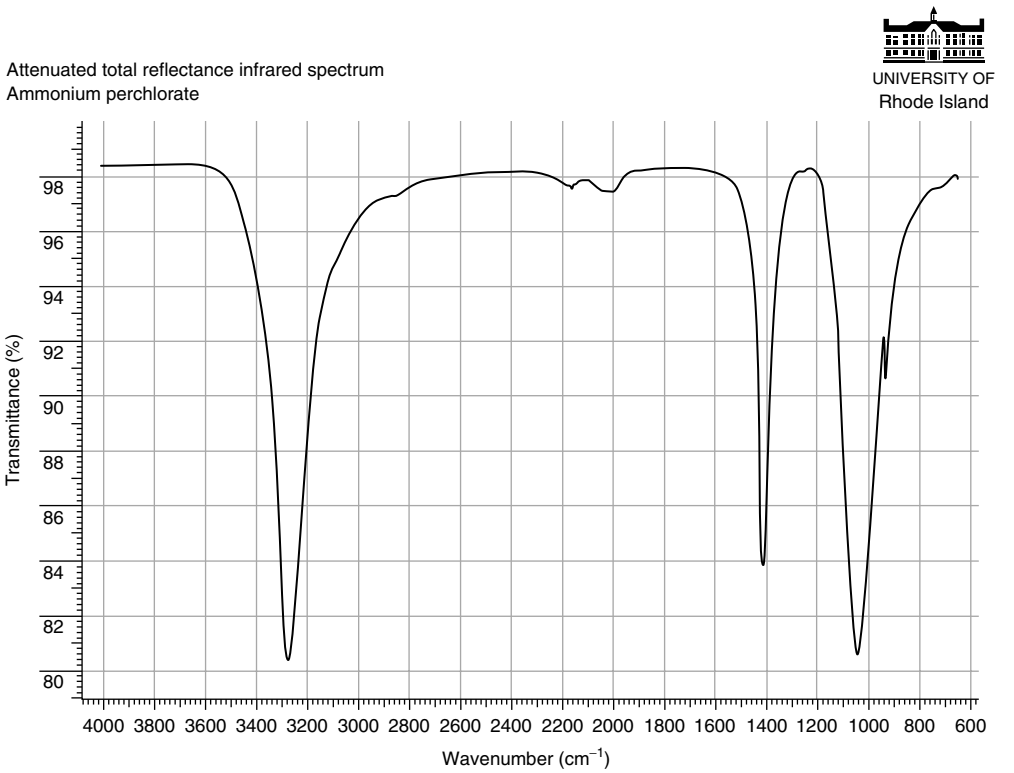

Figure A3 Infrared spectrum of ammonium perchlorate (AP)

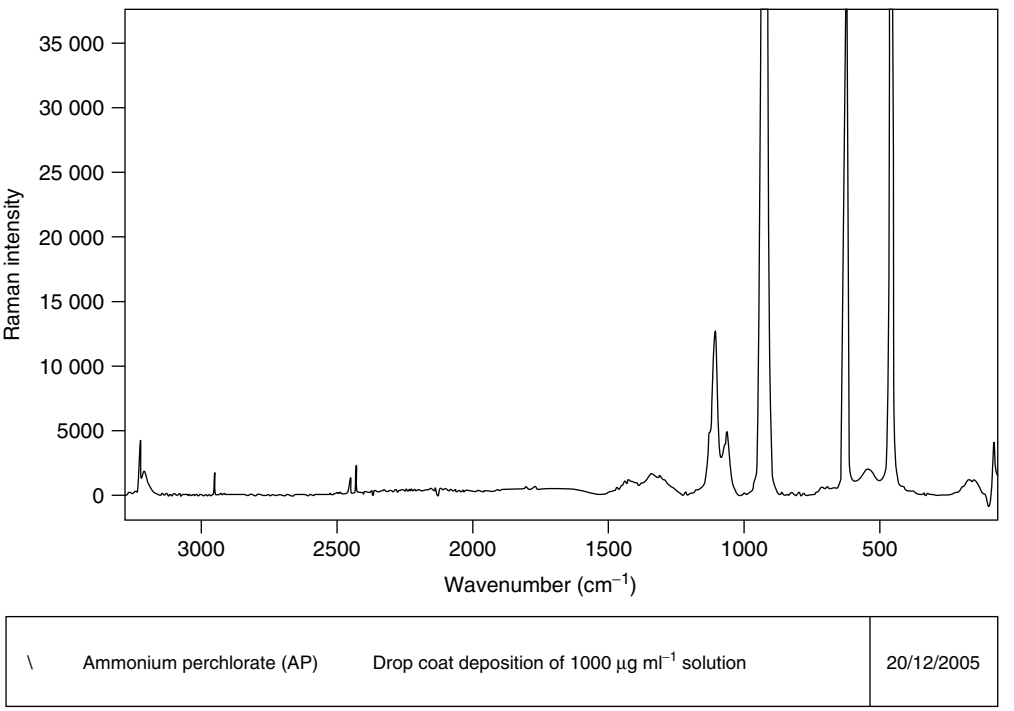

Figure A4 Raman spectrum of AP

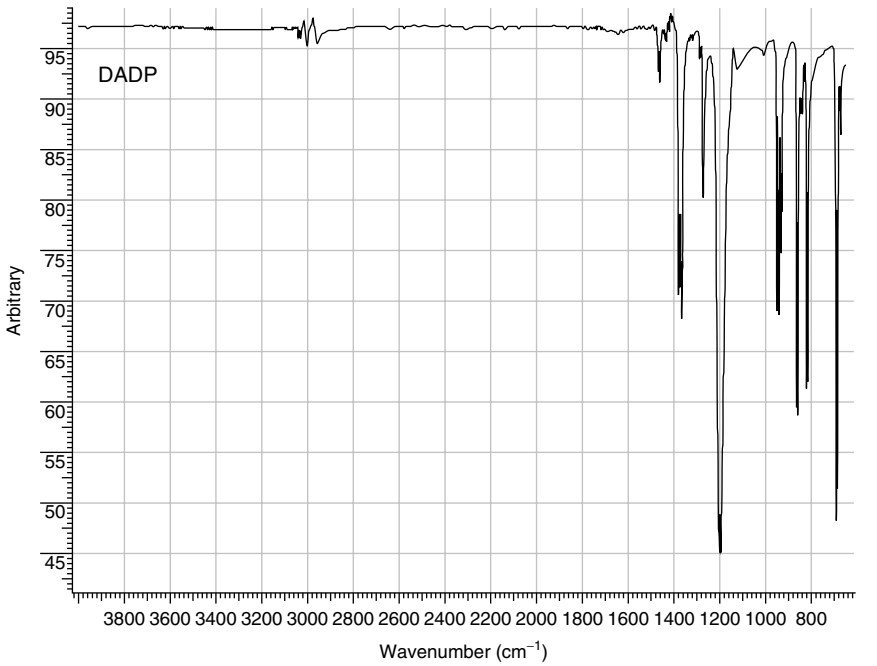

Figure A5 Infrared spectrum of diacetone diperoxide (DADP)

Extraction

Introduction

One of the most crucial stages in the development of a DNA profile is the ability of the scientist to recover cellular material from a substrate and to extract DNA from it in a manner that is suitable for further processing steps such as polymerase chain reaction (PCR). Forensic samples are, however, not always easy to deal with. Samples can be deposited in the most inconvenient of places (*see* **DNA: Sources of**), exposed to the harshest of environments, and mixed with many potential inhibitors of DNA profiling. Many of these factors are outside the control of the forensic scientists.

An Ideal Method

A method suitable for the extraction of forensic samples requires the following:

- DNA is efficiently recovered from the biological sample;

- the extracted DNA is protected from further fragmentation or nuclease action;
- the extracted DNA is free of inhibitory substances that may have a detrimental effect on further processing; and
- the method minimizes the risks of cross-contamination from other samples or sources.

In recent years, as additional types of forensic evidence are developed and implemented, methods are also required that enable the following:

- the coextraction of DNA and RNA and
- the extraction of DNA from plant material of various kinds.

Typical steps in the process are as follows:

- visual examination and presumptive tests to identify the biological source of the sample;
- recovery of biological material;
- lysis of the cells and release of the DNA into solution;
- removal of inhibitory compounds;
- determination of the amount of DNA recovered; and
- if necessary, concentration of the DNA extract.

Any method developed for forensic use must be validated according to the accreditation or other quality system in place in the laboratory. Each of the methods described in this article can include numerous, small, laboratory-specific variations, such as incubation times and temperatures; however, the basic steps are common to all procedures.

Proteinase K/Organic Extraction

The earliest method described for the recovery of DNA from forensic samples involved the use of the enzyme proteinase K, followed by an organic extraction with a solution of phenol and chloroform [1]. Despite the fact that this is a time-consuming method, has multiple transfer steps, and uses hazardous chemicals, it remains a favorite in many forensic laboratories.

Cellular material is recovered from the substrate by scraping, soaking, or other means (*see* **DNA: Sources of**). A simple Tris/HCl buffer containing proteinase K and a detergent such as sodium dodecyl sulfate (SDS) is added to the cell pellet. The proteinase is an enzyme that breaks open the cell and nuclear membranes, releasing the cell contents including the DNA into solution. The phenol/chloroform step coupled with an ethanol precipitation or alternate concentration step successfully removes inhibitors and results in a DNA extract amenable for further analysis. It is particularly useful when small amounts of DNA are expected, such as swabs taken from car steering wheels or touched items.

The DNA that is recovered is double stranded DNA, relatively free of impurities, and can be used for many applications (*see* **Variable Number Tandem Repeats**).

Differential Extraction

Forensic laboratories typically employ a differential extraction method for the separation of spermatozoa from other cells such as vaginal epithelia [1]. Strong disulfide bonds prevent lysis (bursting or breaking up) of the spermatozoa nuclei in the presence of proteinase K and SDS, (a detergent), allowing the more fragile epithelial and other cells to lyse and release their DNA. Separation of the spermatozoa from the lysed cells is achieved by centrifugation and removal of the supernatant (the liquid portion sitting above the separated solids) containing the lysed cellular components. The spermatozoa can then be lysed by the addition of a reducing agent such as dithiothreitol (DTT) in the presence of the extraction buffer, proteinase K, and SDS. Each fraction, the "sperm" and "epithelial" fractions, can then be processed separately typically by organic extraction, phenol/chloroform extraction, ethanol precipitation, or other methods (see below).

Alternative approaches to the separation of sperm cells from epithelial cells include the use of laser microdissection [2] and cell sorting using a glass microdevice method [3]. These approaches have potential for integration into more automated extraction protocols.

Chelex®

With the advent of PCR, Chelex® extraction became widely used [4]. This method generates single stranded DNA suitable for PCR and became the method of choice in many laboratories because of its simplicity, low cost, and lack of harmful reagents.

Chelex®100 is a resin composed of styrene divinylbenzene copolymers containing paired iminodiacetate ions that act as chelating groups. These chelating groups have a high affinity for polyvalent (multiple charges) metal ions such as Mg^{2+} ions. Thus, degradation of DNA in the sample is minimized by chelation of the metal ions inactivating the nuclease enzymes that digest DNA. Chelex® beads in suspension are added to cells recovered from a substrate, and after incubation, the DNA is released from the cells by boiling. The alkalinity of the solution and the high temperature cause the cell membranes to burst, releasing the DNA.

Chelex® is inhibitory to the PCR reaction and it has been observed [5] that long-term storage of samples containing Chelex® beads results in a deterioration of the DNA profile quality.

While Chelex® is suitable for a wide range of sample types, additional clean up and concentration steps are often required for dirty or samples containing very small amounts of DNA. Nevertheless, Chelex® extraction remains a popular choice in forensic laboratories.

Solid Phase Extraction Technologies

In recent years, alternative technologies suitable for manual or automated applications have become more widely used. These methods can also be employed after the separation of spermatozoa and epithelial cells. One of the earliest such methods to be used was DNA IQ™ [6–9].

DNA IQ™

The DNA IQ™ system utilizes a two-step method. First, the cellular material is recovered from the substrate by incubation of the sample to 95 °C with a lysis buffer. Then DNA IQ™, a silica-coated, paramagnetic resin, is added to the sample. The resin binds to DNA with high affinity in the presence of chaotropic elements such as guanidinium, which lyse the cells, denature proteins, and inhibit DNases. A magnet is then applied, which causes the resin, with DNA attached, to congregate on the tube wall nearest to the magnet. DNA is then recovered from the resin using an elution buffer. DNA can be recovered from most forensic sample types, using proteinase K to assist in the extraction of DNA from hair, bone, and spermatozoa [9] and is reported to be particularly suitable for very small samples.

The amount of DNA captured by the resin is roughly proportional to the amount of resin used and can be varied according to the sample type. This has advantages when extracting DNA from DNA database samples where the amount of starting material is large, as a consistent amount of DNA can be extracted and further expensive quantitation steps may not be required [8]. The DNA IQ™ system has been successfully implemented onto robotic platforms [10] and has been used by many laboratories to extract DNA from casework samples, for example, from volume crime cases [7] and envelope flaps [11].

MagAttract®

The MagAttract® system (Qiagen Inc.) also utilizes paramagnetic silica beads to capture DNA after release from cells using chaotropic agents. A similar lyse, bind, wash, and elute protocol is followed [12, 13]. Again, the final elution volume can be altered depending on the concentration of DNA likely to be recovered. This technology has been optimized for use on several robotic platforms, enabling laboratories to customize specific protocols.

Charge Switch™ Technology

Charge Switch™ (DNA Research Innovations Ltd., UK) also uses magnetic bead technology. In this case, however, the magnetic beads are coated with a unique chemical compound that acts as an ionic switch that is dependent on pH. The overall process is the same as that employed by other magnetic technologies. First, the cells are recovered from the substrate and lysed. Then at pH below 6.5, the DNA from lysed cells binds to the particles that are subsequently captured using a magnet. The pH is raised to 7 to allow a washing step to take place before the pH is raised again to 8. At this pH, the charge is neutralized and the DNA is eluted. Again, modifications to the elution volume can be made to alter the concentration of the recovered DNA and the technology has been shown to be applicable to a wide variety of forensic samples [14].

QIAamp Technology

In 1998, Greenspoon *et al.* [5] described the use of QIAamp® spin columns (Qiagen Inc.) as an

alternative extraction method for the extraction of DNA from database samples resulting in DNA that survived long-term storage at −20 °C. In this process, cells are lysed and then placed into a spin column containing a silica-gel-based membrane to which the DNA binds. Following washing steps, aided by centrifugation or vacuum suction depending on the protocol being followed, the DNA is eluted into solution ready for quantitation and/or amplification.

A recent addition to the QIAamp® spin columns is the use of an additional column, known as a *QIAshredder® homogenizing column*, after cell lysis and prior to the binding of the sample to the silica membrane [15]. The use of such columns enhanced the effectiveness of the QIAamp® spin column process, increasing the performance of this extraction system relative to either a Chelex® extraction or an organic extraction.

Solutions for Specific Sample Types

FTA Card

Whatman FTA® cards are extensively used for the collection of reference samples for forensic analysis. The FTA® technology lyses cells on contact, releasing and immobilizing the DNA. An added advantage is that infectious pathogens and other microorganisms are deactivated, enabling long-term room temperature storage of samples [16].

Once the sample is immobilized onto the card, a small punch is taken typically 2 mm across. A simple series of washing steps follows, which removes any inhibitory substances that might be present. The washed punch is then placed directly into the amplification. This method is easily automated [17].

Feces

The extraction of DNA from fecal remains presents particular challenges. It has been shown that swabbing of the outer surface of the stool [18] or collection of tissue paper smeared with feces [19] offers the best chance of success. In the extraction process, it is important to remove as much inhibitory material as possible, particularly the polyphenolic compounds [20]. A number of specific solutions have been developed for the successful extraction of DNA from feces; these include the QIAamp® DNA stool Mini Kit (Qiagen Inc.) and the Ultraclean™ Fecal DNA Isolation Kit (MO BIO Laboratories Inc.).

Extraction from Bone

There are many methods described in the literature for the extraction of DNA from samples of bone (for examples see [21–23]). The most significant difference between the methods described is whether or not a demineralization step is used. There are common themes to most of the methods. First, most bones can be successfully cleaned of surface dirt and potential contaminating substances including extraneous DNA using one or more of the following methods; abrasion with sandpaper etc. The cleaned pieces of bone are then crushed into small fragments, often with the aid of a freezer mill and liquid nitrogen until a fine powder is obtained.

The powder can be demineralized using several changes of 0.5 M ethylene diamine tetra-acetic acid (EDTA), pH 7.5 at 4 °C with agitation over one to two days [21, 22] or as part of the lysis procedure [23]. For most of the methods described, subsequent organic extraction and concentration with a column-based method such as a Centricon™ 30 microconcentrator is suggested.

Teeth

Like bones, teeth are relatively easy to clean prior to extraction. Some complexity is introduced when it is necessary to preserve the external hard surfaces of the tooth, which is important if physical and biochemical tests are also to be carried out. Methods of extraction that do not crush or damage the physical structure of the tooth are required, although this may reduce the maximum recovery of DNA [24].

Hair

As with teeth and bones, hair can be cleaned prior to extraction. One suggestion is the use of sonication in 2% SDS, followed by rinsing in water prior to extraction as an effective method [25]. One method used to optimize the recovery of DNA from root and shafts of telogen hairs (*see* **Hair: Microscopic Analysis**) is to grind the hair after washing using glass grinders, followed by Chelex® extraction. Alternatively, organic extraction methods [26] or solid phase extraction methods such as DNA IQ™ can be used.

Formaldehyde-fixed and Paraffin-embedded Tissues

Formaldehyde-fixed and paraffin-embedded tissues provide a valuable resource for forensic analysis.

Removal of the paraffin can be accomplished by washing the tissue in xylene [27] or by microwave treatment of the paraffin blocks to "melt" the paraffin [28]. A variety of extraction methods can then be used, including organic extraction and Chelex® procedures.

Coextraction of DNA and RNA

Recently, there has been interest shown in the development of RNA-based methods for the identification of body fluids in forensic samples [29]. To maximize the usefulness of such techniques, it is important that both DNA and RNA can be obtained simultaneously from the same sample and methods that accomplish this have been published [30, 31]. In brief, these methods include steps to protect the fragile RNA from RNases and methods to selectively precipitate DNA in the presence of RNA. As the development of the RNA-based methods is in its infancy and has not been widely adopted by forensic laboratories to date, it is likely that refinements to these methods will be made.

Extraction of Plant Material

The use of plant material as a source of forensic DNA evidence has also been recognized. Many methods for the extraction of DNA from plant material are based on the use of hexadecyltrimethlyammonium bromide (CTAB) [32], although these have been more recently replaced by custom-designed commercial kits such as DNeasy Plant Kits from Qiagen Inc. [33].

Contamination

No account of the extraction of DNA from forensic samples would be complete without some mention of contamination. Lessons learned from the study of ancient specimens [34] describe the risks of contamination and precautions that can be taken to minimize the risks. As DNA is recovered from ever smaller amounts of cellular material, this is of utmost importance. Recent adoption of low copy number DNA (*see* **Low Copy Number DNA**) techniques in laboratories typically includes the monitoring of the laboratory environment for extraneous DNA, which has highlighted the importance of protective clothing, frequent changes of gloves, and the decontamination of equipment and surfaces.

Eyewitness: Suggestibility of

Eyewitnesses can be quite accurate in their memory for a witnessed event, but many factors related to eyewitness suggestibility can influence the accuracy of eyewitness accounts. Eyewitness suggestibility refers to the tendency for individuals to incorporate misleading information into their memories for a witnessed event, which may lead to inaccurate eyewitness accounts (*see also* **Hypnosis and Memory**; **Memory: Repressed**). Typically the misinformation occurs on a postevent basis. The process by which one may become an eyewitness includes several stages, all of which may lead to errors in memory for the witnessed event.

The order of the phases as a witness experiences them include: (i) witnessing the event; (ii) possible postevent discussion with other witnesses; (iii) exposure to postevent information, potentially including misinformation, during the delay and/or when

remembering the episode, such as during police questioning; and (iv) a time delay between witnessing the event and being asked to recollect the event. These sources of misleading information may come from external sources, such as postevent narratives, questionnaires, cowitnesses, and investigative interviews, as well as internal sources, such as autosuggestion. The purpose of this article is to review these sources of adult eyewitness suggestibility as they pertain to the process by which witnesses may encounter various intervening events that can skew their memory for the original event. Although many of these and other factors related to eyewitness testimony have been studied with children (*see* **Children: as Witnesses**) and older adults (*see* **Eyewitness Testimony**), we have limited our review to the research on healthy, young adults. However, we included a brief overview of research designed to assess individual differences in adult suggestibility as it pertains to eyewitness memory; in this overview, age differences are noted. Additionally, we have focused our review on six major areas of forensically relevant research in eyewitness memory that reflect both the classic study of and current trends in eyewitness memory research: misleading postevent information and the misinformation effect, cowitness contamination, time delay, suggestive interviewing, individual differences in suggestibility, and false memory formation.

History and Theories of Adult Eyewitness Memory

Alfred Binet (1900) was one of the first to scientifically study the role of suggestive questioning on memory for objects and events [1]. He formally distinguished between *suggestion*, or external, deliberate misinformation, and *autosuggestion*, or internal, self-generated memory distortion. He reported that both can lead to memory errors. In 1908, Hugo Münsterburg published his seminal book *On the Witness Stand*, in which he described errors in witness memory and suggestive interviewing that may bring about false confessions [2]. Münsterburg's writings set the stage for modern scientific investigation of faulty eyewitness accounts, the study of forensic interviewing, and the nature of obtaining confessions. Both Binet's and Münsterburg's works emphasized the fallibility of memory in light of misinformation and foreshadowed theoretical explanations of why eyewitness memory is often inaccurate. In 1932, Sir Frederic C. Bartlett published the results of numerous experiments on memory errors made when participants recalled meaningful material, including memory for (witnessed) faces [3]. Bartlett's work serves as a methodological prelude to much modern eyewitness memory research. Furthermore, he theorized that memory is a reconstructive process rather than verbatim reproductions of what was experienced and therefore prone to errors.

It was not until the early 1970s that psychologists began again to formally investigate eyewitness memory within the context of Bartlett's influential theory of reconstructive memory. Elizabeth Loftus and her colleagues developed a research methodology with which to study the role of suggestive misleading information on memory [4]. As illustrated in Figure 1, subjects in such experiments witness an event, are presented with misleading information, and are tested for their memory for the event. For example, in a classic study by Loftus *et al.* (1978), subjects in both control and misled groups viewed an event depicting an automobile-pedestrian accident, including the view of a stop sign at the intersection between two streets [5]. The subjects answered a series of questions, including one critical question. The control group was asked "Did another car pass the red Datsun while it was stopped at the stop sign?" and thus did not receive any misinformation. The misled group was asked the same question, but "yield sign" replaced "stop sign" in the question; thus, the misled group received misinformation about the sign at the intersection. Later, all participants were administered a two-alternative forced choice recognition test. In the key choice they were shown two slides, one of the car stopped at a stop sign (from the original event) and one of the car stopped at a yield sign. In this study and in numerous other studies, Loftus and her colleagues found that compared to control conditions, misled subjects were much more likely to erroneously remember misleading information as original event information, a phenomenon called the *misinformation effect* [5–8].

Loftus and her colleagues argued that the memory trace for the originally witnessed information was altered and replaced by misinformation via reconstructive processes. Others researchers soon criticized this trace alteration position on grounds that using the methodological procedure shown in Figure 1 to test the misinformation effect produces a bias

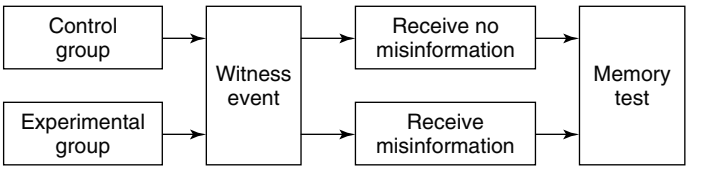

Figure 1 Research methodology used to study the misinformation effect

toward memory for misinformation, and further contended that original event memory traces are still intact but not retrieved, possibly because the misled information is more recent and interferes or blocks accessibility to original details [9, 10]. This notion captures the essence of the coexistence hypothesis and soon researchers began to use a more general term, namely, "*memory impairment*", which was introduced to generically refer to multiple forms of memory distortion while not implying any neuropsychological processes.

One theoretical explanation of memory impairment whether due to suggestion or autosuggestion focuses on inaccurate monitoring of the source of information, leading to confusion between original event information and misinformation [11, 12]. As a result, witnesses may misattribute the source of the misleading information to the original event, producing the misinformation effect. Another recent theory proposed to explain internally generated confusions in memory and resultant false memories for an event is the FTT, which posits that individuals create two independent memory traces for the original event, a verbatim trace and a gist trace [13]. The verbatim trace includes an exact memory representation for the event, while the gist trace includes a schema-based representation of the event. When an individual witnesses an event, both verbatim and gist traces are formed. Initially, access to strong verbatim traces allows adults to produce quite accurate recollections and to simultaneously suppress memory errors. However, verbatim traces fade quickly overtime [14] such that many details of the event are forgotten, but gist traces remain fairly intact. Thus, one's recollection for an original event typically may rely more on gist representations than on verbatim representations. Because gist does not fade overtime as much as the exact details, and as gist is schematic, memory for the original event may be more prone to error when one relies on gist more than verbatim traces.

Extensions of the basic misinformation paradigm shown in Figure 1 have led to current research on sources of adult suggestibility that includes investigation of misleading information in the form of cowitness suggestions and suggestive investigative interviewing. Likewise, changes in memory for the event may occur without deliberate misinformation and instead develop internally via autosuggestion.

Sources of Adult Suggestibility

As we have chronicled above, the psychological study of adults' susceptibility to accepting misleading information as accurate, original event information, includes the scientific investigation of cowitness suggestion, suggestive interviewing by police investigators, and autosuggestion. For instance, witnesses speaking about an event before reporting the event can alter one's memory for the original event and lead to cross-contamination of witness reports [15, 16]. Recently researchers have begun to uncover the extent to which discussing an event with others influences memory. For example, one approach has been to utilize a confederate (an experimenter's assistant who poses as a subject in the study) to provide accurate and inaccurate information after a witnessed event, usually during a memory test, in order to sway the real subject to conform to the confederate's answers. A few studies have used the latter approach and have found that in most situations, individuals conform to the confederate's reports and provide inaccurate information about the event that they witnessed [16–21]. Postevent information in the form of witness discussion may bias a witness to report the postevent information, which may be inaccurate, especially if they do not trust their own memory. Furthermore, sometimes witnesses may be unaware of the influence of others' recollections of the event. In this case, a witness may unknowingly misattribute what others said as a memory for what she/he originally saw or heard. In the course of a

forensic investigation, information supplied by witnesses to investigators may serve as the basis for further police interviews, construction of lineups, and formulation of theories about the witnessed event. Therefore, it is important that a witness not be contaminated by others' view of what happened. After witnessing an event and potentially talking with other witnesses, usually witnesses are interviewed by law enforcement personnel. It is during these interviews when witnesses may be prone to suggestion and changes in memory for the event may result. Furthermore, the eyewitness interview or interrogation can lead to extreme effects of eyewitness suggestibility in the form of false confessions (*see* **Interrogative Suggestibility**) and false eyewitness identification (*see* **Eyewitness Lineups: Identification from**), both of which are beyond the scope of this article.

The scientific study of suggestive interviewing includes investigation of factors that are related to faulty eyewitness memory. Such factors include, but are not limited to, the wording of investigative questions, the time delay between the witnessed event and recall or recognition of the event, the repetition of misinformation, and individual differences in eyewitness memory. In an early example, Loftus and Palmer (1974) presented subjects with a video of a car accident, then later asked them a series of questions about the event [6]. The key question involved a manipulation of the wording of the question in which different subjects were asked to estimate the speed of the moving car that *contacted, hit, bumped* or *smashed* the other car. Subjects who heard *smashed* estimated faster speeds than subjects who heard other verbs. One week later, all subjects returned and were asked additional questions, including whether there was broken glass at the scene of the accident. Those individuals who heard *smashed* were more likely to recall broken glass than those who heard other verbs; in fact, there was no broken glass. Loftus and Palmer's study illustrates how the mere wording of questions can alter one's memory representation for a witnessed event. Theoretically, misleading information may be mistaken for original event information and erroneously remembered as what was witnessed, indicating a source monitoring confusion. Thus, the misleading postevent information creates a bias in memory for recollection of misinformation. From the vantage point of FTT, the misleading event may make it difficult to retrieve an original verbatim trace and/or provides a more recent verbatim representation that is gist-consistent and may successfully compete with the original information at test.

The time delay, or retention interval, between witnessing an event and reporting about the event may lead to inaccuracies in eyewitness memory [22, 23]. For example, subjects in Odinot and Wolter's (2006) study viewed a video of an event and were tested either one, three, or five weeks later. They found that the longer retention intervals resulted in fewer items accurately recalled and more items inaccurately recalled. The decrease in accuracy is not surprising, as this result is consistent with a long history of research on the relationship between retention interval and forgetting [14, 24]. However, subjects also recalled more inaccurate items with a longer delay, in line with our earlier discussion that they may have relied more on the gist of the event. Once again FTT predicts just this sort of dissociative effect of memory; with time, verbatim traces fade (accurate recall decreases with a delay) but the gist traces may remain intact but are schema-based and more prone to supporting memory error (inaccurate recall increases with a delay). Similar results have been found when misinformation is presented to witnesses. The retention interval between witnessing an event and receiving misinformation and the delay between receiving misinformation and reporting from memory what was witnessed both can lead to memory impairment [5, 23, 25, 26].

The study of individual differences in eyewitness memory and testimony include examination of the effects of age on suggestibility and subsequent eyewitness errors. Generally speaking, children are more susceptible to suggestion than adults and a review of this topic is found in the Encyclopedia article Children as Witnesses referred to earlier. Results with older adults have been mixed. Many researchers have found that older adults are more susceptible to suggestive postevent information and as a consequence make more eyewitness memory errors than younger adults [27–30]. However, there are some exceptions in the research literature, in which like the aforementioned studies, older adults demonstrate poorer overall memory accuracy, but they are not more susceptible to the effects of misleading information [31, 32]. Loftus *et al.* (1992) examined numerous other individual differences variables, including gender, occupation, and educational level [29]. Aside from clear age effects, Loftus *et al.*'s results were mixed.

Another approach to studying individual differences in adult suggestibility to misleading information involves a formal test of suggestibility. Gudjonsson (1987, 1997) developed the Gudjonsson Suggestibility Scale II (GSS2) in which individuals are first exposed to a story, and then after a delay are asked a series of questions about the story [33, 34]. After being told that they made many mistakes on their first test, individuals are questioned again. The GSS2 provides two scores that indicate an individual's susceptibility to suggestion: "Yield", which is the tendency to accept misinformation as reality, and "Shift", which is the tendency to change one's answers in response to negative feedback and social pressure. The sum of Yield and Shift scores provides a measure of total suggestibility. Much of the research that utilizes the GSS2 is related to personality characteristics [35, 36] and the interrogation of witnesses [37–39]. For example, Baxter *et al.* demonstrated that subjects were more likely to "shift" their memory reports to accept more misinformation when the interviewer displayed a firm as opposed to a friendly demeanor [37]. In an examination of cross-cultural differences, Pollard *et al.* found that individuals in the United Kingdom were more likely to report misinformation from the onset than their US counterparts, and individuals in the United States were more likely to "shift" their answers compared to the UK sample [39]. Polczyk *et al.* found that older adults were more likely to report misinformation (Yield) than young adults, but older adults did not differ from young adults in the likelihood that they would "shift" their answers in response to negative feedback and social pressure [38]. The GSS2 is an assessment of memory suggestibility in general (*see also* **Interrogative Suggestibility**); however, another example of individual differences in suggestibility involves the variability of response to hypnotic suggestion that may or may not invoke retrieval of true memories (*see* **Deception: Truth Serum**).

False Memories

Inaccuracies in eyewitness memory, whether due to suggestion or self-generated, autosuggestion, all result in distortions that make the formation of false memories for the witnessed event quite likely. False memories due to autosuggestion are considered spontaneous false memories as opposed to those implanted via overt suggestion. The study of spontaneous false memories has proliferated in the past decade and has dominated the use of a methodological procedure known as the *Deese–Roediger–McDermott* (*DRM*) procedure in which subjects are asked to remember schema-based word lists designed to elicit illusory memories [40, 41]. For example, subjects may study *bed, rest, awake, tired, dream*, etc. then are asked to recall or recognize list words. Typical results are that subjects falsely remember a critical (lure) word (e.g., *sleep*) that was not presented but is strongly associated to the list words [42]. Furthermore, much like the research on eyewitness suggestion, subjects falsely remember lure words with high confidence [43] and report details about their (non)occurrence in the list [44, 45]. Also, spontaneous false memories persist overtime [46, 47], a fact consonant with the notion that with delays people are relying on gist traces.

The formation of false memories has been explained by two major theories: FTT and activation-monitoring. FTT posits that false memories occur because of retrieval of gist memory traces that were repeatedly strengthened during encoding as each presented item converges on the theme [13]. Activation-monitoring suggests that false memories occur as a result of a combination of relational (gist-based) processing at study and poor memory monitoring at retrieval [12, 48]. The study of false memories using word lists provides researchers with a methodology that produces high rates of false memories analogs to those studied in eyewitness situations. Furthermore, because word list studies are highly controlled from a procedural standpoint, compared to other stimulus materials they provide greater opportunities to test theories of false memory formation. Such theoretical tests allow researchers to better predict the circumstances under which false memories occur and also how false memories can be reduced. It is important to note that while we have focused on the DRM paradigm, highly similar false recollections occur with more ecologically valid materials including pictures, stories, narratives, and classroom lectures [47].

Summary

Psychologists have also examined factors that can reduce the effects of suggestibility in eyewitness memory. Warnings about misinformation have been shown to reduce the effects of misinformation, but such effects depend on when and how the warning is

administered [49–51]. Likewise, warnings of spontaneous false memories have been found to reduce false memories when the warning is administered after study [52] but such results have been mixed. Nonsuggestive interviewing techniques, such as in the cognitive interview, increase accuracy of memory for a witnessed event [53, 54].

Within the past 10 years, the courts and criminal justice personnel have become more open to considering psychological research on eyewitness memory, particularly with the advent of forensic DNA testing. Wells *et al.* (1998) and Scheck and Neufeld (2000) reported that more than 100 people convicted prior to the use of DNA testing have since been exonerated, and more than 75% of those falsely convicted were convicted on the basis of eyewitness testimony [55, 56]. Currently, the Innocence Project currently reports over 200 exonerations due to DNA evidence (www.innocenceproject.org). Wells *et al.* (2000) reported that, consequentially, there has been a rise in the use of eyewitness memory research in the criminal justice system [57]. Factors that affect and have the potential to reduce adult suggestibility continue to be explored to further our understanding and to inform others (particularly those in the criminal justice system) about the various factors that can lead to inaccuracies in eyewitness memory reports [58, 59].

Eyewitness Lineups: Identification from

The police lineup is a common tool for trying to establish the identity of the perpetrator of a crime. A lineup is likely to be used when there was at least one eyewitness (*see* **Eyewitness Testimony**) who observed the culprit committing the crime (or observed someone just prior to or just after the crime was committed who was likely to have been the culprit). When police investigators have a suspect in the crime, that person or his/her photo is shown to the eyewitness to see if the eyewitness will identify that person as the culprit. Because showing only one person (or one photo) is considered a suggestive procedure, the suspect (or his photo) is embedded among other people (or photos of other people). These other people (or their photos) are not suspects and are called *fillers*. This array of people (or photos) is generally called a *lineup*. The eyewitness is then asked if s/he recognizes anyone in the lineup as having been the culprit. Photographic lineups are much more common than are live lineups and the number of lineup members typically ranges from six to eight. A positive identification of someone from a lineup can be a very powerful form of evidence, commonly resulting in arrest, indictment, and ultimate conviction.

The Development of a Science of Lineups

Behavioral scientists have conducted hundreds of experiments, starting in the mid- to late 1970s, in which unsuspecting people have viewed simulated crimes followed by lineups. On the basis of these experiments, scientists have published several hundred articles warning that the risk of eyewitnesses identifying innocent people is much higher than most people seem to believe. The rate of mistaken identification is not a constant number but instead varies as a function of dozens of factors. These include factors that are not under the control of the criminal justice system (such as witness viewing conditions, stress, whether the witness and culprit are of the same race or not), which are called *estimator variables*. However, the rate of mistaken identification also includes factors that are directly under the control of the criminal justice system (such as prelineup instructions to the eyewitness, the choice of fillers used in the lineup, and cues from the lineup administrator that can influence the eyewitness), which are called *system variables* [1]. Psychological scientists have taken a special interest in system variables because of the potential to use system variables to reduce the chances of mistaken identification.

Although the eyewitness identification literature drew the attention and respect of many psychological scientists, it was not until the mid- to late 1990s that the legal system began to take significant notice. This notice by the justice system was due largely to the advent of forensic DNA testing in which claims of innocence by a subset of convicted people could be tested. In 1996, a US Justice Department report on the first 28 exonerations on the basis of DNA

testing revealed that 24 were cases of mistaken eyewitness identification [2]. By 2007, the number of DNA-based exonerations of individuals who were convicted by juries stood at more than 200 and over 75% of those were cases of mistaken eyewitness identification (see www.innocenceproject.org for an up-to-date internet site that tracks these cases). These DNA exonerations have resulted in greater communication between the justice system and the psychological science on the problem of mistaken identification.

Causes of Misidentification in Lineups

Researchers have discovered a large number of factors that contribute to eyewitness misidentification. Some of these factors are relatively obvious in the sense that they represent conditions of witnessing that are not conducive to forming a good memory of the facial characteristics of the perpetrator, such as poor lighting, distant viewing, short exposure durations to the perpetrator's face, and the use of disguises by the perpetrator. Other factors might be less obvious, such as the stress and fear that sometimes accompany witnessing a crime. Surveys suggest that many people believe that stress and fear could make memory better by making the eyewitness more alert or that the emotion will somehow help the eyewitness form a clear and lasting memory [3].

But, research does not support this contention, indicating instead that stress impairs the formation of memories needed for accurate identification decisions from lineups [4]. Similarly, the use of weapons visible to the eyewitness draws attentional focus to the weapon and detracts from processing of the face of the perpetrator [5]. Another factor that impairs eyewitness identification performance is whether the eyewitness and the culprit are of the same or different race or ethnic background. Research has consistently shown that it is more difficult to recognize a stranger who was viewed on only one prior occasion if that person was of a different racial or ethnic appearance than the witness [6].

Relative Judgments

Having a weak memory *per se*, however, does not fully explain why eyewitnesses make mistaken identifications from lineups. In particular, having a weak memory does not explain why a witness would make a positive identification rather than simply saying "I don't know". A dominant conceptualization among eyewitness scientists is that eyewitnesses are motivated to make an identification (in the interests of justice) and sometimes rely on a "relative-judgment process" rather than absolute recognition to make the identification decision [7]. A relative judgment is one in which the eyewitness compares each lineup member to the other lineup members and decides which one more closely resembles his/her memory relative to the other lineup members.

The relative-judgment strategy can be effective if the actual perpetrator is in the lineup, but it will lead to a mistaken identification if the actual perpetrator is not in the lineup. Experiments have shown that removing the perpetrator from a lineup results in witnesses shifting their identification decision to another lineup member, even though they were warned that the actual perpetrator might not be in the lineup [8]. This phenomenon is especially pronounced when witness's memories for the perpetrator are weak.

Prelineup Instructions

Along these same lines, the failure to use prelineup instructions warning the eyewitness that the perpetrator might not be in the lineup (or suggesting that the perpetrator is in the lineup) leads to high rates of mistaken identification when the actual perpetrator is not in the lineup [9]. This prelineup warning has little effect on the eyewitness's ability to identify the perpetrator if the actual perpetrator is in the lineup. No empirically determined estimates exist of how often perpetrator-absent lineups are shown to witnesses in actual cases. But, the absence of the actual perpetrator in the lineup is not necessarily an unusual situation. It simply means that the person-of-interest (or suspect) is not the perpetrator and that the investigation has focused on the wrong person.

It is not likely that the rate of perpetrator-absent lineups in actual cases can be represented by a single base rate or percentage. Instead, the rate of perpetrator-absent lineups is likely to vary from one case to another and one jurisdiction to another depending on how much or little evidence the detectives feel that they need in order to conduct a lineup [10]. Jurisdictions that are quick to assemble a lineup on the basis of mere hunches would be expected to run a higher rate of perpetrator-absent lineups than would jurisdictions that require good evidence against the suspect before conducting a lineup.

Lineup Composition

Another factor that contributes to mistaken identification is the use of lineup fillers who fail to fit the eyewitness's description of the perpetrator, which leads the eyewitnesses to prefer the suspect (who does fit that description) even when the suspect is not the perpetrator [11]. Consider a case, for instance, in which the eyewitness described the perpetrator as a tall man in his 20s with short dark hair and no facial hair. Suppose that the suspect fits that description but the fillers were short, or had light colored hair, or had long hair, or were in their 40s, or had facial hair. This would make the suspect stand out in the lineup as being the person that the investigators obviously believe committed the crime.

A technique called the *mock witness procedure* has been developed by eyewitness scientists to assess such biases. Mock witnesses are people who have never previously seen the suspect and are simply given the eyewitness's verbal description of the perpetrator. The mock witnesses then view the lineup (or a photo of it) and select the person they believe is the suspect in the case. A fair six-person lineup should result in only 1/6 of the mock witnesses picking the suspect and the remaining 5/6 of the witnesses selecting fillers. The inverse of these ratios (e.g., inverse of $1/6 = 6$) is known as *functional lineup size* [12]. Hence, if 1/3 of the mock witnesses pick the suspect, the functional size would be 3, even if the nominal size (number of persons in the lineup) was 6, 8, or 10. The higher the functional size, the more it is presumed to be protective of mistaken identifications of an innocent suspect.

Influence of Lineup Administrator

Another type of factor that can cause mistaken identifications from lineups is the behavior of the person who administers the lineup. The common practice is for the case detective to administer the lineup. That means that the lineup administrator knows very well which lineup member is suspected of the crime and which lineup members are merely fillers. Most initial lineup procedures use photographs and there is no videotaping of the procedure. When photo-lineup procedures are used, there is no right to have defense counsel or other neutral parties present to observe the procedure. Eyewitness scientists have argued that this procedure creates considerable opportunity for the lineup administrator to influence the eyewitness inadvertently and have argued instead that the lineup procedure should be conducted using an administrator who does not know which person is the suspect and which are fillers [13].

This is known as the *double-blind lineup procedure* [8, 14]. Experimental simulations have shown that lineup administrators do influence eyewitness identifications in a manner consistent with what the administrator is led to believe about which person is the suspect [15]. The precise ways in which this influence occurs are not yet well established, but they appear to be very similar to the experimenter-expectancy effect in which the results of an experiment are influenced by the expectations of the experimenter who tests the research participants [16].

False Confidence

A lineup results in two primary outcomes: the identification itself and the confidence that the eyewitness expresses in the identification. The confidence expressed by the eyewitness is important because tentative or low confidence identifications are usually not considered strong evidence, often do not result in charges, and tend to be unpersuasive to judges and juries. A confident eyewitness, in contrast, is very persuasive [17]. Hence, eyewitness scientists have devoted a great deal of research to the question of how strong or weak the correlation is between eyewitness identification confidence and eyewitness identification accuracy.

As might be expected, the strength of the relation between confidence and accuracy varies considerably across studies as a function of numerous other variables. A meta-analysis of 30 different studies indicated that the average correlation might be as high as $r = 0.41$ [18]. That means that accuracy is accounting for only about 16% of the variance across eyewitnesses in their confidence.

The concept of false confidence refers to a highly confident eyewitness who has nevertheless made a mistaken identification. False confidence can occur for a variety of reasons, including the obvious situation in which an innocent person was identified who happens to have very high coincidental resemblance to the culprit. More interesting, however, is the phenomenon of "confidence malleability" in which a mistaken eyewitness who was initially low in confidence later becomes highly confident.

Evidence for confidence malleability has been shown dramatically with the postidentification feedback effect. After making mistaken identifications, eyewitnesses who are given feedback suggesting that they identified the right person (e.g., "Good, you identified the actual suspect") undergo a distortion in their memory about their initial uncertainty and come to believe that they were confident all along [19]. The postidentification feedback effect has been demonstrated across a variety of experiments [20]. The result of such feedback is the creation of a confident (yet mistaken) eyewitness.

Eyewitness Memory ***see*** Elderly in Court

Eyewitness Testimony

One of the most famous cases involving mistaken eyewitness memory arose out of events that occurred in 1984, when a man broke into two separate women's homes, raped both women, and stole their money and other belongings. One of the victims, 22-year-old Jennifer Thompson identified the same man in a photo lineup and in a subsequent in-person

lineup; his name was Ronald Cotton. Cotton was arrested and charged with two counts of rape and burglary. Even though Cotton had an airtight alibi, the confident eyewitness testimony of Jennifer Thompson was sufficient for the jury to convict him. Cotton was sentenced to life in prison. Nine years after Cotton's conviction, he learned about DNA testing while watching the O.J. Simpson trial. Cotton asked to be tested, and the results proved that Cotton was innocent. In June of 1995, Ronald Cotton was exonerated of the crimes he had once been convicted of and was given $5000 in compensation [1].

As Cotton's case reveals, eyewitness identification is neither always reliable nor accurate (*see* **Eyewitness Lineups: Identification from**). Because eyewitness testimony is a powerful component of criminal court cases, it is necessary to understand the memory processes and variables that influence identifications, and to learn what can be done to prevent these miscarriages of justice.

How Memory Works

After witnessing a crime and being asked to identify the culprit, eyewitnesses sometimes express great confidence in the accuracy of their identifications, saying, "I was so frightened. I'll never forget that face." However, research and real-life cases reveal that eyewitnesses may misidentify the perpetrator. Contrary to popular belief, memory does not function like a videotape recorder. Events are not recorded in the mind so that they can be played back later; rather, complex reconstruction takes place to form the "memory" for the particular event (*see* **Memory: Reconstructive**).

Acquisition Stage

Memory formation consists of three stages: acquisition, retention, and retrieval [2]. The acquisition stage occurs when the original event is perceived. The amount of information encoded into a person's memory system is actually only a small portion of the person's surrounding environment.

Retention Stage

After the information from the event is stored in memory, many factors can affect the memory. This period of time between the event and eventual recall of it is called the *retention stage*. We have known since the nineteenth century that memory fades during the retention interval [3].

The passage of time is not the only factor that can cause memory to falter during the retention stage. Eyewitnesses may overhear a conversation between other witnesses or read a newspaper article about the crime; these are both examples of "postevent information" that can alter the original memory. Sometimes postevent information can even cause a witness to introduce nonexistent objects into the memory. After a person witnesses a crime, he/she may be exposed to information that alters the original memory with the new information or that causes the eyewitness to compromise between the original memory and the new information. For example, in a study conducted by Loftus and her colleagues [4], participants viewed a series of 30 slides depicting an accident involving a red Datsun and a pedestrian. Half the participants watched the car approach an intersection in which there was a yield sign, and the other half watched the car approach the intersection with a stop sign.

After viewing the slideshow of the auto-pedestrian accident, the participants were asked a series of questions, one of which was critical. Half the participants were asked, "Did another car pass the red Datsun while it was stopped at the *stop sign*?" The other half were asked the same question with the words "*yield sign*" replacing the words "stop sign". For half the subjects, the question contained misleading information; that is, they saw a stop sign but were asked about a yield sign or they saw a yield sign and were asked about a stop sign. Twenty minutes later, participants were administered a recognition test.

When given consistent information from the critical question (i.e., saw a stop sign and asked about a stop sign), 75% of the participants accurately identified the correct slide (either depicting a red Datsun at an intersection with a stop sign or a red Datsun at an intersection with a yield sign). If the question they had previously answered included misleading information (i.e., saw a yield sign but asked about a stop sign), only 41% of the participants accurately identified the correct slide. Thus, the misleading question reduced accuracy for identifying the correct slide to below chance level. As demonstrated by this study, postevent information in the form of misleading questions can reduce the accuracy of memory.

Retrieval Stage

In the last stage, the retrieval stage, witnesses try to recall information about an event. They may simply provide a narrative about what happened or answer specific questions. Retrieval can occur many times, for example, during an investigation by law enforcement or during trial testimony. Some of the factors that influence accuracy and completeness of an eyewitness's account during the retrieval stage include the environment in which the retrieval process takes place, the type and wording of questions to obtain information, and who is asking the questions.

Estimator and System Variables

At any point during the three stages of memory, a number of other variables can influence the way in which the information is perceived, retained, and recalled. Researchers often refer to these factors as "estimator variables" and "system variables". Estimator variables include the characteristics of a witness (e.g., an eyewitness's age and race) and the characteristics of an event (e.g., amount of time the eyewitness attentively viewed the culprit, whether or not a weapon was present, and crime scene lighting conditions) [5].

System variables include factors that are under the control of law enforcement or others in the legal system. These include factors such as whether or not the culprit was in the lineup (culprit-present *vs.* culprit-absent lineups), whether the eyewitness was given prelineup instructions indicating that the culprit may or may not be in the lineup, and the composition of the lineup (e.g., the suspect looks significantly different from the other people included in the lineup). The lineup presentation method (simultaneous *vs.* sequential) and any influence the person administering the lineup may have on an eyewitness (e.g., feedback about the person an eyewitness chose as the culprit) are also considered system variables [5].

Important witness characteristics to consider are the age and race of the eyewitness. In particular, research shows that older adults and young children are less accurate than adults with respect to eyewitness memory. Research also suggests that witnesses are better able to identify strangers of the same race than strangers of a different race. This phenomenon is known as *cross-racial identification*. Other important estimator variables to consider are the characteristics of the event. For example, the amount of time that an eyewitness has to view the culprit may affect the reliability of memory. Critically, research indicates that eyewitnesses often overestimate the duration of crimes. Another factor that may affect eyewitness memory is the presence of a weapon; this phenomenon is known as *weapon focus*. Specifically, research has shown that the presence of a weapon during a crime can capture attention, and while the weapon may be well remembered, other details can be impaired in memory, including the identity of the culprit [6].

Sometimes investigators include a suspect in a lineup who is not actually the real perpetrator. Showing these culprit-absent lineups, although not intentional, can present problems. Eyewitnesses may expect the culprit to be present and result in the eyewitnesses choosing the person who looks most similar to the culprit they remember, and subsequently a misidentification occurs (*see* **Eyewitness Lineups: Identification from**).

The composition of a lineup is also crucial. A biased lineup may contain a suspect that is the only person of a certain race when the nonsuspects in the lineup (i.e., fillers) are of a different race or a suspect described as six-feet tall is placed in a lineup with fillers that are all much shorter. As recommended by the National Institute of Justice's (NIJ) *Eyewitness Evidence Guide for Law Enforcement* [7], the composition of a lineup would include fillers who fit the verbal description of the culprit as given by the eyewitness. While some lineup biases may seem subtle and unimportant, they may still greatly affect eyewitness identification. In addition to composition, the lineup presentation method is important. Some research suggests that sequential lineups, in which individuals or photos are presented sequentially rather than simultaneously, may reduce erroneous identifications.

Another system variable that is important to address is the influence that the lineup administrators may have on eyewitnesses. Research shows that confirming feedback (e.g., "Good, you identified the suspect") from a lineup administrator may inflate the eyewitness's confidence in his or her accuracy of the identification. Thus, researchers suggest the use of double-blind lineups in which neither the administrator of the lineup nor the eyewitness knows which lineup/photospread member is the suspect. By using

the double-blind technique, the investigator can neither provide any inadvertent cues nor can he or she provide confidence-inflating feedback.

Estimator and system variables may affect an eyewitness's testimony in several ways. It is important to remember that any combination of estimator and/or system variables could occur in a single case. Depending on which variables are present in a case, an eyewitness's memory may be greatly impaired. Because law enforcement has greater control over system variables than estimator variables, it is important that law enforcement makes every effort to prevent mistaken identifications. In particular, the NIJ recommends the implementation of specific lineup procedures to reduce erroneous identifications. In addition, it is important for the jurors in a trial to be aware of the factors that may influence an eyewitness account.

Juror Knowledge

Over recent decades, researchers have examined whether jurors correctly weigh the variables that affect the reliability of eyewitness identifications. Several studies have revealed that potential jurors show limited understanding of eyewitness memory. For example, Deffenbacher and Loftus [8] administered the Knowledge of Eyewitness Behavior Questionnaire (KEBQ) to college students and lay people. The KEBQ contained 14 multiple-choice questions that assessed jurors' understanding of several eyewitness behaviors. Overall, the results indicated that subjects performed moderately above chance on some questions, but subjects performed at a less than chance level on other questions.

In particular, subjects held misconceptions about the effects of violence and interviewing methods on an eyewitness' memory. Also, subjects misunderstood the slight, positive correlation between confidence and accuracy, the reliability over time of memory for faces, the lower accuracy of cross-race identifications and the fact that trained observers are no more accurate as eyewitnesses than the average citizen. The authors concluded that cautionary instructions and expert testimony are necessary to ensure that jurors correctly evaluate eyewitness evidence.

Likewise, Kassin and Barndollar [9] surveyed college students and lay people about 21 eyewitness phenomena. The results showed that subjects performed at or below chance for 11 of the items. While most subjects correctly understood that severe stress, the eyewitness' attitudes and expectations, and the wording of questions can influence an eyewitness' testimony, most subjects incorrectly believed that violence and exposure time do not affect an eyewitness memory. Subjects showed limited understanding of the forgetting curve, the accuracy–confidence relationship, the inferiority of cross-race identifications, and the lack of increased accuracy of trained observers. These findings indicate that jurors are insensitive to some of the factors that affect an eyewitness' testimony.

Other research suggests that jurors are less aware of estimator variables than system variables. For instance, Benton *et al.* [10] surveyed actual jurors and found that although jurors held misconceptions about both estimator variables and system variables, jurors were generally more insensitive to questions concerning estimator variables. Specifically, jurors performed below chance for 15 of the 22 questions on estimator variables including, but not limited to the following: cross-race identifications, the accuracy–confidence relationship, weapon focus, forgetting curve, exposure time, unconscious transference, and violence. Jurors also performed below chance for four of the eight questions on system variables including the following: lineup instructions, lineup presentation format, description matching, and lineup fairness. The authors concluded that in order to prevent jurors from erroneously assessing eyewitness evidence, expert testimony is crucial.

Additional research suggests that some jurors are too trusting of eyewitness evidence. In particular, Schmechel *et al.* [11] surveyed a large, random sample of potential jurors from Washington, DC and assessed whether the potential jurors correctly understood what makes an eyewitness more or less reliable. The findings indicated that 65% of subjects believed eyewitness identification evidence to be somewhat or very reliable. Furthermore, 46% of subjects incorrectly understood the reconstructive nature of human memory. A substantial proportion of subjects were insensitive to the factors that affect eyewitness testimony including: the accuracy–confidence relationship, trained observers, cross-race identifications, show-ups, weapon focus, violence, prelineup instructions, and lineup presentation format. These results suggest that a sizable proportion of jurors will

begin a trial with dangerous misconceptions about the reliability of eyewitness testimony.

Conclusion

So far, we know from hundreds of research studies that eyewitnesses sometimes inaccurately remember the details of a crime and, even worse, misidentify the perpetrator of a crime. We also know that eyewitness memory is susceptible to distortion during each of the three stages of memory. Whether an eyewitness views a crime in which a weapon is present or whether an eyewitness views an unfair lineup, both estimator and system variables affect the accuracy of eyewitness identifications. Although real-life cases lend support to the empirical finding that eyewitness testimony is fallible, not all participants in the legal system appreciate this fact. In particular, the juror knowledge studies reveal that jurors are generally insensitive to the factors affecting eyewitness testimony. Taken together, these studies suggest that jurors may draw erroneous conclusions from eyewitness evidence and as a result, wrongfully convict innocent individuals. To prevent wrongful convictions, it is important that law enforcement follow the recommended guidelines set forth by the NIJ, and that juries are given cautionary instructions and/or expert testimony on the reliability of eyewitness testimony.

Facial Comparison

Introduction

In general, people are thought to be reasonably good at recognizing faces. Although research indicates that recognition of "familiar" faces can be extremely efficient, even with disguises and poor-quality images, this does not apply to recognition of "unfamiliar" faces [1, 2]:

> At an image level, the variability in the appearance of a given face under variations of lighting, pose and expression far exceeds the variation between two different faces under the same conditions [2].

This describes, in a single sentence, the central issue at hand with regard to the area of facial comparison in terms of both biometric (automated) and "human-based" facial comparison. This does not take away from the fact that facial comparison is regarded as a highly valuable tool for identification, and in many cases is indeed valuable. The number of crimes in which facial comparison plays a role will certainly increase, especially considering the growing number of security cameras.

Within the context of person identification, different processes can be defined. "Recall" is here defined as the process of retrieving descriptive information of a person from long-term memory in the absence of the person, his/her photograph, or other image. Recall requires observation, retention, and reproduction of a person's features. Recall is essential for the production of composite images, as produced by a police artist for investigational purposes. However, these images can only be used as investigative tools, and can never be used as proof of identity. "Recognition" is, in this article, defined as the process of identifying or matching a person, his/her photograph, or image with a mental image that one has previously stored in long-term memory. Recognition requires observation and retention of a person's features and the process of comparison of the retained information with an external image whether it be the life person, a photograph, or composite image. Recognition is important for investigation as well as witness statements. "Comparison" is defined as the process of identifying or matching a person or his/her image with another photograph or image without the use of retained information. For comparison, retention and reproduction do not play a role.

Summarizing, recall requires observation, retention, and reproduction; recognition requires observation and retention; and comparison requires observation. Obviously, for forensic purposes with respect to surveillance images we talk about recognition or comparison in case human operators are involved and about comparison in case (automated) biometrics is involved.

Human Observer

The main questions with respect to forensic image comparison are as follows: "Is the person in image A the same person as in image B?" or "is the person in image A a different person than in image B?" These images can vary greatly in terms of

source (wet passport photo, digital passport photo with and without compression, analog video, and digital video with low or high compression) and quality. In principle, we try to reduce the question to a comparison of two images. In doing so, we test the hypothesis that it is the same person in both images, as well as the hypothesis that two different people are concerned.

Are we actually capable of doing this? Can an unequivocal judgment be made with regard to identity? Can an estimate of a likelihood ratio be made with regard to the hypotheses "the images are of the same person" and "the images are not of the same person"?

Issues Involved in Facial Comparison

The obstacles encountered when carrying out facial comparison can be divided into issues related to the image material itself and issues related to the comparison process.

Image Material. *Image Quality*. The quality of the image material provided for facial comparison varies widely. Quality is poorly defined in this context, but is mainly used in the sense of "identifiability" or "degree of visibility of details". Image quality is influenced by a number of factors that should be described in the report if possible. Image quality is determined by sharpness, contrast, clarity, distance, distortion (teller machines!), resolution, and compression. Figure 1 gives some examples of surveillance and document images of varying quality. These examples vary from "useless" (a) due to image quality and pose, to "good" with minor compression artefacts (d). It would be advisable to summarize image quality in a single number/several numbers to indicate the expected evidential value of an image. Unfortunately, even an approximation of this is not possible at this time, and it is a tricky problem due to the many factors involved in "image quality".

Posture and Position in the Image. Besides image quality, the usefulness of an image is also influenced

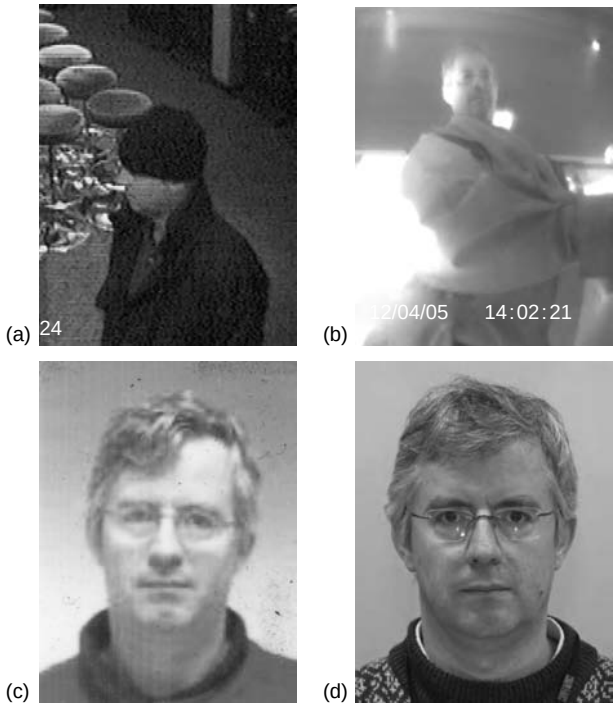

Figure 1 Typical examples of surveillance and document quality images. Quality ranges from "useless" due to image quality and pose (a), "nearly useless" due to camera position and distortion (b), "somewhat useful" due to poor sharpness (c), and "good" with minor information loss due to compression (d)

by the posture and position of the person depicted. Security cameras are often placed high up, and people do not look directly into the camera. The fact that the representation of shapes and distances within the face changes with changes in distance and pose relative to the camera is still poorly acknowledged, resulting in too much reliance on distance measurements in the pictures of the face. Problems can also arise with "controlled" photos: most passport photos are currently taken of the person looking straight at the camera, but sometimes the head is tilted or turned slightly, as a result of which the ears may or may not be fully visible. Mug shots are usually taken of the suspect facing straight ahead and from the left, as a result of which the identifying features on the right side of the face, and the right ear, are usually not visible. Of course, hats, glasses, and disguises also affect the possibilities of comparison: in the case of a camera placed high up, if the suspect is wearing a baseball cap with a bill, this is often sufficient to cover most of the face.

Reconstruction. To overcome problems with posture and position, reconstruction of recording conditions can be used. To reposition someone in the image, the camera system must still be intact and the suspects must cooperate. Foils are used for validation in this procedure, but the influence of the choice of the foils (according to the description of the perpetrator), the methods of processing of the data (one-to-one comparisons with perpetrator images or grouping of "similar" people), and conclusions that can be drawn from such investigation have not been validated yet.

A method that is still in the experimental phase is the use of 3D models for reconstruction [3]. The advantage of this method is that it does not require cooperation by a suspect at the scene of the crime, and that repositioning can take place in a virtual environment. However, making the 3D models is a laborious and time-consuming process. The reliability of the reconstructed models has not been tested yet. The models provide a less natural image, and the value of measurements based purely on 3D models is limited [4].

The use of models of foils for determining the identifying value when making comparisons by means of positioning of 3D models also has not been studied yet.

A benefit of model reconstruction is that all conditions, including lighting, can be modeled in accordance with the images to be investigated as much as possible.

Comparison Process. *Features*. Facial comparison should take place according to a list of facial features. These lists can be drawn up on the basis of historical lists used for facial comparison, feature lists obtained from anthropologists, and discussions with people from other agencies involved in person identification (an example list is provided in Table 1). A problem that remains is the difference in the interpretation of what some features "are". This interpretation depends on education and anatomical knowledge, and experience has shown that it is not always assessed consistently even by the same observers. It is also questionable whether the interpretation of the feature designations is in line with the knowledge of and interpretation by the client (police and judge).

Similarities and Differences. If there is a consensus on the interpretation of the features, the features can be compared. The comparison involves looking at the similarities and differences of a feature on two images. This involves two problems: (i) can people assess differences and similarities (human as a measuring instrument) and (ii) how are the observed similarities and differences interpreted?

Human as a Measuring Instrument. Research has shown that, as a measuring instrument, humans are not good at assessing facial features in which sizes and proportions play a role [5]. The evidential value of sizes and proportions in visual material is also limited because of the image distortion caused by unknown camera equipment, unknown zoom settings, and unknown pixel aspect ratios of digital cameras. Not every human observer assesses the (differences in) shapes of facial features in the same way either [6, 7]. In addition, people are not very consistent in the assessment of similarities between pairs of photos [8]. Although the comparison of familiar or famous people on videos and photographs is efficient, the comparison of unknown people on videos with photographs or in real life is not efficient [1]. However, another study showed that the use of moving pictures can improve the recognition of static, frontal photographs if the images are shown on the same medium (monitor), whereas multiple static images have little added value [9]. In addition

Table 1 Example list of features to be observed for facial comparison

Face	Shape Proportions Hairline/hair growth
Forehead	Shape "Bumps" Horizontal creases Eyebrows
Eyes	Distance Position Color Eye shape (shape of eye slit) Upper eyelid crease Bags Wrinkles at corners of eyes
Nose	Length of nose Width of nose Prominence Symmetry Creases at bridge of nose Profile of nose Shape of tip of nose Shape of nostrils Septum
Middle section of face	Cheekbones/cheek line Cheek-eye groove Cheek-nose groove
Ear	Size Position Shape of helix (outer edge of ear) Darwin's tubercle (bump on edge) Shape of antihelix (fold in ear) Earlobe
Mouth area	Shape of philtrum (groove between nose and upper lip) Moustache or moustache "shadow" Beard or beard "shadow"
Mouth	Mouth size Mouth shape Upper lip Lower lip
Chin	Shape Groove between mouth and chin Dimple Double chin
Lower jaw/throat	Shape Adam's apple
Characteristic features	Skin marks Scars Creases and wrinkles

The list is based on anatomical knowledge, stability over time, and visibility in pictures

to interpretation differences depending on the image material, we also have to deal with the "other race effect", the effect that recognition of people from another, rather than one's own, race may be less efficient [10–13]. These effects have mainly been shown to occur in the case of recognition (memory task: "have you seen this person before?"). One of the theories is that minor variations in facial shape are coded better when looking at images of people of one's own race [12, 13]. Other race effects also appear to occur in facial comparison. Research on humans as a measuring instrument in facial comparison is limited; most of the research concerns "recognition" or "rapid" comparison. We do not know of any studies concerning the quality of man as a measuring instrument according to a structured method.

Interpretation of Observations. Debate on the interpretation/assessment of features as "similar" or "different" often occur during discussions of results like "I see a difference, but it can be explained" and "this is similar to". Even the term "not observable" can cause a difference in interpretation. An example of this in the case of wrinkles: not observable because someone does not have wrinkles, or not observable owing to the photo quality? Does "no wrinkles visible" in both images constitute a similarity if the image quality is good? The question of quality can also be involved in this discussion; a suggestion is to rate the "quality" and "usefulness" of the individual images first, before proceeding with the comparison. Then a selection is made from the features to prevent "looking for" features in a poor-quality image. The drawback to this is that features that may be useful to a limited extent may be eliminated from a comparison too quickly. Another issue is the practical feasibility of this approach; the images should be assessed by two different people in two different rounds to prevent bias as much as possible. Along with the requirement that the comparison should be carried out by more than one person, this may lead to logistic problems.

Individualizing Value of Features. An important question in facial comparison is "How unique is a feature?" Although we have put much time and energy into answering this question, we have not yet been able to answer it, or find literature data that answer

this question. One of the problems is that (anthropological) investigations focus largely on measuring parts of the skeleton and the like, such as measuring the distance between points in the face that can be determined by palpation but are difficult to identify on images. Another problem is that most known measurements have been taken from a very limited, usually Caucasian, population. No answer can be given to the question "How unique is this nose?", and so we depend on the subjective interpretation of the observer. This subjective interpretation is known to depend on the appearance of people in the observer's own environment [12, 14]. Currently we – and others [15, 16] – only designate birthmarks and scars as "strongly identifying".

Final Assessment of Comparison. The combination of "similarities and differences" and "individualizing value" is weighed to achieve a final assessment on the images. Cognition psychology research has shown that people are good at recognizing "familiar" people, but not as good at recognizing "unfamiliar" people. "Familiar" people are people with whom social interaction has taken place, and providing moving images does not improve the recognition task [1, 17]. The extent to which a systematic approach of the comparison task influences the reliability of the final assessment is not known. However, we do know that there is little correlation between the instinctive "certainty" about a comparison judgment and the performance of human observers [1, 17].

Biometrics

Automated facial comparison and recognition still function far from optimal. The best systems have a verification equal error rate (EER) of about 1.5%, and a false reject rate (FRR) of about 10% at a false accept rate (FAR) of 0.1% if "document quality" images are used [18]. The facial recognition systems are still sensitive to aging of the subjects: the FRR increase to about 20% at an FAR of 1% if the picture is 3 years old.

Looking at the performance of facial biometrics systems for investigational purposes of criminals or terrorists on watch list (identification), the best systems find about 60% of the suspects on a list of 1000 people at a setting, resulting in 1% false alarms [19]. Increasing the number of people on the watch list results in about 2–3% points decrease in the number of correct hits with each doubling of the database size. Note that these results are based on experiments with standardized high to medium quality pictures from collaborating subjects. The performance of biometric facial recognition systems decreases quickly with changes in pose and position, lighting, and facial expression. Surveillance images taken under uncontrolled circumstances, using low-quality cameras, mostly placed in conspicuous places (high at the ceiling, low at automatic teller machines (ATMs), "hidden" at the side of entrances) and recording people who do not look into the camera, with changing expression and sometimes partly covered faces, are hardly or not at all recognized by biometric systems. In the past, biometrics also has been proposed as a solution for detecting document fraud by look-alikes: people using genuine documents from other people with similar appearance. Unfortunately, this problem cannot be solved by the current biometric systems, because these systems are based on relative common features and use a relative low resolution (300 dots per inch (DPI) passport images). Although these images have advantages because of the limited memory capacity of embedded memory chips in passports, this limits the usefulness of the facial image for identification purposes. Because of the low resolution, the most identifying features such as birthmarks, wrinkles, and scars are unrecognizable.

Summary

Facial comparison is a wide-ranging forensic technique: it involves disciplines such as image analysis, 3D technology, anthropology, photogrammetry, statistics, and cognitive psychology (human as a measuring instrument). Many steps in the comparison process are still mediocre, poorly or not supported by scientific data. Quality metrics for visual material and the comparison process are still lacking; important steps in the process are subjective. The issues "quantification of image quality", "human as a measuring instrument", and "individualizing value of features" are difficult problems because of the large number of factors involved, the difficulty of measuring man's functioning as a measuring instrument, and the scope of the investigation needed to test individualizing features. In most cases, psychological research concerns recognition of people; as far as we know,

research with regard to facial comparison is limited. It is often assumed that comparison works according to the same basic principles as recognition, but without memory load. Research, development, and elaboration of facial comparison methods still will require much more time, because little hard data is available. Performance of current biometric systems is still too low for forensic purposes, although biometric systems may be useful for automated investigation of standardized image databases. The quality issues of surveillance material limit the options of applicability of biometric systems for uncontrolled situations.

Facial Recognition *see* Facial Comparison, Visual Recognition Systems in Identification

Facial Reconstruction

Once one has built the so-called biological profile, the last thing one can do to help in identifying those remains, is to give the biological profile along with a face. Let us give a practical example: a human skeleton is found; anthropologists determine that it belongs to a 40- to 60-year-old Caucasoid male, about 1.70 m tall, with two dental crowns and

no other particular signs. Comparison with missing persons gives no positive results. All one can do then is to try and divulge the biological profile across television and newspapers, inviting people to say whether they recognize the description or if it suits someone they know. However, rather than divulging a "sterile" description, it may be more effective to show a face along with it. Facial reconstruction from the cranium therefore serves the purpose of triggering people's minds and reaching a suspicion of identity [1–17]. If someone says the biological profile, along with the face, reminds them of Mr Brown, then further analyses are brought forward to verify whether the skeleton indeed belongs to Mr Brown (*see* **Identification of Human Remains**). It is not however an identification method.

Facial reconstruction (preferably referred to by some authors as facial approximation) is practically based on Galen's theory concerning facial structure ("as walls to houses, so are bones to all living creatures, for other features take form from them and change with them"); the face is supposed to be influenced by the underlying bone tissue.

The first facial reconstruction, according to Pliny, was made by Lysistrathos in the fifth century BC using wax casts; this tradition was maintained by the most important Roman families, which kept masks reproducing faces of their forefathers (*majors*) in their houses. The first scientific reconstruction was carried out by His on J. S. Bach's cranium. For several years, this technique was considered as a reliable method in order to obtain the real appearance of dead people, until 1913 when Martin and von Eggeling independently carried out two different reconstructions on the same cranium.

The technique was then dropped for years, until 1924 when Gerasimov developed a method based on the anatomical reconstruction of muscles of the face (the so-called Russian method). This is in stark contrast to the American technique, which is based on the measurement of soft tissue depths overlying the bone. The latter represents the American school and its importance was reported by the Federal bureau of investigation (FBI) Law Enforcement Bulletin in 1946.

Because the relationship between bone and soft tissue is a basic starting point for facial reconstruction, tissue depths are the fundamentals upon which a facial reconstruction is built. For this reason, in literature soft tissue depths have been published for both sexes and several ethnic groups (and more recently for children) [6–10]. These had been already measured in the late nineteenth century in several ways: mainly from pins inserted into the faces of cadavers at specific cranial landmarks. Cadaver data, however, is slightly less reliable mainly because postmortem dehydration may cause some loss of depth. Data nowadays is obtained from ultrasound and computed tomography (CT) technology. Therefore, more modern databases of populations that are radiologically obtained are probably more reliable. Thanks to this type of technology, there is nowadays increasing data concerning the soft tissue facial depths of living individuals on the basis of sex, age, and ancestry. One should, however, always keep in mind that the tissue depth which is used by the operator is an average and depends on an enormous number of variables (weight, sex, age, etc. combined)–some of which are difficult to assess on the skeleton. Thus, the actual depth remains in reality as an unknown variable. The same is applicable to the approximation of other facial areas such as the nose and mouth.

Facial reconstruction can be performed either manually or via sophisticated softwares [18–26] (among other things, bidimensional drawings also can be created which are of a more simplistic nature). Both methods have their advantages: the first is cheaper but consumes more time; the second is quicker but more expensive. The error is comparable, because both techniques follow similar anatomical guidelines. The following is a description of one of the most common manual methods.

Facial reconstruction is carried out on the cranium, or, preferably, on a cast of the cranium, which is usually made in plaster. The first step involves designing the profile from a lateral cranial X-ray (Figure 1), which then guides the 3D final reconstruction. Thirteen cranial points are located on the cranial profile in the X-ray, which guide the reconstruction of soft tissue profile. This allows for a reconstruction specifically made to that particular profile. Tissue depths are given by anatomical tables present in the literature, and the profile is adapted according to variables such as nasal height, height of teeth, chin, etc.

Once the profile is defined, then the 3D reconstruction is performed. A cast of the cranium is usually created; therefore, the reconstruction can be made without working on the real cranium. This is done in order not to damage the original since it may have peculiar lesions which need to be re-examined and

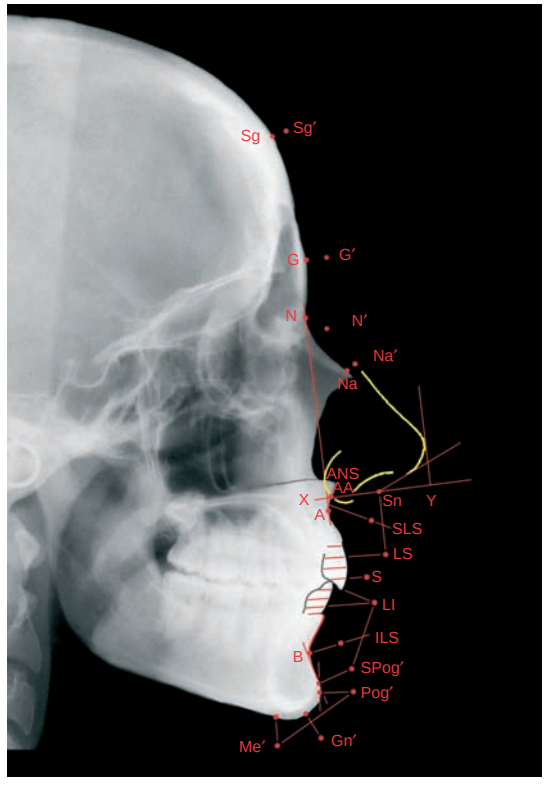

Figure 1 An example of the complex calculations involved in the reconstruction of the profile from the radiograph

are important for the cause of death. A separate cast is made for the mandible.

The 3D technique consists of applying so-called tissue depths onto 31 cranial points. These cranial depths usually consist of toothpicks or rubber depths, which demarcate the exact thickness of the soft tissue at that specific point, according to general anatomical tables taken from living populations and adapted for race, sex, and age. Then plasticine muscle models are put on the bone surface, complying with the anatomical insertions.

At first temporal and masseter muscles are applied onto the cranial cast, followed by buccinator and mouth orbicular muscles. Then mouth elevator and upper lip elevator muscles, zygomatic muscular groups and upper lip, and mouth corner depressor muscles are added. However, vascular and nervous structures, along with adipose tissues, are not identifiable, and this produces a substantial difference between the final reconstruction and the real face appearance. Parotid glands models are placed on the reconstruction as well. The advantage of an accurate muscular reconstruction is to create a more specific guide and to reduce risks of subjective interpretation. A plasticine stratum of skin is finally placed on the muscle groups according to anthropological data coming from the biological profile (Figure 2).

Eyes can be made of plasticine, plaster, resin, and ophthalmic prostheses (Figure 3). The authors use eye resin models that are set into the orbits according to anatomical methods, usually by centering the pupil with the junction of two straight lines between the middle point of lower and upper orbital edges and between outer and inner eye corner.

The nose is modeled mainly according to the results of the 2D profile reconstruction mentioned above. Width of the nose is usually calculated by adding one third of the bone nasal aperture on each side (Figure 4).

The *rima oris* (mouth aperture) is evaluated according to the distance between the two canine teeth (Figure 5).

Figure 2 The various phases of manual facial reconstruction: (a) application of tissue depths on specific landmarks; (b) application of the deep muscles; (c) completion of the muscular structure; (d, e) application of "skin"; and (f) details can then be added such as beard or hair although these may be misleading

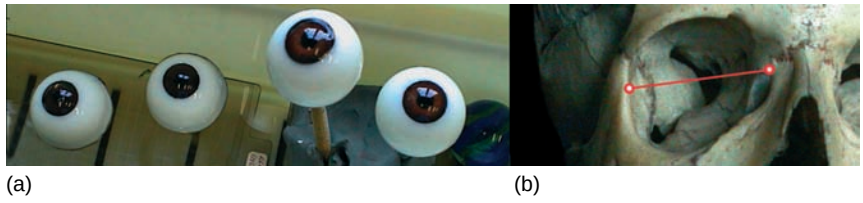

Figure 3 (a) Example of resin eye models and (b) anatomical area of eye alignment within the orbit

Figure 4 The red horizontal line represents the extreme limits of the soft tissue portion of the nose

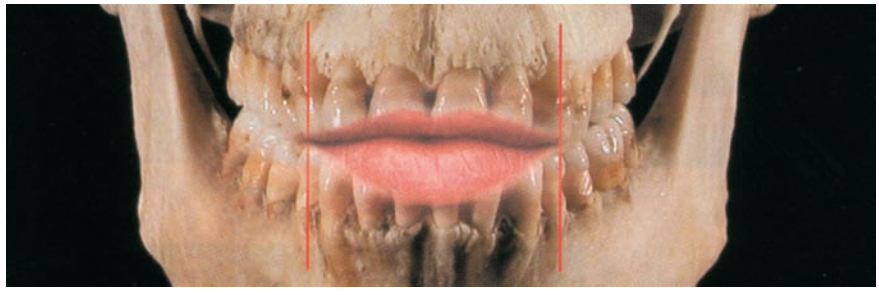

Figure 5 Superimposition of lips onto the dentition, which shows the generic correspondence between the corners of the mouth and the first premolar/canine

Ears, eye color, wrinkles, and eyebrows are obviously not identifiable from the cranium. Reconstruction is the object of a debate, which involves different opinions. There are some people who believe that the facial reconstruction must be as unevocative as possible – therefore gray, with no color. Others prefer color and interpretation. The reconstruction is a last attempt to provide some information

about the identity of subject. The aim of technique requires "facial interpretation", and, according to some authors, must even be similar to a "caricature", in order to stress the personal characteristics and physical peculiarities of that person. Ears, hair styles, eye color, wrinkles, and eyebrows can alternately be added in conformity with race, sex, age, etc., if one wants to give greater "character" to the reconstruction, though the risk may mislead observers.

Sometimes a smiling expression may be useful in order to show a particular odontological profile, such as missing teeth, a wide diasthema, or the presence of dental prosthesis.

It is clear that facial reconstruction is a very gross anatomical exercise – there are many variables which have to be taken into account and also exceptions. The technique shows its clear limits, where the relationship between bone and soft tissue is not easily predictable (for example, mouth and nose). Recent years have seen a considerable proliferation of witty and useful articles that try to make it more accurate particularly in relation to these difficult areas [11–17].

As far as testing the accuracy of approximation is concerned, several types of tests, among which blind tests, have been pursued [27–35]. One of the first tests was a comprehensive study of Helmer [35] who worked with two independent teams that performed double blind facial reconstructions on double castings of 12 skulls. Results proved the large variation in the quality of the reconstruction but the resemblance between the reconstruction and the actual face varied from "slight resemblance" (42%) to "close resemblance" (38%). Subsequent studies in this sense were performed, although it is almost intuitive that the evaluation of "resemblance" can never be free of extremely subjective parameters. Stephan and coworkers [27, 29–34] have given considerable thought (and articles) to this issue, with interesting and useful results. Accuracy of facial approximation has been assessed by resemblance ratings (i.e., the comparison of a facial approximation directly to the target individual) and recognition tests (i.e., the comparison of a facial approximation to a photo array of faces including foils and a target individual). It has been proven that recognition tests are more valid assessment parameters than resemblance ratings since a study in particular has shown that similar resemblance ratings can be given to different facial approximations of the same person, whereas recognition tests produce vastly different results (one is "identified", the other is not). Furthermore, there seems to be no statistically significant difference between resemblance ratings of facial reconstructions to target individuals and to individuals incorrectly identified as the target individuals. The same group of researchers tested 16 facial approximations on 37 assessors of varying age. Only one approximation ended in true positive identification rates above chance at statistically significant levels. It is therefore rare for facial approximations to be sufficiently accurate to allow identification of a target individual above chance. This also suggests that facial reconstruction is not useful in excluding individuals to whom skeletal remains may not belong. At times it may even be misleading. It should therefore be used when all else has failed.

Other authors are slightly more positive and suggest that better results can be expected when the facial reconstruction is performed by a trained scientist and with the more elaborate methods. Thus excellent, good to middle resemblances were reached in 9 out of 25 cases, but success increased with a more elaborate method and with an expert operator in one particular study [28]. Statistical comparisons, however, between measurements on the facial reconstruction and on the actual face showed that some anthropological distances were constantly underestimated or overestimated. Other authors [25] have recently found that in a test with computer-modeled facial reconstructions recognition tests yielded percentage hit rates of 50% above chance. These remain, however, sporadic studies that inevitably have a very strong subjective element (that of recognition) that makes the assessment of accuracy almost impossible. One can actually verify the error as far as anthropometrical measurements are concerned (e.g., correspondence of interpupillary distance and bigonial width between the reconstruction and the actual face), but it is a completely different matter to pinpoint the main factors in recognition.

As mentioned previously, several authors have focused in the past 20–25 years on the potential of computer-aided facial reconstructions, which imply the use of very sophisticated techniques that are used currently by very few teams [18–26]. Nonetheless computerized facial reconstruction in the future may become more user-friendly, more easily accepted, and its future assessment may promote further improvement.

Figure 6 Example of a real case reconstruction. To the left is the facial reconstruction made from a skeleton found in a river. Transmission to the public led to a suspicion of identity and subsequent identification of the victim via the comparison of odontological antemortem and postmortem traits. To the right is the frontal and lateral picture of the living victim

In conclusion, the field is quite active at the moment and much research is still required, although stronger connections with the cognitive sciences should be sought for the achievement of more accurate reconstructions since still much has to be learnt on what actually triggers recognition in the human brain: shape, reflectance, emotion, etc. [36].

It should also be mentioned that in cases in which remains are mummified or putrefied, some authors prefer not to clean the cranium from soft tissues but to rehydrate the tissues and work on reconstructing the original face.

Whichever method one chooses, the important issue is to divulge the final result (Figure 6), which must be released throughout the media, in order to reach the largest population possible and make it easier to achieve a suspicion of identity. It is not an identification method; therefore, once there is an idea of who the person may be, positive identification must be performed by other methods.

Falsifiability Theory

Austrian-born British philosopher Karl R. Popper (1902–1994) is best known for his theory of falsifiability, which he argued depending on the "testability" of the premises underlying the relevant scientific discipline. His 1934 German-language book, *The Logic of Scientific Discovery* [1], was hailed by many other scientists as one of the most important works of the twentieth century.

In his 1963 publication, *Conjectures and Refutations* [2], Popper amplified that the demarcation between true science and pseudoscience is that scientific knowledge is based on falsifiable hypotheses that permit the inference (conclusion) to be drawn that, at least for the present, the underlying premise is probably true or probabilistically likely to be true. In contrast, pseudoscience, or in Popper's words "metaphysics", rests on unfalsifiable or untestable premises from which invalid inferences may well be drawn.

In Conjectures, Popper used his theory of falsifiability in an attempt to discredit psychoanalysis and Marxism, both of which had at some time been postulated as being based on scientific principles, by showing the premises underlying these fields were incapable of verification.

Although likely oversimplified, Popper advocated that the hallmark of science is that the premises upon which a scientific principle rests are capable of being refuted by empirical evidence derived from a physical experiment or through observation.

The term *falsifiability* is often misunderstood by liberal-arts-trained lawyers and judges. It does not mean that a premise is false, but that a hypothesis is capable of being shown to be false by experimentation, observation, or examination of data [3–6].

The ability to explain the meaning of concepts supporting expert opinions is especially crucial to forensic scientists who may be asked to discuss the principle of falsifiability on the witness stand (**Expert Opinion: United States**). Since 1993, the words "falsifiability" and "Karl Popper" have acquired special meaning in legal circles, at least in jurisdictions where courts follow the Daubert (***Daubert v. Merrell Dow Pharmaceuticals***) rules on admissibility of expert testimony.[a]

In the *Daubert* decision, the US Supreme Court delineated a number of different factors by which trial judges are asked to decide whether proffered expert testimony will qualify as "scientific knowledge" shown to be sufficiently reliable to be admitted at trial. One of these factors is its "falsifiability".[b] The court adopted the Popper model of distinguishing reliable scientific knowledge from junk science (unreliable expert opinions) by combining "testability" with "falsifiability". The court explained

> [A] key question to be answered in determining whether a theory or technique is scientific knowledge that will assist the trier of fact is whether it can be (and has been) tested. "Scientific methodology today is based on generating hypotheses and testing them to see if they can be falsified; indeed, this methodology is what distinguishes science from other fields of human endeavor [7].

For this proposition, the Court cited a number of sources, prominent among them being Popper's work [8].

Ever since 1993, courts attempting to apply *Daubert* to specific areas of technical expertise have sought to determine whether the underlying assumptions on which an expert's discipline rests have been tested or are subject to testing. In attempting to resolve this issue, varying results are obtained in court decisions, the outcome in each case depending upon the techniques, the testifying experts, and the tribunal. In doing so, some jurists have exhibited a lack of understanding of the concept of testability. This deplorable result may, in part, be due to the inability of testifying experts to articulate clearly the meaning of falsifiability.

Since the decision in *Kumho Tire* (**Judicial Notice of Scientific Principles and Facts**), however, which held that a *Daubert*-like inquiry requiring proof of

reliability extends to all forms of expert opinion testimony, including that based on technical or specialized knowledge from which opinions are derived, it has become less important to determine whether a particular field qualifies for the label "scientific".

While the US Supreme Court chose Popper's work as the basis for its "falsifiability" and "testability" concepts in the context of the rules of court evidence (**Federal Rule of Evidence 702**), a number of other scientific researchers are less than accepting of Popper's theories. Indeed, some scientists suggest that Popper's view was outmoded even when it was proposed, and that the *Daubert* decision is based, therefore, on a somewhat discredited view of science.[c] Scientist-lawyer Adina Schwartz argued that Popper's falsifiability (testability) concept was an inadequate logical criterion that was developed by philosopher Popper "without appealing to the views of those professing to do science". Dr Schwartz postulated that the Supreme Court's choice of Popper's definition of science over those postulated by other equally prominent philosophers of science was a poor exercise of reasoning [9, 10].

Federal Rule of Evidence 702

All forensic experts are expected to be familiar in some measure with Federal Rule of Evidence 702. While technically applicable only in the United States in federal, civil, and criminal trials, discussion of the rule is featured often in the forensic literature, in symposia, and in seminars that purport to prepare experts for court appearances. Like the court decisions in *Frye v. United States*, *Daubert v. Merrell Dow Pharmaceuticals*, and *Kumho Tire v. Carmichael*, Federal Rule of Evidence 702 has been mentioned by courts worldwide, even in jurisdictions where it does not represent local law.

The rule is part of the Federal Rules of Evidence (FRE), which have been in effect in the United States since 1975. It was amended in 2000, and defines the use of expert testimony in civil and criminal litigation. FRE 702 is included in Article VII of the federal rules that is titled, "Opinions and Expert Testimony." Article VII deals not only with expert testimony in Rule 702 but also with the following:

- Opinion Testimony by Lay Witnesses (FRE 701).
- Bases of Opinion Testimony by Experts (FRE 703).
- Opinion on Ultimate Issue (FRE 704).
- Disclosure of Facts or Data Underlying Expert Opinion (FRE 705).
- Court Appointed Experts (FRE 706).

As it currently exists, Rule 702 provides the following:

> If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise, if (1) the testimony is based upon sufficient facts or data, (2) the testimony is the product of reliable principles and methods, and (3) the witness has applied the principles and methods reliably to the facts of the case.

By the 2000 Amendment, the drafters sought to conform FRE 702 to the requirements of the US Supreme Court decision in *Daubert v. Merrell Dow Pharmaceuticals*, which had interpreted Rule 702 in the context of the "general acceptance" principle of *Frye v. United States*.

Fibers

Introduction

The process of interpretation begins when the expert receives a case: relevant information will be collected, pre-assessment will take place and transfer probabilities will be assessed. We refer the reader to

see **Case Assessment and Interpretation** for preassessment and early interpretation and focus here on interpretation after analytical results. Let us consider a case where, after thorough laboratory examination and consideration of similarities and dissimilarities, two or more fiber samples cannot be distinguished, the question remains as to how best we can interpret this result? In some cases, especially in the United States, forensic scientists express this finding in terms of a "*could have come from*" statement. What is the value of this type of statement? This question probably constitutes the main challenge faced by the forensic fiber examiner.

Unlike glass or paint evidence, where a proof of common source can sometimes be achieved through a physical fit, fibers (excluding pieces of fabrics and some exceptional cases) are always considered as class evidence. In other words, there is probably always more than one item in the world that shares some common characteristics with a specimen of evidential fibers.

However, this does not mean that fibers have little or no value. The evidential value of fibers depends upon a multitude of parameters and is often stronger than a layperson would expect. Fibers can even constitute primary evidence under some circumstances. Their main strength resides in their ability to reconstruct an event or a series of events. It is the aim of this article to present and discuss the interpretation and value of fiber evidence.

Factors Influencing the Value of Fiber Evidence

Fiber evidence is difficult to interpret. While the fundamental parameters such as relevance of the trace, transfer/persistence, and frequency in the population of interest are similar to those related to other trace evidence such as glass or paint, the problems associated with fibers are more difficult. For example, it is not possible to build and maintain a database of clothing types in the same manner than one would do with a database of glass types. In most cases, the questions raised in relation to the significance of fibers are extremely complex.

Since the mid-1980s, different aspects of the evidential value of fibers have been studied, and there is now a clearer view on the significance of fiber evidence [1, 2]. It is generally accepted that the value of fiber evidence depends on many factors that are often complex and interacting. These factors can be classified as known (or usually determinable) or unknown (or difficult to determine) [3].

Factors that are known or that are usually determinable are as follows:

- **The circumstances of the case**

The discovery of fibers may be more or less significant, depending on the circumstances. The forensic scientist needs to consider whether or not fibers can be explained by an alternative hypothesis; i.e., by coincidence or by a real transfer, but one which has an explanation that is not incriminating, or the other, where the explanation may be incriminating. In order to attempt to select between these options, the scientist needs to know the relevant and often detailed information about the circumstances of the case and details relevant to the individuals allegedly involved.

- **The time that has elapsed before collection of the evidence**

The longer the time between the transfer event and the collection, the weaker the evidence. The risk that the relevant fibers are being lost and replaced by nonrelevant fibers *via* secondary or a higher degree transfer increases with time.

- **The suitability of the fiber types for recovery and comparison**

Some fibers are highly colored or luminescent, which means they are not only easier to find and collect but also have more features to examine and to compare with each other. This increases the probability to discriminate fibers that do not have a common origin, and therefore enhance the significance.

- **The extent of the comparative information derived from the samples**

This information may be limited by the laboratory resources or by the size and type of fibers. It is obvious that a "fiber match" is much more significant when complementary and highly discriminating techniques have been used in comparison to simple screening tests.

- **The number of types of matching fibers**

Garments often contain more than one fiber type. This means that a "multiple match" increases the significance of fibers. It should be noted that, in cases involving a blended fabric, the absence of one or more fiber types in the pool of recovered fibers

does not necessarily preclude the blended fabric from being the source of the questioned fibers. Different components of a blended fabric may have different shed potentials, and the number of fibers transferred of different types is not necessarily proportional to the stated composition of the garment. This phenomenon is well known and is called *differential shedding*.

- **Whether there has been an apparent cross transfer of fibers or not**

This situation arises where, for example, fibers found on the victim's garment are not differentiable from the fibers of the suspect's garment *and* fibers found on the suspect's garment are not differentiable from the fibers of the victim's garment. The demonstration of a cross transfer constitutes the ideal situation following the Locard exchange principle. In this case, the significance of fiber evidence is dramatically increased because the chance of finding "matching fibers" in both samples by pure coincidence is remote.

- **The number of matching fibers recovered**

In general, the larger the number of fibers, the smaller is the chance of finding these fibers by chance only. The discovery of a small or an unexpected number of fibers is difficult to interpret and requires good knowledge of transfer and persistence theories.

- **The location of the recovered fibers**

Some locations are more prone to secondary (nonrelevant) fiber transfer than others. In a break-in case, for example, fibers found at the edge of a smashed window are more significant than fibers found on the ground. The link between the perpetrator and the evidence in the latter case is quite unclear, which decreases the significance. Similarly, fibers found on undergarments in a sexual case may be more significant than fibers found on outer garments, for example.

- **The methods used to conduct the examinations**

More discriminating and complimentary methods bring more significant comparative features and decrease the risk of a coincidental match.

Factors that are unknown or that are difficult to determine are as follows:

- **The extent and force of contact**

These factors influence fiber transfer and persistence with respect to both the number of fiber types and the number of fibers.

- **The degree of certainty that specific items were definitely in contact**

In some cases, there is a higher degree of certainty that the items submitted are those involved in the alleged incident. For example, there may be good eyewitness accounts or the suspect may have been apprehended quickly. In other cases, it is quite possible that the clothing is not relevant to the incident. For example, there might have been an opportunity to dispose of the clothing, or eyewitness statements might be unclear.

- **Donor fiber shed potential**

Some fabrics shed more fibers than others, and this must be considered when assessing the significance of the number of fiber types and the number of fibers. This means that it is impossible to give a simple rule that would define a cutoff number of fibers beyond which the primary transfer is certain, as opposed to secondary or higher transfers.

- **Frequency of occurrence of the matching fiber types**

The significance is weighted by the frequency of occurrence of the matching fibers. It is obvious that a match involving common fibers is less significant than that involving rare fibers. It should be noted that, owing to the high degree of variability of fibers, this frequency is generally much smaller than one might expect in the first instance.

Information Available to Assist the Interpretation of Fiber Evidence

The interpretation of fiber evidence requires a systematic study of the different factors described above in light of the context of the case and the hypotheses alleged by the different parties (generally defense and prosecution). This process requires a great deal of experience and logical reasoning. Some valuable information exists through specialized literature or unpublished research projects, and can be used as an aid by the fiber expert during the interpretative process. However, in some cases, the lack of relevant information may prompt the setup of simulation experiments in order to confirm or deny some hypotheses that remain unresolved. Although interpretation problems have engendered great debates within the forensic community over the last 25 years,

significant advances have been made in interpretation modeling (see below).

Most of the information currently available in the area of the interpretation of fiber evidence is related to the following issues:

- fiber transfer and persistence [4–19];
- frequency of occurrence of fiber types or chance of a coincidental match [20–43]; and
- statistical interpretation [44–47].

Fiber Transfer and Persistence

Knowledge of fiber transfer and persistence assists in answering the question as to whether the number of fibers and the number of fiber types found in a given case are likely under the allegation of contact. In other words, knowledge on transfer and persistence assists in answering the competitive questions "what is the probability of finding the number of fibers and fiber types found in a given case if there was a contact?" and "what is the probability of finding the number of fibers and fiber types found in a given case if there was no contact?".

This area of investigation includes the following topics:

- transfer studies;
- studies on differential shedding;
- experiments on the alteration of fiber characteristics in a manner consistent with localized conditions specific to a case; and
- persistence studies.

Since 1975, numerous transfer and persistence studies involving fibers have been undertaken. The results give a general guidance when assessing the number of fibers expected to be found under a given set of circumstances. It is beyond the scope of this article to examine these results in fine detail, but the most important findings are given below.

The number of fibers to be found mostly depends on

- the area of contact;
- the kind of physical contact (number of contacts, pressure, friction, time, etc.);
- the construction of the fabrics involved (donor and recipient);
- the fiber types (generic class, density, diameter, etc.);
- the length of the fiber fragments; and
- whether or not, and how, the recipient is mobile after the transfer event has occurred.

Small fiber fragments on the outer surface of a garment are more likely to be transferred and are generally more persistent on the recipient. Transferred fibers are more or less rapidly lost and redistributed on other locations (on the same recipient or not). Experimental studies have shown that fibers transferred at the time of contact may range from only a few to many hundreds or thousands. When the recipient is mobile, it has been shown that there is a rapid loss of fibers (typically 80% of loss within the first 4 h and 5–10% remaining after 24 h). On the other hand, fibers can persist for periods of many days and even weeks when transferred to a recipient, which remains subsequently relatively undisturbed such as a car seat or a dead body.

As already stated, in blended fabrics, the number of fibers transferred of the different types is not necessarily proportional to the stated composition of the garment. This issue, called *differential shedding*, is important when interpreting findings involving a fabric of blended composition.

The presence of only a few matching fibers may mean that they have been deposited by means of a secondary or subsequent transfer as opposed to a primary one (secondary transfer is the first indirect transfer after primary transfer, taking place *via* an intermediary object; common in contacts involving seating). Other reasons may also account for this situation, including a long time gap between contact/transfer and examination, a redistribution of fibers (e.g., due to the washing of the garment), the use of an inefficient method for fiber recovery, and a coincidental transfer. In all cases, caution is necessary when interpreting the finding of a small number of fibers, especially to items such as underclothing.

In real life, the variables that contribute to the number of fibers that may be transferred are so numerous and unknown that the most reliable assessment of the number of fibers to be found is done by the simulation of the suspected contact with the actual fabrics in the case under investigation. However, pressure of casework in most laboratories would make this type of research work impossible in all but the most critical cases.

Frequency of Fibers

"Fibers are mass produced; they are not like fingerprints or DNA, are they?" This question is typically asked by the defense in court. It is therefore necessary to consider fiber frequencies. Knowledge of these frequencies helps in the assessment of the relative rarity of the fiber features observed during the examination. In other words, the knowledge on the frequency of fibers mainly assists to answer the question "what is the probability of finding the fiber features observed in a given case if there was no contact?". A large number of studies have been achieved over the last 15 years in this area. Crucial information comes from the following sources:

- population studies;
- target fiber studies;
- data collections; and
- trade enquiries.

The population studies have analyzed examples of the normal fiber population that may be expected on a given surface. This is vital information to have at hand when trying to answer the defense question "well surely you would expect this type of fibers to be present on any such surface?" Fiber population studies involve sampling the given surface and classifying the recovered fibers into fiber type and color categories.

Conclusions that can be drawn from the studies that have been carried out so far have shown the following:

- Synthetic fibers form only a low percentage (13–20%) of any population yet studied.
- Most of the color/morphology/generic type combinations (approximately 65%) are represented by a single fiber type only. Synthetic fibers exhibit a very high degree of polymorphism.
- The chance of one type representing >1% of the total population is remote. A collective of synthetic fibers (same type, same morphology, and same color) can therefore be said to be the result of a recent contact with a specific textile and can be considered as being highly significant.

Target fiber studies give some idea of what proportion of the population has fibers of a particular type on their clothing (or car seat, cinema seat, pub seat, etc.). This data incidentally automatically takes into account not only the rarity of a fiber type but also the tendency for this fiber to be transferred or to persist on the receiving fabric. Without being comprehensive, a list of target fiber studies that have been carried out to date include the following:

- a blue wool nylon pullover from Mark & Spencer with sales over 1 million;
- red wool from ladies' pullover and brown polyester of men's trousers on car seats;
- green cotton fibers from Mark & Spencer's leggings and red acrylics from a pullover on car and cinema seats;
- red acrylics from a scarf sold over a five-year period in quantities of 5–10,000 annually in nine European countries;
- blue wool fibers on seats in public houses throughout the United Kingdom; and
- blue wool, gray, and black polyester (all common) as well as blue acrylic (less common) on outer clothing from English households.

Findings of similar studies in different parts of the world regularly appear in the literature. So far, target fiber studies suggest that it is a rare event to find a fiber, even from a very common garment on clothing (or a seat) without the donor recently having been in close contact with the garment in question.

Data bases are generally built using garments received in forensic laboratories for examination. They yield to very detailed information such as the

- frequency of morphological characters within a fiber type;
- frequency of a certain polymer composition within a fiber type;
- frequency of uncommon fiber types in the general population;
- frequency of usage of fiber types in different textiles divided into different categories; and
- frequency of certain fiber-type combinations in different textiles.

One of the criticisms of data bases is that the collection of materials takes too long to accumulate and, hence, the data quickly becomes out of date. However, this criticism only really applies where the measurement of color data is involved. To overcome this problem, some authors have built up a comprehensive and easily updated database using data on

garments offered for sale in mail order catalogs. However, this approach is feasible only in countries where mail order is popular.

Trade enquiries involve tedious and time-consuming investigative work. However, such enquiries can bring extremely valuable information on the relative frequency of a given type of fiber, including sales figures and manufacture figures such as quantity of items dyed using the same dye batch, for example.

Statistical Treatment (Probabilistic Model)

The interpretative process is not entirely free from subjective opinion when dealing with fiber evidence because of the number of interactive factors that must be considered. As a result, a probabilistic model has been proposed as an aid to this process.

Taking note of the fact that the decision process at the time of the trial is based on inference, it appears that the logical rules for thinking about facts in legal cases are those of probability. Only probabilities are able to measure the uncertainty that exists and evolves during every criminal case. Therefore, only a model supported by the mathematical theories of probability is valid.

During the past 25 years, many researchers have shown increasing interest in a probabilistic model based on the Bayes Theorem. This model describes how the elements of proof combine with themselves and evolve during the decision process of the trial, avoiding distortion based on inappropriate use of intuition. The Bayesian framework, or more precisely on the likelihood ratio approach, can help in formulating and assessing the most relevant questions faced by the forensic scientist. The relevant questions are dependant upon the circumstances of the case, but they are all derived from two fundamental questions:

- What is the probability of the evidence if the alleged story is true?
- What is the probability of the evidence if the alleged story is not true (or the complimentary story is true)?

The ratio of these two probabilities is called a *likelihood ratio*. The latter measures the value of the evidence in terms of a pair of hypotheses, indicating if the given set of observations supports one hypothesis more than the other. It clearly shows that the concept of evidence, including fiber evidence, is relative.

The main challenge of a probabilistic model is in the fact that such a model uses data that, in the fibers context, are incomplete and difficult to quantify. Ideally, for each case, a target fiber study and transfer and persistence experiments should be carried out using relevant materials to the context of the case. Of course, such an approach is not practical and the assessment relies rather on the accumulated knowledge derived from experimental studies.

However, the Bayesian approach can still be used as a logical framework to provide the most accurate guide to interpretation currently possible. Conservative estimates that can be seen as "measures of belief" and simulations can also help in going through the process. In other words, this approach greatly minimizes the subjective component of the interpretation process. It is also worth noting that the Bayesian approach has been the initiator of numerous experimental studies, which brought crucial data for the interpretation of fiber evidence, regardless of whether the scientist applies the Bayesian framework or not.

Examples. Various examples of the application of the Bayesian approach to the assessment of the evidential value of fibers were developed in [44, 45] and were further discussed in [46]. Inferential guidelines can be extracted from these scenarios. They ultimately assist the forensic scientist in the evaluation of fiber evidence.

As noted in [45], the main points are described as follows:

- Evaluation of the evidential value of forensic evidence (including fiber evidence) is a matter of probability assessment.
- For the assessment of the strength of the evidence (E), it is necessary to consider the probability of the evidence under two given competing explanations for its occurrence, respectively presented by the prosecutor and by the defense (H_1 and H_2). The value of the evidence is estimated using a likelihood ratio $LR = P(E|H_1)/P(E|H_2)$. Hence, the likelihood ratio is defined not only by the evidence but also by the strategy chosen either by the prosecution or by the defense.
- Evidence (recovered trace and known material) may be to some extent incompatible with the offense. Hence, $P(E|H_1)$ is not always equal to 1

because of their number and position, and because of the phenomena of transfer, persistence, and recovery. There is a need to consider transfer probabilities.

- When traces (recovered evidence and known material) are supposed to be associated with the offense, we also have to allow for the probability of their absence before the commission of the offense. The corollary of this is that, if traces are supposed to be unrelated to the offense, the probability of their presence by chance also has to be considered. There is a need to consider background probabilities.
- The evaluation of trace evidence has to consider all potential recovered traces and not only the concordant evidence. This number of groups has to be considered.
- The number of declared offenders has a significant impact on the likelihood ratio.
- The definition of H_2 excludes the implication of the defendant. Thus, the scientist has to specify the relevant population in which adequate forensic surveys have to be made. There is a need to estimate frequencies correctly.
- In all investigation and evaluation of transfer traces, all possible exchanges have to be investigated including extreme situations in which expected evidence has either not been found or not been produced.

Conclusions

Background data available to the forensic fiber examiner to assist in interpreting the significance of fiber findings has increased greatly in the past 25 years. There is also a deeper understanding of the factors that need to be considered, and acceptance that it is incumbent on the practitioners to assist the court in assessing significance.

Given the circumstances facing forensic fiber examiners in different climatic and socioeconomic environments, local databases and research to put available data in a local context are essential. This type of data is now emerging.

The Bayesian approach has been studied and proposed in the area of fiber evidence. It is increasingly seen as a valid logical framework to provide the most accurate guide to interpretation currently possible. However, it is fair to say that the complexity of fiber evidence (when compared to other evidence categories like glass, for example) remains a challenge, which somewhat inhibits its systematic application in casework.

Ultimately, it is worth noting that the value of fibers is more in their ability to reconstruct an event or a series of events (i.e., "fibers can tell a story") rather than necessarily uniquely identify the source at the origin of a transfer. To make most of their use, they should therefore be used at the activity level and not the source level.

Fire and Energy

Fire is a complex phenomenon, which evolves in the three dimensions of space and time. It is a chemical reaction that occurs in the vapor phase but involves solids and liquids as well, through an energy feedback loop. The energy of the fire drives the chemical processes of pyrolysis and vaporization, which must be maintained if the fire is to keep burning. Fire is an exothermic chemical reaction, i.e., one that gives off energy in the form of heat and light. The understanding of fire requires an understanding of the basic concepts of energy.

Much of what is known about energy involves the transformation of energy from one form to another. For example, gasoline contains chemical energy, and

when burned in an internal combustion engine, the chemical energy is converted to heat energy, which, in turn, is converted into mechanical energy. The power company burns coal to boil water. The steam produced from the boiling liquid moves a turbine, which spins a magnet inside a coil of wires to produce electrical energy. When that electrical energy is passed through a filament to make light or through a resistance element to heat water or air, it is transformed back into heat energy. When supplied to a motor, the electrical energy is converted into mechanical energy.

It is useful to think of energy as *the ability to do work*. Heat energy is actually a form of work. Heat can be used to boil water, and the increase in pressure above boiling water in a closed vessel can be used to move matter, as in a steam engine. Count Rumford's experiment, wherein he used the frictional heat from cannon boring to boil water, allowed for an understanding of the concept of energy transfer [1].

If a glass of ice water is placed in a room, heat will flow from the room into the glass until the ice melts. Eventually, the water will be the same temperature as the room, and heat transfer will cease. Energy transfer that takes place by virtue of a temperature difference exclusively, i.e., flowing from an area of high temperature to an area of lower temperature, is called *heat flow*. In the eighteenth century, Lavoisier and others thought that because heat was flowing, it must be a substance, and they named that substance *caloric*. Count Rumford and James P. Joule, an English physicist, came to understand that what was flowing was energy.

In honor of Joule's work, the basic unit of energy was named after him. The unit of work in any system of measurement is the unit of force multiplied by the unit of distance. In the metric system, the unit of force is the newton and the unit of distance is the meter. A newton is that force that gives 1 kg an acceleration of $1\,m\,s^{-2}$; 1 Nm equals 1 J.

But how does the movement of an object translate to the energy from a fire? As Rumford demonstrated, work can be measured through its ability to raise the temperature of a volume of water by a fixed number of degrees. A *calorie* is defined as the amount of energy required to raise the temperature of 1 g of water $1\,^{\circ}C$. (A corresponding unit, described in terms of degrees Fahrenheit and pounds of water, is a British thermal unit (Btu). One Btu is the quantity of heat required to raise the temperature of one pound of water from 63 to $64\,^{\circ}F$. One Btu equals 252 calories.) Different substances require different amounts of heat to increase their temperature by a specific amount. This parameter is called *the specific heat capacity* of the material and is expressed as joules per kilogram per degree Celsius. In a fire, depending on the duration, different materials can reach different temperatures despite being exposed to the same amount of energy. Just as lifting a weight from one floor of a house to another can take place rapidly or slowly, so can the process of increasing the temperature of a body of water.

The amount of work required to raise a given weight to a given height is the same whether it takes a second, a minute, or an hour. Thus, the *rate* at which work is done becomes important when considering energy or heat transfer. The amount of work done *per unit time* is the quantity of interest.

Power is defined as the work done divided by the time interval. Appliances that use energy are described by the power they produce, either in Btu per hour, or in watts. A *watt* is defined as $1\,J\,s^{-1}$, so, therefore, the time component is built in.

Just like a heating appliance, the size of fire can be described in terms of watts, or more commonly, kilowatts or megawatts. To understand fire, it is necessary to understand ignition sources and fire in terms of its power in watts. Consider a controlled fire, a gas-fired stove-top burner. A typical burner is rated at $12\,000\,Btu\,h^{-1}$. A total of $12\,000\,Btu\,h^{-1}$ equals $3.33\,Btu\,s^{-1}$. One Btu equals 1054.8 J, so that $12\,000\,Btu\,h^{-1}$ burner is putting out just over $3500\,J\,s^{-1}$, or 3500 W. A $40\,000\,Btu\,h^{-1}$ burner, the size typically found in a gas-fired water heater, puts out 11 720 W, and a $125\,000\,Btu\,h^{-1}$ gas furnace delivers 36.6 kW.

The power of a fire in kilowatts is known as its *heat release rate* (*HRR*). The HRR is the single most important property of fire, because it allows predictions of how that fire will behave [2]. The HRR affects the temperature of the fire, its ability to entrain air, and the identity of the chemical species produced in the fire.

The power of fire is an important property to know, but it is equally important to know how that energy is distributed. A total of 20 kW spread evenly throughout a structure by a furnace's circulation fan will keep that structure comfortable on a winter day. Confining or focusing the energy can result in dramatically different consequences. The concept of

heat flux is therefore an important consideration. Heat flux is a measure of the rate of energy falling on or flowing through a surface, and is measured in terms of watts or kilowatts per unit area. Fire can be described as having a heat flux in watts per square centimeter ($W\,cm^{-2}$) or in kilowatts per square meter ($kW\,m^{-2}$); $1\,W\,cm^{-2}$ equals $10\,kW\,m^{-2}$.

All combustible materials have a property known as *critical radiant heat flux*, which is defined as the amount of energy necessary to cause ignition. Typical critical radiant heat fluxes are on the order of $20\,kW\,m^{-2}$.

On a clear day, energy from the sun strikes the earth with a radiant heat flux of approximately $1\,kW\,m^{-2}$, an amount that varies depending on time and location. This is enough energy to cause sunburn in 30 min or less. We cannot increase the HRR of the sun, but we can increase the radiant heat flux by focusing the energy that falls on a large area onto a smaller area, using a magnifying glass. Figure 1 shows what happens if we use a magnifying glass (or a concave mirror) to decrease the surface area by 96%. The $1\,kW\,m^{-2}$ heat flux becomes $25\,kW\,m^{-2}$ at the focal point, which is sufficient to ignite most combustibles. Figure 2 shows burn lines scorched onto the underside of a wooden roof by concentrated sunlight striking a concave makeup mirror in a bathroom. Parallel lines of charring were produced over several days, eventually resulting in the ignition of the roof. Table 1 shows the observed effect of typical radiant heat fluxes.

Chemical Processes

When exposed to heat, materials can undergo physical or chemical changes. Physical changes are

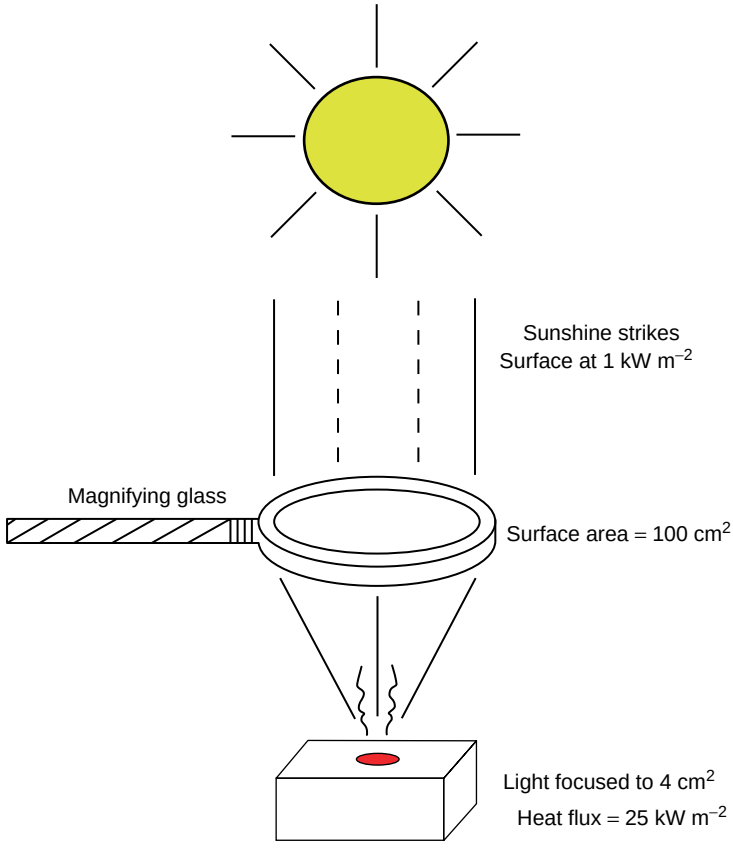

Figure 1 A magnifying glass increases the radiant heat flux from the sun by reducing the surface area that the light covers [Reproduced from Ref. 3. © Taylor and Francis Group, 2006.]

Figure 2 Burn lines scorched into the underside of a roof on successive days. A concave mirror located on a bathroom vanity focused the sun's energy out through the window [Reproduced from Ref. 3. © Taylor and Francis Group, 2006.]

Table 1 Typical radiant heat fluxes

Approximate radiant heat flux ($kW\,m^{-2}$)	Comment or observed effect
170	Maximum heat flux as currently measured in a postflashover fire compartment.
80	Heat flux for protective clothing thermal protective performance (TPP) test.[a]
52	Fiberboard ignites spontaneously after 5 s.[b]
29	Wood ignites spontaneously after prolonged exposure.[b]
20	Heat flux on a residential family room floor at the beginning of flashover.[c]
16	Human skin experiences sudden pain and blisters after 5-s exposure with second-degree burn injury.[a]
12.5	Wood volatiles ignite with intended exposure[d] and piloted ignition.
10.4	Human skin experiences pain with 3-s exposure and blisters in 9 s with second-degree burn injury.[a][b]
6.4	Human skin blisters in 18 s with second-degree burn injury.[a][b]
4.5	Human skin becomes blistered with a 30-s exposure, causing a second-degree burn injury.[a]
2.5	Common thermal radiation exposure while fire fighting.[f] This energy level may cause burn injuries with prolonged exposure.
1.4	Thermal radiation from the sun. Potential sunburn in 30 min or less.[g]

The unit kilowatt per square meter defines the amount of heat energy or flux that strikes a known surface area of an object. The unit (kW) represents 1000 W of energy and the unit (m^2) represents the surface area of a square measuring 1-m long and 1-m wide. For example, $1.4\,kW\,m^{-2}$ represents 1.4 multiplied by 1000 and equals 1400 W of energy. This surface area may be that of the human skin or any other material

changes in state, i.e., from solid to liquid or from liquid to gas. A change in state involves no change in the identity of the molecules or atoms involved. State changes are reversible, i.e., upon cooling, vapors can condense into liquids and liquids can solidify. Chemical processes brought about by an exposure to heat in the presence of oxygen typically include pyrolysis and oxidation. Pyrolysis is the irreversible breaking down of large molecules into small molecules as the result of heating. In a fire, those small molecules are usually oxidized by reaction with atmospheric oxygen. Pyrolysis is also known as *thermal decomposition*.

Gases

Most substances that we encounter in our everyday experience are not pure elements, but mixtures of compounds. The simplest substances are the gases. In a gas, the individual components, atoms, or more commonly, molecules, are not tightly bound to one another. A pure gas can be an elemental gas or it can be a compound. Elemental gases, with the exception of the inert or noble gases (helium, neon, argon, krypton, xenon, and radon), usually exist as diatomic gases, that is, there are two atoms of the same element bound to each other. Thus, hydrogen, oxygen, and nitrogen occur as H_2, O_2, and N_2, respectively. Gases of compounds have at least two different atoms bound together, such as carbon monoxide, CO, or methane, CH_4. The gas, with which we are most familiar, air, consists of approximately one part oxygen to four parts nitrogen.

Gases behave in a predictable fashion when exposed to changes in volume, pressure, or temperature. An important property of all gases is that regardless of which gas we are considering, equal volumes of gases contain equal numbers of molecules. Most gases come very close to obeying the ideal gas law, $PV = nRT$, where P is the pressure, V is the volume, n is the number of molecules, R is a number ($8.314472\,\mathrm{K^{-1}\,mol^{-1}}$) known as the *universal gas constant*, and T is the temperature *in degrees kelvin*. If the size of the container is reduced by half, the pressure doubles. If the number of molecules is doubled, the pressure doubles, or if the container is allowed to expand, the volume doubles. Raising the temperature from 25 to 324 °C (298–596 K) doubles the volume if the pressure stays constant or doubles the pressure if the volume stays constant.

Combustion reactions in gases were among the first chemical reactions studied and understood. The combustion of hydrogen in air to make water is perhaps the simplest. Two volumes of hydrogen plus one volume of oxygen yields two volumes of water vapor.

$$2H_2 + O_2 \rightarrow 2H_2O \qquad (1)$$

The simplest carbon-based combustion reaction involves methane. One volume of methane plus two volumes of oxygen yields two volumes of water vapor plus one volume of carbon dioxide.

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O \qquad (2)$$

Note that if there is insufficient oxygen, carbon monoxide instead of carbon dioxide will be produced. It is worth noting that, while the above reactions have described volumes of oxygen, most combustion reactions take place in air, where oxygen comprises only about 20% of the available gas. Thus, a volume of methane actually requires 10 volumes of air in order to burn completely.

The chemical equations that describe combustion reactions list only the initial and final chemical species. An important by-product of the reaction is heat. The amount of heat produced (energy released) depends on the substance being oxidized. The *heat of combustion* is measured as energy per unit mass, usually reported as kilojoules per kilogram ($\mathrm{kJ\,kg^{-1}}$), but can also be reported as Btu per pound or calories per gram. In the case of gases, the heat of combustion is often expressed as kilojoules per cubic meter or Btu per cubic foot. The HRR is then the heat of combustion multiplied by the *mass loss rate*, the rate at which the fuel is consumed.

A cubic foot of natural gas has an energy content of approximately 1000 Btu, or more than a million joules. If all this energy is released in one second, the explosion will have a HRR of 1 MW. If burned over an hour, as would be typical for a pilot light, the HRR is less than 300 W. The energy released is the same in both cases. The difference is in how fast that energy is released. When one considers the energy available if a $40\,000\text{-Btu}\,\mathrm{h^{-1}}$ burner is left open without a pilot light for an hour, one begins to understand the necessity for safety devices on gas-burning appliances.

Natural gas is composed mainly of methane, CH_4. Liquefied petroleum (LP) gas is composed mainly of

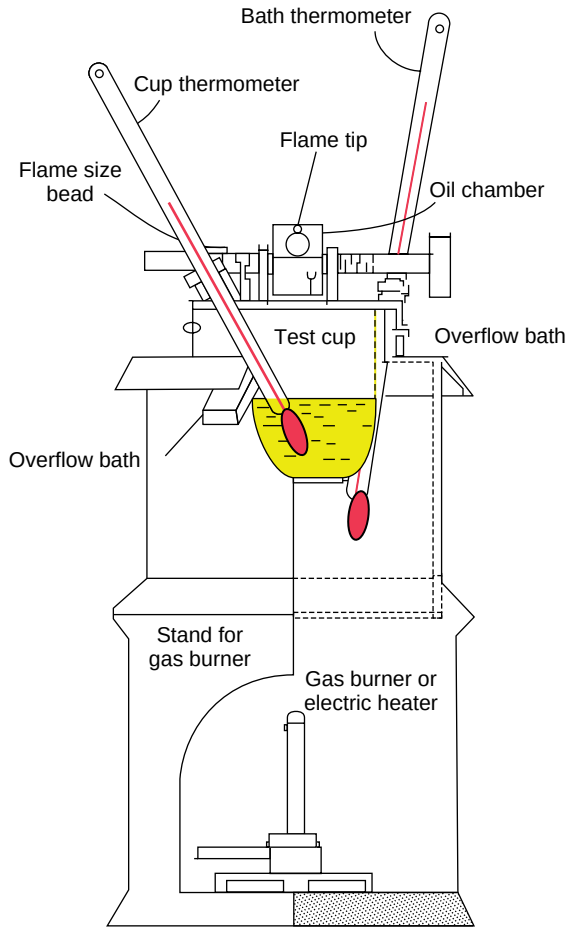

Figure 3 Tag closed cup flash point testing apparatus [Reproduced from Ref. 3. © Taylor and Francis Group, 2006.]

propane, C_3H_8. Where a given volume of natural gas requires two volumes of oxygen to burn, a volume of propane requires five volumes of oxygen. Propane, likewise, contains more energy per cubic foot than natural gas. A cubic foot of natural gas contains about 1000 Btu, where a cubic foot of propane contains about 2500 Btu. Interestingly, a cubic foot of natural gas requires 10 ft^3 of air, and a cubic foot of propane requires 25 ft^3 of air to burn efficiently. This comparison suggests a relationship between the amount of oxygen consumed and the amount of heat capable of being released by a given volume of gas. Hydrocarbon fuels are remarkably consistent in this regard. Completely burned hydrocarbon fuels release 13.1 $kJ\,g^{-1}$ of oxygen consumed (±5%). This relationship forms the basis of oxygen consumption calorimetry as a means for measuring the HRR of fire.

Liquid

The molecules in liquids and solids have an affinity for each other, which reduces the space between the molecules and results in condensation. Liquids typically occupy 1/100 to 1/300 of the volume of a similar number of gas molecules. While many people think of liquids as burning, the fact is that liquids only burn when their molecules are vaporized into the gas phase. Once in the gas phase, or, more correctly, vapor phase, the molecules behave as though they were gases. Combustion can only occur when there is a sufficient number of molecules of

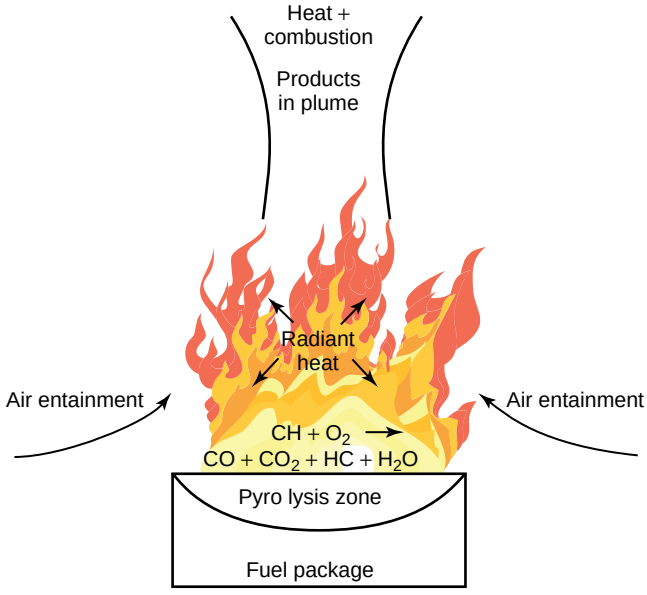

Figure 4 Schematic representation of some of the processes taking place in the combustion of a solid fuel. Combustion continues for as long as the flame radiates sufficient energy back to the surface to produce sufficient quantity of gases and vapors [Reproduced from Ref. 3. © Taylor and Francis Group, 2006.]

the liquid fuel vaporized in the space above a pool of liquid. The temperature at which the concentration of vapors above the liquid in a still pool enclosed in a specified apparatus will ignite when exposed to a flame is known as the *flash point*. A common flash point apparatus, the tag closed cup tester, is shown in Figure 3. The flash point is also referred to as the *piloted ignition temperature*. Typically, ignition cannot be achieved when a liquid is below its flash point, but it is possible to get a sufficient number of molecules of the liquid into the air space above it through atomization or through wick action.

Solids

The chemical processes involved in the combustion of solids are far more complex than those involving liquids and gases. If solids were simply liquids at a temperature below their freezing point (or melting point), describing the combustion behavior of solids would be relatively easy. A candle is an example of this kind of solid. The heat from the flame melts the solid wax to produce liquid wax, and the liquid is then vaporized so that it can combine with oxygen in the air. Most solids, however, and almost all combustible solids, do not melt or vaporize to form liquids or gases and can only be transformed into liquids and gases by breaking down large molecules into new and smaller molecules. There are no gaseous "wood molecules" or "wool molecules", nor are there gaseous molecules of many polymers. When wood burns, it is first necessary to break it down into a liquid or gas through a process known as *pyrolysis*. Whether an ignition source is capable of igniting a particular fuel (a *competent* ignition source) depends on whether it can cause the production of sufficient vapors through pyrolysis. Once these vapors are ignited, the fuel will continue to burn for as long as the resulting flame transfers sufficient energy to the surface of the solid so that it continues to produce vapors. Figure 4 shows the processes involved in the burning of a solid.

Almost all combustible substances are either natural or synthetic polymers. Wood is a mixture of three natural polymers: cellulose, hemicellulose, and lignin. Silk and wool are proteins, another kind of natural polymer. The six most common synthetic polymers are polyethylene, polypropylene, polyvinylchloride, polystyrene, polyester, and polyurethane [3]. When exposed to heat, polymers undergo an irreversible

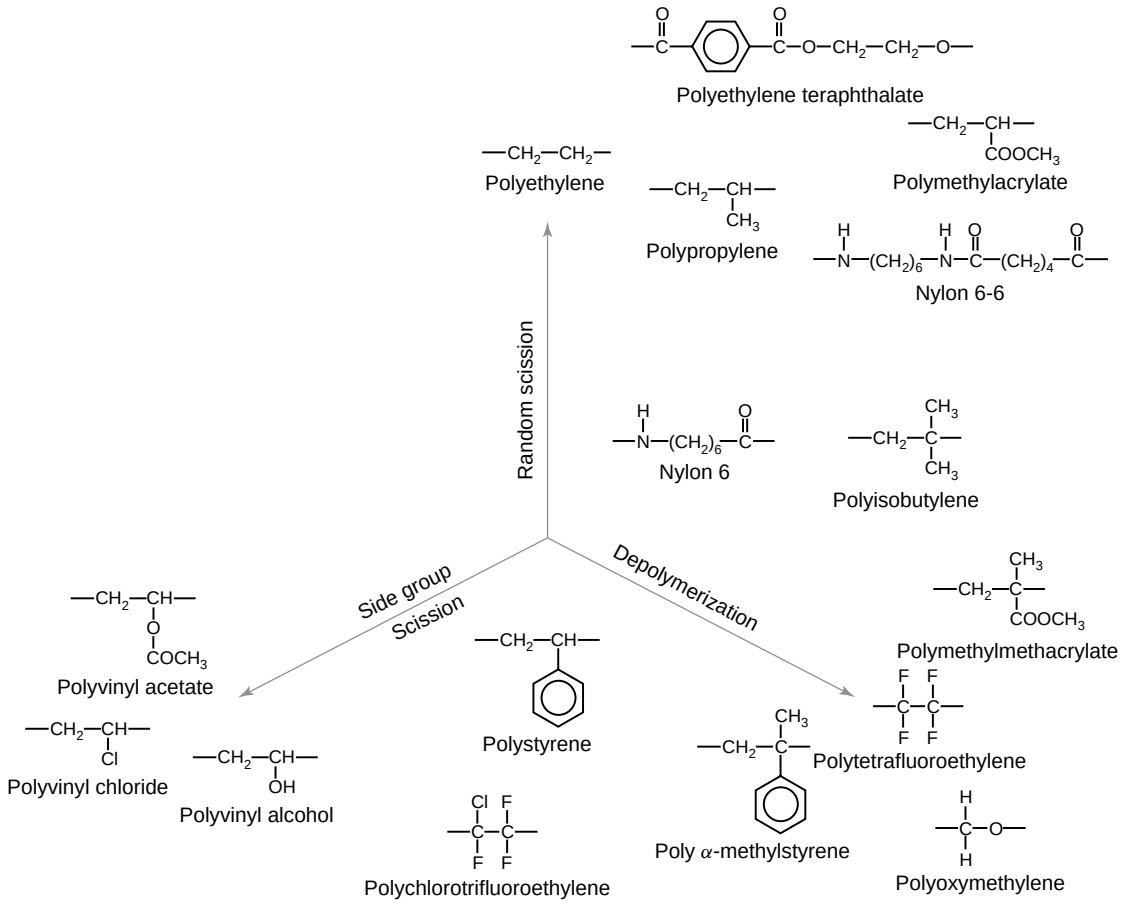

Figure 5 Some commonly encountered polymers and their approximate classification according to their pyrolysis mechanisms [Reproduced from Ref. 7. © Elsevier, 2003.]

decomposition, caused by the breaking of chemical bonds, or pyrolysis. The chemical bonds within the molecules undergoing pyrolysis break in the order of their bond strength. Weaker bonds break before stronger bonds. Bond strength is the amount of energy in kilojoules (kJ) per mole required to dissociate one atom from another. For example, the bond dissociation energy of the carbon–chlorine bond is 330 kJ mol^{-1}, whereas the bond dissociation energy of a carbon–carbon single bond is 350–380 kJ mol^{-1} [4]. When exposed to fire temperatures, therefore, polyvinyl chloride (PVC) loses its chlorine atoms, which rapidly combine with atmospheric water to form hydrogen chloride (HCl). The carbon atoms remain bonded to each other, and, in fact, form double bonds because of the loss of the chlorine.

The progressive dissociation of chemical bonds results in three basic mechanisms by which pyrolysis typically occurs: random scission, side group scission, and depolymerization. Depolymerization, also known as *monomer reversion*, is the simplest mechanism. The polymers simply dissociate into the original monomer. Styrene polymers, acrylics, and polytetrafluoroethylene (PTFE, frequently used as a nonstick surface coating) undergo monomer reversion. Monomer yield for these plastics is greater than 80%. For other plastics, like PVC, the monomer yield is close to zero [5].

Polymers containing many bonds of equal or nearly equal strength tend to undergo random scission. Polyethylene, for example, breaks down into normal alkenes (straight chain hydrocarbons with a double

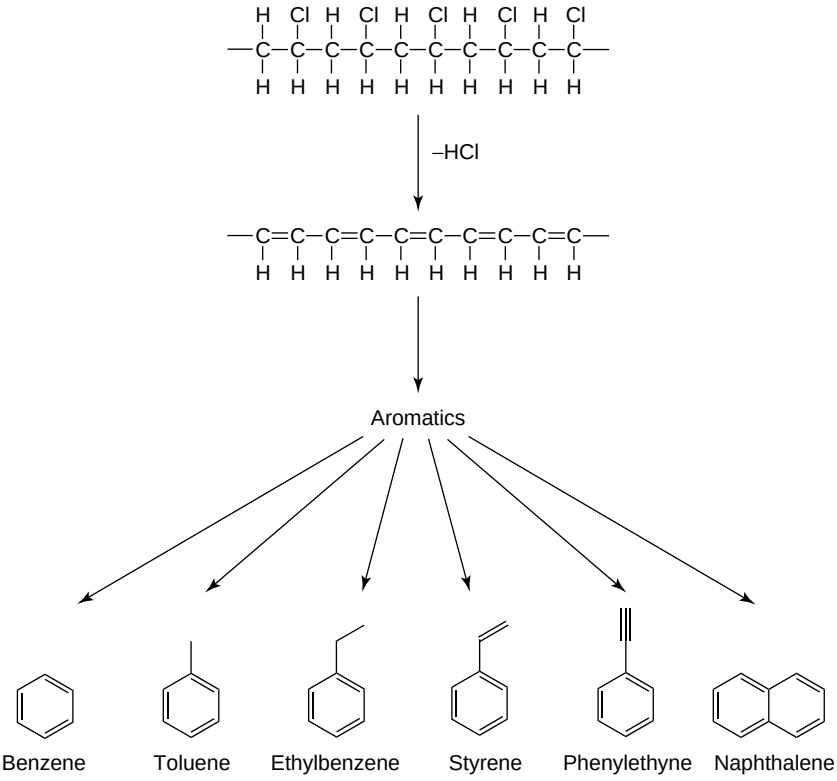

Figure 6 Products of the pyrolysis of polyvinyl chloride (PVC) [Reproduced from Ref. 7. © Elsevier, 2003.]

bond), alkanes (straight chain hydrocarbons) and dienes (straight chain hydrocarbons with two double bonds). Asphalt undergoes the same kind of thermal decomposition, but without the dienes [6]. It is therefore possible to distinguish between asphalt smoke residue and polyethylene smoke residue, even though they are quite similar. Both asphalt and polyethylene (polythene) are common fuels, and their chemical residues are commonly found in samples of fire debris.

Side chain scission involves the selective loss of side groups attached to a long chain backbone. The loss of chlorine from PVC is a typical side chain scission reaction. Many polymers will undergo a combination of mechanisms. Figure 5 is a diagram showing the typical pyrolysis mechanisms of several polymers.

Pyrolysis is, in many cases, a sequential process. After the chlorine atoms are stripped from the PVC polymer (or any polymer that undergoes side chain scission) the remaining backbone of the polymer is highly reactive. The formation of aromatic molecules is relatively straightforward. Aromatics make up over 90% of the detectable residue from pyrolyzed PVC [7]. Figure 6 shows the side group scission mechanism of PVC and the resulting products. Given that there are no aromatic functional groups present in the original PVC polymer chain, it is far from intuitively obvious that PVC should degrade into aromatic compounds. These compounds are some of the same compounds found in gasoline and other petroleum products, but the relative ratios of the aromatics (for example, the xylenes) are different than the relative ratios in petroleum products. For a further discussion of interpretation of aromatics in fire debris, *see* **Fire Debris: Laboratory Analysis of**.

Solids exposed to heat can be expected to do one of three things: melt, dehydrate, or char. Since they are mixtures, as opposed to pure compounds, most solids that melt do not have a sharp melting point, but typically exhibit what is called a *glass transition temperature*. Substances that dehydrate lose water

molecules. These are molecules that are chemically bound to the solid matrix but are only weakly bound. Substances such as gypsum wallboard and concrete contain bound water, and this gives them some of their fire resistance. When the water is released, calcination takes place in the gypsum wallboard. The water released from concrete is thought to play a role in a phenomenon known as *spalling*.

Charring occurs when volatiles (small molecules) are created through pyrolysis and then driven off by the external heat source, where they ignite and burn in air. The flaming combustion above the surface of the solid provides more heat for additional pyrolysis and volatilization. What is left behind is known as *char*. Char can insulate the material below it from the heat source because it is generally less conductive than the solid from which it originated. It is possible to determine an average charring rate for substances exposed to a calibrated energy source such as a furnace, but it is difficult to apply such charring rates to uncontrolled fires. When exposed to postflashover conditions, the charring rate of most common woods has been found to be in the range of $0.5-0.8\,\mathrm{mm\,min^{-1}}$ [8].

The various chemical and physical reactions that materials undergo as a result of exposure to heat are called *fire effects*. The visible or measurable manifestations of these effects are called *fire patterns* [9]. A more detailed discussion of the interpretation of fire patterns appears in **Fire: Dynamics and Pattern Production**.

Fire: Dynamics and Pattern Production

Fire Dynamics and Fire Pattern Production

Although fire is a chemical reaction, the way in which a particular fuel burns is likely to depend more heavily on its physical state, the geometry of the fuel, and its environment than on its chemical nature. For example, a piece of dimensional timber may be exceedingly difficult to ignite, even with a blow torch. If that timber is sliced into kindling-sized sticks, it may be easily ignited with a match. A crumpled-up wad of newsprint will burn much more fiercely if the bottom of the wad is ignited than the top. A vehicle burning in an open field will be much more amenable to examination after a fire than a vehicle that has been consumed inside a garage. The term *fire dynamics* includes both the chemistry covered previously (*see* **Fire: Chemistry of**) and the engineering disciplines of heat transfer and fluid dynamics. It is this combination of chemistry and physics that makes the understanding of fires interesting and difficult. Because of the number of critical factors involved that may affect the behavior of fires, they are sometimes said to be subject to the "Mongolian butterfly" syndrome, wherein the small wind generated by a butterfly flapping its wings in Asia will affect the annual rainfall halfway around the world. The study of fire dynamics attempts to take some of the apparent chaos and make sense of it. In order for this to happen, a basic understanding of the concepts of ignition and flammability is required.

Ignition

All fires begin with ignition, and it is the goal of all fire investigations to determine the ignition source. It is not enough, however, to simply find "an" ignition source. The proposed ignition source must have sufficient energy to cause the proposed "first fuel ignited" to combine with atmospheric oxygen. For ignition to occur, the substance under consideration must first be capable of propagating self-sustained combustion. Ignition is defined as the process by which this propagation begins [1]. In the case of solids, ignition occurs when the heat generation rate in a given volume of material exceeds the heat dissipation rate, and the rate of reaction increases as temperatures rise further. The increasing heat causes chemical bonds to break, and the material decomposes into volatile substances. These volatile substances either ignite in the presence of a pilot, or they auto ignite. Piloted ignition temperatures for solids are generally in the range of $250-450^{\circ}$C, while auto ignition temperatures are generally in excess of 500°C. Either the pilot (a preexisting flame) or the hot environment provides the ignition energy for the gases and vapors evolved by heating.

How easily a substance ignites depends on its size and distribution. A layer of coal dust may burn relatively slowly, while that same dust dispersed into the air will ignite explosively. In general, gases, vapors, and dusts in air ignite more easily than solids.

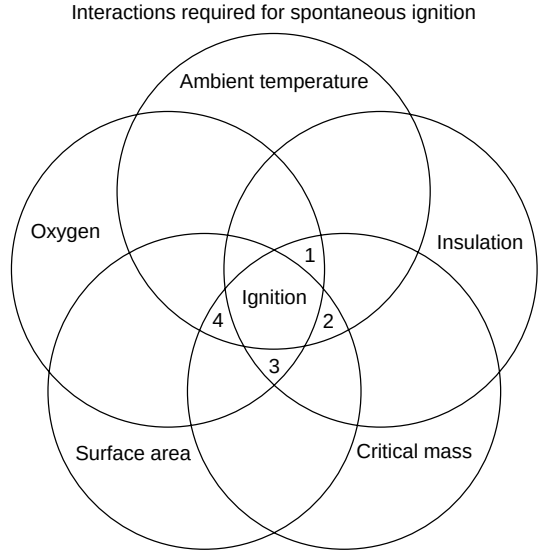

Figure 1 Interactions required for spontaneous ignition to occur

Solids may be either "thin" (<2 mm) or "thick." Generally, thin materials ignite more easily. For thick materials, the fuel's ability to conduct heat away from the surface (thermal conductivity), its heat capacity,

Figure 2 Effect of location on the burning of three identical fuel packages. Each photo was taken 17 ± 1 s after ignition. (a) A couch cushion burning in the center of the room. (b) An identical cushion burning against a wall. (c) An identical cushion burning in a corner [Photo courtesy of Jamie Novak, St. Paul, MN Fire Dept.]

and its density [2] are important. Poor heat conductors ignite at lower temperatures than good conductors. Thus, polyurethane foam will ignite sooner than a polyethylene trash can, which will ignite sooner than a wooden desk.

There are two special kinds of ignition that occur without the application of an external heat source. In chemical ignitions, simply combining a fuel and an oxidizer can result in a fire. A common example of a chemical ignition is the contamination of powdered swimming pool chlorine (calcium hypochlorite) with an organic material. The calcium hypochlorite provides the oxygen, and the organic material provides the fuel. The heat generated by the combustion of the organic contaminant can cause a decomposition reaction to occur in the pile of the remaining calcium hypochlorite. While not technically "combustion," an observer would be hard pressed to note many differences between this reaction evolving heat and light and "a fire."

Self-heating and spontaneous ignition occur as a result of exothermic (i.e., heat producing) reactions, whereby heat is liberated at a rate sufficient to raise the temperature of the material. The exothermic reactions in this case are faster than rusting but slower than fire. The typical spontaneous heating scenario involves the oxidation or polymerization of vegetable oils. Mineral oils such as motor oil, or even gasoline, even when saturated in a pile of rags, do not undergo spontaneous heating at ambient temperatures.

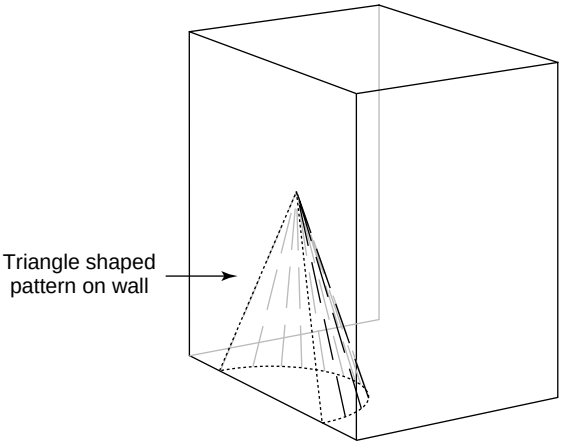

Figure 4 Schematic drawing showing the intersection of an early fire plume with a wall surface to produce an inverted cone pattern

Spontaneous ignition follows the same rules as piloted ignition or ignition by radiant heat, but the balance required to achieve ignition is much more delicate. Figure 1 shows the requirements for obtaining ignition without an external heat source. A balance must be maintained between providing the material under consideration with sufficient oxygen, but also sufficient insulation. The surface area of the material must be large enough to absorb large quantities of oxygen, but configured in such a way that the heat generated does not escape.

Although it is spontaneous, self-heating to ignition is usually a very slow process. This is because the heat is concentrated at the center of the mass of fuel, where there is usually insufficient oxygen for flaming combustion, so the first combustion is a smoldering combustion. Once the smoldering mass penetrates to the surface, flaming combustion can take place. Consequently, spontaneous ignition is frequently preceded by a long period wherein large quantities of smoke are produced.

The time frame in which spontaneous ignition occurs can be remarkably long. Solvents present in a liquid stain in a pile of cotton rags, for example, will use up much of the heat generated by the polymerization of drying oils within the stain in the process of evaporating. It may only be after all of the solvent has evaporated that the heat of the reaction can be absorbed by the cotton substrate. Spontaneous heating to ignition frequently takes place in a matter of hours, but may take as long as 4 days, or even longer.

Flames

A flame is a luminous zone of burning gases, vapors, and fine suspended matter where combustion is

Figure 5 An example of an inverted cone pattern

taking place. The kind of flame that fire investigators are generally concerned with is called a *diffusion flame*. In a diffusion flame, fuel gases or vapors and oxygen combine in a reaction zone because of differences in concentration. Substances move, or diffuse, from areas of higher concentration to areas of lower concentration. Thus, the wax vapors in a candle move away from the wick, where they are most concentrated, into the reaction zone where the vapors combine with oxygen from the air moving toward the flame. Michael Faraday's study of the physics and chemistry of a candle flame, presented in his Christmas Lectures to the Royal Academy, was one of the earliest studies of fire dynamics. Faraday [3] recognized the complexity of the simple candle flame when he wrote, "There is no more open door by which you can enter into the study of natural philosophy than by considering the physical phenomena of a candle. There is not a law under which any part of this universe is governed which does not come into play, and is not touched upon, in these phenomena."

Diffusion flames can be either laminar (orderly) or turbulent (chaotic). Any flame taller than 30 cm (about 1 ft) is likely to contain sufficient disorder to be considered turbulent [4].

Flame temperatures vary widely, depending on whether the flame is premixed or diffuse, laminar or turbulent, the amount of fuel involved and its net energy release. In everyday structure fires, flame temperatures range from about 600 to about 1200°C. The start of flashover, described later, is usually defined as a temperature in the upper layer of 500–600°C. Temperatures of 1300°C are not uncommon under postflashover conditions. At one time, high temperatures were believed to be the result of the use of accelerants. This is an appealing notion; but it is now known that the temperature of a well-ventilated gasoline fire is no higher than the temperature of a well-ventilated wood fire [5].

Flammability

The term *flammability* describes a number of different properties of a material, and many different tests have been designed to measure these properties. The properties of a fuel that may be of interest include the following:

- minimum ignition energy (measured in millijoules);
- flash point (measured in degrees centigrade);
- burning rate or mass loss rate (measured in grams per second);
- heat of combustion (measured in kilojoules per gram);
- heat release rate (measured in kilowatts or megawatts); and
- flame spread rating (measured in arbitrary units compared to the rate of flame spread on red oak or expressed as distance per unit time).

Depending on the fire in question, one or all of these measures of flammability might be of interest to the fire investigator.

In understanding the behavior of fires, the central question is whether a fuel proposed to have been ignited by a particular ignition source is capable of being ignited by that source, and capable of sustaining ignition once it does become ignited. Knowledge of the flammability properties of the

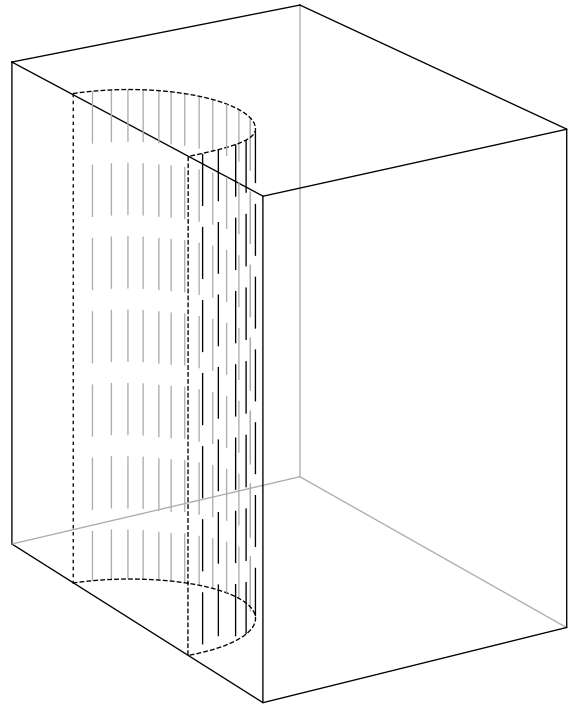

Figure 6 Schematic drawing showing the intersection of a fire plume with a wall surface to produce a columnar pattern

materials involved will often help to settle these questions, but in assessing the progress of a structure fire, the interaction between the burning fuel and the structure, itself, is often the most important interaction.

Heat Transfer

It is the transfer of energy in the form of heat that produces the most damage and leaves behind the artifacts that fire investigators interpret. Heat in fires is transferred by three mechanisms: conduction, convection, and radiation. Usually, heat transfer of all three types is taking place. "Conduction" is defined as heat transfer to another body or within a body by direct contact. Faster moving atoms or molecules in a body transfer heat by colliding with nearby molecules or atoms. An example would be the metal handle of a pot becoming hot because the pot is heated. "Convection" is defined as heat transfer by circulation within a fluid medium such as a gas or a liquid. Warming a fluid (be it liquid or gas) makes it less dense. An example is the warm air rising from just above a warm road surface. "Radiation" is defined as heat transfer by means of electromagnetic energy. An example is the heat from the sun. Just as the heat from the sun arrives at the earth after traveling through a vacuum, radiation in a fire requires no medium and travels at the

Figure 7 An example of a columnar pattern. This fire burned for less than 5 min. The fire did not have much time to interact with the ceiling, so only the beginnings of a V-shaped pattern are visible at the upper edges

speed of light. Infrared is an example of radiated heat.

With rare exceptions, the fire patterns observed in a structure fire are caused by convective or radiative heat transfer. At the beginning of a fire, almost all of the heat transfer is by means of conduction. As a hot gas layer develops (see compartment fires, below), radiation makes more of a contribution, and after flashover, radiation becomes the dominant means of heat transfer.

Compartment Fires

Most people have some familiarity with fire behavior because of their previous exposure to campfires, brush fires, and trash fires. In fire litigation cases, it is often necessary to help the trier of fact get beyond their "understanding" of the behavior of fire so that they understand the behavior of a fire "inside a structure." For decades, fire investigators, as a profession, failed to appreciate the significant differences between unconfined (free burning) fires and compartment fires, and made misinterpretations of what they observed. "Low burning" was thought to indicate that someone intervened to make the fire burn downward, and usually, the proposed mechanism for such downward burning was the addition of an ignitable liquid, or accelerant.

By looking at a simple example of a confined fire, we can begin to understand how interacting with the structure significantly affects the growth and spread of the fire. If we take a typical wastebasket fire with a heat release rate of 150 kW, and place it in the center of a large room, the flame height will be about 1.3 m (just over 4 ft). If the wastebasket is moved next to a wall, cool air can no longer enter the fire plume from the direction of the wall. The length of the mixing region, where flame and air come together, will be extended, and the flame will be taller. Even though we have removed half of the essential mixing air by moving the wastebasket next to the wall, it will not be twice as tall, but it will be taller. If we move the wastebasket into a corner, the flames will be taller still, because only 25% of the radius of the fire plume is open. Thus, it is possible for a fuel package in the corner of a room to appear much more heavily damaged than one might expect. In fact, experiments have been conducted wherein one end of a sofa was ignited, but the other end exhibited much more complete damage, because it was close to the corner. Figure 2 demonstrates the effect of the location of a fuel package with respect to walls. All three photos are of identical polyurethane chair cushions taken 17 s (± 1 s) after ignition.

While its location in a room can dramatically affect the flame height and burning rate of a fuel package, it is the interaction with the ceiling and the resulting production of a "hot gas layer" that produces a phenomenon that is foreign to most people's experience and central to the progress of most structure fires.

If an upholstered chair in a living room is ignited, say by a cigarette, and makes the transition to flaming combustion, the fire's behavior in the early stages will be no different than if the chair were outdoors. When the products of combustion reach the ceiling, however, things begin to change. At first, a thin ceiling layer develops. This layer consists of small particles, aerosols, and gases produced by the fire, i.e., the products of combustion. Some of these products are only partially burned and are subject to later ignition. These products rise because they are less dense than the surrounding air, and they begin to fill up the room from the top down. The particles and gases in the hot gas layer absorb energy from the

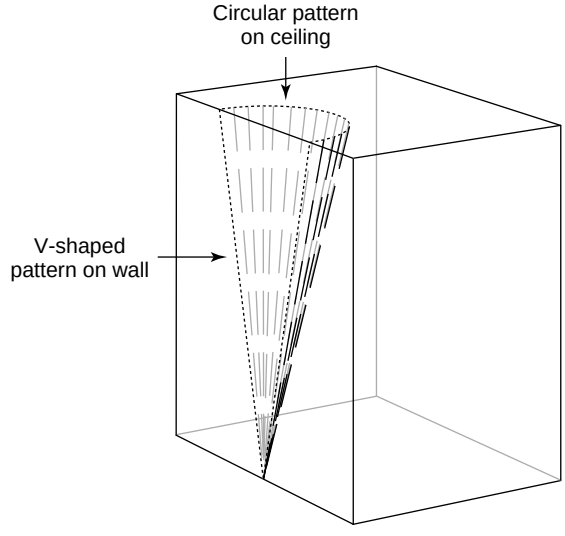

Figure 8 Schematic drawing showing the intersection of a fire plume with a wall surface to produce a V-pattern, and with the ceiling to produce a semicircular pattern

fire plume, and begin to reemit some of the energy. As the fire continues, the layer at the ceiling grows thicker as the burning chair produces more smoke and releases more energy. The hot gas layer then becomes a heat source in itself, emitting some of its energy in the form of radiation, which moves in all directions, including downward. Thus, even without any "help," this fire has the capacity to ignite objects below it. As the fire on the chair continues to grow, it acts as an "energy pump," moving energy into the hot gas layer. When the temperature of the hot gas layer reaches 500–600°C, "flashover" occurs. At this point, the radiant heat flux at the floor of the compartment rapidly rises to at least 20 kW m^{-2}. The transition from preflashover burning to postflashover burning has been described as changing from "a fire in a room" to "a room on fire." The room will continue to burn long after flashover occurs, but the fundamental nature of the fire changes. Prior to flashover, the fire grows as additional fuel is ignited. Once flashover occurs, however, every exposed combustible surface in the room is already on fire, so the only factor that can affect growth is the amount of ventilation available. Prior to flashover, a fire is said to be "fuel controlled." After flashover, the fire is said to be "ventilation controlled." The progression of a typical compartment fire is illustrated in Figure 3.

Figure 9 An example of a V-pattern. This fire was determined to have started at a trash can located at the bottom of the V

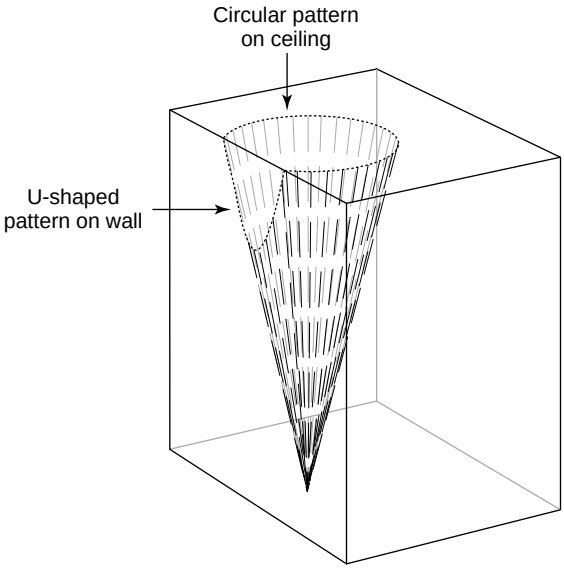

Figure 10 Schematic drawing showing the intersection of a fire plume with a wall surface to produce a U-pattern on the wall and a circular pattern on the ceiling

In the free burning stage, the primary means of fire spread is via convection, i.e., movement of the fluid (air and products of combustion) as a result of differences in buoyancy. After flashover, the primary means of fire growth and spread is radiation [6]. This radiation behaves exactly like visible light, and causes the production of fire patterns in straight lines. "Protection patterns" are formed when objects protect the surfaces underneath or behind them from exposure to radiant heat. Protection patterns are essentially shadows.

One thing that usually happens when flashover occurs is that the windows break. Because window glass often fails when radiant heat fluxes reach 20 kW m^{-2}, breakage of the windows is often considered the event that defines when flashover occurs [7]. The breakage is due to the increased thermal stresses caused by the vast difference in temperature between the exposed glass and unexposed glass under the edge of the window frame.

One of the first tasks of a fire investigator investigating a structure fire is to determine those compartments where flashover occurred and those compartments where it did not. Because postflashover burning can produce patterns that obscure or obliterate patterns that were created prior to flashover, careful interpretation is required in postflashover compartments.

Pattern Development

The observations of "fire patterns" on the surface of a fire scene are the major tools that a fire investigator uses in determining where a fire started and how it moved (*see* **Fire: Scene Investigation**). A "fire effect" is an observable or measurable change in or on a material as a result of a fire. A fire pattern is an identifiable shape formed by a fire effect or group of fire effects. Fire effects are the underlying data that are used by the investigator to identify fire patterns. The recognition, identification, and proper analysis of fire patterns depend on the understanding of the dynamics of fire development and heat and flame spread. This analysis includes an understanding of the way that the three modes of heat transfer (conduction, convection, and radiation) produce the fire effects, and the nature of flame, heat, and smoke movement within a structure.

The patterns that are of most interest to fire investigators are those recorded on two-dimensional surfaces such as walls, ceilings, and floors. Patterns may either be caused by fire intensity or by fire spread. The patterns seen by an investigator represent the entire history of the fire. Each time another fuel package is ignited or the ventilation to the fire changes, the rate of energy production and the heat distribution change. Any burning item can produce a plume and thus a fire pattern. Determining which pattern was produced at the point of origin by the first material ignited is the goal of the fire investigator, but success often becomes more elusive as the size and duration of the fire increases. Patterns can be generated by fire plumes, hot gas layers, and the movement of fires from one compartment to another or from one level of the building to another.

Mature fire plumes are cones, and where those cones intersect ceilings and walls, characteristic patterns are generated. Early in a fire's development, the cone is upright, as shown in Figures 4 and 5. In the midpoint of a fire's development, the plume may assume a columnar shape. Figures 6 and 7 illustrate the development of a columnar pattern. Such patterns are seldom seen and require that the fire be extinguished after the cone stage, but before the formation of an inverted cone.

If the cone of a fire plume has its point at the base of a wall, then a V-pattern will be produced on the wall. See Figures 8 and 9. If the base of the fire is some distance away from the wall, then the wall will intersect the fire plume higher up, and a U-shaped pattern will be produced, as shown in Figures 10 and 11. A semicircular pattern will be produced on the ceiling if the fire is close to the wall, as shown in Figure 12, and a circular pattern will be the result if a fire is in the middle of the room. In a typical fire scene, many or all of these patterns may be observed.

Recognizing fire patterns and how they were produced is a requisite skill if a fire investigator is to accurately determine the origin of the fire, which is the most important activity that must be conducted prior to determining the cause.

Figure 11 An example of a U-pattern. This fire was started at the wall behind the door in the foreground. There was a V-shaped pattern behind the door. The U-pattern was produced farther away from the origin

Figure 12 An example of a semicircular pattern on a ceiling. The semicircular pattern was helpful in determining that the fire started inside the wall, at the location of a three-way switch. One of the switch contacts was found to have melted, and there was arcing on the branch circuit conductor in the wall cavity

Fire: Scene Investigation

This article describes the basic steps to be followed in carrying out a fire investigation. Each fire investigation is different from every other, if for no other reason than that fires occur at different places and at different times. There are sufficient similarities among fires; however, that a standard approach to the process is possible. Not every step will be necessary or practical in every investigation, and there are certainly situations that will not be addressed here that will require some initiative and creativity on the part of the investigator. Many of the routine steps will be possible only if the investigator is the "first responder", or one who is on the scene before it has been significantly altered. Many investigations do not even start until other investigators have had a 6- or 12-month head start, and have reached a conclusion that, for example, a particular product failure caused the fire. An investigator retained by the product manufacturer will thus be relying on the documentation produced by the earlier responders.

Procedures will also vary according to the problem being addressed. In many cases, the cause of the fire is well known, but the investigator may be tasked with addressing a particular question about a particular system.

Recognize the Need

Before covering the subject of *how* a fire investigation is conducted, it is first necessary to understand *why* a fire investigation is conducted. This is the first step of the scientific approach, described in

National Fire Protection Association (NFPA) 921 as "Recognize the Need" [1]. What is it that the entity calling for the investigation needs? The main task of most fire investigators is to determine *where* the fire started and *how* it started, but the word "cause" often has many deeper meanings, depending on the context. In addition to the cause of a fire, one might want to understand the cause of a fire death. There might be a very simple cause determination, such as an obvious cooking fire, but the next question arises "Why did the victim fail to escape"? Was there something wrong with the victim? Was he or she incapacitated? Was there something wrong with the building? Were the exits blocked? Did the smoke alarm function properly, and if not, why not? Did the fire spread too quickly, and if so, why? Fire investigators are frequently asked to determine why a fire spread in the way that it did. This could be due to the nature of the first fuel ignited, the interior finish, the nature of the building ventilation system, the failure of a fire protection system, such as a sprinkler or vent damper or automatic door closure, or because someone propped open the door to the exit stairway.

In many fires, the cause of the fire (the circumstances that brought the fuel and the ignition source together) is reasonably well known because there are reliable eyewitnesses. An inspection of the scene may well verify that, but it is also necessary to understand *why* it happened. It is important to know whether there was a defect in the design or manufacture of an item or whether it was broken or a safety device had been defeated. Many times someone has defeated a safety device. Even after the cause of the ignition is known, it may be, however, necessary to understand why the fire suppression system failed to extinguish the fire.

Even if there is no criminal case, the person who wired around the safety device and caused the loss may be civilly liable to the owner of the building. The owner of the building may be civilly liable to the tenant next door, if he failed to maintain the fire suppression system.

In the public sector, the first goal is usually to determine whether the fire was accidental or deliberate (although this term is eschewed by many observers who say that the motive cannot be ascertained from the science, which is probably true in many cases). That is sometimes the limited assignment of the first investigator sent out by an insurance carrier, but usually an insurance carrier is looking for someone, anyone, who might be held responsible for the fire, other than its named insured.

Presumption of Accidental Cause

The most important thing a fire investigator can do is to keep an open mind. It must be remembered that fires are common, fires can be very difficult to investigate, and *more than 80% of all fires are accidental* [2]. It is this last fact that seems to elude many investigators. The fire scene should always be treated as a crime scene in the first instance. As long as the potential exists for the fire to be determined to be incendiary, there should be site security in place, and mandated procedures designed to protect the integrity of any criminal prosecution. In the United States, the controlling legal authority on a fire investigator's right of entry is the Supreme Court's interpretation of the Fourth Amendment in two Michigan cases, *Michigan v. Tyler* and *Michigan v. Clifford* [3, 4]. In *Tyler*, the court held that an "expectation of privacy" exists even after a building burns; hence, a warrant is required except when there are "exigent circumstances". In *Clifford*, the court held that the need for a warrant existed even in cases of "administrative" searches, i.e., those searches that start out being conducted for purposes other than the collection of evidence in a criminal investigation. Most entries are made either under "exigent circumstances" or with the permission of the owner. When the owner is unavailable to give such permission, it is easier to obtain a warrant than to later explain why no warrant was obtained.

Planning the Investigation

When the fire investigation assignment is received, getting sufficient information will allow the formulation of a reasonable plan. Learn the basics regarding when the fire occurred: which fire department responded; who owns and leases the building; what the building was used for; and what other parties may have been affected by the fire. Private sector investigators may need to coordinate their efforts with both public sector investigators and private fire investigators retained by other parties. Learn to what extent suppression and overhaul may have altered the scene. The investigator may be able to decide whether it is necessary to recruit additional talent or obtain heavy

equipment to assist with the investigation. If there is a credible suspicion of an electrical failure, it is a good practice to bring a forensic electrical engineer to the site. If there is a collapse of a steel truss roof over a 50 000 square foot retail store, it will probably be necessary to rent a crane and hire a cutting and welding contractor.

It is useful to learn as early as possible whether there were any eyewitnesses to the fire. This can save an immense amount of work. Witnesses may have even photographed or videotaped the fire in progress. If a building has a security system, there may be records of alarm activations or possibly video tapes from security cameras.

For most occupancies, the use of the structure is apparent, and the influence of activities of the occupants or the kind of fuels present on the spread of the fire will be simple enough to determine. For industrial occupancies, it is usually necessary for the investigator to become familiar with the peculiarities of the processes taking place by consulting with the plant manager or someone knowledgeable about the systems. The fire history of the facility is also something that should be examined.

Prior to visiting the scene, it is necessary to ensure that one has permission to do so. Authority to enter and investigate most often comes in the form of permission from the owner, but may also take the form of a search warrant or an order of the court. Having made as many preparations as practical, the site visit is the next step.

The Initial Survey

Fire scenes are dangerous places. Safety hazards include the obvious ones, such as structural instability, energized electrical circuits, and leaking fuel gases, but the investigator also needs to consider the less obvious hazards, such as fire gases (CO and HCN), toxic hazards such as asbestos, and biohazards. If conditions exist that prevent the inspection from being conducted safely, steps must be taken to alleviate those conditions before the investigation can proceed.

A brief “walk through” is considered useful by some investigators, and is indispensable in some scenes. For a single house, however, many start with the exterior and then move to the interior, starting with the area of least damage and then moving to the area of greatest damage. Except in the most obvious of cases, it is best not to use the walk through to formulate hypotheses. The best approach is to keep an open mind for as long as possible. Do not hasten the process. Although the investigator is obviously making observations at this point, one should avoid drawing inferences from those observations. Ideally, the walk through will help the investigator formulate a general plan for the conduct of the site inspection.

Documentation

The site condition should be documented before the investigator makes any changes (or any further changes). Documentation can take many forms, but the best form is still photography. If an observation is made, it should be documented. With the advent of digital photography, there is no longer any reason not to take a photograph of every pertinent artifact. Digital cameras, or film cameras with time legends, also serve to document the time spent at a scene, or at least the time between the first and the last photograph.

Other forms of documentation are essential as well. Written notes will document those observations not well suited to photography, and video documentation helps to orient photographs.

The documentation prior to disturbance of any evidence takes time, and it is during that time that the investigator can make the observations necessary to help decide how to reconstruct the fire scene. A preprinted sheet for documenting common building characteristics, such as the one shown in Figure 1, helps this investigator to avoid missing important details.

Another critical piece of documentation, required on all but the simplest investigations, is the sketch. For most buildings, the minimum sketch should be a floor plan. Sometimes, particularly in commercial or industrial buildings, an “as built” drawing of the building can be obtained from the building owner/operator (assuming that the fire did not destroy such documents). Most commercial occupancies have fire escape plans framed on the wall in several places. These are usually sufficient, at least as the starting point for a sketch. A floor plan is necessary because the people reading an investigator’s report (or listening to his testimony) are not going to be familiar with

Figure 1 Checklist describing building conditions

the building. A floor plan is indispensable for getting other people oriented so that they can understand what the photographs show, and what they might mean.

The level of detail on the sketch is up to the investigator, and will be dictated by the needs of the investigation. In many cases, a simple plan view showing rooms and doorways will suffice. If ventilation or escape is an issue, then certainly the location of the windows should be included. If fire modeling is contemplated, then it is necessary to draw not only the doors and windows but also the height of each opening, the ceiling height, the location of each fuel package and the composition and thickness of all interior finishes must be recorded. The best time to gather this information is while the building is being sketched. Getting this information later may not be possible.

The sketch is as good a place as any to orient the building to the earth. A compass is an inexpensive device that should be in every investigator's camera case. "Left" and "right" can be very confusing descriptions, as it is then necessary to say where one is standing and which direction one is facing. Compass directions are much more consistent and easy to understand. An approximate scale is also useful. Such a scale might look like this: ~10 ft. Writing out "1 in. equals 10 ft" is only useful if the sketch is not enlarged or reduced.

Reconstruction

During the process of sketching, documenting, and becoming thoroughly familiar with the fire scene, the investigator has had a chance to make observations about the fire and to formulate a plan for reconstruction. This almost always involves debris removal and may require several hours or days of strenuous physical activity to remove the debris that covers the artifacts that will allow a determination of origin and cause. Although there is heavy equipment that can accomplish this debris removal, starting with heavy equipment will almost always destroy more evidence than it uncovers. Too many investigations have been compromised by bobcats and backhoes used by investigators looking for "pour patterns" or spalling. The causative agent frequently lands in a pile of debris in the parking lot, with no possible way to determine where it was located before it was run over by the heavy equipment. The problem with heavy equipment, efficient though it may be, is that instead of clearing out a doorway or a hallway, it takes down the walls on either side.

Sometime after the burned roofing material is carried outside, interesting artifacts will begin to be revealed. It is necessary to stop periodically and document this potential evidence as it is found. It is frequently necessary to move things out of the way so that debris clearing can continue, then move those things back to their original location to understand their role, if any, in the progress of the fire. In a well-executed debris removal operation, the debris is moved *once*.

Once the debris has been moved out of the way, items should be placed back into their original locations, if possible. Tables and chairs frequently leave "footprints", protected areas on floors that allow for the furniture to be exactly repositioned. Use caution with freestanding items such as tables, however, since it is possible to get them repositioned exactly backwards.

Once the reconstruction is as complete as it is going to get, any portions of the scene that have been changed should be rephotographed, paying particular attention to burn patterns that indicate movement or intensity of the fire, fuel packages, and ignition sources.

A common mistake in the documentation of the scene is the failure to take overall shots of the area where close-ups are going to be taken. Photographs of burn patterns or of small objects that might be ignition sources are just not as useful if there is no photograph that places the subject of the close-up into its context.

Some of the most important artifacts are those that allow the collection of *sequential data*. The fire scene "records" each movement of the fire from one place to another, but often these patterns do not help us learn *when* a particular event occurred, or in which order two or more events occurred. Patterns that give sequential data are the most instructive. Sometimes, it is the orientation of burn patterns on an object that allows inferences to be drawn regarding the object's position when the pattern was created. Fallen objects such as pieces of the ceiling may exhibit smoke or heat damage on the top or bottom surface. It is important to examine this "debris" as it is being removed. Sometimes, the task of moving debris is so large that focus on details such as this can be lost.

The evidence is now exposed and has been documented. The fire investigator is presented with what is likely to be all of the physical evidence there is to see. It is hoped that the work that has been done will allow for the development of a credible hypothesis as to where the fire started, and what may have caused it.

Inventory

In a residential or mercantile occupancy, the inventory is physical evidence that frequently requires documentation. The investigator should at the very least determine that the inventory is consistent with the reported type and level of occupancy. Are there sufficient beds, linens, toiletries, and food for the number of persons reported to be living in a residence? (Do not open the refrigerator to check the food supply until you are ready to leave, especially in the summer.) Private fire investigators are often asked to include an inventory section in their report in order to verify the accuracy of an insurance claim. Assuming that it is the kind of item not likely to have been consumed in the fire, the absence of some items may indicate a fraudulent claim. In fact, it may indicate that those items were removed prior to the fire on the basis of the homeowner's knowledge that the fire was going to occur. Prior removal of contents, or substitution of contents prior to the fire, can be used as evidence of prior knowledge and may overcome a presumption that a fire was accidental. An accident is by definition unexpected.

This author has investigated many fires where the homeowner could not part with his beloved guns or his television, so they were removed before the fire was set. Then, in attempt to "double dip" the missing items were claimed on the insurance inventory. The homeowner may have even been able to document the purchase of items removed prior to the fire. Sentimental or irreplaceable items, such as photographs, are another class of items that are frequently removed prior to an intentionally set fire. Since these items have little or no economic value, the claim that some burglar stole them and then set fire to the house would be curious.

Substituted inventory is an even better indicator of what happened and who is responsible. In one fire investigated by the author, the homeowner first put his valuables in storage, then went to the town dump and obtained what he hoped would be sufficient junk furniture and appliances to support a claim after those materials had been burned to powder. He made the mistake of using too much gasoline, however, and the fire went out for lack of air. There was a trail of broken picture tube glass leading from the driveway into the living room, where a television set with a broken picture tube sat, with not a scorch mark on it.

In one of the author's first fraud investigations, the house was reduced to ashes, but the homeowner had stashed his coin collection in the trunk of his car, where it was later spotted by an alert insurance adjuster. If there are outbuildings on the property, the investigator should document their contents, to make sure that undamaged property is not later claimed as having been destroyed in the fire.

In cases such as these, it is necessary for the arsonists to unwittingly cooperate in their own downfall, if this kind of approach is to work. There may be a legitimate excuse for the photos and other mementoes being found in the chicken house. In such a case, the homeowners must deny removing anything prior to the fire.

Avoiding Spoliation

It often happens that an investigator reaches a point in the scene investigation that it becomes apparent that a particular device malfunctioned and caused the fire. This may be a light switch or a ceiling fan or a cooking or heating appliance, a computer, or any one of the thousands of manufactured products. It may be that a contractor performing a service, such as refinishing the floor or reroofing a commercial building, was on site shortly before the fire, and the evidence seems to point to some careless act on the part of one of the contractor's employees. When this occurs, it is the investigator's job to stop any further activity that might prejudice the rights of an entity that may soon become a party to litigation. The investigation can resume at a later time. If the property is insured, the insurance carrier will look to whoever caused the fire for compensation. That party, in turn, will likely insist on the opportunity to view the evidence. Failure to accommodate potential defendants may result in sanctions against the plaintiff seeking damages, up to and including dismissal of the lawsuit. In noncriminal fire investigations, the rights of all parties to have access to the evidence has been embodied since

the 1970s in ASTM E 860, *Standard Practice for Examining and Preparing Items that are or may Become Involved in Criminal or Civil Litigation* [5].

Spoliation has so far not been an issue in criminal cases, but it is likely to come up in the future, so the concept should not be dismissed out of hand by arson investigators. Spoliation is defined as the "loss, destruction, or material alteration of an object or document that is evidence or potential evidence in a legal proceeding by one who has the responsibility for its preservation" [6]. To avoid spoliation, potential defendants must be put "on notice" and be told when the investigation will proceed, and allowed to send a representative to participate in the continuation of the investigation.

Spoliation is a relatively new concept for many investigators. In the past, an investigator would go to the site, determine the cause, and if that cause was an appliance, it would be collected and taken to an electrical engineer for further evaluation. If the engineer found evidence that the appliance was responsible for the fire, the insurance carrier would make a claim against the manufacturer, and the case would proceed. Such behavior by a fire investigator in the twenty first century, however, will not only prevent the investigator's client from collecting from the manufacturer the defective product, but it is also likely to get the investigator sued, even if he has correctly identified the cause of the fire and it is, in fact, defective.

Defendants no longer simply accept the first determination, and the courts have supported their position. Not only is it necessary to let the manufacturer see its defective product but it is also often necessary to let them see it *in place*, to let them have their own investigator confirm that the product was, in fact, at the origin of the fire, and to allow that investigator to independently rule out other potential sources of ignition. A manufacturer of clothes dryers, defending itself in a product liability action, will likely be successful if the washing machine was not at least preserved for inspection by the manufacturer's chosen investigator.

Claims of spoliation can be taken to apparently ridiculous extremes, and realizing this, NFPA's Technical Committee on Fire Investigations has undertaken to offer guidance not only on what activities constitute spoliation but also on those activities that should *not* be considered spoliation. It is usually necessary to conduct significant debris removal prior to uncovering the cause of the fire. Debris removal to uncover the area of origin should not be considered spoliation nor should removal of the offending device from the scene be considered spoliation, if such removal is necessary to either protect the device, or to identify its manufacturer. Further, it may be possible to eliminate an appliance by a simple nondestructive examination off-site. Note that any device once suspected but later eliminated needs to be preserved so that it can be examined by other parties.

It is scenarios such as this one that can influence criminal cases as well. It is no longer acceptable for a public sector investigator to "eliminate" a reasonable potential source of accidental ignition, and then allow it to be destroyed. A defendant may then claim that he has been prejudiced by the destruction of potentially exculpatory evidence. Such a claim will be especially effective if the only "evidence" of an incendiary cause is the investigator's inability to find any source of accidental ignition in the area identified as the origin.

Claims of spoliation against public agencies are not common, but public sector investigators should not dismiss the idea of preserving evidence for the civil investigation. Running over a fire scene with a bobcat or a backhoe to look for "pour patterns" or spalling, particularly if no such "evidence" is uncovered, makes it next to impossible for the real cause of the fire to be discovered.

Evidence Collection and Preservation

There are basically two types of evidence that fire investigators collect. The most common is samples of flooring, furniture, and other materials suspected of containing ignitable liquid residues (ILR). For a discussion of ILR analysis, *see* **Fire Debris: Laboratory Analysis of**. The other category of evidence is ignition sources that are suspected of having caused the fire, or are collected for the purpose of proving that they did *not* cause the fire. As with other facets of the investigation, evidence collection will be more successful if the fire investigator has a plan. If there is more than one investigator on the scene, all should agree to the plan for evidence collection. The standard that describes appropriate procedures for evidence packaging and labeling is ASTM E1459, *Standard Practice for Evidence Labeling and Related Documentation* [7]. Other standards applicable to fire investigation are described in **Fire Investigator: Standardization, Accreditation, and Certification**.

With respect to the samples collected for ignitable liquid residue analysis, if possible, the samples least likely to contain residues should be collected first. This will minimize the risk of cross-contamination. If comparison samples are to be collected (and it is strongly recommended that they be collected), they should be collected first. Select materials that are identical or nearly identical to the materials suspected of containing ignitable liquid residue. Label the evidence containers with the following information: a unique case number or file number, identifying the fire scene; the sample's serial number; a description of the substrate material; the location of the sample; the date collected; and the initials of the investigator collecting the sample. The labeled containers should be placed at the location where the sample will be collected, and photographed in place before the sample is placed in the can. A second photograph should be taken showing the sample in the can next to the former location of the sample. The location of the sample is the single most important attribute of the sample, so it is important that this information be thoroughly documented. When collecting samples for ignitable liquid residue analysis, the investigator should wear disposable latex gloves, and change gloves between each sample. The gloves should be left behind at the sample location and not placed in the sample container.

There are several choices available for sample containers. Containers should be free of contamination and vapor-tight. Glass has the advantage of transparency and resistance to corrosion, but it breaks. Metal cans do not break, but in the time between the site inspection and any trial, they are likely to corrode. Corrosion can be avoided or delayed by the use of polyester-lined paint cans. The coating is opaque gray or opaque tan, and is the kind used for water-based paints. Such a coating will not influence the laboratory analysis, but it is a good practice to save one can from each batch purchased, in case it becomes necessary to prove this.

Evidence bags made for the purpose are suitable containers, but their only real advantage is their light weight and small volume, which makes it possible for the investigator to carry a large number of them. Major disadvantages include difficulty in sealing, poor containment of wet samples and susceptibility to tearing. Many laboratories find it necessary to repackage evidence delivered in bags. When submitting evidence in bags, a negative control (empty bag) is required.

The location of any sample collected should be noted on the investigator's sketch. An evidence transmittal form (see Figure 2) should be filled out as soon as practical after the samples are collected. Samples should not be held longer than absolutely necessary prior to submission to the laboratory. If hand delivery is likely to create a significant delay, then the use of a common carrier is preferable.

In the context of a joint inspection, all parties should have the opportunity to request that certain items of evidence be preserved for later examination. The person responsible for collection of potential ignition sources (usually the investigator retained by the property owner or their insurance carrier) should photograph each item in place, and then label the item with a label or tag that contains all of the information listed above for ignitable liquid residue samples. Once all interested parties have had a chance to view the items in place, they should be carefully transported to a testing facility. Wrapping the items with shrink wrap, available at low cost at trailer rental facilities and other places, will prevent the loss of loose parts of appliances.

Origin Determination

The determination of the origin of a fire is a fire investigator's most important and difficult task. If one does not find the correct origin, it is practically impossible to find the correct cause. Conversely, if one is able to correctly determine the origin, it is frequently not difficult to find the cause. NFPA 921 provides a long list of factors that need to be "considered" when trying to locate the origin, but the guidance is necessarily incomplete. What do you do after you consider the effects of ventilation? Other texts offer advice on burn pattern interpretation, for example, to examine the beveled edge of a hole to determine which way a fire came through a wall or a floor. What those sketches show is the direction the fire was moving when it *last* penetrated the floor or wall, which is sometimes all one can hope for.

Some things to consider when looking for the origin are the artifacts produced by the confinement

Figure 2 Evidence transmittal used for submission of fire debris samples to a private laboratory

of a hot gas layer. If one observes a smoke horizon or a heat horizon, one can conclude that, in all likelihood, that artifact was recorded on the wall *before* the ceiling in that room failed. This can be very useful, at least when it comes to placing the origin on the correct level of a structure. The absence of evidence of confinement can be almost as useful. Fires that originate in the attic frequently cause ventilation of the roof before the ceiling fails, so there is no confinement. Lightning fires frequently ignite roofs and attics, resulting in characteristic damage.

Structural framing also causes fire to penetrate walls and floors in predictable ways, and the artifacts of a surface penetration can help identify which side of the surface was involved first. If a fire attacks a floor from above, the fire is not going to be influenced by the joists under the floor. If it attacks the floor from below, then frequently, the holes in the floor will be rectangular, with the joists directing the flow of hot gases. The same is true for walls. Straight up and down holes in the drywall, with edges coincident with the wall studs, indicate that the fire came through from the other side. Figures 3 and 4 show such a pattern, and illustrate how it was created. Frequently, such determinations are "no-brainers", but it is easy to be misled by other factors, such as the "lowest burn" or "heaviest burn". That is when one needs to "consider the effects of ventilation".

At other times, the smoke and heat horizons may be the only evidence remaining. In the case where a structure collapses and burns in the basement, one does not usually expect to see a smoke or a heat horizon on the foundation walls unless the fire started in the basement. If the fire started upstairs and burned its way into the basement, there would have been a hole where the fire penetrated downward, thus preventing the formation of a hot gas layer there.

If there are humans, particularly dead humans, in the structure, their activities need to be considered. The individual in Figure 5 caught his shirt on fire in the kitchen, but did not stay there. His presence in the hallway in the area of deepest and heaviest burning, and in an area where there were no potential sources of accidental ignition could have triggered a major criminal investigation. Fortunately, an astute investigator discovered the pan of burned food in the kitchen.

Examination of damage to the electrical system is frequently useful in determining the origin, or in testing a hypothesis about the origin. An electrical

Figure 3 Rectangular burn pattern on a gypsum drywall surface

circuit has the capacity to act as a fire detector. When the insulation on an electrical circuit is compromised by a fire, several things can happen. The carbonized insulation becomes conductive, and arcing through char can occur. This may or may not sever the circuit. Frequently, the current will meet sufficient resistance to flow that it does not open the circuit protection device, and the circuit can be attacked in another area, either upstream (toward the service panel) or downstream (away from the service panel). When the arc causes the wire to sever, current flow downstream ceases, and the point of arc severing furthest downstream can be said to have preceded any other arc severing on that circuit. Usually, the fire department or power company disconnects power to the structure sometime during the fire, and any electrical activity observed necessarily occurred before that happened. Sometimes the fire itself cuts

Figure 4 Location of a "drop down" fire in the interior wall space behind the pattern shown in Figure 3. The cross member stopped the hot coals, and those produced the pattern

Figure 5 The only significant fire damage in this residence was in the immediate vicinity of the body. The victim's clothing was ignited by a small cooking fire that self extinguished [Reproduced with permission from Gardiner Associates.]

off the power, when it burns the service drop, or causes the service entrance cable to arc to the distribution panel. In a fire that exhibits electrical damage in only one part of the structure, the search for the origin should focus on that area. Electrical arc damage is sometimes the only kind of artifact that survives a fire.

There have been only limited studies of the error rate of origin determinations by fire investigators. The studies that have been done, however, suggest that the error rate is alarmingly high. The US Bureau of Alcohol, Tobacco, Firearms, and Explosives (ATF) conducts fire investigation training courses at the Federal Law Enforcement Training Center near Brunswick, Georgia. One of the opening exercises that the ATF employs is to invite course attendees to examine the scene of a test fire and determine the origin and cause. No statistics have been kept on these exercises, but it has been reported that the number of correct determinations is appallingly low. In one exercise that was recorded, ATF Special Agent Steve Carman burned two similarly furnished bedrooms at a Las Vegas, Nevada test site. Fifty-three fire investigators from both public and private sectors, with varying degrees of experience, were asked to determine which quadrant of each room held the origin of the fire. In each case, only three investigators were able to determine the correct quadrant, and none correctly identified the point of origin [8]. The odds of correctly identifying the quadrant of origin by chance alone are 25%. Agent Carman's results indicate that fire investigators who use the area of lowest or deepest charring to indicate the area of origin in fully involved compartments frequently identify the wrong location. It seems likely that the origin of far more fires should

be declared "undetermined", or, alternatively, much larger areas of origin should be determined.

Hypothesis Development and Testing

This is the critical stage of the investigation. Using his or her education, training and experience, and the facts as they have been developed thus far, the investigator may have sufficient information to formulate a fire scenario that accounts for the condition of the scene. Because this step is so dependant upon the individual investigator's experience, it is a subjective exercise, and because it is subjective, it requires further testing if it is to be believed. Investigators who are trying to follow the scientific method as outlined in NFPA 921 may object to this characterization, because they will be basing their hypothesis "solely on the empirical data that the investigator has collected". However, the development of the hypothesis is, nonetheless, a subjective exercise using inductive reasoning, which involves starting with a particular experience and making generalizations. Inductive reasoning leads to probabilities, not certainties. An investigator who has never seen a cigarette thrown into a wastebasket can cause a fire may believe it does not happen and so is unlikely to formulate (much less test) such a hypothesis. The editors of *Fire Findings* conducted an experiment to determine whether a cigarette thrown into a trashcan with paper would start a fire, and it required 132 trials before the first ignition [9]. Had they stopped after 100 trials, they could well have published a report stating that cigarette will not ignite paper in trashcans. They ran a total of 300 tests and got five ignitions.

The overall hypothesis about the cause of a fire may include numerous subhypotheses, the accuracy of which may or may not influence the overall determination. For example, it may be part of the investigator's hypothesis that a particular door was open during the fire. If the door was open, then there should be evidence of burning on the exposed surfaces of the doorjamb and the hinges. If, on the other hand, the door was closed, then there should be mirror images, much like ink blots, on the mating surfaces, as shown in Figure 6.

Note that the hypothesis "test", described above, involves only observation and logic. No laboratory test is required. For hypotheses that state, "That burn pattern was caused by a liquid accelerant," a laboratory test is required. Except in the most obvious cases (none of which occur in a fully involved compartment), it is not possible to credibly state that an accelerant caused a particular burn pattern unless there is confirmation by a laboratory that follows ASTM methodology.

Figure 6 Mirror patterns on the mating surfaces of a door hinge, showing that the door was closed at the time of the fire. Part of the initial investigator's hypothesis was that the exterior door was left open on purpose to provide ventilation. All three hinges were found in the closed position, with screws still in place

For a discussion of the mythology of fire investigation, *see* **Arson Investigation: Misconceptions and Mythology**.

Hypothesis testing requires that the investigator compare his or her hypothesis with *all* of the relevant credible data. It also requires the investigator to be willing to abandon a hypothesis if it is disproved, and to seriously question that hypothesis if the data are merely "consistent" with it.

The identification of the origin of the fire is a hypothesis. Beware of the trap of circular logic. Once an investigator has identified an origin, every potential ignition source outside of that origin is automatically "eliminated", because only ignition sources within the area of origin could have started the fire. This type of thinking can lead to serious errors, the most common being the declaration that

"Since I could find no sources of accidental ignition within the area of origin, this must have been an incendiary fire." Such declarations are sometimes possible, but only in rare cases. For example, if there is a small fire confined to a bedroom closet, and there are no lights or wires or other devices in the closet, it may be possible to state with certainty that the ignition source was an open flame, even if no match of lighter is found. NFPA 921 allows for such a determination in cases "where the area of origin is clearly defined and all other potential heat sources at the origin can be examined and credibly eliminated" [10]. The phrase "clearly defined" is not clearly defined. This ambiguity has been exploited by some investigators to allow them to state that "clearly defined" means whatever they want it to mean (*ipse dixit*). The intent of the passage was to allow a reasonable determination to be made when the ignition source was absent, but not to give license to simply declare a fire incendiary because no accidental cause could be found. The technical committee's discussion of the issue came about when it finally attempted to address the problem of the "negative corpus" fire determination.

Negative corpus is shorthand for "negative *corpus delicti"*. The committee chose not to even mention the phrase in the document to avoid giving the concept any credibility. The same section of the document gives extensive guidance on the concept of "elimination" of a potential cause and states,

> Elimination, which actually involves the developing, testing and rejection of alternate hypotheses, becomes more difficult as the degree of destruction in the compartment of origin increases, and it is not possible in many cases. Whenever an investigator proposes the elimination of a particular system or appliance as the ignition source on the basis of appearance or visual observation, the investigator should be able to explain how the appearance or condition of that system or appliance would be different if it were the cause of the fire.

"Clearly defined", in this investigator's view, means that anyone, even someone completely untrained in the investigation of fires, could look at the damage and unhesitatingly, and without fear of contradiction, point at the location and state, "that's where the fire started". Figure 7 shows what this author had in mind when signing off on the "clearly defined" language.

In those cases where the origin of the fire is less "clearly defined", the absence of any potential heat sources in the proposed area of origin is *data*. It is, in fact, data that is contradictory to the hypothesis that this is the origin, and should cause the investigator to carefully reexamine the hypothetical origin. Is there another area that could reasonably be considered the origin of the fire? Will an investigator

Figure 7 A "clearly defined" origin. The fire began in the wardrobe in the corner. There were no lights or other potential ignition sources in the wardrobe, so a determination that the ignition source was an open flame can be justified. This photo also shows the development of a heat horizon, a smoke horizon, and a well-formed V-pattern caused by the intersection of the fire plume with the wardrobe door [Reproduced with permission from Gardiner Associates.]

retained by another party agree with the hypothetical origin? Certainly, in a fully involved compartment, every potential heat source within that compartment requires careful examination. Heavier damage on one side of the compartment or the other is almost certainly a result of increased ventilation rather than the longer burning time. If there is more than one fully involved compartment, there must be credible data to allow the investigator to decide which one burned first.

The circumstantial evidence that fire investigators use to draw inferences and form hypotheses is frequently subject to more than one interpretation. It is seldom as clear as the "footprints in the snow" analogy used to explain the concept of circumstantial evidence to jurors.

Data that contradicts an investigator's hypothesis about either the origin or the cause needs to be taken seriously. It cannot be discarded merely because "it does not fit". A credible hypothesis should fit all the relevant data.

Once an investigator has developed a testable hypothesis, and then tested it by comparing it against all of the data, a most difficult step remains. That is, the examination of any other hypothesis that explains the data equally well. By this point, it is difficult to maintain an open mind, but be certain that anyone who has an interest in finding an alternate hypothesis will put one forward. The investigator should be able to state that such hypotheses were considered, and be able to articulate exactly why those alternate hypotheses were discarded. In many cases, where an investigator's findings are discredited, it is not because such findings are incorrect, it is because the investigator is unable to credibly articulate why his or her hypothesis is true, and the alternate is not.

There will be times when more than one hypothesis will fit the data. In such cases, the investigator has the obligation to report on all credible hypotheses.

Reporting Procedure

The report may well be the single most important document generated during the fire investigation. It will be the document that prosecutors, defense attorneys, adjusters, and other fire investigators look to in order to understand a fire investigator's procedures and opinions. In some jurisdictions, if the report does not address a particular issue, that issue will be out of bounds when the investigator testifies. If there is an error in the report, it will become the focus for cross-examination. If there is insufficient detail in the report, readers will not understand how an investigator reached his or her conclusions. The quality of the report frequently determines the fate of the case.

Reports can take many forms, ranging from a few comments at the end of a fire report to a very detailed description, running a hundred pages or more. The format of any given report is usually governed by the requirements of the fire investigator's client, whether that is an insurance company, a police agency, a defense attorney, or a prosecutor. Some report formats are dictated by court rules.

A routine fire investigation report should follow the format of a scientific report, containing a background section, a synopsis of important witness observations, a description of the investigator's observations with a sketch and photographs to illustrate those observations, and a conclusion.

ASTM E 620 is the *Standard Practice for Reporting Opinions of Technical Experts*, and generally applies to fire investigators. E 620 requires that the report contains all facts that are pertinent to the opinion rendered, and that there be an identification of those facts that are based on the investigator's observations, as opposed to those facts that the investigator has learned from other sources. It also requires that the report contain the logic and reasoning of the investigator, whereby each of the opinions and conclusions were reached.

There are times when it is appropriate to include a "Discussion" section in a report, particularly if there are alternate hypotheses that explain the condition of the scene. The "Discussion" section is the appropriate place to describe the relative merits of each of these alternate hypotheses.

It sometimes happens that a report deadline arrives before an investigator has been able to obtain or review all of the relevant data. Even in such cases, it is frequently possible to arrive at certain opinions. In most cases, even if an investigator believes that all of the data has been reviewed, it is useful to add a disclaimer to the effect that the investigator reserves the right to amend or supplement the report should additional information come to light.

Summary

To be in a position to conduct a credible investigation, each agency should have a written procedure for investigations, which refers to NFPA 921. Fire investigators need to understand the purpose of their investigation and should formulate a plan for each one. No investigation should be undertaken until the investigative team makes sure that it can be done safely.

Documentation of observations is critical, both to help investigators communicate their findings and to help them remember. Investigations frequently need to be suspended to allow interested parties to be given the opportunity to see a fire scene before it is disturbed. Reconstruction and additional documentation are required once the initial evaluation is completed.

Hypothesis formulation and testing is the most important function of the investigator. Origin determination is a hypothesis that is validated by finding the cause within the area of origin. Finding no cause tends to invalidate the hypothetical origin, and in such a case, the investigator needs to revaluate the origin determination.

Reports can take many forms. They are used to communicate results and memorialize findings. Most reports should follow the basic outline of a scientific report, so that the reader understands both the investigator's observations and his or her reasoning. Record keeping should be consistent, and destruction of documents should be avoided.

Fire and Explosion Investigations: Overview

In forensic science books, the discussions of fires and explosions are frequently grouped together, but there are striking differences between the two. Both fires and explosions are events that cause the destruction of their causative agents, and both require considerable skills, in the field and in the laboratory, to understand the events.

In both fires and explosions, there is sometimes a perceived conflict between emergency responders and investigators. There are times when the emergency response, such as fire scene overhaul, can further complicate the investigator's task. Usually, this is simply an occupational hazard. The extinguishment of the fire or the removal of fire or explosion victims for medical treatment must take priority over the investigation, and most investigators understand this.

Whilst most fires are accidents explosions are generally not accidents. The vapor phase explosions caused by leaks of fuel gas or highly volatile liquids are the exception. While the average residential fire must be considered accidental until it is proven otherwise, there is usually little point in considering the potential accidental causes for a car blowing up in a crowded market. The nature of explosion investigations tends to be different from the nature of fire investigations. Those conducting explosion investigations are typically affiliated with the national government (and perhaps health and safety regulators), while the responsibility for investigating fires usually rests with local authorities. Fires also carry with them the potential for civil litigation, as the

assignment of liability may be on a product incorrectly manufactured or a service negligently provided.

The goal of investigators of both fires and explosions is to scientifically establish what happened and who is responsible [1]. This frequently involves the coordination of several scientific and investigative disciplines, but always requires that there be a principal investigator, who puts it all together, and does the "reality check" at the end. This principal investigator need not be a formally trained scientist, but he is certainly required to think like a scientist, and to follow the scientific method [2].

Problems can arise when the fire investigator is also the person responsible for prosecuting the case if the fire is determined to be incendiary. The knowledge that comes with fulfilling the police responsibilities tends to make objectivity more difficult in fulfilling the scientific responsibilities. Division of responsibilities is perhaps the best way to overcome some of these difficulties.

Fire Debris: Laboratory Analysis of

Introduction

The laboratory analysis of fire debris is one of the most important hypothesis tests that can be performed in an investigation, especially when the investigator forms a hypothesis that the fire was set using ignitable liquids [1]. The vast majority of fire debris analyses are tests for ignitable liquid residues (ILR). Other tests of fire debris will be discussed once ILR analysis is covered.

As a result of what has been learned in the last 20 years about fire pattern production (*see* **Fire: Dynamics and Pattern Production**), laboratory analysis is the only valid way to conclusively determine that an ignitable liquid was used to start a fire, at least in a compartment that has become fully involved. Even when the compartment is not fully involved, and there is a burn pattern similar to the one shown in Figure 1, the investigator still needs to determine the identity of the ignitable liquid.

In the past, the laboratory analysis was regarded as "the icing on the cake," because by the time samples were collected, the fire investigator had already decided what had caused the fire, and the stated purpose of the laboratory analysis was to help determine the identity of the flammable or combustible liquid used to start the fire. Investigators were accustomed to receiving negative reports from their laboratory, even when they "knew" that a fire had been intentionally set with ignitable liquids.

Back in those days, the term *ignitable liquid* had not yet been coined. "Flammable or combustible liquids" were generally referred to, even by people in the laboratory, who had no clue how such liquids

Figure 1 "Obvious Pour Pattern." The only surface that was burned in this mobile home was the floor. There were no furnishings in the house. The carpet was tested and found to be positive for the presence of a medium petroleum distillate such as mineral spirits or charcoal lighter fluid. This is one of the unique cases where visual observation alone can lead to valid conclusions about what caused the pattern

may have been used, as "accelerants." Many of the findings were, in fact, false negatives, because the sensitivity of laboratory methods was just not very good. The sensitivity has improved dramatically since 1974, to the point where one can now see the petroleum products that are a natural part of our background, but many fire investigators still distrust negative reports from laboratories, based on this earlier experience.

The development of analytical procedures has paralleled the development of standards for fire debris analysis. The first vague outline of a standard was not published until 1982 [2], and prior to that, analysts would report that a sample contained "an oily liquid" that had "sufficient similarities" to a known sample of gasoline or kerosene or diesel fuel.

Isolating the Residue

Initial Sample Evaluation

Once the paperwork is done, the first critical step in the analysis of fire debris is the selection of a separation technique. Choosing an inappropriate technique could result in a false negative, a misidentification, the destruction of evidence, or any combination of these. The first step in this selection process (and the first step in any chemical analysis process) is to look at the sample. One purpose of looking at the sample is to ensure that it is what it purports to be. Sample characteristics will determine the most appropriate method for isolating any ILR that may be present. Once the visual examination has taken place, the next step is a "nasal appraisal." Occupational safety experts will no doubt frown on this recommendation, but it can be done carefully. There is no need to put one's nose in the can, even though the analyst can be reasonably certain that the fire investigator who collected the sample has already done exactly that. Unless the sample is a liquid sample for comparison purposes, it can be safely appraised by removing the lid, and waving the hand gently over the top of the sample to see if it exhibits any obvious odors. If there is an odor present, it becomes possible to do a rapid and accurate analysis by removing a small piece of the sample and extracting it with solvent. If the odor is very strong, it is advisable to remove a small piece of the sample and place it into a separate container for analysis.

ILR Isolation Method Selection

Solvent extraction according to American Society for Testing and Materials (ASTM) standard practice E 1386 is an appropriate method for rinsing out empty containers, for extracting small aliquots of samples with a high concentration of ILR, and for isolating residues from very small samples [3].

The vast majority of samples, however, are likely to be samples of burned building materials, floor coverings, and furnishings, which do not exhibit a strong odor, and are best analyzed by passive headspace concentration, as described in ASTM E

1412. This technique is essentially nondestructive [4]. If the analyst decides to use another technique later, running passive headspace concentration will not interfere with that. A schematic representation of the passive headspace concentration principle is shown in Figure 2.

Other methods of isolation have been studied thoroughly over the last 25 years, and while they have some utility, none match the advantages of passive headspace concentration using an activated carbon strip. Static headspace sampling (Figure 3), which involves warming the container and sampling the vapors in the headspace directly and then injecting those samples into the gas chromatograph, is a good screening technique, but it does not result in the production of an archiveable extract, nor does it detect compounds much heavier than C_{15}. Static headspace sampling is described in ASTM E 1388 [5]. Dynamic headspace concentration, described in ASTM E 1413 [6], was useful in demonstrating the effectiveness of adsorption/elution as a valid approach to ILR isolation, but it is destructive, requires far more attention than passive headspace concentration, and the apparatus can be cumbersome and finicky. It is no more sensitive than passive headspace concentration, and it is possible to achieve "breakthrough," which occurs when the carrier gas first moves the analytes onto the adsorbent, then blows them off again. The only advantage that it offers is speed. Solid-phase microextraction (SPME), described in ASTM E 2154 [7], is another option, but it is very labor intensive, and, like headspace sampling, does not have the potential to produce an archiveable sample that can be analyzed again. Using passive headspace concentration results in a solution that can be injected many times, and when the carbon strip is left in the solution, it will gradually readsorb ILR as the eluting solvent evaporates. Juhala reported the readsorption by small potions of activated charcoal that fell off Plexiglas beads in 1982 [8]. The solution can be reconstituted years later if a second look at the sample is desired. Because of the transient nature of many fire debris sample containers, the archived activated carbon strip is often the best evidence after a few years have passed.

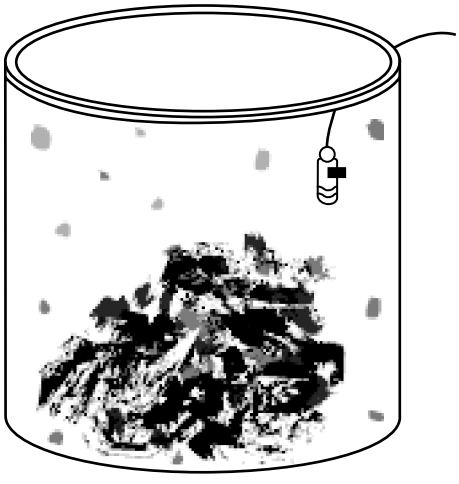

Figure 2 Schematic drawing of passive headspace concentration using an activated carbon strip. Vapors are produced by heating the container with debris to 80°C. The ACS adsorbs the vapors for 16 h, then is rinsed with diethyl ether spiked with 100 ppm perchloroethylene, and the resulting solution is analyzed by GC-MS

Figure 3 Using a gas-tight syringe to withdraw a sample of headspace from a fire debris sample. The headspace sample, about 500 µl, is injected directly into the GC-MS injection port

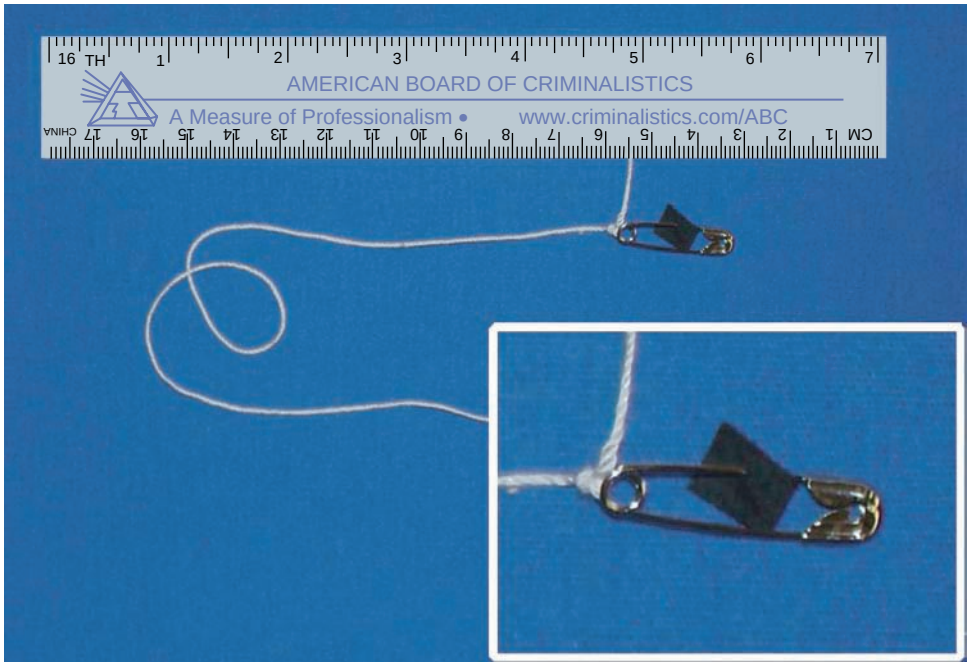

Figure 4 Close-up view of an activated carbon strip

The only equipment required for passive headspace concentration is a convection oven, vials, activated carbon strips (ACS) and a solvent dispenser. Caseload will determine the required oven size.

Every laboratory should optimize the parameters in its ACS procedure to make sure they are getting the best results possible. "Good" results from ACS are those where the chromatogram of the concentrated headspace vapors of a standard closely matches the chromatogram of that same standard in the eluting solvent.

A 10×10 mm carbon strip is the minimum size recommended. A typical carbon strip is shown in Figure 4. This 100-mm^2 strip can easily accommodate the headspace vapors from 10 µl of any ignitable liquid placed on a Kimwipe® in a quart can. It is possible to overload carbon strips, and this results in a preferential adsorption of heavier hydrocarbons with the loss of aromatics, but this effect is generally not large enough to affect the identification. Usually, samples that are capable of overloading the carbon strip will exhibit a strong odor, and the analyst can take an aliquot of the sample, or reduce the analysis time.

For samples with a high water content, there exists a danger that the vapor pressure in the sample container will cause the lid to pop off. This has the potential for contaminating the sample oven. A "pressure relief device" is easy to construct for such samples. Puncture a small hole in the lid, and cover with cellophane tape. Figure 5 shows a can so equipped.

The analysis time of a typical ACS procedure is 16 h. The analyst is encouraged to experiment with different adsorption times and temperatures, with the goal of finding a balance between the maximum recovery and the minimum time necessary. Sixteen hours is convenient because the samples can be put in the oven at 4 : 00 p.m. and taken out at 8 : 00 a.m. the next day. One of the major advantages of ACS is that it requires very little attention from the analyst. Once the strip is in the can and the can is in the oven, nothing is going to happen until it is time to take the strip out of the can, put it in the vial, and add the eluting solvent. At this point in the analysis, however, the analyst must be extremely attentive to the procedure. Once the carbon strips are taken out of the sample container, they have an identical appearance. It is at the point of placing the strips into

Figure 5 One-quart can be equipped with a "pressure relief device," a short strip of cellophane tape over a small hole pierced in the lid

their vials that an unrecoverable error can occur – a strip can be misidentified.

Many laboratories use a preconcentration step, wherein they add approximately 500 μl of solvent to the strip in a vial; then after the strip has had a chance to equilibrate, it is removed and the solvent is evaporated down to 100 μl or so. This will result in a fivefold increase in concentration, but that increase can usually be achieved electronically with very little loss of signal or increase in noise. The first analysis, in this analyst's view, does not require the preconcentration step. That can be accomplished at a later time, if necessary, but preconcentration runs the risk of skewing the results. The only appropriate way to evaporate the solvent is to blow a stream of dry nitrogen over it. Heating the solvent may result in the loss of lighter ILR components.

Solvent Selection

The solvent used for the elution is another critical choice. The most popular eluting solvent is carbon disulfide; a highly toxic, carcinogenic, teratogenic, smelly, nasty liquid that will ignite upon exposure to boiling water. It does work very well to elute aromatics and aliphatics approximately equally from activated carbon strips, but so does diethyl ether. There have been studies to indicate that carbon disulfide is superior to diethyl ether, or to pentane, the other solvent recommended by ASTM Committee E 30 [9]. Another study [10] found only marginal differences between diethyl ether and carbon disulfide when applied to carbon strips exposed to 10 μl samples of ILR. Carbon disulfide was originally selected as a fire debris solvent because of its relatively quiet signal when passing through a flame ionization detector (FID). When using a mass spectral detector, that advantage disappears because the detector is turned off while the solvent is passing through. Some concerns have been expressed about the capability of diethyl ether to form explosive peroxides, but that will not occur if the ether is kept in a refrigerator and used on a regular basis. Explosions of cans of ether have been reported only when those cans have been unused for years. Carbon disulfide, diethyl ether, and pentane are all highly flammable, but with respect to fire, carbon disulfide poses the greatest risk in that it has the lowest ignition temperature and the broadest flammable limits [11]. A comparison of the properties of the three solvents recommended by ASTM E 1412 is shown in Table 1.

Internal Standards

There are two places in the analysis of fire debris where the use of internal standards is appropriate. Addition of an internal standard to the sample itself allows the analyst to develop at least a qualitative feel for the "tenacity" of the sample, and for the effectiveness of the isolation procedure. This may be accomplished by the addition of 3-phenyltoluene (20 μl of a 2.5% solution of 3-phenyltoluene in ether). In the eluting solvent, a second internal standard consisting of 0.1% (100 ppm) perchloroethylene is added.

If the 3-phenyltoluene does not appear in the chromatogram, this means that the sample is exceedingly tenacious, and suggests that the tenacity of the sample might be the reason that the chromatogram appears so flat. If the perchloroethylene peak does not appear, that means something has gone wrong with the injection. Comparison of the signal from the sample to the perchloroethylene signal allows for a semiquantitative determination of the amount of ILR present.

Table 1 Elution solvent comparison [a]

	Carbon disulfide	Diethyl ether	Pentane
Flash point	−30 °C (−22 °F)	−45 °C(−49 °F)	−40 °C (−40 °F)
Lower explosive limit (LEL) (% vol in air)	1.0	1.9	1.5
Upper explosive limit (UEL) (% vol in air)	50.0	48.0	7.8
Specific gravity	1.3	0.7	0.9
Boiling point	40 °C (115 °F)	35 °C (95 °F)	36 °C (97 °F)
Autoignition Temp	90 °C (194 °F)	180 °C (356 °F)	260 °C (500 °F)
Exposure limit, TWA[b]	4 ppm	400 ppm	600 ppm
Exposure limit, STEL[c]	12 ppm	500 ppm	750 ppm
Carcinogenic	Yes	No	No
Teratogenic	Yes	No	No
IDLH	500 ppm	19 000 ppm[LEL]	15 000 ppm[LEL]
FID signal	Small	Large	Very large
Cost per liter[d]	$431.70	$71.05	$62.85

[b] Time-weighted average for an 8-h exposure
[c] Short-term exposure limit (up to 15 min)
[d] J. T. Baker, online catalog 24 Nov 2008. All prices are for case quantities of Ultra Resi-analyzed grade

For 10 μl standards of known ignitable liquids isolated according to ASTM E 1412, the two internal standard peaks are roughly on the same order of magnitude as the sample peaks. Blanks are run using the 3-phenyltoluene applied to filter paper, and the blank strip is eluted with the spiked solvent. The advantages of using internal standards far outweigh any disadvantages. Some analysts may perceive a danger of being accused of "contaminating" a sample, but this is easily overcome by having a proper blank in the file.

Advantages and Disadvantages of Isolation Methods

Two drawbacks have been cited for use of the ACS method, the time required to perform the adsorption, and the relative lack of sensitivity compared to SPME. If laboratories were in the habit of providing same-day service, then the first argument might have merit. If laboratories "batch" their fire debris work and make their clients wait up to six weeks for results, a 16-h versus a 15-min analysis time is meaningless. With respect to sensitivity, the ACS method is capable of routinely detecting 0.1 μl of ignitable liquid from a nontenacious background.

The fire debris analyst's job is to help the fire investigator understand whether a foreign ignitable liquid was present at the fire scene. Fire debris laboratories now have the ability to detect the solvent in polyurethane finish five years or more after it has been applied to a hardwood floor. There is normally no need for more analytical sensitivity than that.

The "screening" of fire debris samples does not make much sense, unless there is a national emergency and the investigator needs results right away. For routine analysis, passive headspace concentration, according to ASTM E 1412, should be the norm. Solvent extraction, as described in ASTM E 1386, is appropriate for sampling aliquots of very strong samples or for extracting very small samples or empty containers.

Steam distillation, shown in Figure 6, may be selected in cases where it is desired to produce a neat liquid extract of the fire debris. The benefit of this is that a vial of the liquid can be brought into a courtroom, shown to a jury, lit on fire on a Q-tip, and passed around. Since steam distillation is only appropriate on very concentrated samples, however, it is preferable to make sure that the sample is preserved, and the sample itself can be passed around for the jury to smell. For the most part, steam distillation is a technique whose time has come and gone.

A comparison of the advantages and disadvantages of the various isolation techniques is shown in Table 2.

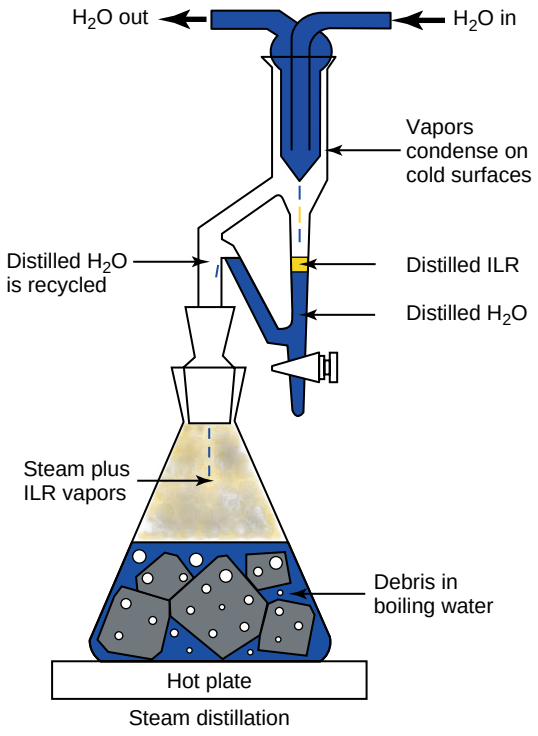

Figure 6 Steam distillation apparatus. The sample is boiled. Vapors condense on a "cold finger" and fall into the trap, which allows the water to recycle, while the immiscible oil layer builds up on top of the water column

Analyzing the Isolated ILR

Despite the improvements in separation and detection technology, the overall approach to identification of ILR is the same as it was in the early 1970s. A chromatogram from the sample is compared with chromatograms from known standards, and the analyst determines whether there are "sufficient similarities" to make an identification. What has changed is the quantity of information available because of the increased resolution provided by capillary columns and the ability to obtain a mass spectrum up to 10 times per second, as well as the reaching of a consensus on the meaning of "sufficient." So, while there is more information to compare, the technique is still one of pattern recognition and pattern matching.

An argument can be made that when one looks at a mass spectrum, one is looking at structural details, rather than simply matching patterns, but the patterns still have to match. The same argument has been made about structural elucidation in the use of FTIR for drug identification. While it would be nice to think that analysts routinely consider molecular structure, the day-to-day operation is one of pattern matching.

Fire debris analysis involves a different set of parameters than those employed by environmental scientists, who are typically trying to quantify the components of an oil spill or contaminants at a Superfund site. Environmental methods typically assume the presence of gasoline or other petroleum products, and then look for benzene, toluene, ethylbenzene, and xylene (BTEX) to quantify the amount present. Unless they are trying to identify the source of the spill, environmental analysts are usually not employing the same skill set used by fire debris analysts.

If one considers the nature of many petroleum products and the processes that are going on when these products are isolated from debris samples, one can begin to appreciate why chromatographic patterns look the way they do. Many petroleum products are straight-run distillates, particularly the medium and heavy petroleum distillates (HPD). The overall pattern of these products is a Gaussian (bell-shaped) distribution of peaks, dominated by the normal alkanes.

A fractionation process similar to distillation occurs when an ILR is isolated from a sample. This is caused by the very low vapor pressure of ILR compounds above C_{18}. If they do not get into the air in the headspace, they will not be adsorbed onto the carbon strip.

The ASTM standards give examples of many of the patterns that an analyst is likely to see in positive samples, and there is a detailed compilation of hundreds of patterns available in a standard text [12]. Both the ASTM standards and the gas chromatography mass spectrometry (GC-MS) Guide provide sufficient parametric information to allow the analyst to set up an instrument to provide patterns that look very much like the ones in the texts. While these texts are a great resource, it is imperative that every fire debris analysis laboratory has its own library of ILR. This provides for patterns with the exact same retention times, mass spectra with the exact same fragmentation patterns, and a quality assurance tool to let the analyst know when there has been some drift in the instrument, and when it is time to run a new set of standards. Whatever approach is taken, it will take time to develop the ability to recognize ILR patterns.

Table 2 Comparison of ILR isolation techniques

Method	Advantages	Disadvantages
E 1385 steam distillation	Produces a visible liquid, simple to explain	Labor intensive, destructive, not sensitive, requires expensive glassware
E 1386 solvent extraction	Useful for small samples and empty containers, does not cause significant fractionation, useful for distinguishing HPDs from each other	Labor intensive, expensive, co-extracts nonvolatile substances, increased risk of fire, solvent exposure, destructive
E 1388 headspace sampling	Rapid, more sensitive to lower alcohols, nondestructive	No archiveable sample, not sensitive to heavier compounds, poor reproducibility
E 1412 passive headspace	Requires little analyst attention, sensitive, nondestructive, produces archiveable sample, inexpensive	Requires overnight sampling time
E 1413 dynamic headspace, using activated charcoal	Rapid, sensitive, produces archiveable sample, inexpensive	Labor intensive, subject to breakthrough, destructive
E 1413 dynamic headspace, using Tenax	Rapid, sensitive	Labor intensive, requires thermal desorption, no archiveable sample, destructive
E 2154 solid-phase microextraction (SPME)	Rapid, highly sensitive, useful for field sampling with portable GC/MS	Labor intensive, expensive, requires special injection port, reuse of fibers, no archiveable sample

Table 3 Ions characteristic of compound classes

Ion	Compounds
57	Alkanes
83	Cycloalkanes
91	Toluene, xylenes
105	C_3 alkylbenzenes
117	Indan, methylindans
119	C_4 alkylbenzenes
131	Methyl, dimethylindans
142	Methylnaphthalenes
156	Dimethylnaphthalenes

The mass spectrometer provides the ability to simplify what can be very complex and confusing patterns. This is a result of the ability of the data analysis software to separate out only those peaks having particular ions present in the pattern. For instance, if one wants to look at the normal alkanes, one only needs to obtain an extracted ion chromatogram (EIC) for $m/z57$ (hereafter referred to as *ion 57*) and most of the balance of the components will disappear. It is thus possible to break down a total ion chromatogram (TIC) into its component parts. This approach to data analysis is known as *mass chromatography* and was first proposed by Smith in 1982 [13]. There are basically two ways to approach mass chromatography, the single ion approach, and the multiple ion approach. Dolan [14] has proposed referring to the single ion chromatograms as "extracted ion chromatograms" (EIC) and multiple ion chromatograms as "extracted ion profiles" (EIP). Whether the analyst prefers EICs or EIPs, the same ions, the ones shown in Table 3, are used to identify the compounds commonly found in petroleum products.

When working with software that scales the EIC or profile to the tallest peak, some caution is advised when using multiple ions. To the extent that the second, third, and fourth ions contribute to a pattern, they tend to make it more complicated, thus defeating some of the purpose of extracting the ions in the first place. To the extent that these additional ions do not contribute, they may convince the analyst that he or she is seeing more than what is actually present. Finally, to the extent that these additional ions are present at substantially lower concentrations, they would be better observed on their own, rather than in the profile. Figure 7 is a comparison of ion 57 from a kerosene standard versus a profile based on ions 57, 71, 85, and 99. The profile is slightly more complicated, but since ion 57 is the base peak for almost every component in the chromatogram, the ion 57 profile is the tallest.

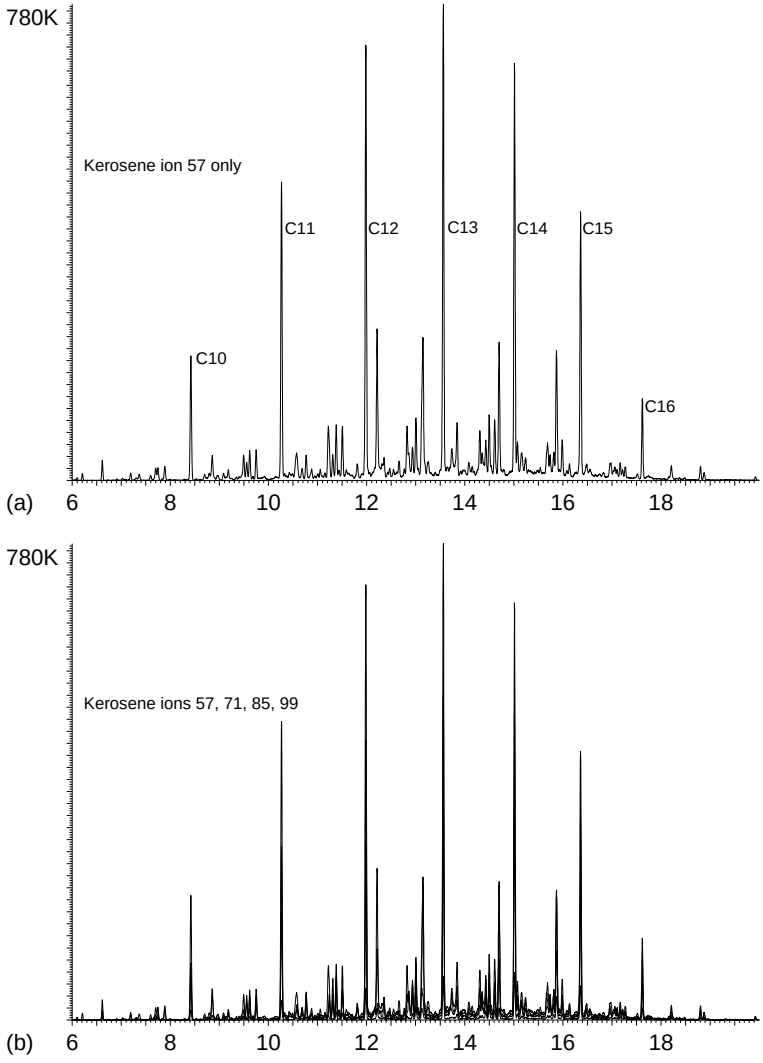

Figure 7 Ion profiling vs. ion chromatography. Comparison of the ion 57 chromatogram (a) with the ion profile combining ions 57, 71, 85, and 99 from a kerosene standard (b). The four ions in the profile are plotted in the merged format. Plotted individually, they are all very similar, with ion 57 presenting the tallest peaks

Another example is shown in Figure 8, which presents ions 128, 142, and 156, the naphthalenes, from a gasoline sample. In the top chart, the ions are combined into a profile, which, although it gives the analyst an idea about the relative abundance of the three ions, shows very little detail for the dimethylnaphthalenes represented by ion 156. When the extracted ions are presented separately, the analyst still gets the quantitative data by reading the abundance numbers next to the *Y* axis, but also gets to see the fine details in the shape of the peaks at the right side of the chart.

A similar example is shown in Figure 9(a). These charts show ions 91, 105, and 119 from a 75% evaporated gasoline "standard." (The term *standard*, when used herein, is intended to mean "known reference material," rather than a standard reference material. The gasoline was purchased from a gas station.) The effect is even more pronounced at 90% evaporation, shown in Figure 9(b), when the ion 91 peaks are

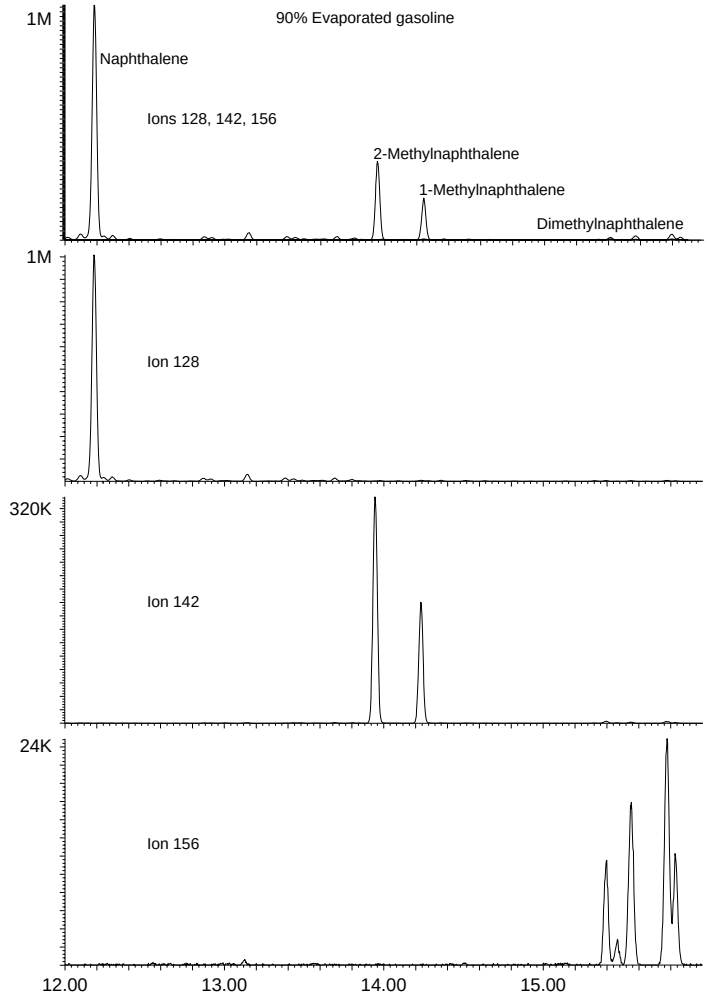

Figure 8 Ion profiling vs. ion chromatography. Comparison of the ion profile of the naphthalenes from a gasoline standard (top chart). Compare with the detail provided by presenting the three ions (128, 142, and 156) separately

smaller. Whether an analyst chooses extracted ion chromatography or extracted ion profiling is largely a matter of taste. The typical set of six ion chromatograms used in many laboratories to document the presence of gasoline is shown in Figure 10, and the set of three ion chromatograms used for distillates is shown in Figure 11. The details of each are discussed below.

Criteria for Identification

Most of the chromatograms that an analyst uses to make a positive identification of an ILR will match at the level of the TIC. Samples with low concentrations of ILR or high backgrounds, or a combination of both, can sometimes yield a positive identification for ILR if the analyst is very careful. Generally, but not always, if the TIC from the sample does not match the TIC from the standard, the sample is likely to be negative. Examples of cases where this is not true are presented following this general discussion of criteria for identification of an ILR in routine cases.

ASTM E 1618 identifies eight classes of ignitable liquids identifiable by GC-MS [15]. These classes are as follows:

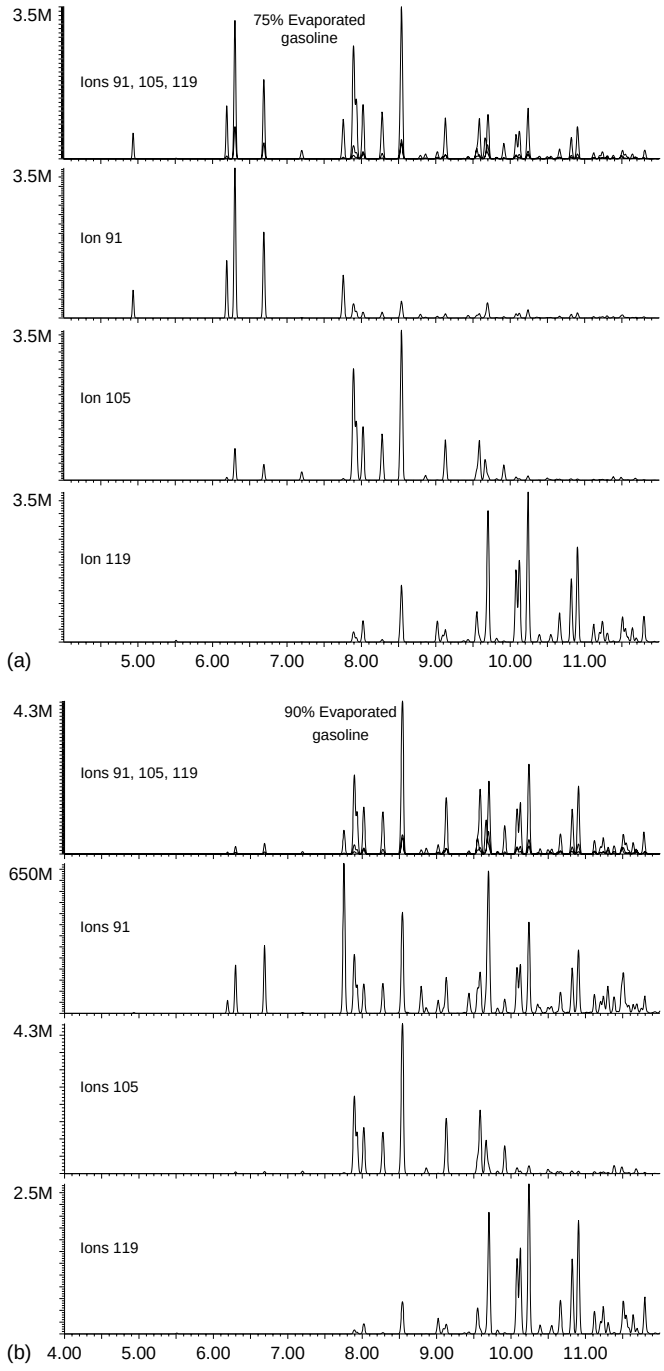

Figure 9 (a) Ion profiling vs. ion chromatography. Comparison of ion profiles from 75%-evaporated gasoline. The top chart shows a combination of ions 91, 105, and 119. The next three charts show those ion chromatograms plotted independently. (b) Ion profiling vs. ion chromatography. Comparison of ion profiles from 90%-evaporated gasoline. The top chart shows a combination of ions 91, 105, and 119. The next three charts show those ion chromatograms plotted independently. Note the improvement in the level of detail presented for the xylenes

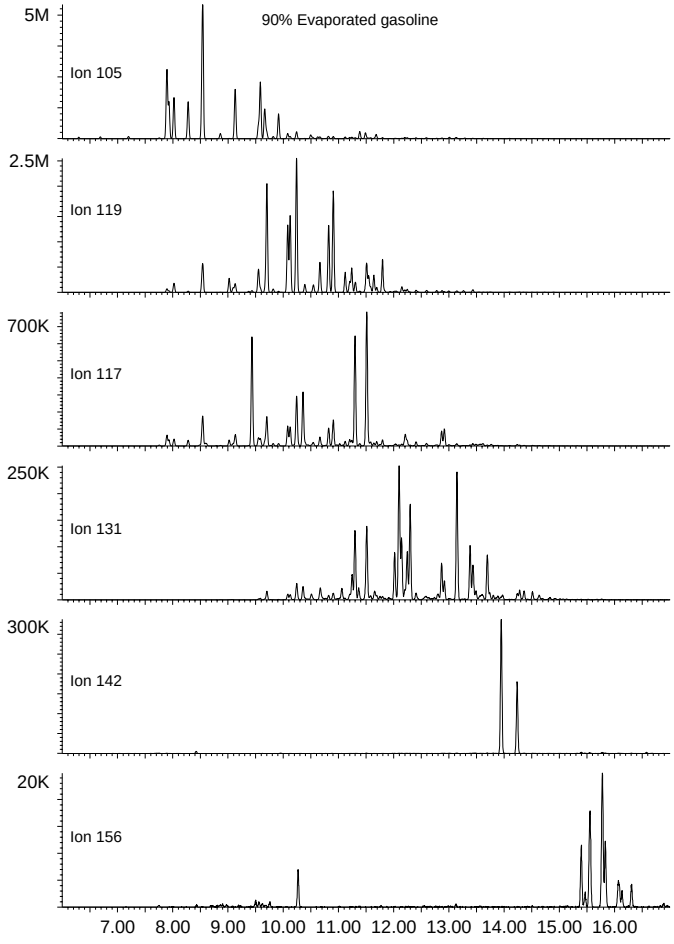

Figure 10 A typical set of six ion chromatograms used to document the presence of gasoline. Ions commonly used are 105 for C_3 alkylbenzenes, 119 for C_4 alkylbenzenes, 117 for indan and methyl indans, 131 for dimethyl indans, 142 for 2- and 1-methylnaphthalene, and 156 for dimethylnaphthalenes

- gasoline
- petroleum distillates
- isoparaffinic products
- aromatic products
- naphthenic–paraffinic products
- *n*-alkane products
- oxygenated solvents
- miscellaneous.

With the exception of gasoline, and the oxygenated solvents, each of the above classes can be divided into three further classes according to the average molecular weight: light (C_4–C_9), medium (C_8–C_{13}), and heavy (C_8–C_{20+}).

The standard presents criteria for the various kinds of compounds (alkanes, cycloalkanes, aromatics, and condensed ring aromatics) found in each one of these classes. The alkanes include both straight-chain and branched hydrocarbons, and can be extracted using ion 57. The cycloalkanes are mostly substituted cyclohexanes, which can be seen by extracting ion 83. Cycloalkanes also have a strong ion at 55, and as the length of the substituted alkane increases, ion 57 begins to dominate the mass spectra. “Aromatics” means alkyl-substituted benzenes with a single ring. These can be extracted using ions 91, 105, and 119. Ion 91 will show toluene and xylenes, ion 105 will show xylenes and C_3 alkylbenzenes, and ion 119 will

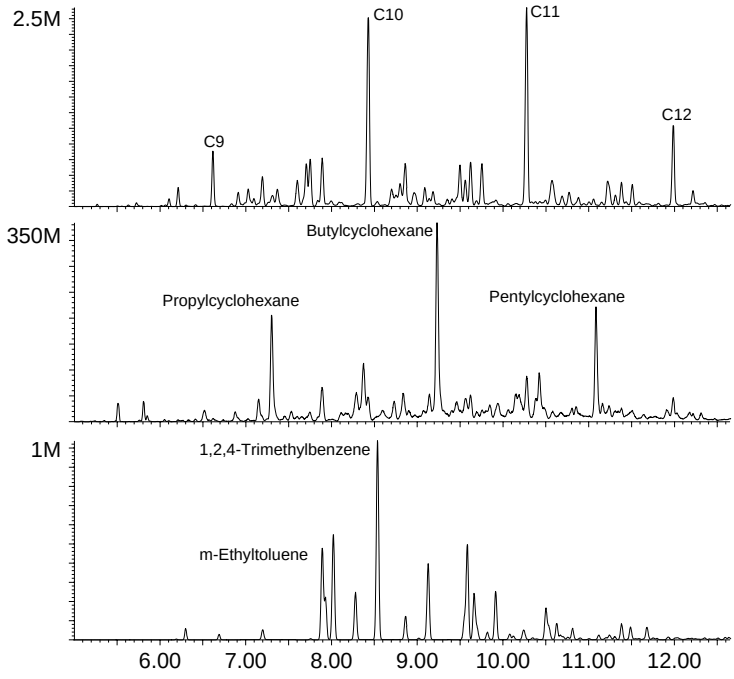

Figure 11 A typical set of three ion chromatograms used to document the presence of distillates. These are the ion 57, 83, and 105 chromatograms from smokey bear charcoal lighter, a medium petroleum distillate

show C_4 alkylbenzenes. There will be some overlap in the EIC, as shown previously in Figure 9. "Condensed ring aromatics" refers to indans and naphthalenes. Indans have a five-member ring attached to a benzene ring, and may be substituted. The naphthalenes that we usually see are naphthalene itself, 2- and 1-methyl naphthalene (written in that order because that is the order of elution from a nonpolar column) and the dimethyl naphthalenes. Naphthalene presents a single peak when ion 128 is extracted, there are two peaks for the dimethyl naphthalenes seen when ion 142 is extracted, and eight peaks in the dimethyl naphthalene chromatogram seen when ion 156 is extracted. The indans can be visualized by extracting ions 117 and 134.

Identification of Gasoline

The composition of petroleum products as found in fire debris is influenced by three factors: crude oil parentage, the effects of petroleum refining processes, and the effects of weathering. Gasoline is the way it is largely because of the second of these influences, petroleum refining. Although all crude stocks contain aromatics, aliphatic hydrocarbons comprise the bulk of most crude oils. Because the aliphatics cause knocking in gasoline engines, the value of the crude stock is enhanced by reformation through a process of dehydrogenation. Toluene and xylenes are the most abundant compounds produced in these processes. Gasoline does contain numerous light aliphatics, as light as butane, that are present when the gasoline is first pumped, but by the time it has been through a fire, most of the aliphatics lighter than toluene have dissipated. Consequently, toluene is usually one of the first tall peaks seen in a sample of gasoline, and once it has weathered to 50% or more, the toluene is much lower than the C_3 alkyl benzene or xylene peaks. Gasoline changes considerably as it evaporates, which is what makes it one of the more challenging classes to identify. When a Gaussian distribution of normal alkanes changes because of evaporation, it is still a Gaussian distribution of normal alkanes, just a heavier one. Most of the samples of gasoline that this author has seen in samples of fire debris have been more than 75% evaporated.

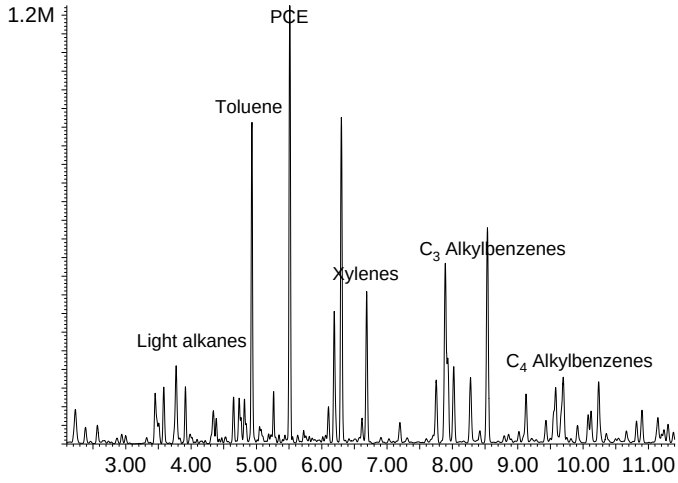

Figure 12 Total ion chromatogram of fresh gasoline. On a piece of filter paper 10 μl was spotted and the headspace was concentrated using ASTM E 1412. The eluting solvent was diethyl ether spiked with 100 ppm perchloroethylene, shown here eluting between toluene and the xylenes

Gasoline is probably the most frequently misidentified ILR. That is because many of the compounds present in gasoline as it comes from the pump are also produced when polymers degrade as a result of exposure to heat. The key to avoiding misidentifications is making sure that the ratios between groups of compounds and within groups of compounds are consistent with the standard. Toluene is a very common pyrolysis product. It is an unusual fire debris sample that does not contain toluene. Since it is one of the first compounds to evaporate, one does not expect to see a tall toluene peak in the absence of equally tall xylene peaks. Figure 12 shows the chromatogram of a 10 μl standard of gasoline adsorbed using an activated charcoal strip, and eluted with diethyl ether spiked with 100 ppm perchloroethylene. The toluene and xylene peaks are almost equally tall. If a fire debris sample contains toluene from gasoline, it will be accompanied by xylenes and the higher peak groupings of gasoline. Toluene that is not so accompanied comes from something other than gasoline.

Xylenes are also produced by the decomposition of plastics, but they are the first group of compounds that can be examined for correct intergroup ratios. Figure 13 shows ion 91, the base ion for xylenes, from gasoline in three different stages of evaporation, kerosene, and a medium petroleum distillate (MPD). The relative ratios for the three peaks are almost indistinguishable. Note that the ethylbenzene peak in the 50% evaporated gasoline is slightly lower. This trend continues as the degree of evaporation increases, but generally, we will find that if the xylenes in our sample are from a petroleum product, they will have this ratio. Note that there are three isomers of xylene, ortho-, meta-, and para-, but that the three peaks seen in these chromatograms actually represent four compounds, because meta- and paraxylene cannot be resolved except in the longest columns. If xylenes are found in ratios other than the one shown in Figure 13, particularly if ethyl benzene is the tallest peak in the group, one can safely conclude that neither gasoline nor any other petroleum product was the source of the xylene.

The next group to consider is the C_3 alkyl benzenes. This is by far the most important of the patterns in any sample of gasoline. Like the xylenes, it is also found in all petroleum products from which the aromatics have not been removed, and unless evaporation has decreased the concentration of the lighter compounds, the peak ratios will always be the same. This group seems to show up in many samples that contain no gasoline, and it is the failure to exhibit the proper ratio of peaks that is sometimes the analyst's only clue that he is looking at a 'difficult' sample. Figure 14 shows just one such sample, as well as four standards that exhibit the proper ratios

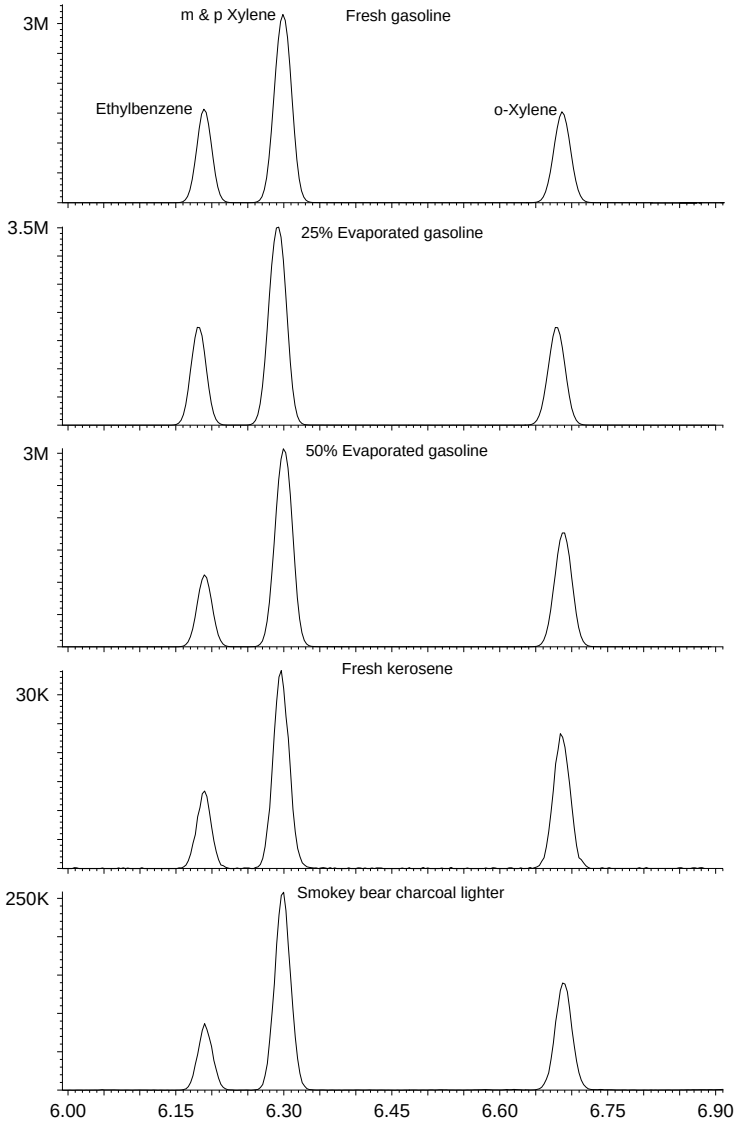

Figure 13 Ion chromatogram for ion 91 from gasoline in three different stages of evaporation, kerosene, and a medium petroleum distillate. Note that the relative ratios for the three peaks in the xylene group are almost indistinguishable. Evaporation causes the ethylbenzene peak in the 50%-evaporated gasoline to be slightly shorter

of components in the C_3 alkyl benzene group. As with the xylenes, meta- and paraethyltoluene cannot be resolved, although the resolution is somewhat better here than in the xylenes. In nearly all cases where the C_3 alkyl benzene group is, in fact, present as a component of a petroleum product, the pseudocumene peak will be the tallest. In fact, in almost all samples found positive for gasoline, because most of the residues encountered will be highly evaporated, the pseudocumene peak will be the tallest peak on the chart.

Note that in the questioned sample at the top of Figure 14(a), it is the second peak that is the tallest, not the pseudocumene peak. The first peak has the same retention time as *m*- and *p*-ethyltoluene, but the shape is wrong for petroleum, and the mass

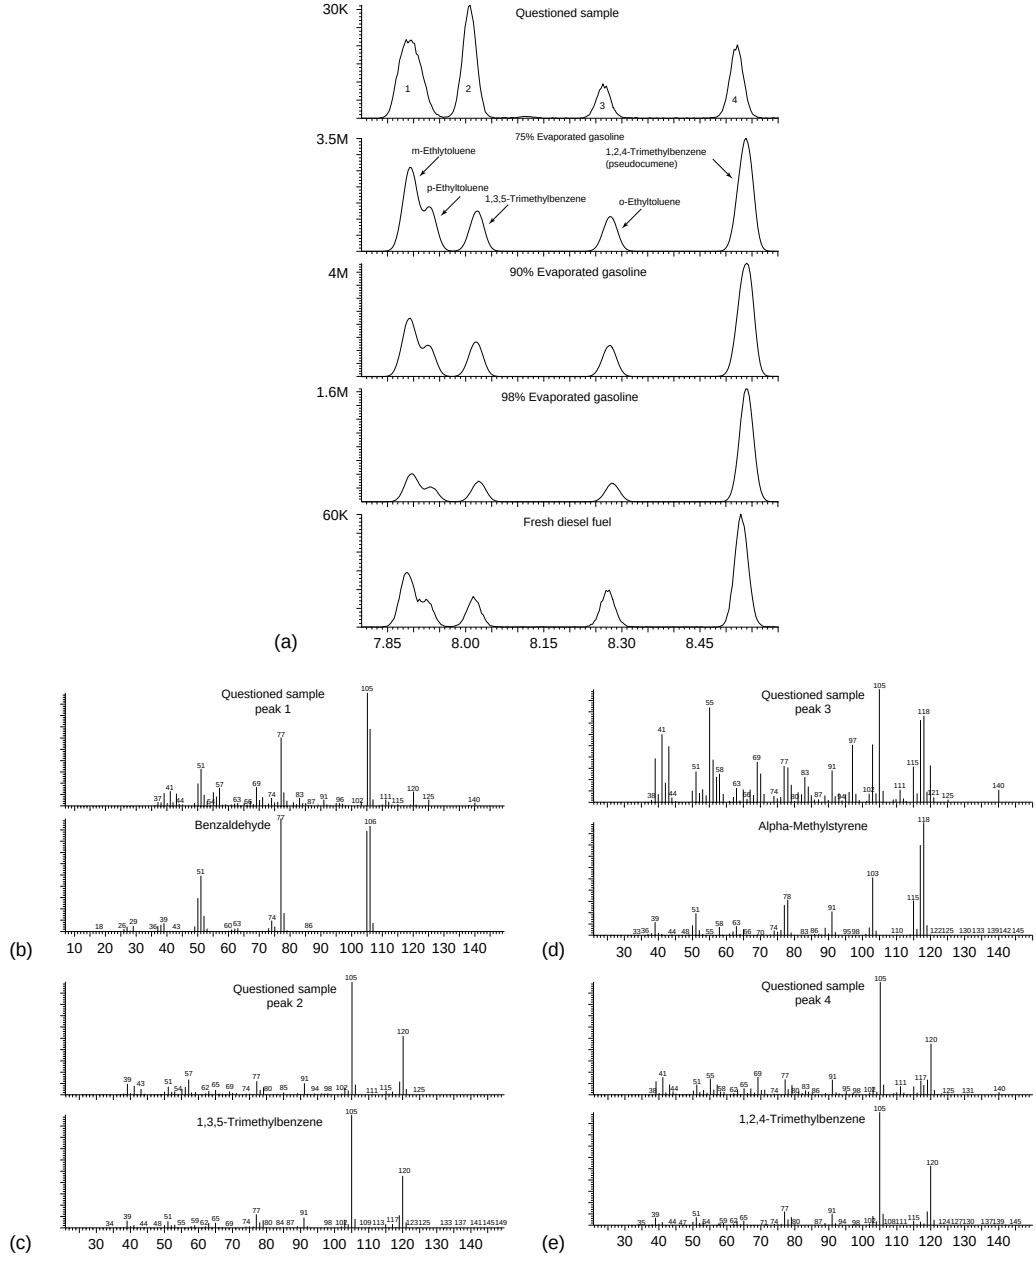

Figure 14 A study of the C_3 alkylbenzene group. Part (a) shows an unknown sample (top), gasoline in three stages of evaporation, and fresh diesel fuel. The TIC did not look like gasoline, but based on this and a few other ion chromatography comparisons, an analyst called the *sample positive for gasoline*. The mass spectra shown in (b) through (e) showed that two of the peaks, #1 and #3, were not gasoline components. (b) Mass spectrum and library match of the first peak in the top chart shown in Figure 14(a). This peak actually represents benzaldehyde, and not *m*-ethyltoluene. (c) Mass spectrum of the second fully resolved peak in the top chart shown in (a). As with gasoline, this peak is identified as 1,3,5-trimethylbenzene. (d) Mass spectrum of the third major peak in the chart shown at the top (a). This mass spectrum changed across the peak, but clearly contained α-methylstyrene. 1-decene, a common decomposition product, was also suggested by the spectrum. There may be some *o*-ethyltoluene co-eluting as well, but that cannot be demonstrated. (e) Comparison of the mass spectrum fourth peak in the chart shown in (a) with 1,2,4-trimethyl benzene (pseudocumene). This is a reasonably straightforward match

spectrum indicates that the peak actually represents benzaldehyde. The mass spectrometer unequivocally identified the second peak in the questioned sample as 1,3,5-trimethyl benzene, but the third peak, which may have represented *o*-ethyltoluene, also contained a significant 118 ion, indicating the presence of α-methylstyrene, a common pyrolysis product.

Simply matching the components when the ratios are not right can lead to misidentifications. The odds against three background components co-eluting in exactly the right concentrations to skew the peaks in this group are pretty high. Three other samples from the same fire scene were misidentified, and exhibited similar peak ratios and mass spectral characteristics. As with almost all misidentifications, there was not a good pattern match with the TIC. Extracted ion chromatography or extracted ion profiling can be very useful; however, the analyst should remember that it is a spectral as well as a chromatographic technique. The spectra should be examined, especially when the peak ratios are not the same as seen in the standard. A word about the use of the mass spectrometer beyond generating mass chromatograms is in order.

Most analysts use the mass selective detector or mass spectrometer as a tool for generating EIC and EIP. Obviously, if one is looking at very simple mixtures or single components, the mass spectrum is necessary in order to make an identification. A sometimes-overlooked function of the mass spectrometer is the evaluation of EIC and profiles. As was shown in Figure 14(a), an EIC with the intra-group ratios just slightly "off" has the potential to be misleading. Figures 14(b) through (e) shows the mass spectra of each of those five peaks, as well as the library's best match. The first peak, which is coincident with *m*-ethyltoluene, has a large peak at m/z 77, but no such ion is present in the spectrum of *m*-ethyltoluene. There may be some *m*-ethyltoluene hidden under this peak, but there is definitely some benzaldehyde as well.

One way to tell whether there are co-eluting compounds under a chromatographic peak is to examine the mass spectra at different points across the peak. If it is a pure compound, the mass spectrum will change little, if at all. In Figure 14(c), the second peak in the five-peak group is a near-perfect match for 1,3,5-trimethylbenzene, which is the third peak in the five-peak group required to identify gasoline. The third peak, whose mass spectrum is shown in Figure 14(d), clearly contains more than one substance, but the strong peak at 118, as well as the retention time, tell us that there is α-methyl styrene co-eluting. Like the second peak, the fourth peak is a pure compound, and a nearly perfect match for pseudocumene. Because the peak ratios are off, and especially because two of the four peaks in the ion 105 chromatogram represent compounds not found in gasoline, it must be concluded that the first identification was in error.

Background subtraction is a tool found in most data analysis software, and can frequently resolve questions as to whether a particular compound is actually present. A detailed evaluation of the quality of the spectra underlying a mass chromatogram, whether it is a single ion extraction or a multiple ion profile, should be carried out periodically, but it should routinely be carried out on any sample where either the peak ratios or retention times are "just a little off."

Note in Figure 14(a) that when a sample is sufficiently evaporated, the peaks at the left side of the chart begin to diminish. This is not an unexpected result. The initial guidelines for identifying gasoline stated that the *m*-ethyltoluene/pseudocumene five-peak group was still present in gasolines that had lost 90% of their fresh weight. Actually, this group does not disappear until the gasoline is more than 98% evaporated. If this group cannot be positively identified, an analyst is on very thin ice indeed when identifying a sample as containing gasoline. In such a case, there must be a peak-for-peak match of all of the higher peak groupings.

As with many of the other components of gasoline, this 5-peak group is present in almost all petroleum products from which the aromatics have not been removed. The bottom chart in Figure 14(a) is from unevaporated diesel fuel.

The C_4 alkyl benzenes are best viewed by extracting ion 119. Because there are more ways to build a C_4 alkyl benzene than a C_3, this is a more complex pattern, but it is present in almost all petroleum products. Figure 15 shows the patterns found in highly evaporated gasoline, as well as in kerosene and diesel fuel that are produced by the presence of the C_4 alkyl benzenes. Note that in kerosene and diesel fuel, the pattern is more complex than in gasoline.

The next group of compounds that need to be present in order to make a solid identification of gasoline is the indans. These can be extracted using ions 117 and 131. The doublet at 11.3 and 11.5 min in the

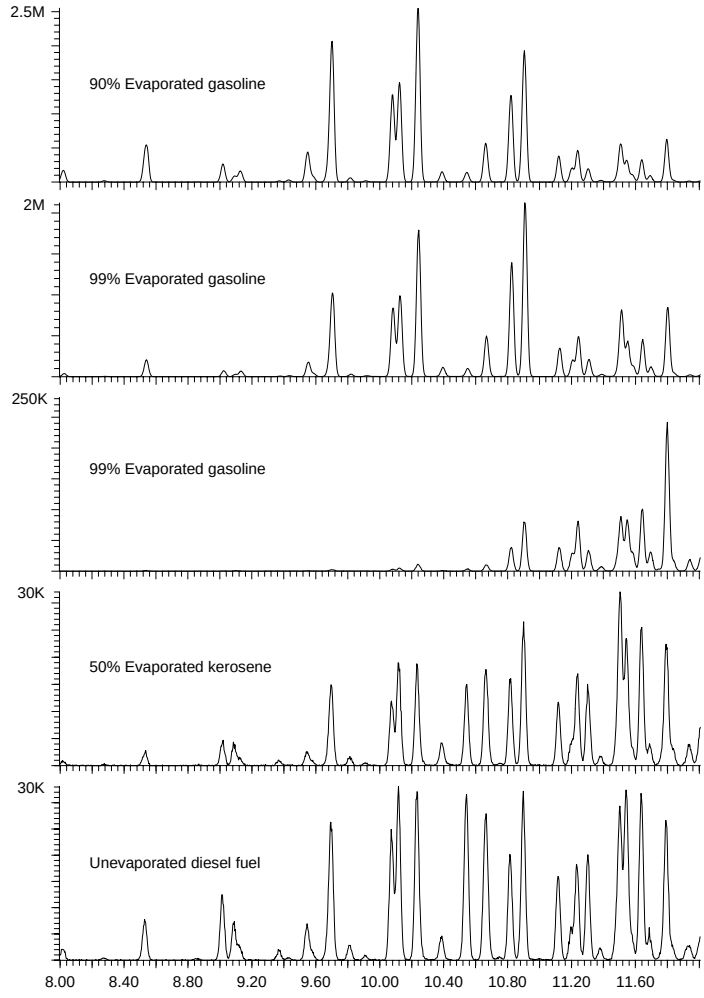

Figure 15 C_4 alkylbenzenes represented by ion 119 in gasoline in three different stages of evaporation and unevaporated diesel fuel. All samples were prepared by spotting 10 µl on a piece of filter paper, and processed using ACS adsorption/elution

ion 117 chart is, in this analyst's experience, always present. It has traditionally not been an absolute requirement of the ASTM standards, but it probably should be. The standard states, "Indan (dihydroindene) and methylindans are usually present." The first tall peak in the 117 chart is indan, appearing at 9.4 min. Figure 16 shows the peak groupings characteristic of gasoline for the indans, methylindans, and dimethyl indans. Like the C_3 alkyl benzenes, the indans and alkyl-substituted indans can be found in roughly the same proportions in gasoline that is 98% evaporated. Other petroleum products, particularly the distillates, contain indans and methylindans, but their mass chromatographic patterns are more complex than the ones for gasoline.

The next group of compounds that should be present in a sample identified as containing gasoline is the methyl- and dimethylnaphthalenes. Naphthalene is also present, but naphthalene is so common that its presence in a sample is all but meaningless. 2-Methylnaphthalene elutes before 1-methylnaphthalene, and is almost always more abundant than the 1-methylnaphthalene. In any case where this ratio is reversed, the extract should

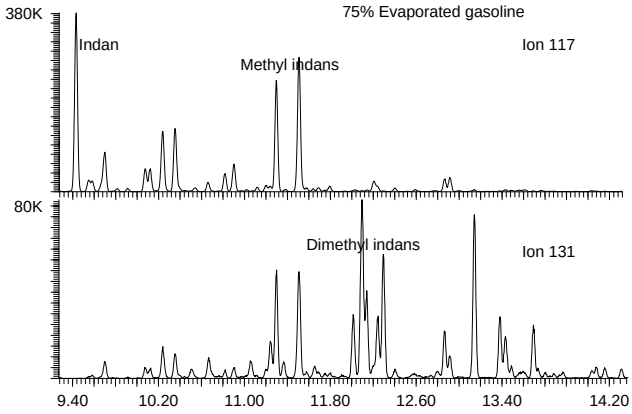

Figure 16 Ion chromatograms for indan, the methylindans, and dimethylindans found in 75%-evaporated gasoline

be considered suspect. The boiling point of the methylnaphthalenes is high enough that the ratio, unlike xylenes or C_3 alkyl benzenes, is unlikely to be affected by evaporation. All petroleum products are likely to contain both the naphthalenes and the dimethylnaphthalenes, and the ratios should be highly comparable.

There are some aromatic products in the marketplace that meet almost all of the ASTM criteria for the identification of gasoline. Such products are used as solvents for stains, insecticides, and industrial and commercial products. The way to differentiate these aromatic products from gasoline is to look for the presence of alkanes. All gasolines contain high percentages of alkanes when fresh, but even highly evaporated gasolines do contain some branched alkanes. Straight-chain hydrocarbons are an unusual finding in gasoline, because they are an undesirable component in that they cause knocking when burned in gasoline engines. Knocking is the premature detonation of a fuel, and occurs more readily with straight-chain hydrocarbons than with branched-chain hydrocarbons or aromatics. Resistance to knock is known as the *octane rating*. Octane rating is based on a scale of 0–100, where 0 is the resistance to knock of 100% *n*-heptane and 100 is the resistance to knock of 100% iso-octane (2,2,4-trimethylpentane). *N*-octane actually has an octane rating below zero.

Identification of Distillates

Most distillates that are likely to be encountered in fire debris are straight-run distillates from crude oil. They have not been subjected to cracking or reforming, so they lack the high aromatic content found in gasoline, but there are still aromatics present. The distillates are characterized by an abundance of normal alkanes, but there are also branched alkanes and cycloalkanes present.

Distillates are usually easy to find, except for light petroleum distillates (LPDs), which might be missed unless the analyst checks for them in every sample before calling it negative. Because of their high volatility, they tend to be present at low concentrations in fire debris samples, and are typically crowded against the left side of the chart, where they may be mistaken for decomposition products. This is a particular hazard when the higher boiling components are decomposition products. LPDs do not generally exhibit the Gaussian distribution so frequently seen in MPDs and HPDs. When the peaks that elute prior to eight min are examined, and the analyst sees a mixture of cycloalkanes, branched alkanes, and perhaps some normal alkanes in the C_7 through C_9 range, an LPD should be suspected. The analyst should have in the library as many LPDs as possible, because the patterns tend to vary from one to the other, unlike the heavier distillates. Figure 17(a) shows three different brands of cigarette lighter fluid, each exhibiting a different pattern of peaks. The recommended EIP for LPDs are 57, 55, 83, and 91, as can be seen in Figure 17(b). This particular LPD is unusual in that it contains xylenes, but no toluene is present. Because of their high volatility, LPDs are not persistent in the environment, and are not usually expected to be found as background material. There are some

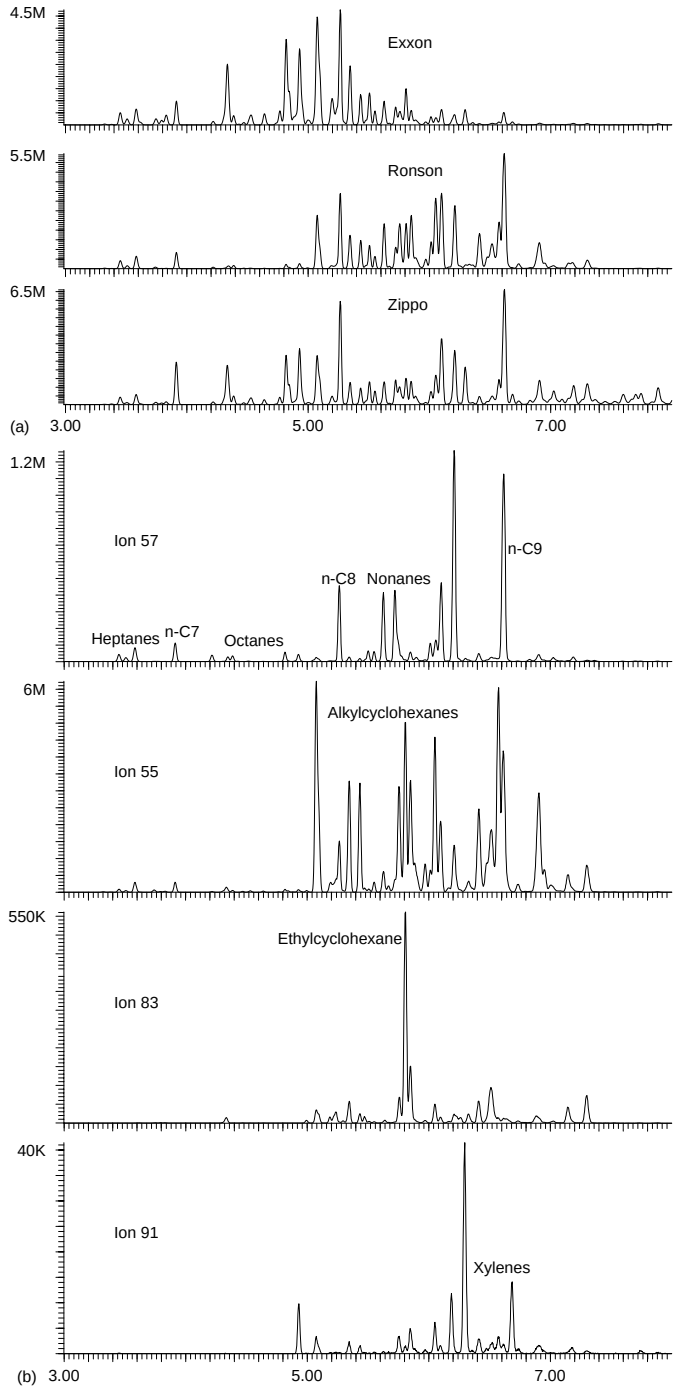

Figure 17 (a) Total ion chromatograms of three different brands of cigarette lighter fluid. (b) Ion chromatograms of ions 57, 55, 83, and 91 from a standard of Ronson Lighter Fluid

cleaning agents and automotive products that contain LPDs, but if the sample was collected from somewhere other than the garage, the workshop, or under the kitchen sink, a finding of LPD generally indicates the presence of a foreign ignitable liquid.

This is not the case with medium or HPD, which are far more common in our environment [16]. A typical medium petroleum distillate, Sparky charcoal lighter fluid, is shown in Figure 18(a). The ions necessary to make a good identification of a medium petroleum distillate are 57 and 83, shown in Figures 18(b) and (c). The analyst should also check for ion 105 or 91, in order to be certain that the aromatics have not been removed, in which case, a proper description of the residue would be a de-aromatized distillate. (De-aromatized distillates were once a separate ASTM class, but difficulty in defining the cutoff percentage caused the committee to discontinue the use of this class in 2006.) One does not notice much difference between the TIC and ion 57, because distillates are dominated by the normal and branched alkanes. The alkylcyclohexanes, which elute about halfway between the normal alkanes, present an overall appearance similar to that of the alkane chromatogram. If the normal alkanes are not present, or if they are present at approximately the same concentration as the branched alkanes, an isoparaffinic product should be suspected. When the cycloalkanes are present at a concentration greater than about 25%, a naphthenic–paraffinic source is indicated. In most distillates, the cycloalkanes will be present at about 5–10% of the concentration of the normal alkanes.

Medium petroleum distillates cover a wide range of products, and may be used as fuels, such as lamp oil or charcoal starter, or as solvents, such as mineral spirits or insecticide carriers. This wide range of products and formulations requires that the library of reference materials include numerous MPDs.

HPDs include kerosene and diesel fuel. Except for HPDs that are formulated for specific applications, such as jet fuel, the carbon number range of HPD can vary. Thus, unless one has a sample of the unevaporated liquid, it is difficult to determine the degree of evaporation of the residue isolated from a sample. In northern parts of the USA, diesel fuel sold in the winter may actually be kerosene.

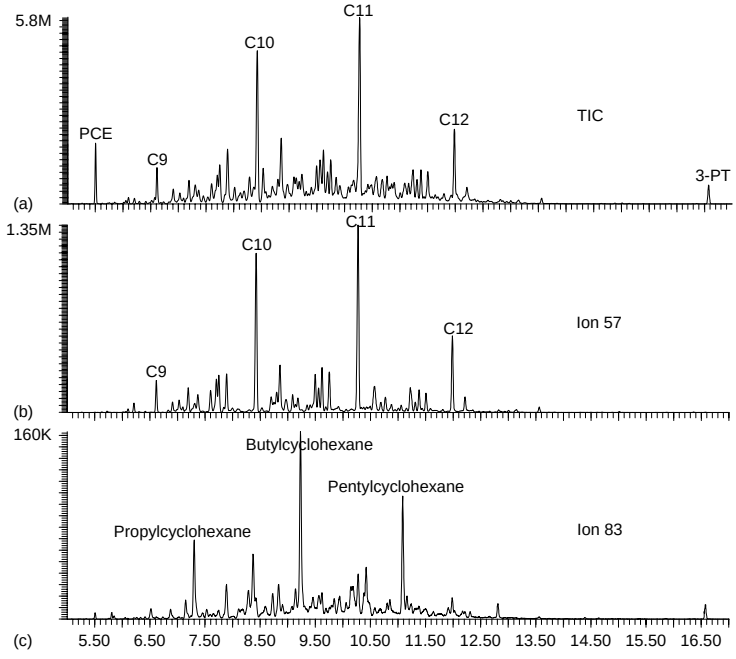

Figure 18 Total ion chromatogram of a typical medium petroleum distillate, Sparky Charcoal Lighter Fluid (a), and ion chromatograms of ion 57 (b) and ion 83 (c)

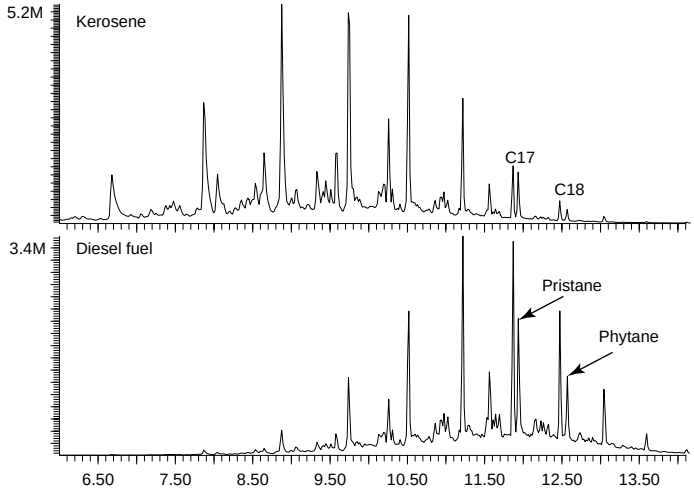

Figure 19 Total ion chromatograms showing a comparison of kerosene and diesel fuel

Figure 19 shows a comparison of kerosene and diesel fuel. These distillates come with built-in carbon number markers, in the form of pristane and phytane. Pristane is 2,6,10,14-tetramethyl pentadecane, $C_{19}H_{40}$, and it elutes immediately after normal heptadecane. Phytane is 2,6,10,14-tetramethyl hexadecane, $C_{20}H_{42}$, and it elutes immediately after normal octadecane. Thus, one looks for the two doublets on the high side of the bell-shaped curve and can count up and down from there. In Figure 19, these doublets occur at 12 and 12.5 min. One can see that the kerosene, which is a known standard that has been evaporated to 50% of its original volume, ranges from C_{11} to C_{19}, while the diesel fuel range is from C_{12} to C_{21}. If the kerosene is evaporated further, it will look more like the diesel fuel. Had the diesel fuel been evaporated less, it would look more like the kerosene.

As with the medium petroleum distillates, interpretation of a finding of HPDs should be approached with caution. There are numerous household products that contain HPDs, including many of the same kinds of products in which MPDs are found. The safer charcoal lighters are made from kerosene rather than mineral spirits. They are safer because of their higher flash point. Figure 20 shows a TIC of lemon oil furniture polish. This polish has a carbon number range from C_{12} to C_{22}, with C_{17} being the tallest peak on the chart. The limonene peak at the left side of the chart could easily be attributed to a pine substrate. Pinenes and limonene are very common in samples containing structural (coniferous) wood. This particular furniture polish, if found in a fire debris sample, could easily be reported as diesel fuel.

It is not even necessary for an actual liquid to be present in order for a distillate to be detected. Figure 21(a) shows the TIC of a piece of pine wood that was stained with Minwax® finish 10 months before it was subjected to headspace concentration. The naturally occurring terpenes, α- and β-pinene and d-limonene, are the dominant peaks on the chart, but the mineral spirits solvent is still clearly visible. When ions 57 and 83 are extracted, the terpenes disappear, to yield the charts shown in Figures 21(b) and (c). These results show the critical necessity of asking for comparison samples, particularly when samples of flooring are submitted for analysis. The flooring does not need to be recently painted in order to exhibit the distillate solvent used to apply the floor coating. This author has reported finding distillates 24 months after application [17] and has detected distillates in samples of finished flooring and furniture up to ten years old. There is no reason to believe that these solvents do not persist indefinitely, trapped in either the wood matrix or in a polymer coating matrix.

In addition to the distillates that are present as distillates, there are some distillate-like residues produced as the result of decomposition of other products. Asphalt is what is left at the bottom of the distillation pot after all of the volatiles have been

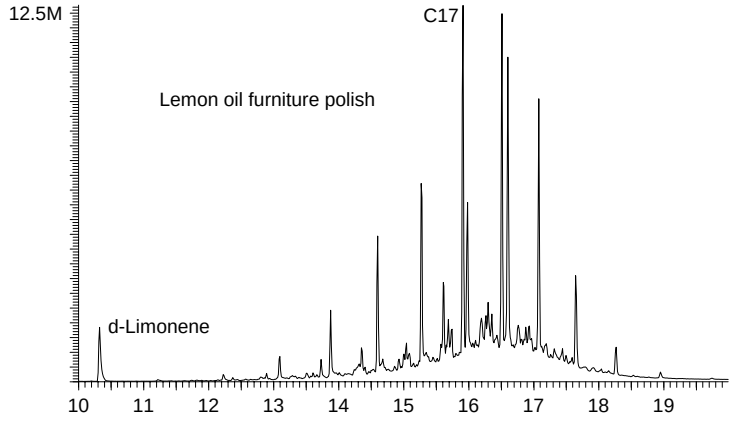

Figure 20 Total ion chromatogram of lemon oil furniture polish. This sample could easily be reported out as diesel fuel

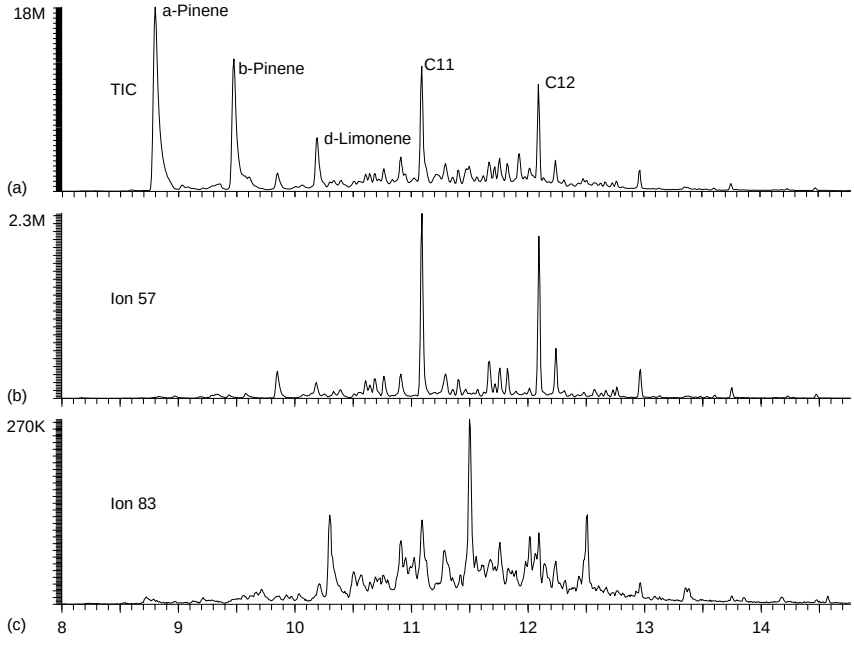

Figure 21 Total ion chromatogram of a piece of pine wood stained with Minwax® Finish 10 months prior to its analysis (a), and ions 57 and 83 from the same sample (b and c)

distilled from crude oil. It contains hydrocarbons ranging from C_{30} to C_{60}. When these long-chain hydrocarbons undergo pyrolysis, they do so in much the same way as the long-chain hydrocarbons in polyethylene, i.e., via random scission. This results in the presence of normal alkanes in the range of C_9-C_{18} [18]. When these pyrolysis products are present in fire debris that is subjected to headspace concentration, they produce a chromatogram that can be and has been mistaken for the chromatogram of a HPD. Such a chromatogram is shown in Figure 22(a). In 1982, it was reported that roof shingles could produce "accelerant-like residues," and at that time, there were no methods available for distinguishing HPDs

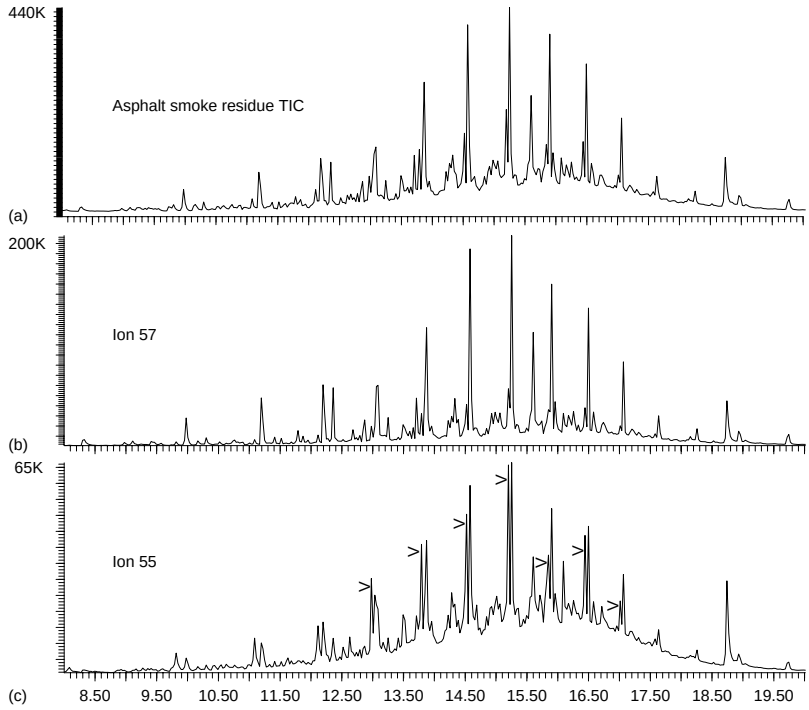

Figure 22 (a) Total ion chromatogram of asphalt smoke residue, of the type that can be mistaken for a petroleum distillate (b and c). Comparison of ions 57 and 55 from the asphalt smoke residue shown in the TIC. The growth of the peak in front of the normal alkane when comparing 55–57 demonstrates the presence of alkenes, which allows the identification of the residue as a decomposition product rather than a foreign petroleum distillate

from asphalt shingle residues [19]. The increased use of capillary columns allowed for the occasional visualization of a double-peak kerosene, sometimes called *pseudo kerosene*, but even with capillary columns, it was not uncommon for asphalt residue to be misidentified as a liquid petroleum distillate. This author learned how to make the differentiation in 1995 in connection with the investigation of an insurance claim that had been erroneously denied because of a finding of HPDs where none should have been present. Figures 22(b) and (c) show how the distinction is made. One compares ion 57 with ion 55. If a second peak appears in front of the *n*-alkane peak, or if a small peak grows larger, one can conclude (particularly after examining the mass spectrum) that the second peak is the 1-olefin. A sample such as this must be classified as asphalt smoke condensate or asphalt decomposition residue, and unless the possibility that asphalt residue got into the sample can be categorically eliminated, this material must be identified as being native to the scene.

The amount by which the olefin peak "grows" will vary depending on the sample. When one looks at kerosene and diesel fuel, the only difference between the appearance of the ion 55 chart and the ion 57 chart is that the abundance of ion 55 is lower. The relative abundances of the individual peaks with respect to each other do not change.

Another way to distinguish asphalt decomposition products from HPDs is to look for the cycloalkanes. They are not present. There will be a Gaussian pattern observed when ion 83 is extracted, but this is due entirely to the presence of the olefins. The ion 83 and ion 55 ion chromatograms show the same peaks. Asphalt smoke condensates also contain little, if any, pristane and phytane.

Polyethylene is another substance that produces a distillate-like appearance in the chart, but if the capillary column has any resolution at all, it will be obvious that one is looking at polyethylene residue, rather than at a distillate. Figure 23(a) shows the TIC of polyethylene smoke condensate. All of the peaks

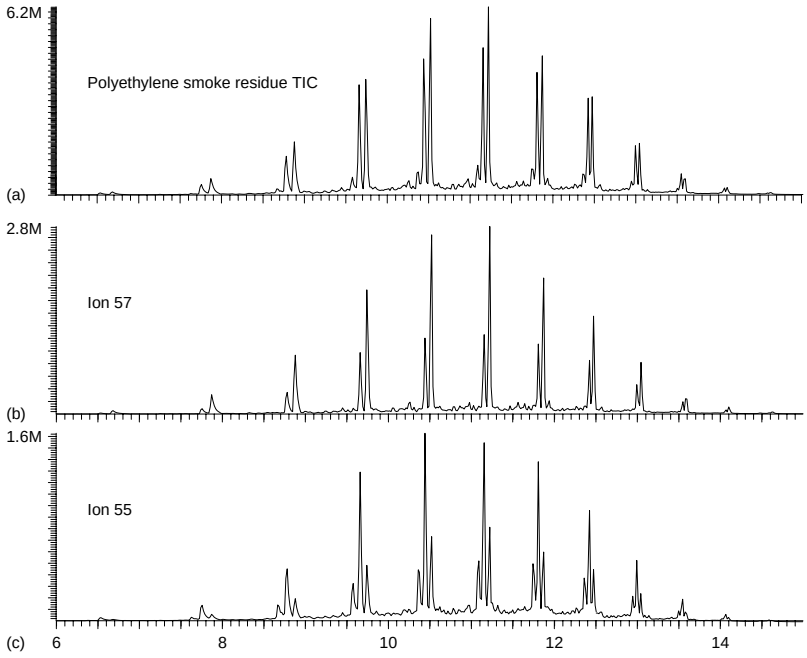

Figure 23 (a) Total ion chromatogram of polyethylene smoke residue. The first peak in each doublet is the alkene and the second is the alkane. Pristane, phytane, cycloalkanes, and aromatics are all absent. Ion 57 (b) and 55 (c) chromatograms of polyethylene smoke residue. In the ion 55 chromatogram, a third peak, representing the n, $(n-1)$-diene appears

are doublets and most are actually triplets, owing to the presence of the 1,$(n-1)$-diene in the mixture. When one looks at ion 57 and compares it with ion 55, as shown in Figure 23(b), the growth in the olefin peak is obvious, in that it becomes taller than the alkane peak. The diene peak also grows, because the dienes contain more ion 55 than ion 57. Lubricating oils are subject to the same decomposition processes as asphalt and polyethylene.

A careful examination of the chromatographic and mass spectral data will prevent the analyst from misidentifying decomposition products as distillates, but automation of pattern recognition presents some dangers if not handled properly. With all computer "answers," one should always do a "reality check." The same pattern recognition software that allows a mass spectrum from an unknown compound to be matched against the spectra of 100,000 compounds can be applied to chromatograms. The chromatogram is converted using Microsoft Excel into a bar graph that has the same general appearance as a mass spectrum. This graph can then be compared against a library of known ignitable liquids that have been similarly transformed. Like the mass spectral libraries, "extra" peaks do not necessarily keep the library from recognizing a "match." The polyethylene smoke condensate chart shown in Figure 23(a), matched up against a library that contains only ignitable liquids, will yield a match of exceptionally high quality for diesel fuel. This is why it is necessary to populate ignitable liquid libraries used for this purpose with known background chromatograms. The chart would make an even better match for polyethylene smoke condensate, but only if it is in the library.

Identifying Other Classes of Products

The remaining classes of ILR can frequently be identified by what is not present, as well as what is. A de-aromatized distillate, for example, will have a signal from the aromatics that is less than 1% of the signal from the aliphatics. Otherwise, it will look the same with respect to both the alkanes and the cycloalkanes. Because of environmental regulations governing the aromatic content of distillates there

has been, since 1973, an ASTM standard for this determination. ASTM D 3257-01 is entitled *Standard Test Methods for Aromatics in Mineral Spirits by Gas Chromatography* [20], and uses a specified test blend for calibration. If the calculation of aromatic content is an issue, forensic scientists might avoid a *Daubert* challenge by using this established method, rather than devising a new one.

The normal alkane products are very easy to recognize, as long as one makes sure that one is looking at a homologous series of normal alkanes as opposed to a homologous series of aldehydes or some other group of homologs that are pyrolysis or decomposition products. Groups of compounds that differ from each other only in that they have one additional CH_2 group look pretty much the same as a series of normal alkanes, and require some caution. Figure 24 shows a series of normal alkane products marketed by Exxon, as well as a sample of Lamplight Farms Ultra Pure Lamp Oil®, which also consists of normal alkanes. One common source of normal alkanes is carbonless forms (documents), and the bottom chromatogram in Figure 24 shows the chromatogram of concentrated headspace vapors from a 5 cm × 5 cm square of a carbonless form. These forms contain microspheres filled with the normal alkane solvent that, when broken, causes the color to develop in the ink. There are only a few microliters per square foot, but this concentration is easily detectable. Figure 25 is a scanning electron micrograph, showing the bottom surface of a carbonless form. Normal alkane products are also found in some brands of linoleum floor covering. Any time a sample is collected from a floor likely to have linoleum in its structure (kitchen, bathroom, laundry room), a finding of normal alkanes is probably not meaningful. A comparison sample is an absolute necessity in such cases.

Isoparaffinic hydrocarbons are made by removing the normal hydrocarbons with a molecular sieve. These liquids are becoming more common as petroleum refiners move to more environmentally friendly and odor-free replacements for the straight-run distillates such as mineral spirits. Similar to the isoparaffinic hydrocarbons are the naphthenic–paraffinic products, which are characterized by an abundance of cycloalkanes. Whereas one might expect to find cycloalkanes present at less than 5% in the isoparaffinic hydrocarbons, they may be present at up to 30% in naphthenic–paraffinic products. The distinction requires looking at the ion profiles for the cycloalkanes versus the alkanes, as well as looking at the abundance numbers on the left side of the chart. Figure 26 shows a comparison of the ion 57 and ion 83 chromatograms from Isopar H®. Contrast this with Figure 27, which compares those same ion chromatograms from a naphthenic–paraffinic solvent, Vista LPA 170®. Instead of having an ion 83 chromatogram that is 2% the height of the ion 57 chromatogram, in the naphthenic–paraffinic solvent, the ion 83 is more than 30% of the height of the ion 57 chromatogram. Also, note that the tall peaks in the ion 57 chromatogram from the naphthenic–paraffinic product are not normal alkanes, but are branched alkanes.

Another way to make the distinction between the isoparaffinic products and the naphthenic–paraffinic products is to take an average mass spectrum. Representative isoparaffinic hydrocarbons are shown in Figure 28. A mass spectrum of any of these looks very much like the mass spectrum of a single alkane. Ion 57 is the base peak, and the other fragments are spread out in a Gaussian distribution with a spacing of 14 mass units between them. A typical isoparaffin average mass spectrum, that of Isopar L®, taken over a 3-min portion of the chromatogram, is shown in Figure 29.

The same exercise can be performed on the naphthenic–paraffinics, several of which are shown in Figure 30. The average mass spectrum of a typical naphthenic–paraffinic product, shown in Figure 31, looks quite different from that of the isoparaffinic product. While it still exhibits a base peak of 57, it will be very rich in 55, 69, and 83.

The identification of other ILR requires an individual examination of the peaks in the chromatogram. It is possible to find just about any compound in just about any sample. Findings of alcohols, turpentines, aromatic solvents, and other “flammable” liquids need to be viewed with great caution. ASTM E 1618 recommends not making an identification of these single compounds unless they are present in such concentrations that the signal is at least 2 orders of magnitude greater than the background. Just about every fire debris sample will contain methanol, though most laboratories do not routinely check for methanol. Just about every fire debris sample will contain toluene [21]. Unless these substances are present at concentrations sufficiently high for the

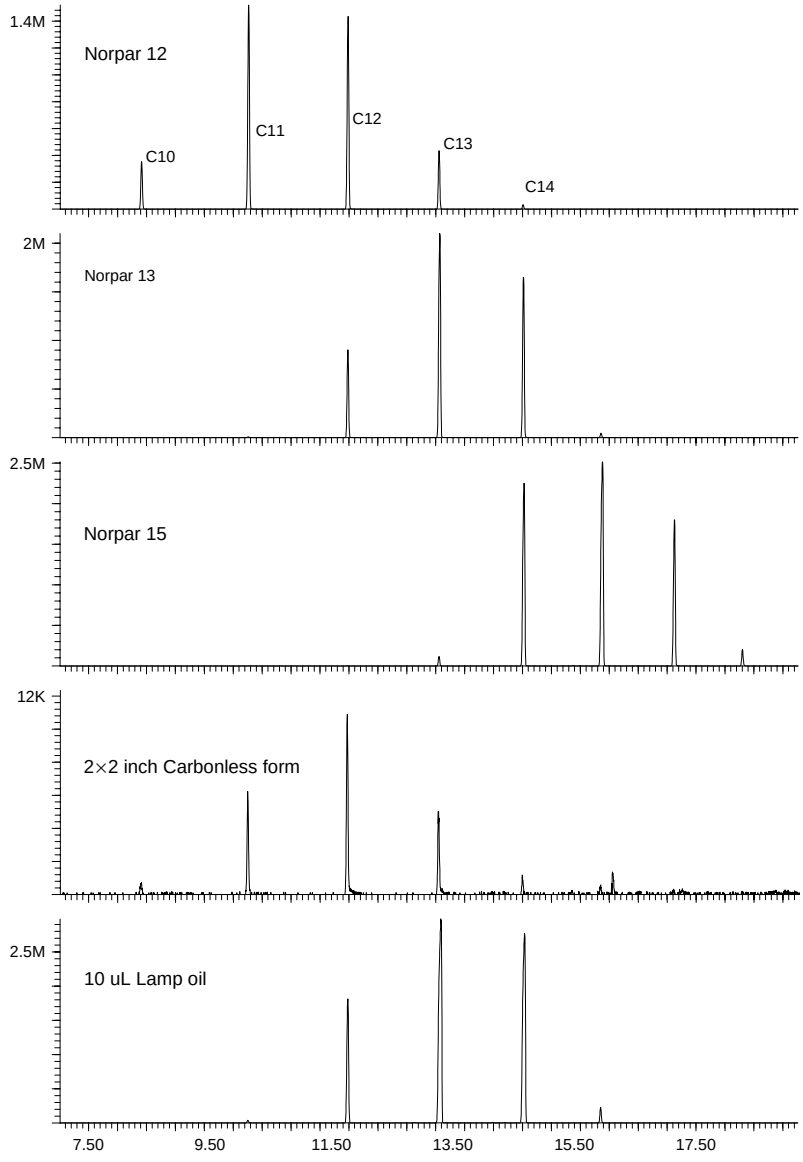

Figure 24 Ion 57 chromatogram of three Exxon Isopar® products, compared with an ACS extract from a carbonless form, and the ACS extract of a 10 μl sample of Lamplight Farms® Ultrapure Lamp and Candle Oil

analyst to feel comfortable saying they are not native to the background, they should not be reported.

Identity of Source

The ability to match a weathered ILR with a proposed source of unburned ignitable liquid has eluded fire debris analysts until just recently. The environmental forensics community has developed some tools to identify the sources of petroleum spills, but they have the advantage of having huge quantities of material available for characterization. Petroleum hydrocarbons contain trace quantities of biomarkers, substances that have changed little since they were first

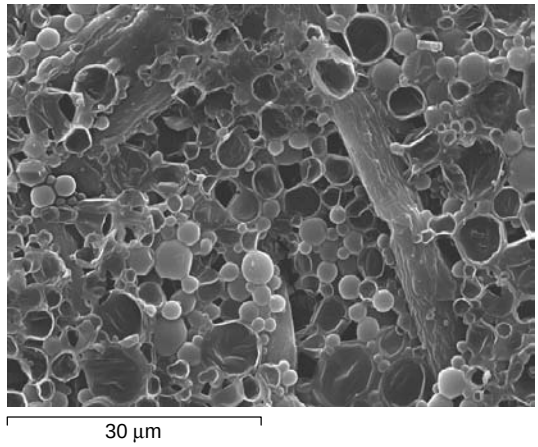

Figure 25 Scanning electron micrograph of the underside of a carbonless form. The microspheres range in size from 2 to 20 µm, and are filled with normal alkanes

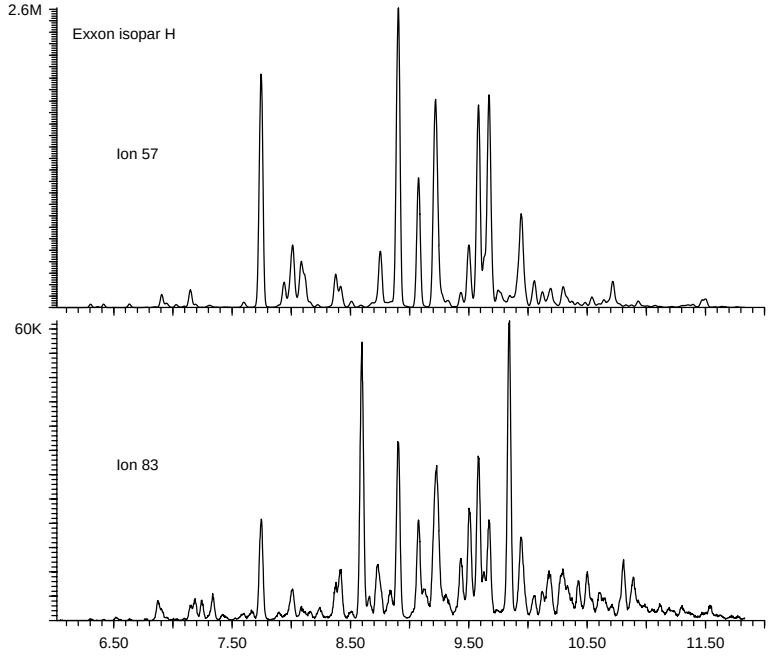

Figure 26 Comparison of the alkane (ion 57) and cycloalkane (ion 83) chromatograms from Exxon Isopar H®. The cycloalkane peaks are only about 2% of the height of the branched alkane peaks

synthesized inside a living organism. The relative amounts of these biomarkers frequently allows for the identification of the source of a major spill. Polycyclic aliphatic and aromatic hydrocarbons are also useful in "fingerprinting" hydrocarbons. Examination of additives, such as oxygenates, or in the case of old gasolines, the alkyl lead compounds, can also provide clues as to the identity of the source of a spill. There are three levels of influence on the composition of petroleum. The primary influence is the genesis of

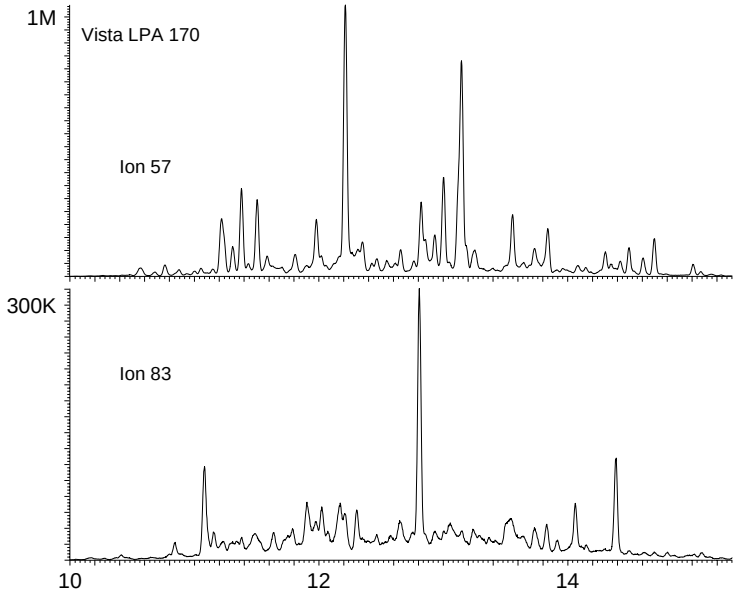

Figure 27 Comparison of the alkane (ion 57) and cycloalkane (ion 83) chromatograms from Vista LPA 170, a naphthenic–paraffinic product. The height of the cycloalkane chart is about 30% of the height of the branched alkane chart

the petroleum, i.e., including its geographic location, the original source of the oil (terrestrial or marine), and the conditions in the rock where the oil resided for millions of years.

The second level of influence affecting the hydrocarbon fingerprint is processes imposed on the hydrocarbon by the refiner. Activities such as distillation, hydrocarbon cracking, isomerization, and alkylation change the composition of the fuel.

The tertiary influences are those that occur after the petroleum product leaves the refiner. The most important tertiary influence that is of interest to fire debris analysts is, of course, weathering, or evaporation. Mixing in the service station tank is also critical. Because the tanks are seldom empty, each time a new delivery is made, the fuel service station tank assumes a new, temporary, identity. For a more extended discussion on chemical fingerprinting in the environmental forensics arena, see *Introduction to Environmental Forensics*, reference [22].

Some of the most comprehensive work to identify the source of ILR from fire debris was done by Dale Mann in 1987 [23, 24]. Using a 60-m column, Mann learned that it was possible to make comparisons on samples of fresh gasoline, and correctly identify the source by examining the relative ratios of the light hydrocarbons, ranging from *n*-pentane to *n*-octane. It is, unfortunately, exactly these hydrocarbons that are lost before a gasoline is even 25% evaporated. Mann's second paper describes the limitations of making comparisons between ILR and fresh samples, because of the contamination of the residues with pyrolysis products, changes introduced by the isolation method, and the loss of volatiles resulting from weathering. Comparison of residues with fresh sources was, therefore, not frequently studied after Mann's extensive work. Recently, however, Dolan and Ritacco reported that they had devised a way to measure the relative abundances of 20 peak pairs in gasolines, and were able to identify the source of 30 samples that were evaporated to 25 and 50%. This process uses the relative abundances of branched alkanes that occur generally in the center of the gasoline chromatogram. Because the peaks are sequential, eluting only a few seconds apart, the relative ratios are not significantly affected by evaporation. The peaks examined are all minor components. The major components of gasoline are similar enough to each other that they are not useful in discriminating between sources [25].

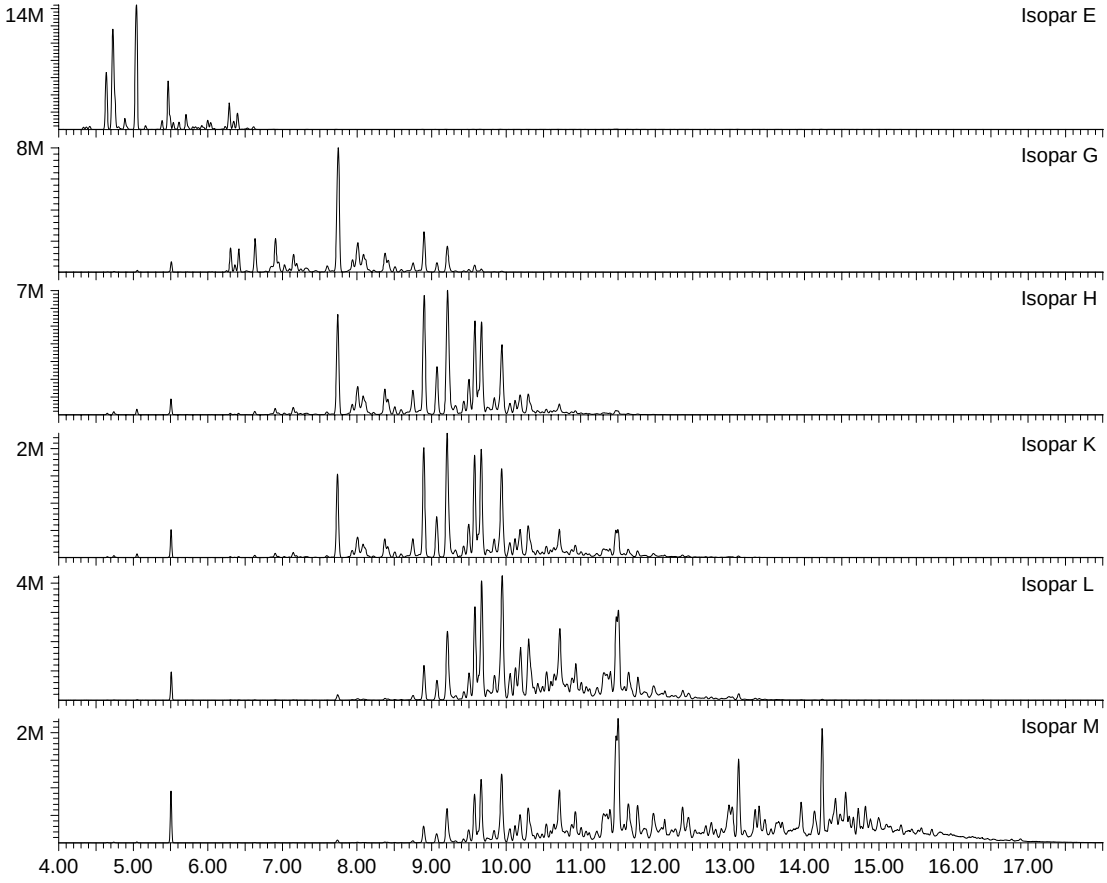

Figure 28 Total ion chromatograms of six isoparaffinic hydrocarbon products, Exxon Isopars ® E, G, H, K, L, and M

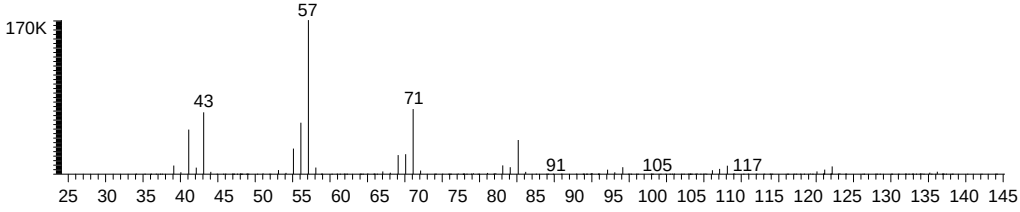

Figure 29 Average mass spectrum taken from Isopar L, over the range of 9–12 min. This spectrum has a very similar appearance to that of a branched alkane

Following up on this work, Wintz and Rankin applied principal components analysis (PCA), only to learn that while the ratios within the pairs show little, if any, change between unevaporated and 50%-evaporated gasoline, only a few of those pairs were actually useful in distinguishing between one gasoline source and another, and some of those pairs occurred in the LPD range, so they are unlikely to be found in gasolines evaporated to more than 50% [26].

Further work by Barnes and Dolan identified six ratios of sequentially eluting minor components in 50%-evaporated gasoline, and four ratios in 75%-evaporated gasoline. Using these ratios, they were able to successfully discriminate among 16 gasoline

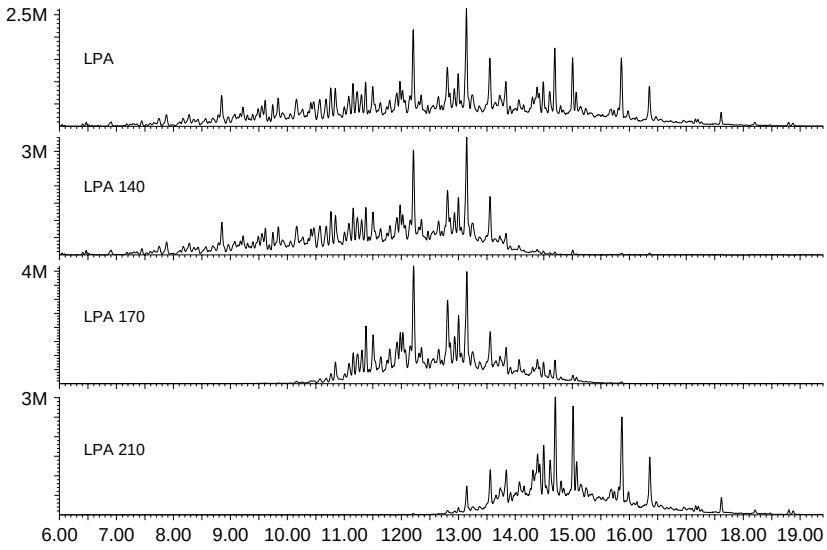

Figure 30 Total ion chromatograms of 4 naphthenic–paraffinic products, Vista LPA, LPA 140, LPA 170, and LPA 210. The numbers approximately correspond to flash points

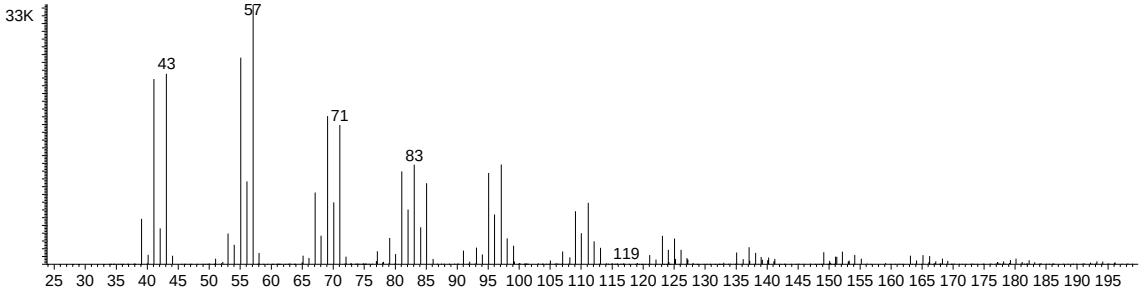

Figure 31 Average mass spectrum of Vista LPA®, taken from 8 to 17 min

samples evaporated 50%, and 10 gasoline samples evaporated 75%. They used a blind study to confirm the ability of the technique to correctly identify the source of three gasolines, matched against a library of 10 candidate sources. The techniques uses a 60-m column, and is automated using a target compound program that takes the abundance of the base peak from the mass spectrum of each compound of interest, and divides the base peak abundance of the later eluting compound by the base peak abundance of the earlier eluting compound. The authors state that this technique not only appears to work but also is most useful for eliminating a source, and caution that the analyst's statement of conclusions reflect that a common origin is indicated, but is not a certainty [27]. Sandercock and DuPasquier have reported being able to distinguish 32 out of 35 gasolines by collecting selected ion monitoring (SIM) data of the polynuclear aromatic hydrocarbons from a 200 μl sample, and then applying PCA to the data [28].

While doing comparisons of gasolines, or any ignitable liquids for that matter, the best approach would seem to be to first take the proposed source liquid, and evaporate some of it so that it matches the residue in terms of carbon number range. Once this has been accomplished, a detailed examination of the finer points in the chromatogram should be carried out.

A really "good match" between chromatograms not only matches the peaks but also matches the valleys. When one is trying to determine if an ILR could have come from a particular source, the valleys should match. Examining multiple EICs for both quality and quantity would also seem to be a necessary step when doing comparisons. This practice has been codified with respect to the analysis of distillates heavier than kerosene in ASTM D 5379-00 *Standard Practice for Oil Spill Source Identification by Gas Chromatography and Positive Ion Electron Impact Low Resolution Mass Spectrometry* [29]. The approach in this method is to compare 24 EIC of polynuclear aromatics and other biomarkers. This is similar to Sandercock and DuPasquier's work.

Pepler has reported making brand identifications of gasolines by using high-resolution mass spectrometry to detect high molecular weight additive packages in gasolines that have lost all of their volatile materials [30].

Given the state of the art, it is probably a good thing that comparisons are not frequently requested.

Other Fire Debris Analyses

Most public crime laboratories in the United States limit their practice of fire debris analysis to the detection of ignitable liquids. There are, however, other chemical analyses that are occasionally requested in the context of a fire investigation. If chemical incendiary materials are suspected of having been used, the laboratory may be asked to check for such substances as glycols, brake fluid, chlorine residues, and residues of road flares. Glycols and brake fluid are detectable using gas chromatography-mass spectrometry. Nonhydrocarbon chemical incendiary substances may be detected by a combination of elemental analysis and microscopic examination.

Laboratories are also sometimes asked to check for the presence of animal or vegetable oils in the samples of debris suspected of having undergone spontaneous heating. Such oils are not amenable to the direct analysis by GC-MS because of their high molecular weight, but it is possible to derivatize vegetable oils that produced fatty acid methyl esters (FAME), which can be analyzed by GC-MS. In a typical FAME analysis, the debris samples are extracted with *n*-heptane. The filtered extract is then derivatized using 2 N potassium hydroxide in methanol. After agitation and centrifugation, the heptane solution is analyzed directly. Depending on the extent of the fire damage, it may be possible to characterize the original oil, but much caution is required, as the fatty acids that are most susceptible to spontaneous heating are the ones likely to be diminished in concentration. Generally, samples are simply reported as containing vegetable oils or not. The technique described above is capable of detecting quantities of vegetable oil as small as 10 mg.

Other laboratory analyses frequently requested include the nonchemical variety, such as the examination of appliances or devices, which are believed to have been instrumental in the ignition of the fire. Such analyses are generally not conducted in crime laboratories, but are instead conducted in private facilities by electrical engineers or other experts [31].

Reporting Procedures

The analyst's report can be one of the most important documents generated during the investigation of a fire. The report, therefore, should be written carefully enough so that readers are not misled. The objective of fire debris analysis is to determine whether there is any *foreign* ILR present in a sample.

The report from a forensic science laboratory is supposed to be a *scientific* report. As such, it should include an introduction, a section detailing the test methods and results, and a discussion and conclusion section, if necessary. The laboratory report should also state what was done with the evidence. There is an unfortunate tendency in some agencies to provide checklists and merely state "positive for gasoline," or "negative for accelerants," rather than preparing a real laboratory report. Reading such a report, a reviewer cannot tell whether the analyst used a GC-MS or a Ouija board.

Given that it is now possible to store templates with all possible results in them, the excuse that it is "too time-consuming" to prepare an understandable narrative report should be regarded as unacceptable. Although laboratory reports are intended to assist investigators, they should also be understandable to individuals requested to review that work. As a minimum, a report should include the following:

- An identification of the fire in question.
- A description of how the sample was delivered to the laboratory, when, and by whom.

- A description of the samples, including container size, substrate material, and a reported location from where the sample was collected.
- A description of the isolation procedure used to separate the ILR from the sample substrate.
- A description of the analytical technique applied to the sample extract.
- The results of the analysis of the data.
- A discussion of the meaning of the results, if there is any chance of misinterpretation or misuse.

In the discussion section, the analyst can provide examples of potential sources for whatever ILR may have been identified. This is also an appropriate place to put in a disclaimer about the possibility that the ILR may not be foreign to the background.

- A conclusion or bottom line, understandable to even an attorney is a helpful thing.
- A sentence stating what has happened to the sample.

If a substance that is natural or incidental to the background is found, it is the analyst's job to say so. ASTM E 1387 and E 1618 both allow for the inclusion of disclaimers, on both positive and negative reports. With respect to negative reports, a disclaimer to the effect that negative results do not preclude the possibility that ignitable liquids were present at the fire scene, but may not have been detected for a variety of reasons including detection thresholds, is suggested as an aid to help readers avoid misunderstanding the report. Likewise, in the case of a positive report, the standard states, "It may be appropriate to add a disclaimer to the effect that the identification of an ILR in a fire scene does not necessarily lead to the conclusion that a fire was incendiary in nature. Further investigation may reveal a legitimate reason for the presence of ILR." Certainly, a finding of gasoline in the living room is noteworthy. It is not so noteworthy to find gasoline in the basement near the chain saw.

On occasion, it seems that the fire debris analyst is too eager to "help" with an arson investigation. Reporting a sample as being "positive" when all the analyst has identified is background compounds is neither helpful nor morally defensible. Karen and Paul Stanley of Akron, Ohio, were falsely accused of setting the fire that killed their infant son. The fire debris samples were submitted to a laboratory that reported finding "turpentine" in a sample consisting of charred Douglas fir. The laboratory analyst at the very least should have reported the finding of turpentine with a caution stating that the turpentine was indistinguishable from naturally occurring turpentine found in coniferous woods. The case was dismissed after the prosecutor saw the light [32].

A similar case of an analyst being too "helpful" occurred in a homicide case in Georgia, where the laboratory analyst reported finding "toluene, a flammable liquid" on a suspect's "clothing." Actually, the "clothing" included a pair of tennis shoes, and the examination of a new pair of tennis shoes directly from the shoe store revealed the presence of a high concentration of toluene. A closer examination of the first analysis revealed that in addition to toluene, diethylene glycol and butylated hydroxytoluene (BHT) were also present in the suspect's shoes and the exemplar shoes in identical relative proportions. Less than a year earlier, there had been a presentation on the analysis of suspects' shoes in arson cases at an American Academy of Forensic Sciences (AAFS) seminar [33]. Perhaps, if the analyst had attended that presentation (or read the proceedings), the toluene would have been recognized for what it was.

Record Keeping

Each case file that includes a positive identification of an ILR should contain not only the sample charts but also charts of a standard to which that sample can be compared. This means that both the sample and standard should be printed with the same axes scales, so that the data can be easily reviewed. Even if there is no criminal prosecution, the analyst should be aware that many fire cases involve civil litigation, so the case file should be kept for a reasonable period of time.

Electronic data files should also be protected and stored. There are only a few versions of GC-MS data analysis software in widespread use, so it is possible for one analyst to review another's raw data. Such reviews should be facilitated by the preservation of the data. Instrumental data such as tune reports or spectrum scans should be kept, if only to keep track of the performance of the instrument. Certainly, if a case file has matching standards and samples, there is no need to review the tune report for that particular week. No matter what happened, the instrument tune

parameters would not cause a false positive. Blanks, on the other hand, should be stored somewhere, particularly for those cases where the detection limit of the procedure is being pushed.

Conclusion

The isolation and identification of ILR from fire debris samples is an important part of the fire investigation process. The fire debris analyst should be familiar with the common techniques of fire investigation and understand the language used by investigators. If an ILR is identified, a hypothesis that a fire was incendiary may be supported, and a long litigation process may ensue, either in criminal or civil court. The laboratory results are often the deciding factor in a prosecutor's decision to indict, or an insurance company's decision to resist a claim.

The technology for fire debris analysis has improved dramatically over the last decades, to the point where our methods are now as sensitive as they need to be, and possibly more sensitive. The analytical procedure requires focus and creativity, but also adherence to the generally accepted criteria for making an identification. The analysis should be conducted in such a way that it is capable of being reviewed by another analyst, and such reviews should be not only expected but also welcomed. Science is based on "multiple witnessing." Fire debris analysts need to be acutely aware of the stakes involved in what they are doing and of the need to communicate effectively about the meaning of their findings.

JOHN J. LENTINI

Fire Investigator: Standardization, Accreditation, and Certification

Introduction

The adoption by the fire investigation community and the larger forensic science community of standards began in the mid-1970s in the United States, but did not reach fruition for 10 years in the case of fire investigators, and 15 years in the case of fire debris analysts. Adoption of standard methodologies began in the early 1990s, although some primitive "standards" were available for laboratory analysts as early as 1982.

As with the introduction of any new standard, be it for individuals, institutions, or methodologies, there was a substantial rearguard action that needed to be overcome before the standards could be characterized as "generally accepted". All of the forensic disciplines have struggled with these concepts as they tried to define what was meant by the various standardization terms, and how standardization programs could be implemented.

The Quality Triangle in Forensic Sciences

The concept of the quality triangle in the forensic sciences was first presented in the early 1990s. Lawrence Pressley, a former Quality Assurance Director at the FBI Laboratory, is generally credited with the image shown in Figure 1, which ties together accreditation, certification, standardization, and proficiency testing. As interdependent and seamless as these concepts may now seem, they have not come together without some resistance.

Fire investigators embraced certification in the late 1980s, but many fiercely resisted the idea of standardization (some still do). Crime laboratory directors embraced the idea of accreditation in the early to

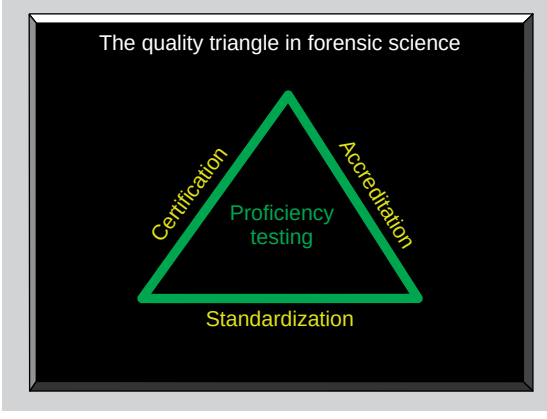

Figure 1 The Quality Triangle in Forensic Science represents the current paradigm for quality assurance in forensic science laboratories in the US

mid-1980s, but resisted the idea of individual certification, as did some individual practitioners (some still do). The Criminalistics Section of the American Academy of Forensic Sciences (AAFS) voted in the mid-1990s to join with the American Board of Criminalistics (ABC) in supporting certification of individuals, and the American Society of Crime Laboratory Directors (ASCLD) finally decided to support the ABC program in the late 1990s. Some conflicts still exist, such as the debate over who should pay for proficiency testing – the individual who needs it to maintain his or her certification or the laboratory, which needs proficiency testing to maintain its accreditation. Despite these peripheral disagreements, the forensic quality triangle is the paradigm of the current era.

On August 9 and 10, 2004, the American Bar Association House of Delegates, representing the ultimate consumers of the work product of all forensic scientists (including fire investigators), passed the following resolution:

> Resolved, That the American Bar Association urges federal, state, local and territorial governments to reduce the risk of convicting the innocent, while increasing the likelihood of convicting the guilty, by adopting the following principles:

1. Crime laboratories and medical examiner offices should be accredited, examiners should be certified, and procedures should be standardized and published to ensure the validity, reliability, and timely analysis of forensic evidence.
2. Crime laboratories and medical examiner offices should be adequately funded.
3. The appointment of defense experts for indigent defendants should be required whenever reasonably necessary to the defense.
4. Training in forensic science for attorneys should be made available at minimal cost to ensure adequate representation for both the public and defendants.
5. Counsel should have competence in the relevant area or consult with those who do where forensic evidence is essential in a case.

The consumers are now demanding what the leaders of the forensic science and fire investigation professions have been advocating for more than a decade. Not all of the parts in the quality triangle can be applied to fire investigation, due to the unavailability of accreditation for field investigators and the lack of proficiency testing. The entire triangle can, however, be applied to the laboratory analysis of fire debris. The individual parts of the forensic quality triangle as it applies to fire and explosion investigations are addressed.

Method Standardization

For over a century, the American Society for Testing and Materials (ASTM) (now known as *ASTM International*) served as a standards development organization and followed rules set forward by oversight bodies such as the American National Standards Institute (ANSI) and the International Organization for Standardization (ISO). The National Fire Protection Association, also following ANSI rules, promulgated standards for fire equipment and fire departments. These standards development organizations have always responded to a perceived need for standards coming from within a particular community.

ASTM Committee E30 on Forensic Sciences got its start in 1974, largely based on the perception of the forensic engineering community that standards were required in order to conduct valid investigations of incidents resulting in product liability litigation. The standards promulgated were general in nature, and by the early 1980s, the engineers had written all of the standards that they thought were necessary. The engineering standards, dealing with the collection of information [1], reporting of opinions [2], evaluation of technical data [3], and the prevention of spoliation [4] have since been generalized to apply to all forensic investigations, both civil and criminal. These engineering standards are frequently cited in fire investigations.

Committee E30 became dormant throughout most of the 1980s, but in 1989, ASTM approached the American Academy of Forensic Sciences and E30 was revitalized. The first new standards adopted by E30 were fire debris analysis standards. These were adapted from a document promulgated by the Forensic Science Committee of the International Association of Arson Investigators (IAAI) entitled "Guidelines for Laboratories Performing Chemical and Instrumental Analysis of Fire Debris Samples" [5]. The first edition of ASTM E 1387, Standard Test Method For Flammable or Combustible Liquid Residues In Fire Debris Samples by Gas Chromatography, was adopted in 1990 [6]. This standard test

method, as well as other fire debris analysis standard practices, has been well accepted in the forensic science community (*see* **Fire Debris: Laboratory Analysis of**).

Beginning in 1985, the National Fire Protection Association (NFPA) Technical Committee on Fire Investigations worked on developing a guide for fire and explosion investigations. The resulting document, known as *NFPA 921*, was first published in 1992 [7]. The initial reaction to NFPA 921 was mixed. Partly because the document described numerous "misconceptions" (*see* **Arson Investigation: Misconceptions and Mythology**) held by many fire investigators, the holders of those misconceptions fiercely resisted acknowledging NFPA 921 as a standard of care. By 2000, however, most responsible fire investigators accepted the necessity of a standard to bring some measure of quality to the profession. The IAAI president publicly endorsed the adoption of NFPA 921, and the US Department of Justice issued a research report entitled "Fire and Arson Scene Evidence: A Guide For Public Safety Personnel" [8]. In the last decade, numerous courts, ruling on reliability challenges have accepted NFPA 921 as the *de facto* standard of care for fire investigation. Investigators who follow NFPA 921 generally have their opinions admitted, and those who do not generally have their opinions excluded, at least with respect to civil cases [9]. (US courts seem reluctant to exclude the opinion testimony of law enforcement officers, even if their methodology is well outside generally accepted norms.)

Because of the relative rarity of explosions and the near monopoly of government investigative agencies in explosion investigations, standards development organizations have not yet prepared any standard documents. The US Justice Department did publish *Guide for Explosion and Bombing Scene Investigation* in 2000 [10].

Accreditation

As used in this context, the term *accreditation* is intended to apply to agencies and institutions, while the term *certification* applies to individuals. Currently, accreditation is available only to forensic science laboratories conducting analysis of fire debris and explosive residues. Accreditation is not available to agencies that conduct fire or explosion investigations in the field.

Accreditation is an increasingly important way by which agencies and companies demonstrate that their work meets certain minimum standards. Both public and private forensic science laboratories may seek accreditation from the American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB) or from other "registered" companies (registrars) that audit the accredited organization to a particular standard. Testing and calibration laboratories are generally accredited to ISO 17025, *General Requirements for the Competence of Testing and Calibration Laboratories* [11] A modified version of ISO 17025 is used by ASCLD/LAB in its accreditations [12]. Accreditation is becoming more common for police and fire departments, as well. Whichever registrar and agency or company chooses, the agency is required to have in place a written quality assurance program, and be able to demonstrate to auditors sent by the registrar that the quality assurance program actually assures quality, and that individuals in the organization actually follow the program.

Certification

Certification is a voluntary process of peer review by which a practitioner is recognized as having attained the professional qualifications necessary to practice in one or more disciplines [13]. Some employers "certify" their employees, but real certification requires that the certificate be provided by someone who does not necessarily have an interest in the applicant's ability to be recognized as an expert. This article focuses only on certification offered by third parties.

In a properly designed certification program, the initial certification is only a gateway to continued professional development. Getting through the application and test process certainly requires the acquisition and demonstration of a set of knowledge, skills, and abilities that members of the profession believe are necessary, but it is the maintenance of certification that makes a program valuable. Valid certification programs have four necessary attributes:

1. a credentials check;
2. a validated process, usually a written examination, wherein the certification body tests the knowledge, skills, and abilities of the applicant;

3. a means of revoking the certification of individuals who violate a code of professional practice; and
4. a recertification program, which requires the certified individual to document continuing professional development.

Some private organizations offered certification programs, but they were really nothing more than diploma mills, which took the applicant's money in exchange for a certificate, but such certification had no real meaning. As a result, various boards have been set up by professional organizations to accredit certification programs. The Forensic Specialties Accreditation Board (FSAB) is a corporation created by the AAFS to accredit certification bodies. FSAB generally requires that certification bodies applying for FSAB accreditation demonstrate that their program embodies the four requirements listed above.

The ABC offers certification for fire debris analysts. In order to become certified, applicants must demonstrate appropriate education, training, and experience prior to being allowed to challenge an examination, which contains a large component of general forensic science knowledge in addition to knowledge of fire debris analysis. Documentation of annual participation in a proficiency testing program is required to maintain certification. Every five years, the certified individual is required to document a satisfactory level of continuing professional development. Recertification points can be obtained by attending meetings, serving on technical committees or as an officer of a forensic science organization, publishing articles or books, and giving presentations. Only a very small percentage of practicing fire debris analysts holds ABC certification. As is the case with many certification programs, the first individuals to become certified are the leaders of the discipline.

Fire scene investigators can obtain certification from the IAAI or from the National Association of Fire Investigators (NAFI). Both of these programs require an application process, passing an examination, and documenting continuing education. Because of the nature of the work, proficiency testing is not available for fire scene investigators.

As with fire debris analysts, a significant percentage of the practicing fire investigators in the United States have certification from neither the IAAI nor the NAFI.

JOHN J. LENTINI

Fire Modeling and Its Application in Fire Investigation

Introduction

Why do we investigate fire and explosion incidents?

The answer is that fire and explosion incidents must be investigated for the purpose of understanding failure. A failure can be defined as an "... unacceptable difference between expected and observed performance" [1]. Individuals involved in the forensic investigation and analysis of fire and explosion incidents are usually tasked with rendering opinions as to the origin, cause, responsibility, and/or prevention of such incidents. From a technical perspective, the investigation will provide a physical description of fire events, identify failure modes and causative factors, provide feedback on design, identify noncompliance with appropriate standards and practices, or evaluate the validity of analytical tools. From a forensic perspective, investigators identify "more probable than not" scenarios to a "reasonable degree of scientific certainty" that help the client, as well as the court, to understand the technical issues and perhaps to determine fault or assign responsibility.

The investigation process contributes to a compilation of fire statistics for use in the development of educational programs, fire prevention codes, standards, and training. Furthermore, such investigations produce a compilation of requisite understanding of specific fire scenarios by applying fundamental knowledge to the incident under study. Thus, it is essential that valid and accurate determinations of the origin and cause of a fire be obtained so that the aggregate product of the investigation process provides essential information for protection of lives and property. NFPA 921 *Guide for Fire and Explosion Investigations* was developed to assist in improving the fire and explosion investigation process and the quality of information resulting from the investigation process based on reliable scientific principles [2].

The Essence of the Investigation Process

The essence of the investigation of fire and explosion incidents is embodied in the "... use of a systematic approach with attention to all relevant data". NFPA 921 recommends the use of the scientific method, which has traditionally been used in the physical sciences and forms the basis for scientific and engineering investigations, including fire and explosion incidents [2].

The scientific method as applied to fire and explosion incidents involves the following steps: recognize the need, define the problem, collect data, analyze the data, develop a hypothesis, and test the hypothesis. As discussed in NFPA 921, a typical investigation may include the documentation of an incident scene during a scene inspection or a review of any previous scene documentation; the collection of evidence; interviews with eyewitnesses; review and analysis of previous investigations; and the collection of data from other appropriate and relevant sources. This data is then analyzed to produce a hypothesis or group of hypotheses to explain the origin and cause of the fire or explosion event [2].

The most important step of the scientific method as it applies to fire investigation is the testing of hypotheses using "... the principle of deductive reasoning where the investigator compares his or her hypothesis to all of the known facts as well as the body of scientific knowledge associated with the phenomena relevant to the specific incident". The use of the scientific method will frequently uncover new data for analysis, which may result in the need for previous determinations to be reanalyzed. This iterative process is highly desirable and quite necessary for a reliable investigation [2]. Valid implementation of the method in the investigation requires the use of fundamental knowledge associated with the combustion and fire sciences.

Fire Is a Complex Phenomenon

Above all, "combustion" is a chemical process that involves the reactive combination of a fuel and an oxidizer. Generally, combustion phenomena can be categorized into two groups: "desired combustion" (e.g., a building furnace or a campfire) and "undesired combustion" (e.g., a house fire). Although sometimes treated by different professional communities as distinct processes, undesired combustion involves the

same fundamentals as desired combustion. The study of desired combustion (i.e., the combustion sciences) has been somewhat limited to gaining fundamental scientific knowledge. On the other hand, undesired combustion (i.e., the fire sciences) has included a wider diversity of the unwanted fire problem and has tended to be more empirical in its study and practical application. The body of knowledge with respect to the combustion and fire sciences includes many textbooks, most notably Glassman [3], Cox [4], Friedman [5], Quintiere [6], Karlsson and Quintiere [7], Drysdale [8], and the (Society of Fire Protection Engineers) *SFPE Handbook* [9]. In addition, there is a relatively large body of peer-reviewed research in both the combustion and fire sciences literature.

The study of unwanted fires forces together many otherwise discrete specialties [4] such as thermodynamics, fluid transport, heat transfer, and combustion chemistry. The reason for this integration of fields is the highly coupled nature of the phenomena occurring simultaneously. Even with the wealth of information and knowledge in the combustion and fire sciences, because of the complexity, the engineer has been forced to exploit solutions that are empirically based. However, the advancement and evolution of the combustion and fire sciences have helped to build a more secure technical foundation for the discipline of Fire Protection Engineering [4]. The challenge for the fire investigator is the practical application of fundamental knowledge to the investigation of fires that have occurred in the field. Such fundamental and empirical knowledge can be exploited through the development of models to simplify the analysis of the combustion phenomena that limit practical application.

The Use of Applied Knowledge in the Investigation of Fires

In order to render accurate and reliable determinations associated with particular fire incidents, the investigator must "understand the fire." This understanding of specific fire events can be derived both qualitatively and quantitatively from more discrete aspects of basic knowledge, from empirical data or formulations, and/or from a compilation of quantitative tools that embody a collective form of basic knowledge. A significant increase in the wealth of fundamental knowledge and the exponential advancements in computer technology have allowed the development of computer fire models. Such tools can be used as part of a fire dynamics analysis.

Fire dynamics analysis consists of the use of mathematical equations or models derived from fundamental principles or empirical data. These range from simple algebraic equations to computer algorithms incorporating many individual equations. Fire dynamics analysis can be used to predict fire phenomena such as time to flashover, upper layer gas temperatures and concentrations, and smoke concentrations and flow rates. Characteristics of the environment, such as unburned fuel, surface temperatures, and actuation time of smoke detectors, heat detectors, and sprinklers are also amenable to analysis. In addition, fire dynamics analysis can be used to predict the effects of changes to the environment, such as the opening or closing of doors, window breakage, or other physical events [2].

The authority of fire dynamics analysis relies on its use of a robust scientific approach to evaluate hypotheses regarding fire origin, cause, and the growth or decay of the resulting fire. These types of analyses generally use building data and fire dynamic principles to predict the environment produced by a fire under a proposed hypothesis. An analysis of the spread of the fire and resulting damage, as well as the time line of the fire, are potential products of such an analysis. The results can be compared to physical and eyewitness evidence to support or refute the hypothesis [2]. Thus, mathematical modeling provides the investigator with tools for the testing of hypotheses associated with the origin and cause of a particular fire. Even when the origin and cause of the fire are not an issue, these modeling tools can also be used to evaluate the factors associated with producing the resulting damage to property or injury to people (i.e., "The origin and cause of the loss").

Brief History of the Use of Fire Models

While the most identifiable fire models were developed after the introduction of the personal computer in the early 1980s, the first book devoted to the use of modeling in fire research was published in 1959 [10]. Philip Thomas and Peter Hinkley [11] developed the first zone fire model in response to two major fires. The first occurred in 1953 at the General Motors hydraulic transmission plant at Livonia, Michigan. The second fire occurred a few years later at the Jaguar Automobile Production Plant in the United Kingdom. Both fires grew rapidly, due to the production of flammable vapors from the heating of

the built-up steel deck roof, and exceeded the ability of fire suppression resources. One result of these fires was an interest in determining if roof venting could have made a difference and could have provided protection in a manner that would eliminate the need to erect fire walls in these spaces [12].

Thomas and Hinkley [11] conducted extensive experiments and formulated a means of determining roof vent requirements based on equilibrium flow rates between the mass flow into the upper layer and the mass flow out of the roof vents. Since this work was done prior to the common availability of personal computers to practicing engineers, Thomas and Hinkley incorporated their results in the form of nomographs that provided engineers with a reasonable approximation of the venting requirements under a range of building dimensions and fire scenarios.

The initiation of preflashover zone fire modeling can be traced to the mid-1970s with the publication of a description of the fundamental equations by Quintiere [13]. On the basis of these equations, the first generation of zone fire models were published by Pape and Waterman [14] and by Emmons and Mitler [15]. Following the introduction of these two models, a number of zone fire models for mainframe computers were subsequently developed. In 1985, the first zone model, ASET-B, was written specifically for the newly available personal computers [16].

Since the 1980s and the introduction of the first generation of compartment fire models, many models of similar construct have been developed around the world. Many of these models provided a user-friendly Graphical User Interface (GUI) that helped to initiate a large expansion in their use and application. As early as 1985, it had become broadly accepted that future advancements in Fire Protection Engineering would be through the use of computer modeling [17].

Friedman [18], and more recently, Olenick and Carpenter [19], have compiled surveys of available fire models, which include some 170 associated models (http://www.firemodelsurvey.com). The most identifiable fire models in use today include FPEtool [20], Consolidated model of Fire Growth and Smoke Transport (CFAST) [21], and Fire Dynamics Simulator (FDS) [22] models that are all products of the Building Fire and Research Laboratory (BFRL) at the National Institute of Standards and Technology (NIST). Today, fire models are being used by engineers and architects, building officials, the fire service, investigators, building and fire code developers, materials and systems manufacturers, fire researchers, and educators.

Overview of Fire Models

What Is a Model?

Generically speaking, a model can be thought of as a tool for simulating and predicting the behavior of a complex entity or system. All models require input, the processing of the input, and the output of the predicted results. Usually, due to the complexity of the natural world as viewed as a system, a practical model requires that simplifying assumptions be made, but such simplifications tend to limit the range of applicability of the model. Models can evolve from empirical data or as a result of existing knowledge from Physics or Chemistry, or a combination of both.

Although a somewhat common perception, a model does not need to be mathematical in nature. There are two broad classes of models, namely, physical models and mathematical models. Physical models endeavor to reproduce phenomena in a simplified physical situation. Reduced-scale physical models are a common form of modeling because full-scale experiments can be prohibitively expensive, intractable, or altogether infeasible. Reduced-scale modeling does not simply mean conducting experiments at a reduced physical scale. In addition to reducing the linear dimensions of a physical system, it is also necessary to maintain mechanical, thermal, and chemical similarity in the reduced-scale model through dimensional analysis or from the fundamental equations describing the phenomena [10].

Mathematical models are sets of equations that describe the behavior of a physical system. Mathematical models can be further divided into two classes: probabilistic models and deterministic models. Probabilistic models attempt to simulate the range of possible outcomes of the random behavior of a system, while deterministic models assume that, given a well-defined physical system, the system's behavior can be entirely and accurately predicted. These classes have some crossover, in that probabilistic models include within their construct some deterministic modeling algorithms. In general, the aim in the use of physical models is to discover fundamental laws governing the behavior of systems. A mathematical model can be constructed on the basis of derived laws that can then be used to predict the behavior

of novel systems. Thus, physical and mathematical models can be interrelated and complementary [10]. In the context of this discussion, the focus is on deterministic fire models.

What is a Deterministic Fire Model?

A deterministic fire model is a mathematical representation of the processes encountered in "fire" by interrelated expressions based on known physics and chemistry. Although the implication from the term *fire model* is that the combustion process is modeled directly, due to the complexity of the phenomenon, "fire models" provide engineering approximations of the time-varying characteristics and impact of a user-defined mathematical representation of a fire. That is, the model usually requires that the user input a predefined growth rate of the fire. This requirement is the result of limitations associated with the modeling of the spread of flames on combustible surfaces, although as models improve in their predictive capabilities, this current situation will change [10]. In order to discuss the types of available fire models, it is helpful to understand the phenomena being studied.

What Are We Trying to Model?

All fires must behave according to fundamental principles, but can vary depending on the conditions in which they occur. It is the purpose of modeling to describe how a particular fire behaves based on fundamentals as well as the specific conditions.

There are two broad classes of the physical circumstances of a fire, that is, those fires that occur in the "open" or "unconfined" fires, and those fires that occur in an enclosed space, commonly referred to as *structure fires*, *compartment fires*, or *room fires*. More specific variables that characterize the environment include the fuel(s) involved, the configuration and arrangement of the fuel(s), the physical characteristics of the building, the location of the fire origin, the location and the capabilities of building occupants to mitigate the fire event, and any passive or active fire protection systems.

A good example of a fire burning in the "open" is a campfire. In the simplest terms, the wood of the campfire provides the gaseous fuel required for combustion and producing the volume of luminescent flames. This flaming region generates products of combustion (e.g., soot, carbon dioxide, carbon monoxide, and water vapor) that are transported vertically to the surrounding environment due to buoyancy through the formation of a thermal plume above the flaming region. (While buoyancy is a well-defined phenomenon, for the purposes of this discussion, the term *hot air rises* is sufficient to understand the concept.) The hot gases rise in the thermal plume and mix with the surrounding air until the temperature difference between the products of combustion and the surrounding air is zero. This heat transfer process is called *convective heat transfer*. The fire also transfers heat through thermal radiant energy to adjacent objects (e.g., the ground, human clothing, and skin) that will increase the temperature of those objects. In general, the energy transferred to the surrounding environment from a fire burning in the "open" is lost with no feedback process from the environment to the fire that can modify the fire's behavior.

In contrast, a fire burning in an enclosure will experience feedback from the local environment that can modify its burning characteristics. A good example of an enclosure fire is shown in Figure 1(a), which illustrates the cross section of a room with a floor, walls, a ceiling, and an open doorway. The room contains a wastepaper basket, a sofa, and a table. For this example, the wastepaper basket is the first item ignited and the sofa and table are potential secondary and tertiary fuels. In the initial stages of the fire growth, the thermal plume will rise and impinge on the ceiling surface above and will broadly redirect the flow from a predominately vertical direction to a predominately horizontal direction. As the hot gases flow horizontally in all directions from the ceiling impingement region, a thin layer is formed that is referred to as a *ceiling jet*. Initially, the ceiling jet will be relatively thin in depth, but as the ceiling jet reaches adjacent vertical walls, the flow will be generally redirected back toward the thermal plume and create a quiescent hot upper layer that is greater in depth than the original ceiling jet as shown in Figure 1(b). As the fire grows and as more products of combustion are produced over time from the fire, the hot upper layer will grow in a more uniform depth, and the interface between the hot upper layer and the cooler lower layer will descend.

As the hot upper layer descends and reaches the top of the open doorway, as illustrated in Figure 2(a), the difference in pressure on the inside of the doorway relative to the outside of the doorway causes the products of combustion from the hot upper layer

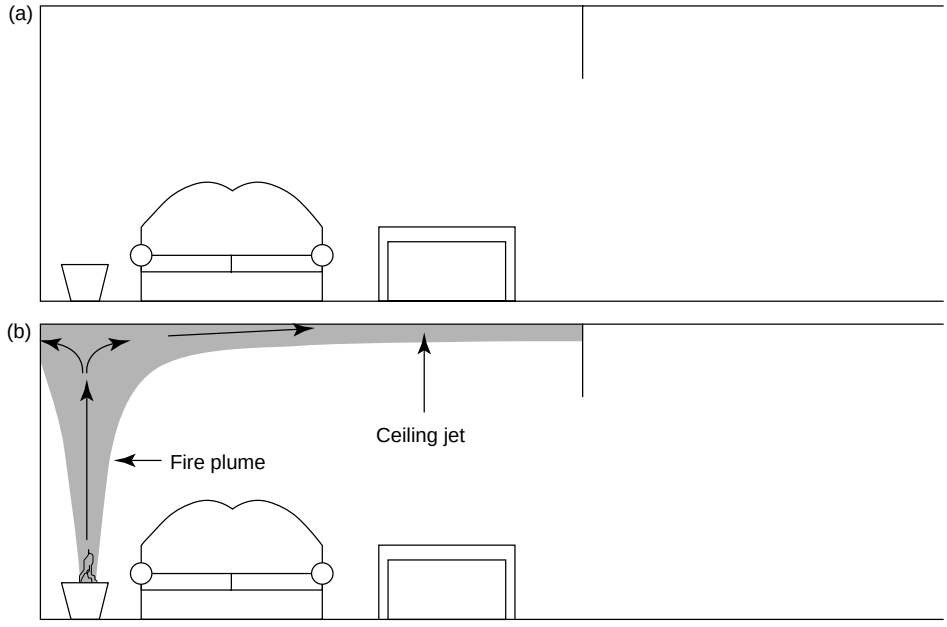

Figure 1 (a) An illustration of the cross section of a room with an open door and containing a wastepaper basket, a sofa, and a table. (b) An illustration of a flaming fire in the wastepaper basket forming a thermal plume above and producing a ceiling jet under a confined ceiling

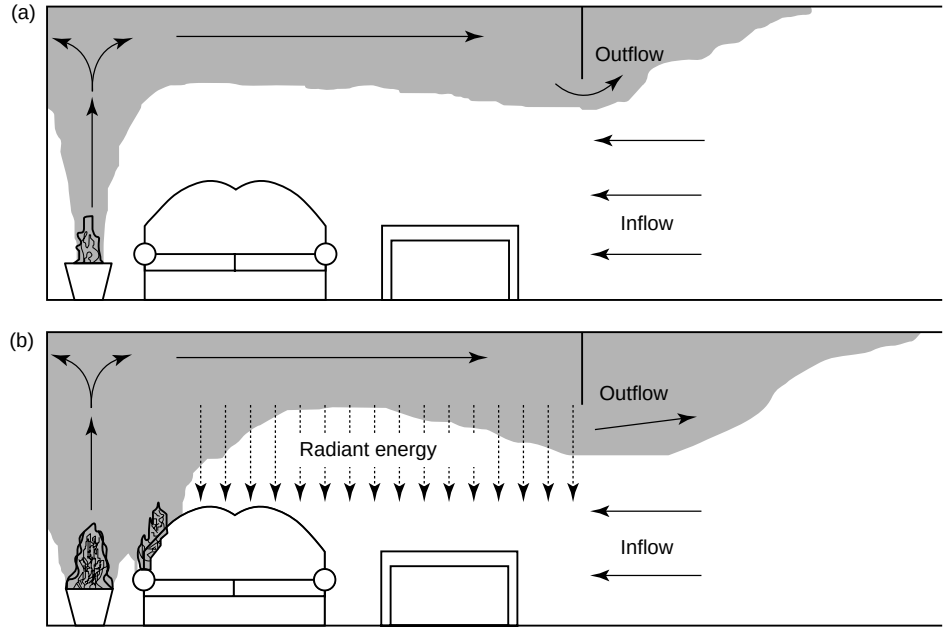

Figure 2 (a) An illustration of the increasing depth of the upper layer and the flow of hot products of combustion out of the top of the doorway. (b) An illustration of the growing fire and the descending interface between the hot upper layer and the cooler lower layer relative to the position of the ceiling

to flow out of the doorway. Owing to the law of conservation of mass, if the generation rate of the products of combustion from the fire does not exceed the exhaust rate of the products of combustion flowing out of the doorway, the hot upper layer will not descend any further. If the fire grows in size and the generation rate exceeds the exhaust rate, the bottom of the hot upper layer will continue to descend below the height of the doorway, as shown in Figure 2(b). The fire is analogous to a "pump" that produces and transports mass and energy to the hot upper layer from the fire source and as the fire grows, the size, and temperature of the hot upper layer will increase. As the upper layer increases in temperature, radiant energy becomes the dominant mode of heat transfer and will begin to transfer heat to the fuel below, as shown in Figure 3(a). Also, a well-defined flow pattern will be established at the doorway, with the hotter products of combustion flowing out the upper portion of the doorway and cooler ambient air flowing into the compartment in the lower portion of the doorway.

If the fire continues to grow and the upper layer temperatures approach approximately 500°C (900°F), there will be a continued increase in the intensity of the thermal radiant energy transferred to the exposed combustible contents in the room, and the surface temperature of these fuels will increase. When the upper layer temperature reaches approximately 600°C (1100°F), there is sufficient thermal radiant energy exposure (i.e., $20\,\mathrm{kW\,m^{-2}}$) to instantaneously ignite most combustibles in the room, as shown in Figure 3(b) [2]. This phenomenon, known as *flashover*, is illustrated in Figure 5. Flashover is not a discrete event in time, but an interval of time that is commonly characterized by (i) the transition from a localized fire to a general conflagration within the room when all fuel surfaces that can burn are burning; (ii) the transition from a fuel controlled fire, where there is plenty of air available and the fire is controlled by how much surface area is involved, to a ventilation controlled fire, where the size of the fire is determined by how much available air can reach the fire; (iii) the sudden propagation of flame through unburned hydrocarbons in the upper layer [8]. Once flashover conditions have been reached and the fire continues to grow in size, postflashover conditions or

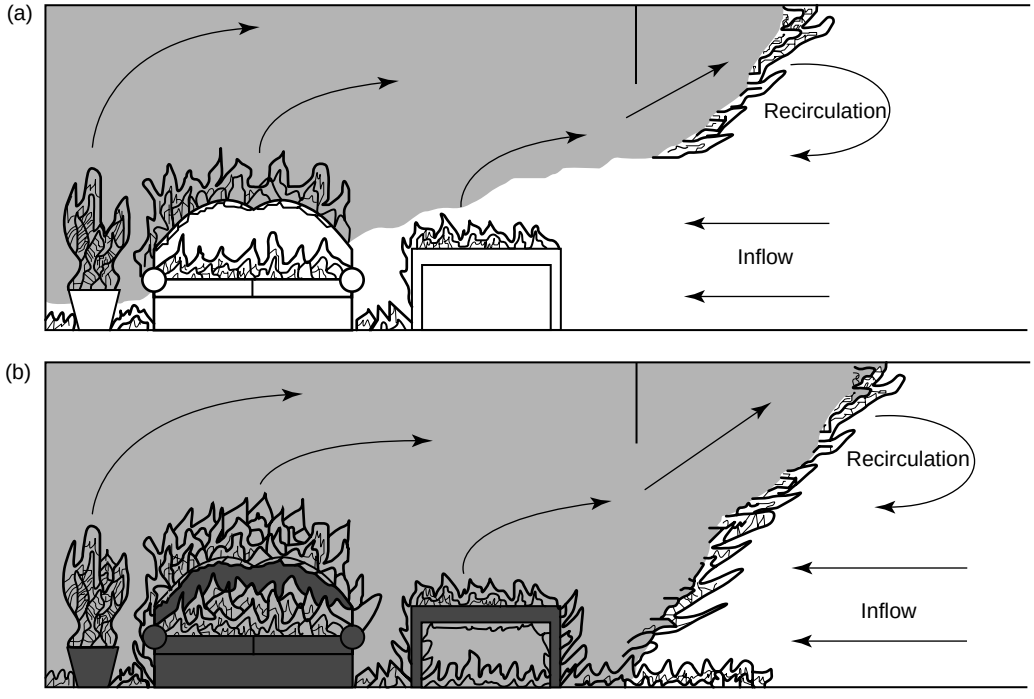

Figure 3 (a) An illustration of the onset of flashover due to thermal radiant energy from the upper layer. (b) An illustration of postflashover conditions or a fully developed compartment fire

full room involvement will follow in the majority of compartment fires unless the fuel is consumed, the fire is oxygen limited, or the fire is suppressed [2].

There are, of course, more phenomena associated with wanted and unwanted combustion that can be modeled and that are not addressed in this overview of fire modeling. Such additional phenomena can be used to test hypotheses associated with the investigation of fire and explosion incidents using the scientific method. The additional phenomena include patterns of thermal damage, activation of fire-detection devices, occupant egress from buildings, fire endurance of structures, generation of toxic gases, human respiratory uptake of toxic products, and fire suppression. The discussion of fire models for this article is necessarily limited to the commonly used models, with additional references for fire modeling included in the section "Further Reading" at the end of this article.

Types of Deterministic Fire Models

Deterministic fire models can range from simple correlations of empirical data to higher complexity models requiring weeks of computing time using multiple computer processors. The following sections provide an overview of the most commonly used types of fire models. Additional information on these and other simplistic correlations can be found in NFPA's *Fire Protection Handbook* [23] and SFPE's *Handbook of Fire Protection Engineering* [9].

Simple Correlations. A common example of a simple mathematical model is an equation describing the relationship between the heat release rate of the fire and the diameter of the surface area of the fire [24]:

$$\frac{L}{D} = 0.2\left(\frac{Q^{2/5}}{D}\right)$$

where, L is the average flame height in meters, D is the diameter of the fire in meters, and Q is the heat release rate in kilowatts. The correlation was developed on the basis of experimentally measured flame heights for different size fires (i.e., heat release rate and diameter).

FPEtool is the most well-known collection of simplistic computer simulation procedures that have been developed by multiple researchers [20]. Some of these correlations are for unconfined fires, including buoyant gas head [25], plume temperatures [26], rate of lateral flame spread [27], and radiant ignition of an adjacent fuel [28]. The remaining correlations are associated with confined fires and include average upper layer temperature [29]; ceiling jet temperatures [26]; mass flow through a vent [30]; smoke flow through an opening [25]; thermal detector and sprinkler response [31]; the occurrence of flashover [32]; and the limit on the size of a fire due to nonforced ventilation flows [33]. At the other end of the range of complexity are models that describe the behavior of fire in one or more rooms.

Deterministic mathematical fire models are further classified into two classes: (i) zone models and (ii) field models.

Zone Models. The zone model is the more common type of fire model available today. The dominant characteristic of the zone-type fire model is that it divides the individual compartment(s) into a relatively small number of discrete and relatively large zones that are implemented as control volumes. The most recognizable implementation is the two-zone model, where there is a hot upper layer and a cooler lower layer, as shown in Figures 4 and 5., but one-zone models have also been developed for both pre and postflashover zone models [34]. The size of and the conditions within each zone are calculated using the conservation equations (i.e., conservation of mass and energy) based on the fire source and thermal plume acting as a pump and transport mechanism for mass and energy to the upper layer by the thermal plume and ceiling jet. The model assumes that each zone is uniform with respect to the key variables such as temperature, soot, and gas concentrations (e.g., oxygen, carbon monoxide, and unburned hydrocarbons). In addition, the zone model assumes that when the mass and energy are generated from the fire source, they are instantaneously transported to the upper layer with no lag time associated with the transport. Thus, the transport time details are lost with the simplistic implementation of the assumptions associated with zone models [16]. The fundamental principles behind the zone fire model formulation are described by Quintiere [13].

While there are fundamental characteristics associated with the zone-type fire models, not all zone models have the same implementations with respect to the mathematical treatment of the relevant phenomena associated with compartment fires. For example, there are models that are able to handle only

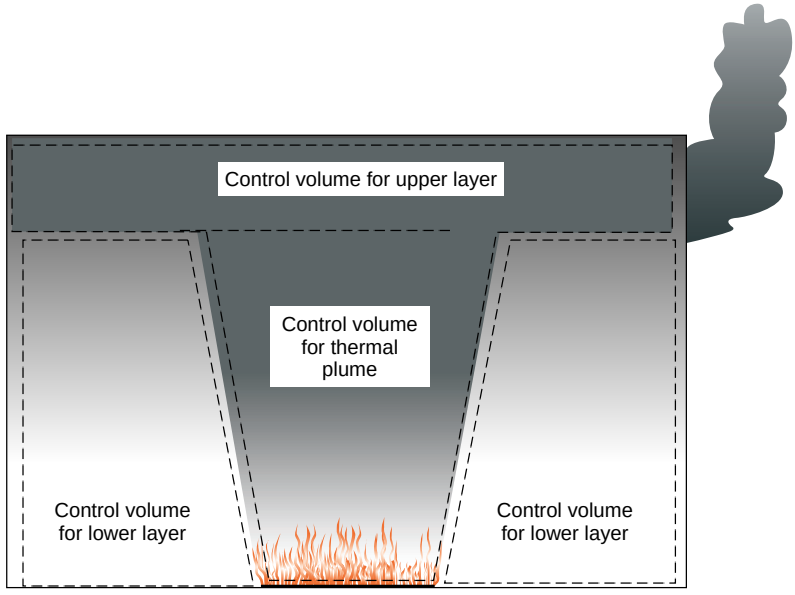

Figure 4 An illustration of a fire in a compartment with an opening on one end. The dotted lines show the zones or control volumes for the upper layer, the thermal plume, and the lower layer

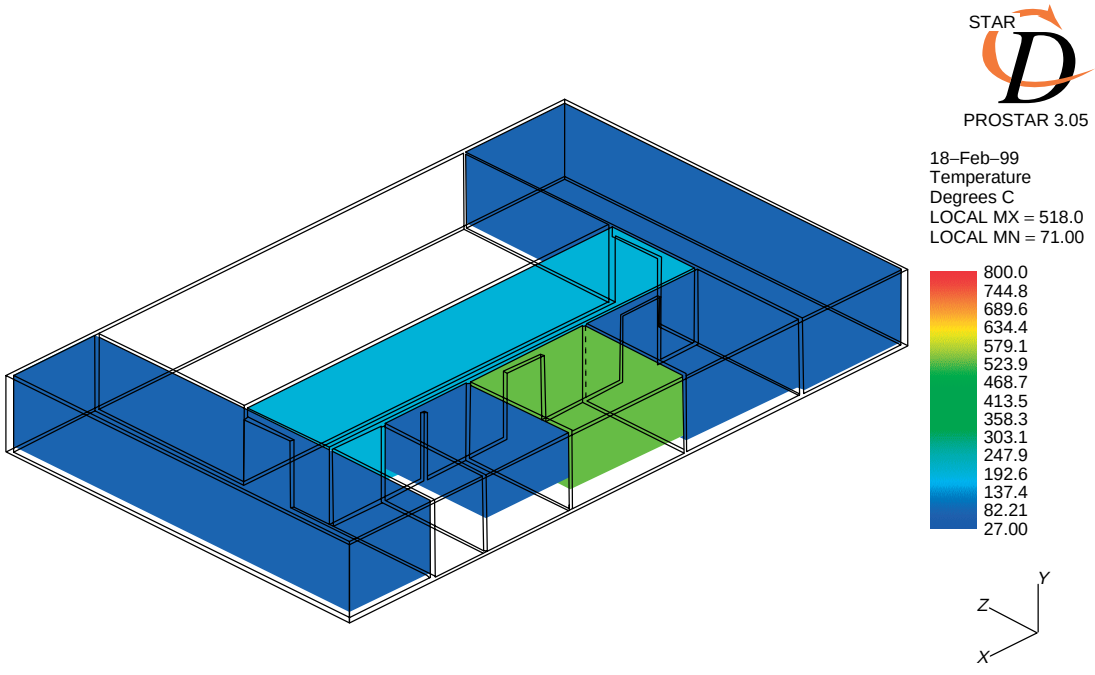

Figure 5 An illustration of a fire in a building in a middle room with an open doorway to the center hallway. There are three open doorways that connect other rooms to the center hallway and one partially closed doorway to an adjacent room. The depth of the upper layer interface is graphically illustrated for each room and the color gradient displays the average upper layer temperature

the compartment of fire origin, while others have multiroom capabilities. Other significant differences include the treatment of the combustion process and availability of oxygen, heat transfer between zones and to compartment surfaces, and pressure driven flows between zones and through vents such as doors, windows, and stairwells.

CFAST is one of the more well-known zone models in existence today. It is a multiroom model that predicts conditions within a structure resulting from a user-specified fire. CFAST Version 6 can accommodate up to 30 compartments with multiple openings between compartments and to the outside. The program inputs are a basic description of the building geometry (e.g., width, depth, and height); information describing common vents between compartments; the thermophysical properties of the compartment bounding surfaces; the heat release rate of the fire; and species yields of the products of combustion. The program calculates the average temperature, depth, and species concentrations in the hot upper layer and the cooler lower layer in each compartment. CFAST also includes very limited mechanical ventilation capabilities (i.e., HVAC systems), a ceiling jet algorithm, capability of multiple fires, heat transfer to other fuel targets, activation of thermal detection and suppression systems, and a flame spread model [21]. The CFAST model and associated technical documentation can be downloaded from the Internet (http://cfast.nist.gov/) at no cost.

Zone models, through their capacity to provide results relatively quickly on personal computers, allow for relatively inexpensive parametric studies to be conducted, and have proved to be a practical method for providing estimates of fire processes in enclosures.

Field Models. A field model differs from a zone model in that instead of a single point of averaged data for a finite area or volume, a "field" of multiple data points is resolved. The most identifiable field model for use in fire modeling incorporates the computational fluid dynamics (CFD) technique. Thus, the most important characteristic of a CFD fire model is the density of spatial resolution of the fire environment in terms of temperature and concentrations throughout the compartment relative to a zone model, which uses a single averaged data point. The CFD technique involves dividing up the volume of interest into relatively small and discrete control volumes, also known as *cells*, as shown in Figure 6. Like a zone model, the CFD technique utilizes the conservation equations (i.e., conservation of mass, momentum, and energy) to solve the flow variables at multiple points in the domain of interest, as shown in Figure 7. As the detailed structure is calculated on the basis of a more detailed implementation of the fluid mechanics equations, the CFD solution is more fundamentally based than zone models.

While many general-purpose CFD models have been developed and used in the modeling of fire, the most widely distributed and commonly used CFD model in the fire protection engineering community is FDS. FDS consists of two computer programs and

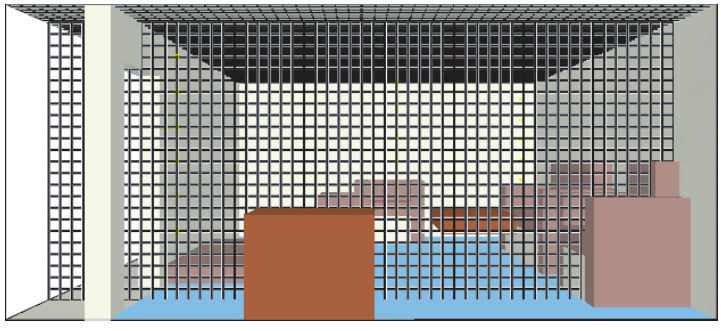

Figure 6 An example of the graphical output from the FDS model for a residential compartment fire with an open door. The size and number of cells in two dimensions are superimposed graphically in the model and are typical of the practical cell resolution associated with the modeling of a compartment fire

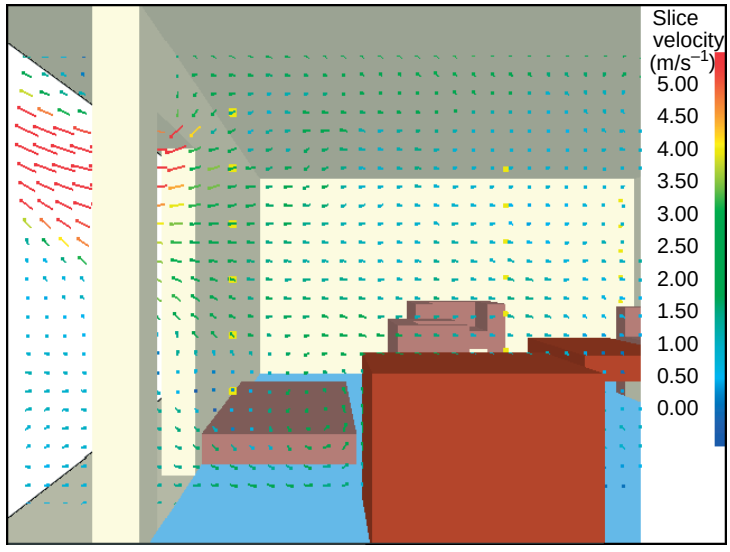

Figure 7 An example of the graphical data that can be superimposed onto the FDS model. Each graphic "arrow" is a vector within a plane or "slice" of the compartment that represents the predicted result for each of the selected cells. A vector provides the magnitude of the predicted value (in this case, the velocity of the flow) through its length and the direction through the orientation of the "arrow". The vectors within the doorway region in this case show the flow of hot gas out of the top of the doorway and the flow of relatively cooler gas (i.e., air) in at the lower portions of the doorway. The color (or gray-scale) gradient of the vectors is an additional means to visually characterize the velocity data

is designed to model fire-driven flows for low-speed, thermally driven flow with an emphasis on smoke and heat transport from fires. The first program is the actual FDS solver for the system of equations as described in McGrattan [22]. An input file is generated by the user that describes the geometry and sets up the simulation. This file is read by FDS and then run for a specified simulation time. The result is an output data file that can be viewed by the second computer program called *SmokeView* [35]. These two programs and associated technical documentation can be downloaded from the Internet (http://www.fire.nist.gov/fds) at no cost.

Current versions of FDS incorporate a more complex combustion model that releases fuel from the fire source and tracks the amount of fuel and oxygen in each cell. When the proportions of fuel and air are mixed in the right proportions, the fuel is burned (i.e., "mixed is burned"). This models assumes that the time to mix the fuel and air is much longer than the time for the fuel and air to react and is called *mixed is burned* model. FDS also handles thermal radiation, as well as the activation of thermal detectors and water spray from sprinklers.

While a CFD fire model provides greater resolution, to support more sophisticated applications of a model, there are trade-offs with respect to the required computer resources, the time required to run the models, the skill level of the user, and the associated costs of each. Thus, the use of CFD for all fire modeling applications is not always appropriate.

Overview on the Selection of Fire Models

Postfire reconstruction lends itself readily to the use of fire models. The appropriate selection and application of fire models to the investigation of fire and explosion incidents require an understanding of the fundamentals of fire dynamics, mathematical fire models, and their associated limitations with respect to the specifics of individual fire events. Several case studies of fire incidents using computer fire models have been published [36–41]. Such case studies generally demonstrate how a computer model used as part of a more general engineering analysis is a powerful tool. Most fire modeling applications that occur today, and that have occurred in the recent past, are performed in the context of the fire

litigation environment. Unfortunately, most of these applications are never published in the fire science literature.

Advantages and Limitations

The advantage of using fire models in fire investigation has been previously discussed with respect to their use within the context of the scientific method. The value of fire models is in their practical ability to address more complex phenomena, issues, and fire scenarios than other types of analytical tools. In short, fire models can help to quantify the limits of what can and cannot happen, based on scientific principles and analysis.

There are also limitations associated with the use of fire models. The current state of the art requires that the user provide the growth rate of the fire through a prescribed heat release rate history. Data sources for the thermophysical properties of commonly used building materials are somewhat limited. Similarly, the environmental conditions (geometry, fuel, and ventilation) for a specific fire scenario may not always have been documented at the fire scene or may not be available from other means. In addition, the uncertainty in the predictions is usually not obtainable for specific fire scenarios. The use of approximations in constructing a fire model also yields limitations with respect to the application to a specific scenario. The full limitations associated with the application to specific fire scenarios are, as yet, unknown. These issues involved in the evaluation of fire models have begun to receive attention in the technical fire community [10].

Any endeavor to model the behavior of fire also requires knowledge of the underlying physics and chemistry [5]. The previously discussed limitations tend to be overshadowed by the limitations associated with inappropriate use of fire models. Inappropriate use is usually the result of ignorance of fire dynamics and fire modeling. Fire modeling, as well as fire investigation, should only be conducted by individuals who have a sound knowledge of the principles of science and engineering and how these may be applied to understanding fire dynamics. Many fundamentals are intuitive, but misleading determinations can be drawn from postfire evidence and the results of fire modeling unless the investigator understands the science and dynamics of fire [42]. Thus, the onus of responsibility for appropriate application lies with the user of the model.

Model Selection

When solving technical problems, it can sometimes make good sense to limit the number of variables under study. It takes a high level of scientific knowledge of fire to ascertain which phenomena are important and which are not [17]. First and foremost, the appropriate selection of a fire model must include an assessment of the physics and chemistry required for the specific application and a determination of whether the model incorporates sufficient details for appropriate application.

Owing to the number of classes of models, a decision must first be made with respect to which class of models to use (e.g., zone or field model). For example, with respect to the prediction of the time for smoke detector activation, there are algorithms incorporated into both zone and field models. The selection of the most appropriate model needs to be based on the variables required to provide sufficient accuracy to predict the activation time. Accurate prediction requires that the local conditions (e.g., soot concentration and velocity) at the location of the smoke detector be resolved by the model to support the activation algorithm. A zone model would not be the most appropriate choice for this application because the upper layer (where the smoke detector would be located) is described by an averaged value. This limitation is not true for the field model. In addition, the zone model makes the assumption that the mass and energy generated by the fire source are immediately transported to the hot upper layer; thus, any transport time by the thermal plume and ceiling jet is ignored. As the transport time can be an important component to the time of smoke detector activation, the zone model would not be the most appropriate choice.

Once the selection of a class of models has been made, there can be a number of models within that class from which to choose. Again, this selection process must include an assessment of the Physics and Chemistry required for the specific application and a determination of whether a specific model incorporates sufficient details for appropriate application. Validation studies can provide some insight into this selection process.

Validation

The most important attribute of computer fire models is their ability to predict the relevant fire phenomena within their stated limitations. The predictive capability of a model depends on both the current state of fundamental knowledge for the phenomenon being modeled and the translation of that knowledge into a mathematical algorithm [10]. The predictive capability of fire models can be limited since these models rely on approximations for naturally occurring phenomena. There can also be additional uncertainty introduced depending on the knowledge and skill of the user. The level of uncertainty for a particular application can range from insignificant to rendering the model invalid and scientifically unreliable.

Validation is the process of measuring the level of uncertainty of the model's predictions. The general limitation of the validation process is that complete validation of any fire model for all fire scenarios is impractical. The American Society of Testing and Materials (ASTM) has developed guides to documenting and evaluating fire models [43, 44], and the SFPE has begun to take on the task of providing guidance documents on the use of fire models [45].

Numerous validation studies of computer fire models have been undertaken. The US Nuclear Regulatory Commission has begun the process of evaluating and validating models within the room of fire origin [46]. The model surveys by Friedman [18] and Olenick and Carpenter [19] also include reference to *validation studies*.

Summary

A failure can be defined as an "... unacceptable difference between expected and observed performance." Fire investigators and fire analysts are usually tasked with rendering opinions as to the origin, cause, responsibility, or prevention of such incidents. The essence of the investigation of fire and explosion incidents is embodied in the "... use of a systematic approach with attention to all relevant data". NFPA 921 recommends the use of the scientific method, which has traditionally been implemented in the physical sciences and forms the basis for scientific and engineering investigations, including fire and explosion incidents.

The challenge for the fire investigator is the practical application of fundamental knowledge to the investigation of fires that have occurred in the field. Such fundamental and empirical knowledge can be exploited through the development of models to simplify some of the complexities of the combustion phenomena that limit practical application.

In order to render accurate and reliable determinations associated with particular fire incidents, the investigator must "understand the fire." Fire models can be used as part of a fire dynamics analysis. The results can be compared to physical and eyewitness evidence to test an investigator's hypothesis. Modeling tools can also be used to evaluate the factors causing damage to property or injury to people (i.e., "The origin and cause of the loss").

A deterministic fire model is a mathematical representation of the processes encountered in "fire" by interrelated expressions based on known principles. Deterministic fire models can be simple correlations of empirical data or highly complex models requiring considerable computer processing power. The appropriate selection of fire modeling to the investigation of fire and explosion incidents involves an understanding of the fundamentals of fire dynamics, mathematical fire models, and their limitations with respect to the specifics of individual fire events.

Firearm Discharge Residue: Analysis of

Introduction

Numerous serious criminal offenses as well as many terror activities involve firearms. During discharge of a firearm, a variety of materials (accompanying the bullet) are emitted from the muzzle and other possible openings in the firearm. Throughout this text, the term *firearm discharge residues* (*FDR*) is used for all these materials. FDR may originate from primer, gunpowder (propellant), lubricant and metals of the bullet, cartridge case, and the gun barrel. The term *gunshot residues* (*GSR*) is used in this text for primer residues only, although in the relevant literature GSR or cartridge discharge residues (CDR) are sometimes used instead of FDR, whereas the term *inorganic GSR* refers to *primer residues* and the term *organic GSR* refers to *propellant residues*. Analysis of FDR on relevant exhibits can assist in reconstruction of a crime and might provide evidence against suspects involved. For instance, detection of FDR on a suspect or his clothing may link him to a firearm-related crime.

The following topics are reviewed in this treatment:

1. Detection and analysis of primer residues (GSR);
2. detection and analysis of gunpowder (propellant) residues;
3. the techniques of associating firearms and ammunition with gunshot entries; and 4. estimation of the time since shooting.

Several publications provide a comprehensive background on some of these topics [1–7]. Detection of firearm imprints on the hands of a suspect may assist in linking him to a firearm-related event. Estimation of shooting distance may be useful in reconstruction of the crime. Both topics are not in the scope of this treatment and appear as separate contributions in the encyclopedia (*see* **Firearms: Identification of Handling of Firearms/Trace Metal Detection**; **Shooting Distance: Estimation of**).

The Chemistry of Firearms Ammunition

Cartridge Cases

The cartridge case is designed to house the primer and propellant and to securely retain the bullet (projectile) in the neck. The vast majority of cartridge cases are made of brass (approximately 70% copper and 30% zinc) but other materials such as steel, coated with zinc, brass, gilding metal (approximately 90% copper and 10% zinc), or copper; nickel-plated brass; cupronickel (approximately 80% copper and 20% nickel); gilding metal; aluminum; Teflon-coated aluminum; and plastic are also encountered.

Projectiles

Conventional projectiles for firearms are bullets. Pellets and slugs are used for shotguns. A wide range of bullet types is available based on differences in composition and the geometrical design of the bullet core and bullet jacket. Bullets are unjacketed, jacketed, or partially jacketed (semijacketed). When firearms had relatively low muzzle velocities, bullets were made of almost pure lead. Commercial lead-alloy bullets are hardened by alloying with antimony or, less commonly, with tin. The concentration of antimony may vary considerably, from 0.5 up to 12%. Unjacketed bullets may have their surfaces coated with a very thin layer of copper or brass. This is referred to as a *wash* or *coat* and is not a bullet jacket

in the conventional sense of the word. Unjacketed bullets are frequently lubricated with some form of wax or grease to prevent or reduce fouling in the barrel of the firearm. Jacketed bullets consist of a lead core surrounded by a jacket of harder material. Usually the core is left exposed at the base of the bullet; however, the bases of total metal jacket (TMJ) bullets are completely covered by the jacket. Jackets are commonly made of copper, brass, copper–nickel alloy, or mild steel.

Primers

Primers for center fire ammunition are housed in small metal cups that fit into a recess (primer pocket) in the center of the base of the cartridge case. In rimfire ammunition, the priming composition is housed inside the cartridge case in the hollow perimeter of the base. Priming compositions are mixtures which when subjected to percussion provide sudden burst of flame that serves to ignite the propellant within the cartridge case.

In general, small arms primers consist of the following components: an initiating explosive (initiator), an oxidizer, a fuel, a sensitizer, a friction material, and a binder. Examples of those types of compounds are the following:

Initiators:
lead or silver azide, mercury fulminate, lead styphnate, diazodinitrophenol.

Oxidizers:
barium nitrate, barium peroxide, potassium chlorate, lead dioxide.

Fuels:
antimony sulfide, gum arabic, calcium silicide, aluminum powder.

Sensitizers:
tetracene, trinitrotoluene (TNT), pentaerythritol tetranitrate (PETN), tetryl.

Friction materials:
ground glass, aluminum powder.

Binders:
gum arabic, dextrin, glue.

Sometimes, in the priming composition, more than one compound from any of the above classes may be used. Modern primers are mostly noncorrosive and nonmercuric (NCNM). A typical centerfire primer cap produced today might contain lead styphnate, antimony sulfide, barium nitrate, and tetracene. Not all primers, however, contain compounds of antimony and barium. Some. 22 caliber rimfire cartridges contain either lead and barium or only lead compounds.

In 1980, Dynamit Nobel AG commercialized a new ammunition, called *Sintox*^{TM}, developed to minimize airborne lead levels and possibly other metallic residues such as barium and antimony [5]. In this ammunition, lead styphnate is replaced by diazodinitrophenol and barium nitrate and antimony sulfide are replaced by a mixture of zinc peroxide and titanium metal powder respectively [7]. This primer also contains tetracene and cellulose nitrate. The use of this primer coupled with a TMJ bullet eliminates the health hazard problem. Since then several other ammunition manufacturers have started introducing lead-free ammunition.

Propellants

Modern smokeless gunpowder for small arms ammunition almost exclusively contains cellulose nitrate (nitrocellulose, NC) as the main explosive component (single based). Other explosive ingredients may also be present, for example, glycerol trinitrate (nitroglycerine, NG) (double based) and nitroguanidine (triple based, unlikely to be encountered in small arms ammunition). Propellants also contain stabilizers such as diphenylamine (DPA) or ethyl centralite (EC), flash inhibitors such as 2,4-dinitrotoluene (2,4-DNT), and 2,6-dinitrotoluene (2,6-DNT) and plasticizers such as diethyl phthalate and dibutyl phthalate. Some inorganic materials such as chalk, graphite, potassium sulfate, potassium nitrate, and barium nitrate are added to improve ignitability, facilitate handling, and minimize muzzle flash.

The Mechanism of FDR Formation

When the firing pin strikes the primer of a cartridge, it provides a burst of flame without the development of a detonating wave [7]. The flame causes the propellant to ignite. It burns fast (deflagration) but does not detonate. When the bullet leaves the muzzle of a firearm, the pressure is vented to the atmosphere. This typically occurs before all of the propellant is consumed, causing fragments of unburned gunpowder to be emitted from the firearm. Other particulates

originate from the decomposition of the primer and from the metals of the cartridge and the firearm. The process of their formation may be described in the following manner [8]: the expanding gases from the propellant deflagration initially compress the bullet axially, so that it expands radially. The enlarged bullet is then "swaged" through the barrel by the rapidly increasing gas pressure. This results in strong frictional heating. Also, the rifling rips small fragments from the bullet, and these particles are in part melted and in part vaporized. The metal vapors from the projectile mix with the vapors of the decomposition products of the primer and are ejected from all possible openings in the firearm and may be deposited on surfaces in close proximity to the firer. In flight, the vapors condense into liquid phase and then solidify to particles. Unless modified in the liquid state by impact, they appear as spheroids in the size ranging from less than 1 up to 10 μm [2, 9]. Thus, the composition of the formed particles may have contributions from the primer, the bullet, the cartridge case, the gun barrel, and the propellant, although the term *primer residue* is occasionally used.

Detection and Analysis of GSR (Primer Residues)

This section discusses various methods of detection and characterization of primer residues mainly on suspects, their clothing, and their belongings. The focus of the discussion is on GSR particle analysis by scanning electron microscopy combined with energy dispersive X-ray analysis (SEM/EDX), since nowadays this is the method of choice in advanced crime laboratories.

Color Tests

The earliest method to detect FDR on shooters' hands was introduced in 1933 by Teodoro Gonzales [5]. It is known as a *dermal nitrate test* or *paraffin test*. Molten paraffin was poured on the hands of the subject and allowed to solidify to form a cast on the hands. When the paraffin froze, it was peeled off and sprayed with a 0.2% solution of DPA in concentrated sulfuric acid. The reagent gives a deep blue coloration with nitrates and nitrites that may originate from gunpowder and primer residues. However, even though nitrates and nitrites may come from other sources (e.g., fertilizers, urine), this test is not specific to nitrates and nitrites only. Other oxidizers like chlorates, iodates, permanganates etc. may give a positive reaction. On the other hand, also false negative results were common. In spite of these drawbacks, the test has been used for many years. Finally, it was abandoned by most of the forensic laboratories. However, the test is still employed in number of places in the world [2]. Recently, the US Department of Energy's Sandia National Laboratories, working with Law Enforcement Technologies Inc., announced the development of the ISID™-1 (Instant shooter ID Kit). It appears that it is an updated version of the "dermal nitrate" or "paraffin" test. As in the case of the "dermal nitrate" test it was argued that "The concerns of non-specificity of the ISID™-1 kit need to be critically evaluated in light of its potential usefulness in the field and any legal issues associated with its documented 'false positives"' [10].

The Griess reagent used to detect nitrites is discussed in a separate contribution of the encyclopedia (*see* **Shooting Distance: Estimation of**).

In 1959, a test was developed for detection of lead, barium, and antimony, which may be found in modern ammunition primer residues [11]. The method did not gain wide acceptance because of lack of specificity of the color reactions, insufficient sensitivity, interference of the color reactions among the three elements, and the instability of the colors developed.

Bulk Instrumental Analytical Methods

Lead, antimony, and barium may be found on the hands of persons who were not involved with firearms but generally in smaller quantities compared to firers. Thus, developing a quantitative sensitive method for those elements could assist in differentiating between "innocent" people and those involved in shooting.

In this paragraph, bulk instrumental analytical methods are discussed. The term applies to those methods that determine bulk concentration of the constituents in the analyzed sample. With regard to GSR analysis, the analyzed sample is a collection of many particles. Contrary to the bulk method, a method for particle analysis, like SEM/EDX, can analyze discrete particles in the sample.

In the early 1960s, neutron activation analysis (NAA) was applied for detection of trace elements with high sensitivity [5, 12]. Although this method

was not applicable for lead, it was used to determine minute quantities of antimony and barium. In 1971, atomic absorption spectrophotometry (AAS) was developed for GSR analysis. Conventional flame AAS had sufficient sensitivity for detection of the lead quantities on firers' hands, but it was not sensitive enough for detection of antimony and barium. Development of graphite furnace atomic absorption spectrophotometry (GFAAS) solved this problem. GFAAS is relatively time consuming and is subject to some interferences due to the presence of high concentrations of nonanalyte constituents. Many forensic science laboratories have used NAA or GFAAS for GSR analysis in casework.

Some other bulk analytical methods have been studied recently for GSR analysis in hand samples [5]. Among these, two methods have been implemented in casework: inductively coupled plasma atomic emission spectroscopy (ICP/AES) [13] and inductively coupled plasma mass spectrometry (ICP/MS) [14, 15]. ICP/AES is a rapid, multielement technique that is relatively free of matrix interferences, but commercial instruments lack the sensitivity required for accurate determination of antimony at the relevant levels [14]. ICP/MS is now a widely accepted method for trace and ultratrace analysis of a variety of liquid, gaseous, and solid samples in many applications. Analytical benefits of the method are low detection limits, wide linear dynamic range, relative freedom from interferences, and good precision and accuracy [14]. Nonetheless, the latest survey [16] showed that the most popular bulk analytical method for GSR analysis was GFAAS.

GSR Particle Analysis by SEM/EDX

Up to the mid-1970s, the accepted methods for GSR analysis in casework were bulk analytical techniques described above. In the second half of 1970s, several studies were reported indicating that much higher evidential value could be obtained by examining the composition and morphology of discrete particles formed during a firearm discharge with the aid of SEM/EDX analysis. Continuous improvements in the SEM and EDX technologies are also reflected in the GSR analysis by SEM/EDX. Nowadays, most manufacturers of the SEM/EDX equipment offer automated search systems for GSR particles, which makes the analysis much easier when compared to manual search, which is very tedious. The principle of the automated search is similar to the manual search, namely, detection of a suspected particle by the backscatter electron (BSE) signal and its analysis by EDX. Nevertheless, even with the automated search systems the analysis may be quite long, amounting to several hours per square centimeter of a sample, depending on the surface density of particles having high average atomic number.

Sampling of GSR and Their Persistence on Various Surfaces. To collect GSR samples for SEM/EDX, most of the crime laboratories use 25- or 13-mm-diameter SEM aluminum stubs coated with adhesive tape (tape-lift method) [16]. The coated stubs are kept in GSR collection kits, which are commercially available or may be prepared in the laboratory. To collect particles from a surface (e.g., a hand), the stub is pressed repeatedly against the surface (see subsequent discussion).

The tape-lift method was shown to be the most efficient method of collection among three examined methods (tape-lift, glue-lift, and concentration methods) [17]. It was reported that in practice there might be an intrinsic difficulty in concentrating GSR on a small area due to pile-up and clogging of the filters used [18].

In the United Kingdom, swabs have been used to recover GSR and gunpowder residues from skin surfaces of a suspect. The propellant residues are extracted from the swabs by organic solvents and filtered through membrane filters on which the GSR particles are collected and examined by SEM/EDX [19].

A comprehensive study was conducted on collection efficiency of GSR particles from hair and hands using double-sided adhesive tape [20]. Tape-lift was found to be a suitable method for collecting GSR from hair, contrary to the previous claim [21]. No significant difference was found between collection efficiency of this technique and the more complicated method of swabbing the hair by use of a comb with a solvent-dampened cloth and filtration, proposed elsewhere [21]. It was found that 200–300 dabbings are necessary to achieve maximum collection efficiency from hair with the double-sided adhesive.

In several studies, the recommended collection procedure from hands by tape-lift method is to press the stub repeatedly against the hand until it has lost its stickiness per subjective assessment [1] The concern regarding continual dabbing was that skin debris

might conceal GSR particles from view. Nonetheless, it was found [20] that 50–100 dabbings are necessary to achieve maximum collection efficiency from hands, while stickiness appeared lost after about 20–30 dabbings. In a subsequent study [22], it was demonstrated that there is no substantial danger of concealing GSR particles by continuous dabbings of hands up to 50 times.

Clothing and other surfaces may be sampled for GSR by tape-lift method or by vacuum filtration [19, 23].

Once GSR particles are deposited on the hands, they are continuously lost as a result of the normal activities of a living person [12]. It is difficult to generalize as to how long GSR would be retained since it depends on the type of activity [12, 24]. While laboratory tests using bulk analytical methods have indicated that GSR remain on the hands for only a short time (perhaps 1 or 2 h) in actual cases, detectable amounts have been found several hours later, perhaps due to higher initial amounts of GSR [12]. Using particle analysis, it was reported that the probability of finding GSR on hands more than 3 h after firing is very low [21]. A subsequent study [25] has confirmed that there is a rapid drop in GSR particle count as a function of postfiring collection time, with the largest loss occurring in the first 3–4 h. Laboratory experiments showed that 30 min after firing no significant difference was observed between samples collected from the right and left hands with regard to the number of GSR particles found, although the shooter used one hand for firing [21]. The accumulated casework experience of about 12 years in Israel has shown that in only a very few cases a large number of particles was found in hand samples and in significantly lower number of these cases considerably more particles were found on one hand as compared to the other one, so that some inference could be made concerning the firing hand [26].

A much longer persistence of GSR was found on hair and clothing [21]. Persistence of 24 h was observed in laboratory experiments when the hair had not been washed [20]. So far few crime laboratories have introduced sampling hair for GSR, and this topic was not discussed in the recent meeting on GSR [27].

Compositions, Classification, and Interpretation. As was pointed out earlier, the composition of GSR particles may have contributions from several sources. It was shown that when using lead bullets in ammunition 70–100% of GSR particles are lead [8]. If the bullet is coated with copper or brass, the result is the same except that a substantial portion of all the particles contains some copper. If jacketed or partially jacketed bullets are used, the fraction of lead particles in the total collection is greatly reduced. Only a small portion of the particles contains copper and the total number of particles is smaller as well. It could be concluded from these observations that most of the lead in GSR comes from the projectile rather than from the primer. In another study [28] using X-ray diffraction (XRD), it was found that lead in the metallic form is found to be the main constituent of all GSR tested. The significant difference found between the GSR compounds' composition formed by ordinary shots (involving bullets) and primer shots can be explained by the far higher temperature and pressure of the former, resulting in almost total combustion of primer components as well as involvement of the projectile [28].

In their pioneering extensive study, Wolten *et al.* [1, 29, 30] proposed a classification scheme for GSR. They divided GSR into two categories: (i) unique or characteristic and (ii) consistent. The compositions they considered to be unique are as follows:

1. Pb, Sb, Ba
2. Ba, Ca, Si with traces of S
3. Ba, Ca, Si with traces of Pb if Cu and Zn are absent
4. Sb, Ba.

The compositions considered as consistent:

1. Pb, Sb
2. Pb, Ba
3. Pb
4. Ba if S is absent or present only as a trace
5. Sb (rare).

In both categories, one or several of the following and only the following elements could also be present: Si, Ca, Al, Cu, Fe, S, P (rare), Zn (only if Cu is also present), Ni (rare and only with Cu and Zn), K, and Cl.

It should be emphasized that the concentrations of the elements in the GSR particles are highly variable due to the very fast process of their formation.

The modifications proposed by Wallace and McQuillan [31] resulted only in two alleged "unique"

compositions for GSR: (a1) Pb, Sb, and Ba and (a2) Sb and Ba.

The definition of "unique" for these compositions was based on the experimental fact that they had thus far (at the time of definition) been observed only in GSR (*see also* **Identification and Individualization**).

The problem of classification of various compositions of GSR particles has continued to be a source of concern in casework and of interest for research, in particular the alleged "unique" compositions to GSR. Nowadays, most of the experts prefer to use the term *characteristic* instead of *unique* [27]. These compositions were found among particles produced by fireworks [32] and particles collected from various parts of cars and individuals involved in various automobile-related jobs [33]. It was observed, in particular, that particles of composition (a2) might be found, although in very small amounts, in residues from fireworks and among particles collected from automobiles. Very few particles of composition (a1) were found in the residues of one of the types of the tested fireworks. However, an additional element of magnesium (unusual to GSR) was present in those particles. In another study, Torre *et al.* [34] reported that some types of brake linings contain lead, antimony, and barium and they can represent a source of particles showing GSR-like elemental profiles. Most of these particles could be easily discriminated from GSR by means of the high levels of iron or the presence of "prohibited" elements in the EDX spectrum. However, particles with iron at minor or trace levels and lacking "prohibited" elements were also found but did not have spherical morphology. In view of these findings, the morphological criterion becomes more important for identification of GSR than was suggested by the ASTM committee [35].

It was proposed [36] to include the characteristic particles' composition: Pb, Ba, Ca, Si, and Sn, formed in discharge of Sellier Bellot, Prague (SBP) ammunition in the category of "unique" or characteristic compositions. This proposition was based on the extensive computerized casework experience of the authors that could lead to a statement that such a composition has thus far been observed only in GSR associated with the SBP ammunition.

Stoney pointed out [37] that it is not possible to reach uniqueness through statistics. Nevertheless, with the advent of autosearch systems for GSR in numerous crime laboratories, it may be much easier than before (using a manual search) to experimentally assess the rarity of various GSR compositions in a similar manner as the contribution of automated systems for fingerprint and firearms identification.

In any case, it is very important to compare the GSR compositions found on a suspect with the GSR compositions of the spent cartridge cases (if found) at the scene of crime. Sometimes, the evidential value of such comparisons may be much higher than the extent of "uniqueness" of the GSR particles found on the suspect, for instance, if the GSR particles found on a suspect are consistent with the GSR in the spent cartridge cases of a rare ammunition.

Several studies [38–40] reported the formation of "mixed compositions" GSR particles when firing different ammunitions from the same firearm. These findings are consistent with previous studies [8, 31], which claimed that conventional thorough cleaning of a handgun does not remove all GSR particles.

Until now, there has been no consensus among the forensic science laboratories regarding the number of particles needed to confirm the presence of GSR. There is much more agreement regarding the wording of reports when a laboratory decided that there is a positive result. In such a case, the statement: "The sample is consistent with the suspect having discharged a firearm, having been in the vicinity of a firearm when it was discharged, or having handled an item with GSR on it" resembles the phrasing of most of the laboratories [16, 27]. Regarding the vicinity of a discharged firearm, two recent studies [41, 42] showed that the maximum number of GSR could be found in the right front quadrant at a distance of 2–4 m with respect to the shooting firearm position and shooting direction. It was observed that there is an imminent danger of contamination of people who appear at the scene several minutes following shooting.

The possibility of GSR contamination of the law enforcement personnel or of the law enforcement premises should be taken into account when interpreting results in any particular case [27]. It was recommended that GSR sampling should be done at the scene, where permissible, and as expeditiously as possible and if the subject's hands cannot be sampled before placing the subject in a police vehicle, the subject's hands should be bagged in order to prevent possible contamination. It was suggested that in order to better distinguish between GSR from contact with law enforcement and a civilian shooting event,

a policy such as that set forth in some EU countries (e.g., Germany) should be set, which mandates that all domestic law enforcement use ammunition with taggants detectable by SEM/EDX [27].

Proficiency Tests for GSR Analysis by SEM/EDX. Recently, proficiency tests for GSR particles examination have been designed. For example, the tests prepared by Collaborative Testing Services, Inc. (CTS) were based on GSR suspensions in organic solvents. Owing to the large variation among the samples, it was impossible to assess and compare precisely the proficiency of the various laboratories participating in the test. Lately, a major advance was achieved in the European Network of Forensic Science Institutes (ENFSI) proficiency tests on identification of GSR by SEM/EDX. In these tests developed by Niewoehner *et al.* [43], for the first time "synthetic GSR particles" (pseudoparticles) were prepared by microelectronics technology on the stubs. All the participating laboratories received the same samples, namely, stubs having a flat surface with the same number of pseudo (two-dimensional) particles, in the same locations on the stub, and with the same size distribution. In the GSR2003 test, the pseudoparticles were of Pb, Sb, and Ba composition and having sizes of 2.4, 1.2, 0.8, and 0.5 μm. Although these samples differ from real-life samples of GSR, it seems that at present they are the best to evaluate the proficiency of the procedures used and the SEM/EDX equipment for GSR detection and analysis.

Other Instrumental Methods

Several other instrumental methods have been studied for GSR analysis. Most of them are still in the research phase and cannot be used in casework. Hellmiss *et al.* [44] used SEM equipped with AES analyzer instead of EDX. This method permitted the analysis of elements with low atomic number and elements whose peaks overlap in EDX. Using simultaneous Auger electron spectroscopy and ion sputtering etching, a profile of the in-depth composition variations of GSR was studied.

Micro-X-ray fluorescence (XRF) has been used recently in growing number of crime laboratories for elemental analysis of trace evidence, sometimes instead of SEM/EDX and sometimes in combination with SEM/EDX. Micro-XRF has also been studied for GSR analysis [45, 46]. However, it cannot be used for single particle examinations owing to the problems of spatial resolution. Nonetheless, it has been implemented operationally for GSR deposit analysis around the bullet holes.

Ikeda *et al.* [47]) demonstrated the application of scanning electron microscopy/wavelength dispersive X-ray spectroscopy (SEM/WDX) for detection and analysis of GSR particles from hands, hair, and clothing of a shooter. The authors reported that the method has been implemented in casework.

Time-of-flight secondary ion mass spectrometry (TOF-SIMS) was studied recently for the analysis of GSR [48]. The method may be used as a complimentary technique to SEM/EDX, since it has the capability of depth and trace elements profiling.

Additional techniques that have been studied for GSR analysis are focused ion beam (FIB), Raman microscopy, and laser-induced breakdown spectroscopy (LIBS).

Detection and Analysis of Gunpowder Residues

As was discussed in the previous section, SEM/EDX is a well-established method for detection and analysis of GSR (primer residues) on double-sided adhesive-coated aluminum stubs used to sample a suspect, his clothing, or his belongings, and is used by most of the forensic laboratories in the world. The method however, has the following drawbacks:

1. It is quite slow even when using an automated search system.
2. It has a relatively low "success" rate of detection (about 10%) [19, 26].
3. Not all primer residues are considered "unique" to discharge of firearms.
4. There is a low variability in compositions of primers.

Detection of gunpowder residues on suspects may have an additional evidential value for linking them to a firearm-related offense.

Analytical methods for the detection and identification of propellants or their residues are similar to those employed for the analysis of explosives or explosive residues in postblast samples, e.g., gas chromatography/mass spectrometry (GC/MS), gas chromatography/thermal energy analyzer (GC/TEA), or liquid chromatography/mass spectrometry (LC/MS).

The amounts of propellant residues that may be left on the shooter's hands several hours after shooting may be very small (normally in the nanogram levels) [19].

To the best of the author's knowledge, only two methods have been used operationally for detection and identification of propellant residues on shooters' hands: high performance liquid chromatography with a pendant mercury drop electrode detector (HPLC/PMDE) and GC/TEA due to their high sensitivities i.e., between tens to hundreds of picograms for NG, 2,4 DNT, and 2,6 DNT. The Forensic Science Service in the United Kingdom employs the same method for sampling and analysis of traces of explosives and gunpowder residues on suspects and their clothing [19]. These residues are recovered from the skin by a swabbing kit (nonwoven cotton cloth prewetted with a mixed solvent of 80% isopropanol and 20% water). The swabs are used to sample hands, face, and neck of a suspect. In addition, there is a nail scrapper and a swab threaded through a comb to sample the hair. Clothing and other items are sampled by vacuum filtration on 1-μm membrane filters. Sample extracts are filtered for GSR (primer) particles and cleaned up by solid phase extraction (SPE) in a microcolumn procedure using Chromosorb 104 as adsorbent. The samples are then analyzed by HPLC/PMDE and by GC/TEA.

In general, the question of which and how many techniques are required for confirmation or identification of an explosives trace is complicated, and there is no single answer [49]. Although comprehensive identification by MS would be a method of choice, it is not sensitive enough in many real-life cases.

The swab method to collect primer and gunpowder residues has not been adopted worldwide, in spite of its potentially higher evidential value. It is reasonable to assume that development of an operational method to analyze propellant residues in combination with primer residues on the stubs would encourage at least some of the laboratories to adopt analysis of both types of residues.

Micellar electrokinetic capillary electrophoresis (MECE) with a diode array UV detector was studied to analyze propellant residues on adhesives. Despite the high discrimination power of the technique, it appears that it is not sensitive enough to be implemented in casework [50].

In recent years, ion mobility spectrometry (IMS) technology has gained widespread use in the detection of trace explosive evidence owing to its portability, good sensitivity (comparable to GC/TEA), reasonable selectivity, and high speed of analysis [51]. A method in which the clothing is first sampled by double-sided adhesive for GSR analysis by SEM/EDX, followed by vacuum collection for propellant residue examination by GC/TEA, IMS, and GC/MS was introduced recently into casework in the Israel Police [52]. A novel method was reported for extraction and analysis (IMS and GC/TEA) of gunpowder residues on double-sided adhesive-coated stubs after they were examined for GSR by SEM/EDX [53].

Chemical Analysis for Associating Firearms and Ammunition with Gunshot Entries

The most conclusive way to link a fired projectile to a firearm is by identification of the unique markings of the barrel on the projectile (*see also* **Firearms: Bullet and Cartridge Case Identification**). Quite often in casework, however, the recovered projectiles are so damaged or disintegrated that the quality of marks (if still identifiable) is not sufficient for comparison. In such circumstances, it is impossible to achieve a definite linkage. Some level of association might be obtained by comparison of class characteristics such as the caliber or the width of lands and grooves if this can be assessed from the damaged projectile or its fragments.

There is no method for conclusively associating a firearm or ammunition with a gunshot entry. A class characteristic linkage may be obtained by measuring the diameter of the gunshot entry and by comparing chemical compositions of FDR in the bullet hole perimeter and around it, FDR in the barrel of the weapon, FDR in the spent cartridge case, and the composition of the fired projectile. Also, unfired ammunition, if apprehended with the suspect, may be analyzed for the above purpose.

Analysis of all the components of the FDR (GSR, propellant residues, and metal particles from a projectile) may serve this purpose.

The level of association will depend on the rarity of the examined compositions and on the extent of contamination that each component of FDR leaves in the firearm. The higher the contamination, the lower the extent of association obtained for a particular shot.

GSR Analysis. There is little variability in primer compositions used nowadays for manufacturing various types of ammunitions [3, 5, 7]. Samples may be collected from gunshot entries by double-sided adhesive tapes on stubs (that are used to collect samples from suspects or their clothing), examined by SEM/EDX, and compared with samples collected from the barrel of the suspected firearm and the spent cartridge cases found at the crime scene. Alternatively, the gunshot entry may be cut if it is in clothing or skin mounted on a stub and examined after coating with carbon in the high-vacuum SEM/EDX or without any coating in the variable pressure SEM/EDX. Micro-XRF may also be used for the analysis [45, 46], but with less accuracy because its spatial resolution is not sufficient for single particle analysis.

If spent cartridge cases are not found at the scene and no suspected firearm is apprehended, evidence may be obtained from the shooting tests of unfired ammunition if found in the possession of the suspect.

However, the problem of "mixed primer compositions" should be taken into account, since each round leaves "primer memory" in the barrel [8, 31, 38–40].

Gunpowder Residue Analysis. Several studies were conducted for analysis and comparison of unfired and fired propellants. Andrasko [54] used a GC equipped with a flame ionization detector (FID) and an HPLC equipped with a variable wavelength detector. He reported that the amount of propellant flakes recoverable from clothing (shot from distances shorter than about 50 cm) around the bullet hole was sufficient for the analytical techniques used. A similarity in composition was observed between the propellant particles recovered from the spent cartridges or those recovered from the clothing and the unfired propellant from the same ammunition box. Andrasko showed that the composition of subsequent shootings with the same weapon using ammunition from various manufacturers did not indicate any contamination from the propellant flakes from previous shootings.

MacCrehan *et al.* [55, 56] used MECE for analysis and comparison of fired and unfired propellants. Similar to Andrasko, MacCrehan *et al.* found that compositional analysis of the propellant provides information that can associate residue samples with unfired gunpowder. In shooting experiments using consecutively different ammunition brands (several rounds for each brand), they found only a trace of the previously fired powder in the first shot and none in the next shots.

It is apparent that the behavior of gunpowder residues is different from that of GSR (primer residues). As mentioned previously, GSR of "mixed compositions" are formed when firing different ammunitions from the same firearm. Examined propellant residues might, therefore, be more useful than GSR for associating firearms and ammunition with gunshot entries.

Analysis of Projectiles. Elemental composition is a well-established point of comparison for source discrimination for many types of materials that cannot be distinguished on the basis of their physical properties [57]. One application where elemental analysis has been used is the compositional analysis of bullet lead (CABL). In the past, NAA enabled good discrimination between various lots of bullets [58]. Recently, ICP/MS has been successfully used for this purpose as it is one of the most sensitive methods for elemental analysis [59, 60].

It was shown that considerable variability exists among lead sources despite manufacturers' efforts to control the concentrations of selected elements [57]. On the other hand, in a considerable number of cases, very different elemental signatures may be found even within a single box of bullets, in particular, regarding trace elements [60]. Randich *et al.* [61] have shown that data for lead alloys supplied to two major ammunition manufacturers confirm that multiple indistinguishable shipments of lead alloys from secondary lead refiners to the ammunition manufacturers are made each year and over a period of many years. They have also shown that distinguishable compositions can come from the same melt or "source" of lead alloy. Therefore, they argued "that there is no scientific validity to any conclusions more positive than attributing the possible association as to molten source among bullets from different samples". A similar view was expressed in the recent report on the subject by the US National Academy of Sciences [62].

In examination of very small bullet fragments found in victim's clothing, the risk of contamination from various sources increases, making the trace element analysis less suitable. In such circumstances, a more suitable method for comparison of small quantities of lead is the determination of lead isotope composition, measured as lead isotope ratio [63].

Lead occurs in nature as a mixture of four stable isotopes. Three of these isotopes, having atomic masses of 206, 207, and 208, are the end products of three natural radioactive decay series. The fourth isotope of atomic mass 204 occurs naturally as a nonradiogenic isotope. There is a relatively large variation in the lead isotopic composition in nature. This fact may be useful for discrimination of various sources of lead in ammunitions. Several technologies were used to measure lead isotope ratio in research and casework for discrimination between ammunitions: thermal ionization mass spectrometry (TIMS), sector field-inductively coupled plasma mass spectrometry (SF-ICP/MS), and secondary ionization mass spectrometry (SIMS) [59, 60, 63, 64]. Recently, a new technology of multicollector inductively coupled plasma mass spectrometry (MC-ICP/MS) has been introduced in the field, resulting in better performance, sample throughput, precision, and accuracy with respect to the isotope ratio as compared to the previous technologies mentioned above [65].

It was shown [66] that various mechanical or chemical methods of cleaning do not completely remove lead deposits ("lead memory") from barrels of firearms as was found for GSR. The implication of this effect is that the lead isotope composition of an FDR deposit collected from a barrel at a certain time will be a combination of the lead deposits produced by various firings prior to the sampling. Consequently, this phenomenon lowers the level of association that may be obtained by comparative analysis of lead between a firearm, the fired ammunition, and the gunshot entry in a particular shooting.

Estimation of Time Since Discharge

In a series of papers, Andrasko *et al.* [67–70] presented a novel method for estimation of time since discharge for some types of weapons and spent cartridge cases. Using solid phase microextraction (SPME), samples are taken from the atmosphere inside the barrel of the weapon or the cartridge case and analyzed by GC/TEA, GC/FID or GC/MS, all of which can detect a variety of combustion products. Estimation of time since last discharge is based on the escape rate of the volatile discharge residues from the barrel or the cartridge case as a function of time. The method was studied for shotguns, rifles, pistols, revolvers, and spent cartridges cases. The type of ammunition used, the temperature of storage, cleaning of the barrel after shooting, and the number of shots fired can all influence the results.

Firearm Examination: Ballistics

Internal Ballistics

The Association of Firearm and Tool Mark Examiners (AFTE) Glossary defines internal ballistics as "the study of the motion of the projectile(s) within the firearm from the moment of ignition until it leaves the barrel" [1].

When the firing pin strikes the primer[a] of a cartridge,[b] the priming compound inside the primer is crushed between the anvil (which may form part of the cartridge case or part of the primer itself) and the firing pin. This causes the priming compound to detonate, producing a flash which in turn ignites the propellant. The propellant inside the cartridge then begins burning. It should be noted that the propellant burns very rapidly but does not explode. As the propellant burns an enormous amount of gas is formed, which in turn causes pressure to be built up within the cartridge. The pressure continues to increase inside the cartridge. Eventually the projectile begins to move out of the mouth of the cartridge case and enters the lead; at this point the projectile makes contact with the rifling,[c] which retards the movement of the projectile due to the sudden resistance increase between the projectile and the rifling. The pressure exerted on the base of the projectile overcomes this resistance and the projectile moves forward, rotating with the rifling. The pressure caused by the build up of gases will accelerate the projectile's movement down the barrel until the projectile leaves the muzzle [2–4].

The following scenario serves as an example in which the study of internal ballistics may play a role in the examination of an internal ballistic–related case. Mr X, a well-known hunter and reloader, is out one day testing his latest "load" for his next hunting trip. The first cartridge that is fired causes the firearm to "blowup", severely wounding Mr X. The firearm together with the reloaded ammunition is submitted to the forensic firearms laboratory. In the first instance, the forensic firearm investigator would examine the fired cartridge case and any cartridges for signs of pressure and overloading. Additionally, through the aid of different types of testing equipment, such as pressure barrels fitted with piezoelectric transducers,[d] the amount of pressure generated inside the submitted reloaded cartridges can be measured and recorded. This will aid the forensic firearm investigators in determining whether or not the pressure generated by the reloaded cartridges meets the set specifications, such as those developed by Sporting Arms and Ammunition Manufacturers' Institute (SAAMI) or Commission Internationale Permanente (CIP), with respect to the amount of pressure that can be safely generated by a specific cartridge. If it is found that the generated pressure exceeds the recommended maximum pressure, the reason for the firearm blowing-up could possibly then be attributed to possible incorrect reloading procedures having been followed [3, 5, 6].

Specialized equipment used to measure chamber pressure, such as pressure barrels fitted with piezoelectric transducers, is not necessarily found in all the forensic ballistic laboratories. In some cases, it may be necessary to seek the assistance of a commercial ammunition manufacturing facility, an ammunition/firearm "proof"[e] facility, or another government agency to assist in a specific instance where chamber pressures need to be established.

The internal ballistic properties of a firearm and cartridge will determine a number of factors, such as projectile speed, rate of spin, stability in flight, and recoil.

Intermediate Ballistics

Intermediate ballistics is defined by Moss *et al.* " . . . as the study of the transition from internal to external ballistics, which occurs in the vicinity of the gun muzzle" [5, p. 53].

Intermediate ballistics is a field of study, which is positioned between the fields of internal and external ballistics. Following the firing process, there are also a number of other components, besides the projectile, which exit the muzzle. These are known as *gunshot residues* (GSRs) and consist of primer residues, gases produced by the burning propellant, soot, partially burnt and unburnt propellant particles, and particles arising, from the projectile. These components affect the intermediate ballistics.

The intermediate ballistics of a firearm influences a number of factors associated within the field of forensic ballistics, such as the accuracy of the projectile, level of noise created during the firing process, muzzle flash,[f] and the dispersion of primer residues, soot and burnt and partially burnt propellant particles. Thompson [6, p. 159] is of the opinion that the region of intermediate ballistics extends down range from the muzzle of the firearm to the point where the projectile finally passes out of the influence of the propellant gases. He states that the region of intermediate ballistics is typically " . . . half a dozen or so calibres long . . .". However, depending on the ammunition and firearm type, this may extend to a greater distance from the muzzle [2, 4, 6, 7].

Besides the theoretical aspects surrounding intermediate ballistics, the study of intermediate ballistics

from a forensic firearms perspective is more concerned with how it relates to the field of range determination. This is discussed in section "Range Determination".

External Ballistics

External ballistics can be defined as a study of the projectile's trajectory between the muzzle of the firearm and the target, and the influence that various factors have on the trajectory of the fired projectile. The question of "where did that shot come from?" is typically answered through the study of external ballistics. As has already been alluded to, there are a number of factors that influence the trajectory of a projectile. These include the projectile's mass, caliber, shape, sectional density, spin, etc. There are also external factors that influence the trajectory of a projectile, and these include atmospheric density, temperature, pressure, viscosity, and gravity [1, 6].

The forensic firearms investigator will mainly use external ballistics to determine the position from where a projectile could have been fired through trajectory[g] determination. This is often important in reconstructing a shooting incident.

The remaining speed, energy, time of flight, and drop for a projectile can be determined for specific distances based on tabulated information. A trajectory of a projectile can be calculated and determined through the use of various mathematical formulas and calculations, which is a very complex and time-consuming process. Trajectories of projectiles are now solved through the use of external ballistics computerized programs. A number of these programs are available on the commercial market. The more accurate programs are those that will allow the input of the angle of incidence (entry into the target) and projectile details such as caliber, ballistic coefficient, muzzle velocity, etc., and will be able to essentially work backward to calculate the possible point of discharge of the firearm. One should always keep in mind that although it might be possible to determine an area where a firearm was discharged, the *exact* position of the shooter is often difficult to pinpoint, particularly over long ranges [6].

Terminal Ballistics

Terminal ballistics can be divided into two sections, namely, terminal ballistics with respect to the study of nonbiological matter and terminal ballistics with respect to the study of biological matter (which is commonly referred to as *wound ballistics*).

Terminal Ballistics (Nonbiological Matter)

Terminal ballistics is defined in the AFTE Glossary as "the scientific study of the impact or penetration of projectiles in any substance heavier than air and their effects on the object struck" [1].

Terminal ballistics looks at the effect that the projectile has on the object (target) and the effect that the object (target) has on the projectile. When a forensic firearm investigator is called upon to reconstruct a shooting incident, he or she is faced with the terminal effects that the fired projectile had on its target. With this information, the forensic firearm investigator can assist in the reconstruction of the scene of a shooting incident. It is important therefore to be able to interpret the terminal effects of the fired projectile. A fired projectile will invariably do one of the three things, or a combination thereof, when striking an object. It will penetrate an object, or perforate an object, or ricochet from an object.

Terminal Ballistics (Biological Matter)

Wound ballistics is defined in the AFTE Glossary as "the scientific study of the effects of penetrating projectiles on the human or animal body. It is a branch of terminal ballistics" [1, 2].

No study of wound ballistics would be complete without a thorough understanding of the human anatomy. Besides the obvious importance of being able to better understand the interaction between a projectile and various parts of the human body that may be struck by a projectile, an understanding of human anatomy will place the forensic firearms investigator in a better position to interpret the results of a medicolegal examination report.

An important aspect of wound ballistics involves the mechanism by which a wound is created. In some instances, these "aspects" are visible and in other "aspects" they may not be so visible [4].

The identification of wounds plays an important role from an investigative perspective. This includes the correct identification of a wound, be it an entrance or exit wound, as well as correctly identifying the general characteristics of the wound that may indicate the range at which the shot was fired [2]. In some

jurisdictions, notably in the United States, courts have required that, beyond the investigator's visually perceived description, the study of wounds requires the testimony of a forensic pathologist or medical examiner's assistance with training in gunshot wounds.

One of the most evidential aspects of terminal ballistics, from a forensic perspective, is the ability of the forensic firearms investigator to determine the range at which a shot was fired. This can play a significant role in either supporting or refuting an allegation of the distance between the muzzle of the firearm and the target (victim) at the time the firearm was discharged.

Range Determination (General Aspects)

Range (distance) determination is defined by the AFTE Glossary as "The process of determining the distance from the firearm, usually the muzzle, to the target based upon patterns of gunpowder or gunshot residues deposited upon that target. Where multiple projectiles, such as shot, have been fired the spread of those projectiles is also indicative of the distance." The aforesaid approaches consider that standard ammunition is used for both rifled and smooth-bored barrels (firearms) [1].

The value of accurately determining the distance between the muzzle of the firearm and the target lies in either supporting or refuting an allegation relating to the position of the shooter and the target (normally the victim). For this very reason, it is essential that the forensic firearms investigator correctly identifies and evaluates the evidence that he or she has before him or her in determining the correct range.

A factor that must always be kept in mind with cases involving the determination of the range between the muzzle of the firearm and the target is that an exact distance can never (and should never) be given. The result obtained from conducting a range determination examination will provide the forensic firearms investigator with a minimum and maximum range between the muzzle of the firearm and the target or a median value with uncertainties.

Range determination can be divided into two sections, namely the range at which a shot was fired with a cartridge loaded with a single projectile, such as those used in rifles and handguns (where the examination of GSR is used to determine the range) and the range at which a shot was fired with a cartridge loaded with multiple projectiles, such as pellets loaded in shotgun cartridges (where the examination of the spread of shot is used to determine the range) [2, 4, 7].

Generally, rifle-barreled firearms are used to shoot single projectiles and smooth-bore firearms (shotguns) are used to fire cartridges loaded with multiple projectiles (pellets). However, shotguns are also commonly used to fire single projectiles such as rifled slugs.

Range Determination (Single Projectile Cartridges). With respect to range determination involving a rifled barrel, the forensic firearms investigator relies on the pattern of GSRs found on the target to determine the range between the muzzle of the firearm and the target.

When a cartridge with a single projectile is fired, not only does the projectile exit the barrel but so does soot, gaseous primer residues, partially burnt/unburnt propellant and projectile particles (i.e., GSRs). These gaseous residues and particles disperse from the muzzle of the firearm expanding in diameter with distance from the muzzle of the firearm. As these particles are very light they do not travel far from the muzzle and in many cases are unlikely to strike a target further than 1 m away. The further these particles move from the muzzle of the firearm the larger diameter and less dense this circular pattern becomes [2, 4, 7].

On the basis of the examination of the GSR pattern, the forensic firearms investigator can conduct test firings using the same firearm and ammunition onto similar target surfaces to determine the approximate distance between the muzzle and the target. It is common practice to enhance the lead and propellant present in a GSR pattern using colorimetric tests [7].

Range Determination (Multiple Projectile Cartridges). The fundamental principles involved in determining the distance at which a shot was fired with using single or multiple projectile cartridges are closely related. With cartridges loaded with multiple projectiles, the method used to determine the range between the muzzle of the firearm and the target primarily involves the examination of the spread of the pellets. Therefore, it is possible to estimate the firing range over a relatively long distance. As with cartridges loaded with single projectiles, the presence

of GSRs on a target does have significance when it comes to a shot at a close range [7].

Barrel length, whether a cartridge is loaded with a single or multiple projectiles, is relevant to the amount of GSR emitted from the muzzle.

The main factor that is considered when determining the range between the muzzle of the firearm and the target when using a cartridge loaded with multiple projectiles is the spread of the pellets. This is due to the fact that when a cartridge loaded with pellets is fired using a smooth-bored firearm, the pellets in a pattern will spread in a reasonably predicable manner. As the distance between the muzzle of the firearm and the target increases, the diameter of the pellet pattern increases and the density of the pellet pattern decreases. The pattern can be reproduced by conducting tests with the same firearm and ammunition so as to determine an approximate range between the muzzle and the target [2, 7].

End Notes

[a.] A primer contains a stable but shock-sensitive explosive mixture, which when struck (typically by the firing pin) explodes and ignites the propellant held within a cartridge.

[b.] A cartridge is a single unit of ammunition consisting of a primer, cartridge case, propellant, and projectile(s).

[c.] A combination of helical grooves, which are either cut or formed inside the barrel of a firearm. The purpose of rifling is to impart spin on a projectile, which aids in the stabilization of the projectile in flight.

[d.] A piezo-electric transducer is a device that can be used to measure pressure through the use of a quartz or tourmaline crystal.

[e.] A "proof facility"' is a facility which tests the safety of a firearm or ammunition by measuring the pressure generated in the firearm (using overloaded cartridges) or ammunition during test firing.

[f.] Muzzle flash occurs when the hot gasses and burning propellant particles exit the muzzle of the firearm along with the fired bullet and mix with the oxygen in the surrounding air.

[g.] A trajectory of a fired bullet can be described as the curved path, which the fired bullet follows between the muzzle of the firearm and the target.

Firearms: Bullet and Cartridge Case Identification

Overview

The identification of fired cartridge cases and fired bullets to the firearm responsible for their discharge is correctly termed *firearms identification*. This is a subdiscipline of the field of forensic firearms

investigation and is wholly laboratory based due to the need for specialized equipment including a comparison microscope, camera(s), sensitive scales, and other measuring apparatus.

Firearms identification is by far the most specialized form of toolmark examination. In firearms identification, the firearm is the "tool", while the ammunition components receive toolmarks as they come into contact with various components of the firearm during the loading, chambering, firing, extraction, and ejection cycles. For example, the passage of the bullet through a barrel will cause a striated toolmark along the long axis of the bullet where it is in intimate contact with the bore, while the firing pin will cause an impressed toolmark where it strikes the primer of the cartridge upon discharge.

Whereas traditional toolmark examinations can sometimes be very difficult to successfully carry out due to the enormous amount of variation possible during their formation, firearms identification is simplified in that the cartridge will be marked more or less in the same predictable manner every time the firearm is discharged. Despite this, however, firearms identification is often challenging. Competent experts require a broad knowledge of firearms and their operation, ammunition types, the principles of toolmark identification, manufacturing techniques, materials science, and various optical instruments to make correct determinations. There are several main texts dealing with the technicalities of firearms identification [1–4].

Toolmarks

In order to understand firearms identification, a brief discussion on toolmarks and a description of some important definitions is necessary. A toolmark is formed when a harder object comes into contact with a softer object with sufficient force to cause deformation to the softer item. If the two items are of similar hardness, and if sufficient force is applied, both items will be deformed and damaged to some degree. There are two main types of toolmarks: striations and impressions, although a toolmark can consist of a combination of these two marks. The quality of any toolmark produced is dependent on variables such as the amount of force used in its formation, the relative angles between the two objects when they make contact, and the relative hardness of the two objects. Also relevant is the amount of use the tool has had since making the original mark as that part of the tool responsible for making any mark may change with use, abuse, corrosion, or by other means. If a tool surface changes over time for whatever reason, test marks made with the actual tool may not be able to be identified to a toolmark in question owing to the changes to its microscopic features.

Striations

Striations are formed when force is applied by a harder object along the surface of a softer object, leaving a series of parallel scratches, referred to as *striae*. The depth and spatial relationship of the striae to each other are made by the features existing on that part of the tool in contact with the softer item. The features responsible for making the marks may be quite gross and visible to the naked eye, but usually a microscope and correct lighting is needed to visualize them properly.

Impressions

Impressions are formed when a harder object contacts a softer object without either surface sliding against each other. The features existing on the surface of the harder object are then recorded on the softer object, creating a negative pattern of the detail where contact was made. Again, the features responsible for making the mark may be coarse and visible to the naked eye, but a microscope with correct lighting is normally needed to visualize them properly.

Class Characteristics

Class characteristics refer to the design features of any particular tool, and are determined prior to manufacture. They are usually discernable to the naked eye. An example of class characteristics in a firearm include the bore diameter, the number, width and depth of the lands and grooves cut or formed into the bore, and the direction and rate of twist of the rifling. Class characteristics are used to determine the type of firearm used in a shooting incident, or at least narrow the field of search considerably. Manufacturers of firearms and tools are free to employ whatever class characteristics they wish when making their products, hence many firearms from

different makers have similar class characteristics, resulting in a large group of firearms that leave similar marks. Conversely, manufacturers sometimes choose such unusual class characteristics that it can narrow the search considerably to one or only several possibilities, to the exclusion of all others.

Some simple examples of using class characteristics in a practical sense follow:

- A .30 caliber bullet can be excluded as having been discharged from a firearm with a .22 caliber bore.
- A .32 caliber bullet with rifling engravings of six lands and grooves with a left twist can be excluded as having been fired in a second .32 caliber firearm with six lands and grooves with a left twist, if the widths of the lands and grooves differ.
- A .22 caliber fired cartridge case with a round hemispherical firing pin impression could only have been discharged from other .22 caliber firearms with firing pins that leave the same size and shape firing pin impressions, assuming there are no other discernable class characteristics present on the cartridge case to narrow the field of search further. All .22 caliber firearms that do not leave the same shape and size of firing pin impression can be excluded as having discharged that cartridge.

Subclass Characteristics

Subclass characteristics are a smaller group within any set of class characteristics and are created during manufacture. They are reproducible features resulting from manufacturing processes that can be mistaken for individual characteristics. The highest potential for the production of subclass characteristics occurs in components that have been consecutively manufactured – the toolmarks left behind by the various machining processes using the same tool may not change appreciably over time on successively made items. Therefore, it is important to understand the manufacturing processes that are applicable to various firearm components and establish what changes can be distinguished over time in the microscopic imperfections of consecutively manufactured components. If subclass characteristics are present on any firearm part, these may or may not be confused with any individual marks left on ammunition components, depending on the orientation of the subclass features to the surface being marked.

Individual Characteristics

Individual characteristics are irregularities or features that are randomly acquired or generated and are crucial in the identification process. They are normally microscopic in nature and require correct illumination under a microscope to be seen. They are formed during manufacture and with use of the item, although subsequent abuse, corrosion, and damage can create further individual characteristics over time. Individual characteristics allow the expert to definitively identify, or exclude, a firearm as having discharged a bullet or cartridge case.

The Comparison Microscope

The comparison microscope is the most important instrument used in the forensic firearms laboratory and its basic features have not changed much since its introduction to the field of forensic firearms in the mid-1920s. The comparison microscope is essentially two microscopes joined together with two sets of stages movable in the x, y, and z axis, various adjustable light sources, and two sets of objective lens. By virtue of an optical arrangement in the bridge, both fields of view are connected so that two separate items can be simultaneously compared under the same magnification. Features vary slightly between makes and models; however, all have the ability to move the stages either independently or in concert. An important and necessary feature is a prism within the bridge, which creates a central vertical dividing line between both fields of view. When the central divider is moved from left to right, it enables the relative positions of various class and individual features to be easily viewed and compared.

The light sources can include incandescent bulbs and optic fiber types. However, the type of lighting utilized is not as crucial as providing even illumination from the same relative angle to the items being compared. As toolmarks are three dimensional, both striated and impressed marks are visualized by shining light obliquely across their surface topography. This causes shadows and reflections, which are seen as light and dark areas within the field of view. If the intensity of the light sources differs or the angle of

the light source differs substantially between the two sides, the resultant images formed will be dissimilar, making the comparison difficult, if not impossible.

The range of magnification used on the comparison microscope for most work varies between approximately 8× and 40×, although some circumstances may require lower or higher magnifications from 2× to 100×. It would be considered very unusual to observe toolmarks at magnifications over 100× using an optical microscope. Some European agencies have utilized scanning electron microscopes (SEMs) fitted with dual stages for comparisons of toolmarks; however, this is not the norm and this equipment has not been adopted by most forensic firearms laboratories. The advantage of using an SEM for comparisons is that the limited depth of field experienced at high magnification when using an optical system is negated.

Modern comparison microscopes can be fitted with cameras for both still photographs and video recording. Digital cameras are becoming more commonplace owing to their ease of use and the ability to print immediately, allowing instant assessment of the quality of the image. Measurements can also be taken using the microscope by a variety of means including graduated eyepieces and micrometers, and digitally.

The stages are usually multiadjustable to allow bullets and cartridge cases to be manipulated in three dimensions. This allows for every surface of the items to be examined minutely and optimizes the correct positioning to best visualize important or identifying features.

Bullet Identification

The forensic firearms expert faces three main types of problems when carrying out bullet comparisons. The same three problems are also applicable to fired cartridge cases.

1. Given a fired bullet, determine what type of firearm could have discharged it.
2. Given two or more bullets, determine if one or more firearms were used and how many bullets were discharged from each. There is still a requirement to also determine, if possible, what type of firearm was used.
3. Given one or more bullets and one or more firearms, determine which firearms discharged which bullets.

Finding answers to the problems above is achieved by using the comparison microscope and associated equipment to examine the class and individual characteristics of the fired bullets, imparted by the firearm responsible.

When bullets are fired through firearms with rifled barrels such as pistols, revolvers, and rifles, the circumference of the bullet in contact with the bore is engraved with the rifling existing in that barrel. The rifling is a series of helical grooves cut or formed into the inner surface of the barrel to impart a spinning motion to the projectile around its long axis. This spinning motion provides gyroscopic stability to the bullet and therefore, accuracy after it leaves the barrel. The number, width, and depth of the grooves, the direction of twist (clockwise or counterclockwise), and the rate of twist are determined by the manufacturer. These class characteristics vary from one firearm to another, but some forms of rifling are more popular and common than others.

The grooves in the rifling are unsurprisingly referred to as *grooves*, while the proud areas between the grooves are referred to as *lands*. The rifling engravings left on a fired bullet are therefore referred to as *groove impressions* and *land impressions* and they will slant to either the right or left side from the long axis of the bullet depending on whether the rifling rotated clockwise or counterclockwise, respectively.

In order to determine which type of firearm may have discharged a fired bullet (assuming no firearm was recovered), the rifling characteristics engraved by the responsible firearm are measured on the bullet. A comprehensive database of firearm manufacturer's specifications can then be referred to, which will eliminate most firearms, leaving only those with the same class characteristics. The Federal Bureau of Investigation compiles and regularly updates the most comprehensive reference data available for this task, referred to as the *general rifling characteristics* (*GRC*) file. This is made available free of charge to government forensic firearms laboratories worldwide upon written request.

It is evident that the absence of a suspect firearm does not preclude microscopic comparisons if two or more bullets are submitted to the laboratory. But if one or more suspect firearms are also submitted, test-fired samples have to be obtained to allow direct comparison. If test firing is to be carried out, all class characteristics of the suspect firearm(s) must first be

undifferentiable from the class characteristics seen on the crime bullets. Firearms with different class characteristics from those seen on the bullet can be eliminated as being responsible; there would be no need to conduct a microscopic comparison as they could not have been discharged from a weapon with incompatible class features.

Bullets recovered from crime scenes are rarely in good condition as they have usually impacted with various objects, including people, causing varying degrees of deformation. Therefore, the key consideration when test firing suspect firearms is to recover the bullets in a pristine condition, unmarked except as a result of its passage through the bore. Ideally, the bearing surface – the portion of the bullet in contact with the bore – should not be distorted or shortened from excessive mushrooming. This ensures that the entire striated surface of the bullet is available for examination, maximizing any information present.

Testing is usually carried out into a large water tank, although a number of other mediums, such as cotton waste and sawdust, have been used to trap fired bullets. If bullets are of hollow point design or of high velocity (greater than approximately $610\,\mathrm{m\,sec^{-1}}$), they will often fragment upon striking the water. Recovery in waste cotton can often address this issue. Such cartridges can also be "downloaded" by removing the bullet and reducing the amount of propellant in the cartridge case. This will normally reduce the velocity sufficiently to ensure that the bullet does not break up or overexpand when striking the water.

At least three test shots are initially discharged when preparing comparison samples but more are often required if the test results are poor. Ammunition that is the same as used in the crime should be chosen for the tests, or as close as possible to it if unavailable. For this reason, forensic firearms laboratories usually have large ammunition reference libraries containing as many different calibers and loads of ammunition possible, to ensure a suitable type is available for most situations.

Before the crime bullets are compared, comparisons should always be made between the test-fired bullets to assess the quality and quantity of individual characteristics present. The quality of the test results may be variable if the bore is rusty, pitted, or contains other debris that is expelled on each subsequent shot. If one test bullet cannot be matched with another, there is little hope of matching a test to a crime bullet. Another advantage to carrying out a test-to-test comparison is to check the functioning of the comparison microscope and that the magnification on both sides is even. Once the expert has established which features are consistently reproducing on the test-fired samples, those features can then be searched for on the crime bullet(s), firstly to correctly orientate the test to the crime bullet, then to either identify or exclude it as having been fired from the suspect firearm.

There are three main conclusions that can be reached upon completion of the microscopic comparison of fired bullets:

1. The bullet can be identified as being discharged from the firearm serial no. *xxxx.*
2. The bullet can be excluded as being discharged from the firearm serial no. *xxxx.*
3. The comparison is inconclusive; the bullet cannot be identified or excluded as having been fired in the firearm serial no. *xxxx.*

Inconclusive results are quite common. Often excessive damage has been occasioned to the bullet, or for various reasons there has been a lack of reproducibility of individual characteristics. Some laboratories may be more definitive in the event an inconclusive result is reached and divide an inconclusive result into further categories, which suggest a greater possibility, or not, as having been discharged from the firearm in question. All that the expert can honestly state, however, is that the bullet *may* have been discharged from the suspect firearm, *or any other firearm with those same class characteristics.*

The opinion formed by the expert must be based solely on his examination. It should not be colored by any other considerations such as being privy to other information in an investigation, which may suggest the guilt, or otherwise, of any person. As an example, eye witnesses may identify a person as having carried out a shooting. If this information is stated in the accompanying report when the examination is requested, this may create the belief in the mind of the expert that he will definitely be able to identify ammunition components to the firearm submitted for examination. All experts must be aware of the effect of "confirmation bias" when carrying out examinations.

In order for the expert to competently carry out bullet and cartridge case comparisons, there is a requirement to understand what constitutes an

identification and what does not. In other words, how much agreement in the individual characteristics is required to definitively state that a firearm, to the exclusion of all others, was responsible for discharging a bullet. This skill is developed over time underpinned by training, knowledge, and experience. But the only way to gain this understanding is to conduct thousands of "known matches" and "known nonmatches" using the comparison microscope.

When comparing bullets that have been test fired from the same firearm, the expert is comparing "known matches". There is no question that the bullets were fired from different guns, so the amount of agreement of striae on the bullet's bearing surface is usually substantial. That is not to say the majority of striae agree in known matches, for each comparison is different and the number of matching striae will vary. There is always a small amount of striae that do not match, but as long as the expert can reconcile the reasons for this, this is not an issue.

However, if the expert compares bullets he *knows* have been fired from two different firearms (with the same class characteristics), he is comparing "known nonmatches". The amount of matching striae in these situations is minimal. There is always some random matching of striae, but it is far less than what is seen in a known match. The expert therefore develops a "feel" for what constitutes an identification and what does not. Since the 1990s, however, this subjective approach has been criticized more and more by defense counsel, particularly in the United States. Their argument has been that this method is unreliable. To address these criticisms, conservative criteria for the identification of striated toolmarks was further developed and exhaustively tested. This approach to tabulating what is seen when comparing striated toolmarks is commonly referred to as *applying the principles of consecutive matching striae* (*CMS*).

Consecutively Matching Striae

CMS are sets or series of scratches that successively match without interruption, within a striated toolmark. Applying CMS to a striated toolmark simply allows the expert to *quantify* what is seen through the comparison microscope. After comprehensive research, two sets of conservative criteria were reached, one for two-dimensional marks and the other for three-dimensional marks, to allow the expert to confidently state whether an identification existed or not. CMS was not devised to replace the traditional subjective approach to matching striae, but to supplement it. Arguably, its greatest utility is application to toolmarks that are borderline as to whether an identification can be determined or not. If the criteria was met or exceeded, an identification could be reliably reported.

The conservative criteria for identification is as follows [5]:

In a two-dimensional toolmark, that is, a toolmark that has no appreciable surface contour, two groups of at least five matching striae appear in the same relative position or one group of eight.

In a three-dimensional toolmark, a toolmark that has discernable surface contour, two groups of at least three matching striae appear in the same relative position or one group of six.

In both cases, the possibility of any subclass characteristics influence must be ruled out.

Experience has shown that applying CMS could result in an identification being classed as inconclusive; this is due to the conservative nature of the CMS criteria. However, to date, it has never been reported in the literature that an identification has been erroneously arrived at by applying the CMS regime. Not all experts within the field of firearms and toolmarks agree on the necessity to apply CMS in conjunction with the traditional "pattern matching" approach, but it is accepted by many practitioners as being a valid additional tool to apply during the comparison of striated marks.

Cartridge Case Identification

Whereas bullets are normally engraved only with striated marks, cartridge cases are usually marked with a combination of striated and impressed marks. There is currently no criteria for the identification of impressed toolmarks; however, studies have been conducted into this issue[6, 7]. As the cartridge undergoes the loading, chambering, firing, extraction, and ejection processes, different components of the firearm mechanism contact various portions of the cartridge case, leaving a mark. As the cartridge case is made of a softer material than the action of the firearm, it will be marked accordingly. The main components that leave marks are those made by the firing pin, breech face, extractor, ejector, chamber,

the anvil, (in rimfire firearms) and the magazine. An identification of any or all of these marks can be made but only some (the firing pin, the breech face, and the anvil) are indicative of a discharge. Others indicate that a cartridge may only have been chambered in the firearm or cycled through the action.

Firing Pin Impressions

The firing pin (or hammer nose or striker, depending on the firearm) is responsible for striking the primer, thereby causing a discharge. An impressed mark is the normal result and its size, position, and spatial relationship to the other marks are important class characteristics. The tip of the firing pin usually contains sufficient individual characteristics to identify the firearm responsible, without the need to rely on additional marks. It should be kept in mind however that the firing pin, like many of the components relied upon for the comparison of fired cartridge cases, can be removed and changed so *all* the marks on a fired cartridge case should be taken into consideration before a conclusion is reached.

Breech Face Impressions

Breech face impressions are caused when the head of the cartridge is forced rearwards against the breech face upon discharge. The gas pressure, which drives the bullet from the barrel, also pushes in all other directions from within the cartridge case. In particular, the rearward action of the case opposite to the direction of the bullet will often leave an imprint of the features of the breech face on the case head. The primers of centerfire cartridges are especially prone to being marked by the breech face as they are made of a softer, thinner metal than the cartridge case.

The marks caused by the breech face are indicative of the machining processes used to form that part of the firearm. For example, if a milling machine was used to cut a circular recess for the case head, it could be expected that microscopic circular machining marks were left behind as a result of that process. A filed breech face might leave parallel marks on a case head – these may appear to be striations; however, the mark is still an *impression* of those striations. Other features of the breech face may also leave identifiable marks such as the aperture cut for the firing pin and various recesses cut for other components such as the extractor and ejector. If these shapes are present, they are often excellent class characteristics to assist determining the type of firearm used in their discharge.

Extractor Marks

The extractor is a small component on the side of a breech bolt that assists in removing a fired cartridge case or unfired cartridge from the breech of the weapon. As the action is opened, the extractor moves rearwards, whether attached to the breech bolt (as in a bolt action rifle) or not (as in a break action shotgun). The extractor may leave an impressed or striated mark, or both, depending on its particular arrangement in the firearm. The extractor on a self-loading firearm is more likely to leave a mark than, for instance, the multiple extractor of a revolver. This is primarily due to its greater relative force and speed of its operation.

The position of the extractor mark in relation to other marks is a useful class characteristic. If the mark contains sufficient individual characteristics, it may be used to identify a particular firearm.

Ejector Marks

The ejector is used to expel a fired case or cartridge from the weapon. Ejector marks are caused by the tip of the ejector as they make impact with the case or cartridge. A part of the mechanism, usually opposite the extractor, pushes on the cartridge rim. The rotating force produced while the extractor still grasps the rim on the other side, throws the cartridge or case from the action in a spinning fashion. The speed and force applied to the action when operated will often affect how far the case is thrown from the firearm and may also affect the quality of the ejector mark.

The position, shape, and size of the ejector mark are useful class characteristics. If the mark contains sufficient individual characteristics, it may be used to identify a particular firearm.

Chamber Marks

Chamber marks are produced by irregularities within the chamber, whether formed by the manufacturer such as an extractor cutaway, or by damage or corrosion. Chamber marks can consist of impressed

or striated marks. Impressions are produced when the case wall expands into unsupported areas of the case wall, while striations are caused when irregularities within the chamber scrape against the case wall upon loading, or more likely, upon extraction. They may be used to provide proof of discharge but as they may also be indicative of chambering only, some caution must be exercised when examining these marks to ensure the correct cause is determined.

Anvil Marks

Anvil marks are applicable to rimfire cartridge cases. When a rimfire cartridge is placed in the chamber, the rim of the cartridge overlaps the chamber mouth. The anvil could then be said to be an area extending outward in a ring, several millimeters from the chamber mouth. (In centerfire cartridges, the anvil is part of the cartridge itself and is located within the primer.) The anvil will be the location directly opposite the firing pin – this could be located at any point within 360° dependent on where the manufacturer has designed the position of the firing pin. Upon discharge, the cartridge rim is sandwiched between the tip of the firing pin and the anvil. This process will impart an impressed mark into the underside of the rim and any individual features existing at that location can be used to identify the firearm responsible.

Anvil marks have a much greater potential to be useful for identification if the firearm has been repeatedly dry-fired. Dry firing is the firing of a firearm when no cartridge is present. In a rimfire firearm, the firing pin will strike the anvil. Deformation to the chamber mouth and possibly the firing pin itself will occur over time, giving both the anvil and firing pin further individuality.

Miscellaneous Marks

Other parts of the firearm sometimes leave marks on cartridge cases, but these are usually due to particular peculiarities of a firearm and/or ammunition. These components can include magazine lips, ejection ports, feed ramps, and other parts dependent on how the action works.

Marks can also be accidental in nature and unrelated to the firearm. Cartridges that have been placed in a pocket with keys and coins, or left in a toolbox with tools may be marked at random by any number of hard surfaces. Noticeable marks can also be left by the cartridge manufacturer on ammunition components, which survive the firing process. Sometimes it is impossible to determine if a mark was firearm related or not, without the responsible firearm available for examination and testing.

Firearms: Identification of Handling of Firearms/Trace Metal Detection

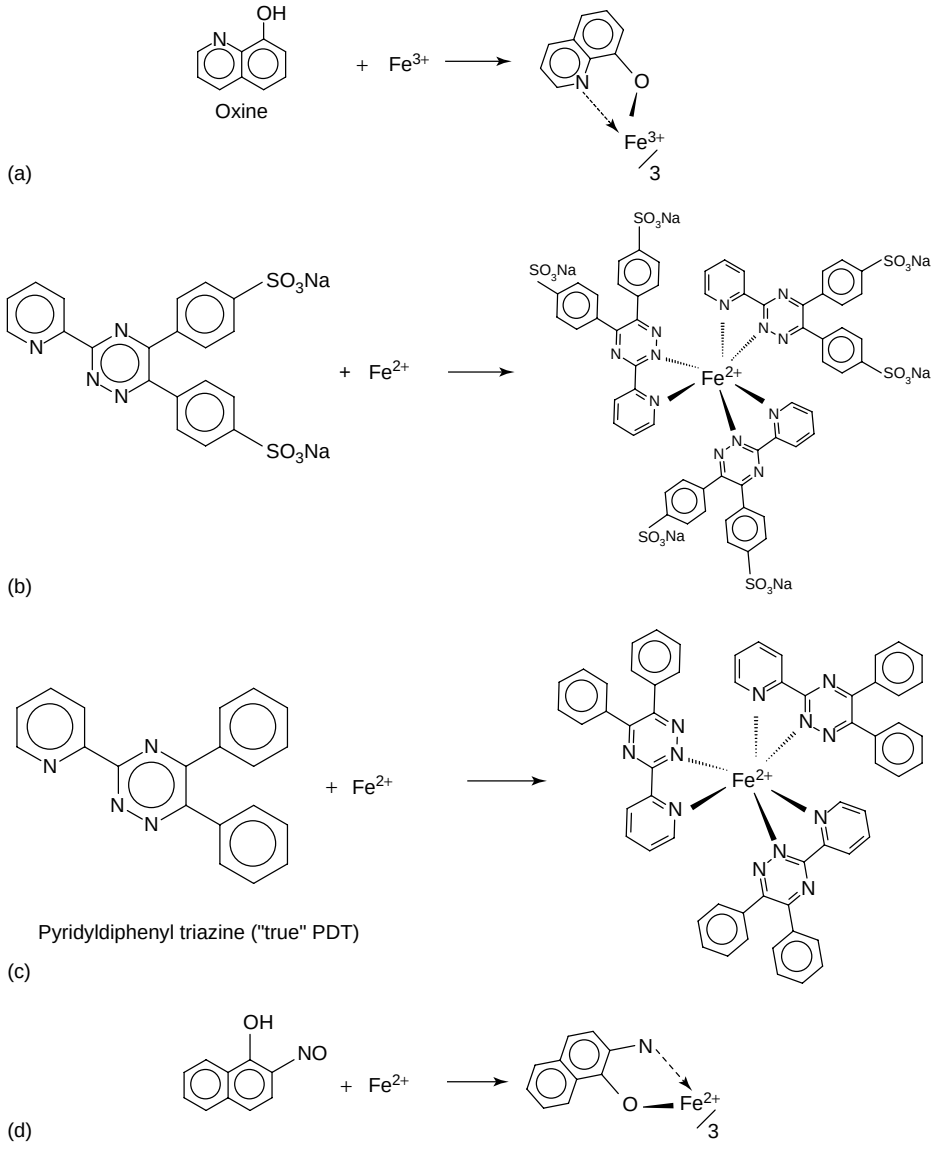
In the investigation of crimes involving the use of firearms, the forensic scientist is often asked to demonstrate a link between a suspect and a weapon. In homicide and suicide–homicide investigations in

which death is caused by shooting, a crucial question often is, who held the gun? The development of the scanning electron microscope (SEM)-based method for the unequivocal identification of gunshot residue (GSR) on the hands of a person suspected of having fired a weapon did not resolve the problem (*see also* **Firearm Discharge Residue: Analysis of Microscopy: Scanning Electron Microscopy**). The microscopic particles associated with the firing action are difficult to find, and their presence on the particular person does not necessarily prove that he fired the weapon [1, 2].

In its 1970 publication *trace metal detection technique* (*TMDT*), The National Institute of Law Enforcement and Criminal Justice in the United States has suggested applying the chelating agent oxine (8-hydroxyquinoline) to subjects' hands in order to detect metal traces that have been transferred from metallic objects, such as weapons, onto the holders' hands. The process involved spraying the hands, or dipping them in isopropanol solution of the reagent and, after air drying, observing them under short wavelength ultraviolet (UV) illumination [3]. The latent impressions resulting from handling a metallic object such as (but not only) firearms, show up as stains. There are stains that are colored while others fluoresce, depending on the particular metal involved. The test was thus named *TMDT*. Shortly afterward, the *TMDT* was thoroughly investigated by Stevens and Messler [4]. They ascribed the formation of the stains to the reaction between oxine and traces of metals that have migrated to the hand through handling the metallic objects (Figure 1(a)). In the case of firearms, the metal is mostly trivalent iron (Fe^{+3}). Stevens and Messler studied several factors that might affect the performance of the oxine reagent and suggested ways for optimal photography of the results [4]. They observed a correlation between the weapon's condition and the quality of the marks: stronger stains were obtained with low-quality, rusty handguns. The authors explained this observation by the presence of larger amounts of iron oxide (rust) on old or poorly maintained weapons, which reacts with the chelating reagent more readily than metallic iron. They also noticed a connection between the amount of perspiration on the hands and the quality of the marks: better marks were obtained on more perspiring hands.

In 1976, Goldman and Thornton reported a new and improved trace metal detection reagent: 3-(2-pyridyl)-5,6-diphenyl-1,2,4-triazine-p, p'-disulfonic acid, disodium salt trihydrate known also as *PDT* or *ferrozin* [5]. In contrast to oxine, *PDT* chelates only divalent iron, Fe^{+2} (Figure 1b). Its sensitivity in solution was found to be similar to that of oxine, but it had one striking advantage over the original TMDT test: the color developed is readily visible and may be easily photographed at room light. As the complex has a deep magenta color, no particular photography film was required. The authors also noticed that a positive reaction is dependent, to a considerable extent, on the amount of perspiration on the hands of the subject. The suggested procedure was quite simple: spraying the hands with methanolic solution of *PDT*. Traces of divalent iron show up as magenta stains within 1 min. Exposure to long wavelength UV light accelerates the color formation. Most heavy metal ions do not interfere with this reaction, but some anions, particularly cyanide, do by competing with *PDT* for the iron. In a following article [6], Thornton and Stoney recommended a modified *PDT* reagent. The improved reagent, 3-(2-pyridyl)-5,6-diphenyl-1,2,4-triazine (Figure 1c), has the same core structure as *PDT*, but lacks the two sulfonic acid groups. Consequently, it produces with divalent iron an analogous chelate (devoid of the sulfonic groups), whose color is very similar to that of the former. The major advantage of the modified reagent is its solubility in nonpolar solvents such as acetone, whereas *PDT* is soluble only in relatively polar solvents, which can also dissolve the stains of the magenta complex. The suggested technique [6] involves spraying the subject's hand with 0.5% reagent solution in acetone, and if divalent iron is present, a magenta stain should appear instantly. The authors reported the molar absorptivity of pyridyldiphenyltriazine–iron chelate to be 24 000 at 555 nm, slightly lower than 27 900 at 562 nm for the *PDT* chelate, but still sufficiently high to ensure a visible reaction with microgram amounts of iron. Later on, this modified reagent received the name PDT, since pyridyldiphenyltriazine is the parent compound, and the former reagent (Figure 1b) is but a chemical derivative [6]. Thus, in the rest of the article, reagent (Figure 1c) is referred to as PDT.

Shortly afterward, it was noticed that although the new PDT was advantageous over the previously tried reagents, it suffered from a significant drawback; in many cases, colored stains could not be



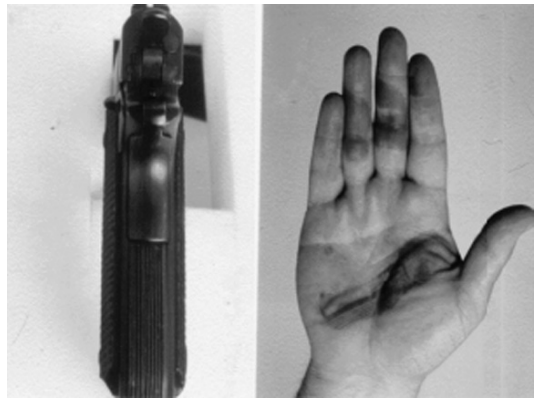


Figure 1 (a) The oxine reaction with trivalent iron; (b) the reaction between *PDT* with divalent iron; (c) the reaction between pyridyldiphenyltriazine ("true" PDT) and divalent iron; and (d) 2-nitrozo-1-naphthol reaction with divalent iron

developed even after a confirmed recent contact with firearms. This happened particularly when the tests were carried out more than 30 min after contact. The rationale to this phenomenon was suggested independently by Glattstein and Kraus in Israel [7] and Lee in Hong Kong [8]. Both groups assumed that the amounts of iron in its divalent state (Fe^{+2}) on the hands were insufficient for a positive PDT reaction. This could arise from either fast oxidation by air oxygen of the divalent iron, which is originally present [7], or from an initially small amount of Fe^{+2} on the hand due to rust (basically Fe^{+3}), covering the object [8], or a combination of both. Oxidation by air oxygen also explains why relatively old impressions could not be developed with PDT, since divalent iron is known to quickly oxidize by air to the trivalent state, particularly in a moist environment. Both groups suggested the

(a)

use of the mild reducing agent, ascorbic acid, in conjunction with the PDT reagent. Ascorbic acid was found to considerably enhance the sensitivity of the PDT technique, allowing the detection of much older firearms impressions. Since 1980, the improved technique has been in operational use by crime-scene officers in the Israeli Police, and became a part of the "field test concept" there [9]. Spray cans containing PDT and ascorbic acid became commercially available under the trade marks Ferroprint™ and Ferrotrace™. It could visualize latent iron impressions on the hands hours after contact [10]. Quite often, the shape of the PDT impressions could be associated with certain firearms. Profiles obtained from commonly used handguns were reported by Glattstein *et al.* [11] (Figure 2).

In his 1986 article, "The Detection of Iron Traces on Hands by Ferrozine Sprays" [8], C-W Lee reported the results of a comprehensive study, which was aimed at optimizing the PDT technique. He tried several reducing agents (ascorbic acid was the most efficient), examined potential interference by traces of other metals (copper, zinc, nickel, aluminum, tin, lead, and chromium) and suggested ways to remove them, or interpret the results in their presence. Lee also outlined a procedure for transferring iron traces from hands onto filter paper for persons who refuse to have their hands sprayed by the reagent. Of the metal ions tested, only aluminum formed the familiar magenta color with PDT, but the color intensity of the product was 350 times lower than that of the iron complex. Ni^{+2} on the other hand, had an inhibitory effect on the formation of the iron magenta complex.

Despite the significant improvement of the PDT technique, there were still too many occasions in which the modified reagent showed insufficient sensitivity. The next series of comprehensive studies started with an attempt to design chelating agents

that would provide a deeper color (higher absorptivity) with iron. More than a dozen analogs of PDT have been synthesized and tried. In solution, eight of them exhibited higher sensitivity than the parent compound to Fe^{+2}. The gain, however, was insufficient (not more than 50% increase in color intensity) to justify the use of these noncommercial compounds as practical reagents [12]. Comment *et al.*, from the University of Lausanne compared the performance of four potential reagents for the detection of firearms impressions on the hands. Besides the three previously mentioned chelating agents, their study also involved a fourth one, 2-nitroso-1-naphthol (Figure 1d). PDT showed the highest sensitivity of all four. Furthermore, the marks developed by PDT were the most stable and showed the highest resolution [13]. A similar study on TMDT, which was concluded without specific preference, was published a few years earlier by Katzung [14].

In the last decade, more qualitative and quantitative characteristics of the PDT reaction have been reported. Studies were carried out not only for sensitivity enhancement but also for court argumentation. Leifer *et al.* reported that about 70% of a large number of volunteers developed visible stains after holding firearms. They did not notice significant differences between males and females in the effectiveness of the technique or in stain quality [15]. Avissar *et al.* presented, for the first time, quantitative data on the amounts of iron that migrate from a firearm to the palm. Iron levels between 21 and 315 ng cm^{-2} have been measured on the palm after a single grip that lasted 1 min. These authors found that the amounts of iron transferred to the palm depended primarily on the levels of palmar moisture and, to a lesser extent, on gripping duration. Thus, only a few seconds of gripping were required for developing good marks (corresponding to 80 ng cm^{-2} of iron) on highly moistured hands, whereas much longer gripping periods were necessary to develop marks of similar intensity on relatively dry hands [16]. Experiments by the same group that aimed at studying the effect of sweat components on metallic iron dissolution were carried out in aqueous solutions. The authors found that chloride ions in physiological concentrations remarkably enhanced iron dissolution, while serine, the major amino acid in palmar sweat, had a detrimental effect on this reaction. Urea, another sweat component, had only a minor effect on the dissolution rate. The authors proved that most of the iron is transferred from the weapon to the skin by a chemical process (dissolution) and not by mechanical friction. Almog *et al.* also quantified the correlation between moisture levels on the hand and the quality of the developed stains. They divided the population into three categories based on their iron uptake. Similarly to *fingerprint donor* for the person who leaves the latent finger marks, they used the term *iron acceptor*, or simply *acceptor*, for the person who adsorbs iron traces upon gripping an iron-made object (*see also* **Friction Ridge Examination (Fingerprints): Interpretation of**). Accordingly, the three categories mentioned above can be termed *good*, *average*, and *weak acceptors*, being determined by the intensity of the PDT mark, which, in turn, depends on the amount of perspiration on their hands [16, 17].

Four death investigations, in which the use of the PDT technique helped the investigators answer the critical question, "who held the lethal weapon", have been reported and discussed by Leifer *et al.* In one of those cases, a PDT impression developed not on the palm but on the hip. In another case, a suicide–homicide investigation, PDT results reversed the initial, "obvious" conclusion of the investigators [18] (*see also* **Suicide (Behavior)**).

Firearms: Overview

Overview

Forensic firearms investigation is the discipline concerned with the technical analysis of crime where firearms have been used. Firearm crime includes unlawful possession of firearms and related items, where shots have been discharged into the air or other objects such as cars or buildings, to serious crimes where people have been wounded or killed by the discharge of firearms. Firearms investigation could be considered as a specialized form of crime scene examination and such is the depth of knowledge and expertise required to competently investigate shooting crimes from a technical viewpoint; it is a complete field of study in itself.

Firearms investigation is often referred to as *forensic ballistics*; however, this is a technically incorrect term, and ballistics refers purely to the study of projectiles in motion. "Forensic firearms examination" is sometimes used but this can infer that the discipline is purely laboratory based. "Forensic firearms investigation" is the most appropriate term to describe the science as it encompasses the diverse range of examinations carried out at the shooting scene and in the laboratory.

The Laboratory

Most forensic firearms laboratories are owned and financed by their respective governments, usually a state or federal authority due to the costs involved in buying the necessary equipment and hiring/training staff. Modern police jurisdictions have police officers or civilian experts trained in the investigation of shooting incidents, usually located in their own separate section of the police forensic services division. Where there is no internal forensic firearms investigation section within the police department, this role may be contracted out to a larger law enforcement agency. There are some private individuals or companies who do have their own laboratories; however, these would not normally be responsible for the investigation of a shooting incident immediately after it had occurred. They would become involved at a later date, usually at the request of the lawyer

defending the person/s charged, to test the thoroughness of the work carried out by the government laboratory.

There is quite a wide variation around the world between different forensic firearms laboratories and the services they provide. There are a number of reasons for this including how the section may have developed historically, financial considerations, and the particular types of firearm crime most commonly encountered in that jurisdiction. For instance, it would be uncommon for a small jurisdiction to have a scanning electron microscope (SEM) for the analysis of gunshot residue from primer components if the authorities only encountered this evidence infrequently. If this expertise was required, there are usually protocols in place to have that evidence examined by larger laboratories equipped for such analysis. This may or may not be on a cost recovery basis.

Staffing of laboratories is commensurate with the amount of work encountered in that jurisdiction involving the criminal use of firearms. Some forensic firearms sections also have other responsibilities and roles such as servicing and repairing police firearms. The extra workload involved in providing an armoring service may then require staffing levels above that needed to carry out the forensic firearms investigation role. In such situations, personnel may either maintain their separate and distinct roles or carry out all the functions in that section.

The depth and breadth of any examination undertaken at the shooting scene or in the laboratory is normally commensurate with the seriousness of the crime. Consequently, minor incidents are usually not investigated to the same extensive level as a wounding or death. Examinations are very dependant on the circumstances of the incident in question and what may be of crucial importance in one investigation may be irrelevant in another. For example, whereas determining the distance between the victim and the offender may be critical in one incident, the condition of the safety mechanism of the firearm may be the most important factor to consider in another. What needs to be explored will be due to the relevant aspects of each particular case and after determining what is and what is not in dispute.

Broadly speaking, firearms investigation can be separated into several main roles: the investigation and reconstruction of the shooting incident, gunshot wound interpretation, laboratory examinations, report preparation, and expert testimony.

1. The reconstruction of the shooting incident

There are many considerations for the firearms investigator at the scene of a shooting crime but of prime importance are issues such as the following:

- Where was the victim located at the time of the shooting?
- How was the victim's body positioned at the time of impact?
- Where was the shooter located at the time of the shooting?
- How was the firearm held by the shooter?
- How many shots were fired?
- What was the sequence of the shots?
- Can the bullet paths and angles be determined?
- What was the physical condition of the responsible firearm when located in regards to the chamber, magazine, safety catch and so on?

The competent and thorough examination of a shooting scene is vital to the overall investigation mainly due to the potential at that juncture to lose critical evidence if it is not properly carried out. Staff in some jurisdictions are laboratory based only and do not attend shootings scenes; this role being undertaken by crime scene officers. However, it may be preferable that firearms investigators conduct shooting scene examinations as part of their role to place the incident in a more complete context; this may be especially relevant when conducting other examinations later in the laboratory. In the event that a death has occurred, again depending on the jurisdiction in which the shooting took place and the duties and responsibilities of the staff from the forensic laboratory, shooting investigation can also include assisting the forensic pathologist during autopsies upon gunshot victims.

2. Gunshot wound interpretation

Although the forensic pathologist (i.e., a medical examiner) is responsible for actually conducting the examination upon a shooting victim, it is not unusual for a firearms investigator to be present during the autopsy to offer advice and assistance in areas such as the following:

- interpretation of the wound/s such as which are entries and exits;
- the approximate distance at which the shot was fired in close range discharges;
- determination of the bullet path through the body;
- the possible orientation of the victim when struck;
- the possible sequence of shots in incidents where more than one impact is present; and
- recovery of projectiles and other evidence for later examination.

Once all the evidence has been recovered from the scene and during the autopsy (if applicable), a number of examinations are then carried out in the laboratory. These may include, but are not limited to, the examination of recovered projectiles and other types of evidence and/or tests to estimate the firing distance, to determine the bullet trajectory or path, etc.

3. Laboratory examinations

The expert conducts a wide range of laboratory examinations upon firearms, fired and unfired ammunition, bullet damaged clothing, and related items. Often these examinations cannot be completed until other forms of analysis are conducted first, such as testing for fingerprints and swabbing for DNA. The sequence of examination regime is not rigid but is dependent on the context of the case and on the priorities at the time, with due consideration to maximizing all the available evidence. Laboratory examinations can include the following:

- examination of suspect firearms for features, operability, function, safety, trigger pressure, etc.;
- microscopic comparisons between fired bullets and cartridge cases test fired in suspect firearms, to those recovered at the shooting scene;
- serial number restorations upon defaced/obliterated serial numbers on firearms;
- gunshot residue tests to indicate the manipulation or the use of a firearm and/or establish the approximate distance between the shooter and the target (close range discharges only);
- shotgun pellet pattern tests to establish the approximate distance between the shooter and the target;
- ejection pattern tests to assist determining where the shooter may have been positioned at the time of discharge; and
- various other tests as deemed necessary by the circumstances.

4. Preparation of reports and expert testimony

The final part of the investigation is the preparation of technical reports. Reports should ideally articulate what was done during each stage of the investigation, what exhibits were collected, and the results of all the examinations conducted. Reports should not be overly technical and contain jargon, making it difficult to understand by the layperson but the specifics referred to must still be technically correct. If requested by either the prosecution or defense legal representative, the expert would also attend court or other tribunal to orally give evidence of their involvement in the investigation.

There is only one forensic association worldwide that is primarily involved with firearm investigation, the Association of Firearm and Toolmark Examiners (AFTE). It has a membership of approximately 1000 individuals from 40 countries. A scientific journal is produced quarterly and an annual training seminar is held, usually within the United States. More information about AFTE and firearms investigation can be obtained from their website: www.afte.org. Another excellent website for reliable information on firearms identification is www.firearmsid.com.

Firearms: Scene Investigation

Introduction

Shooting scene investigation is a specialized form of crime scene examination, but the techniques applicable to general crime scene investigation are still relevant. It relates to the recording and collection of specific evidence that is unique to a shooting scene, to enable accurate interpretation and reconstruction of the events that have occurred. Forensic firearms examiners provide a service and pool of expertise in matters relating to the investigation of shooting incidents. Their main functions are as follows:

- interpretation and reconstruction of shooting scenes;
- identification of firearms through the examination of cartridge cases and bullets;
- safety testing of firearms;
- general identification of firearms and firearm components;
- identification of ammunition;
- performance of ammunition;
- distance determination of shotgun patterns;
- distance determination from propellant patterns;
- restoration of erased serial numbers on firearms;
- checking firearms against an unsolved shootings database; and
- validating or negating victim/offender/witness statements.

The following provides an overview of the types of evidence that can be found at shooting scenes, as well as from victims and offenders.

The Shooting Scene

Documenting the position and condition of all relevant exhibits at a shooting scene is critical to ensuring that the combined evidence can be accurately evaluated and interpreted. There is only one opportunity to 'get it right' and failure to do so results in the loss of evidence, which cannot be recovered at a later stage.

Firearms

The condition of a firearm at a crime scene should be consistent with the circumstances of the alleged offense. If it is not, then it must be explained. The following details should be checked and recorded.

- condition of the breech i.e., unloaded or loaded with a live round or spent cartridge case;
- action cocked or uncocked, open or closed;
- position of hammer or cocking piece i.e., cocked or uncocked;
- magazine type and contents;
- position of any safety catch – on or off;
- relationship of the firearm to other exhibits and features at the scene; and
- any visible blood or biological tissue present on the firearm or within the muzzle of the barrel.

Before removing a firearm from the scene, consideration should be given to any requirements for DNA or fingerprint examination. It is essential that any such exhibits are not exposed to contamination.

Live Ammunition, Fired Cartridge Cases or Fired Bullets

Live ammunition can be found with the firearm or lying on the ground at the scene. Depending on the size of the cartridge case, fingerprint examination and DNA analysis should be considered.

Fired cartridge cases are unlikely to retain fingerprints or DNA evidence owing to the heat and pressure generated within the chamber of the firearm at the time of firing or because of other environmental and circumstantial factors. The only exception to this is if there is a suggestion the offender has handled

the cartridge cases postfiring, in an effort to remove evidence from the scene.

When searching for spent cartridge cases, consideration should be given to the use of the following to aid in the search:

- metal detectors
- explosive sniffer dogs
- line searches.

Fired bullets can retain trace evidence such as biological material and therefore can be a rich source of DNA evidence as well.

Projectile Impact Damage

This occurs when a bullet impacts an object during flight. Impact damage is commonly seen in building exterior and interior walls, windows, vehicles, and clothing at shooting scenes. There are two main considerations with this type of evidence. The first is to confirm the damage has been caused by a bullet. If the cause of the damage is uncertain or unknown, there are two presumptive tests that can be used to determine if the damage was caused by a bullet. Sodium rhodizonate can be used to determine if lead residues are present. Lead is the most common element used in the manufacture of most bullets inner core. Dithiooxamide (DTO) is used to test for copper residues. Copper is the most common metal used in the manufacture of the outer jacket material on many bullets. If both the lead and copper tests are to be conducted, it is imperative that the DTO test is conducted before the lead test. This is because the mild acidic solution used in the lead test also transfers copper residues.

The second consideration is to determine if the impact damage can be used to determine the path of the bullet and the approximate position of the shooter at the time of firing. A minimum of two separate reference points are required for this purpose, for example an entry and exit hole through an inner gyprock wall of a house. A colored plastic or wooden probe can be placed through both holes allowing an angle of incidence (entry) to be determined. Other measurements such as the height of the impact above the floor and its relationship to other features of the scene are also important. This combined information together with trigonometric calculations, can be used to determine the position of the shooter.

An alternative method of achieving a similar result, while demonstrating the approximate trajectory or path of the bullet, is the use of colored stringlines. Again, two reference points are required. By following the stringline/s back to a common point or to a maximum/minimum height, the approximate position of the shooter can be determined. Colored stringlines and probes can be readily photographed, which makes them useful for court presentation purposes as well. However, stringlines suffer from sag over extended distances, which can lead to inaccurate findings. Therefore, they should only be used over shorter distances.

Laser devices/pointers can also be used to identify possible trajectories if there are two or more linked features. They can be particularly useful over longer distances, where stringlines become impractical. However, lasers point in straight lines and if using such a device over an extended distance, allowance must be made for trajectory variations owing to factors such as bullet drop. Test firings over the distance in question may be necessary to determine the actual amount of bullet drop, as bullets do not travel in a straight line relative to the vertical plane, owing to the factors such as gravity. Unlike stringlines, the path indicated by a laser cannot be photographed in daylight conditions.

Bullet impacts into some materials can leave features, which assist in determining their direction of travel. The ‘pinch point’ is one example frequently seen on the sheet metal of motor vehicles. This is a small circular area of surviving paint at one end of a bullet entry hole or ricochet mark. It represents the first point of contact of the bullet and therefore provides directionality to the impact mark. Another feature of bullet impact marks in motor vehicles is called the ‘bow effect.’ These are fracture lines in painted sheet metal, which often must be enhanced with the use of a fingerprint powder that contrasts against the painted surface. The fracture lines have the appearance of a bow wave or a shock wave and show the direction of travel of the bullet.

Holes in Glass

There are a number of pitfalls interpreting holes in glass. Bullet holes are generally round and larger than the caliber of the bullet. Radial and concentric fracture lines emanate from the center of the hole. This applies to safety glass and window glass. The

bullet usually penetrates the glass and so a second strike inside the room is likely to be found. The presence of lead or copper close to the impact point may serve as an indicator of an impact being made by a bullet. This may be confirmed by sampling the area around the questioned hole using the DTO and/or sodium rhodizonate presumptive tests.

Where multiple bullet impacts occur to a glass window, it is possible to determine the 'sequence of shots' by reference to the radial fracture lines from one impact terminating against radial fracture lines from an earlier impact.

Stone damage may result in an irregularly shaped hole and the radial fracture lines may emanate from one edge of the hole, if the stone has not penetrated. The presence of the projectile is the best indicator of the cause of the damage, and a careful search should always be made for any relevant object.

A ball bearing fired from a slingshot often leaves a small round hole, which exhibits crushing around the outside with a cone of glass knocked out from inside. Damage by a ball bearing that has not penetrated the glass may leave a small round symmetrical hole with fine crushing around the outside edges. Again, a careful search for the projectile may confirm the cause of the damage.

A bullet produces a hole that has the shape of a truncated cone with the larger base at the point of exit and the smaller at the point of entrance of the bullet.

Bullet Ricochet

Ricochet is the deflection of a projectile(s) after impact. The amount of deflection depends on the medium involved. As a general rule, studies have shown that a bullet is deflected to some degree after passing through any material that offers even minor resistance, i.e., color-bond fencing, household glass windows, or windscreen glass. Bullets also ricochet off solid mediums such as roads or brick walls if the angle of incidence is other than 90° to it. As a general rule, bullets fired into yielding materials such as sand, have a higher angle of departure than the angle of incidence. Bullets fired into nonyielding materials such as concrete, have lower angle of departure than the angle of incidence.

Ricochet is an important consideration because it is a common defense raised by barristers and solicitors to account for the wounds sustained by a victim following the actions of the accused.

Shotgun Patterns

Shot shell cartridges contain multiple pellets. The dispersion pattern left by shot shell pellets can be used to express an opinion as to the range of the shot. Elongated patterns are indicative of angled shots. The dimensions of the pattern must be recorded accurately so that subsequent test firings using the actual firearm and similar ammunition can be made in an effort to replicate the pattern. The number of pellet impacts and their relative size assist in determining the type of shot shell load used. Shotgun wads can travel out to a distance of approximately 30 m, depending on the length of the shotgun barrel. They can also assist to identify the type of shot shell load.

Shooting Suicides

Shooting suicides can represent a particularly difficult form of shooting interpretation because it is possible that an apparent suicide is in fact a concealed murder. To resolve this question, the following are signs which generally indicate suicide:

- **History**

The victim may have a history of trouble or depression.

- **Firearm**

Should be identified as being one available to the victim.

- **Suicide note**

May be left at the scene. (Is it the victim's handwriting?)

- **Wound site**

Victims will usually shoot themselves in one of the preferred areas:

under the chin
inside the mouth
between the eyes
in the temple
in the center of the chest.

All these wounds exhibit evidence of having been fired from close to, or in contact with the body, i.e., powder tattooing (burnt and partially burnt

propellant grains embedded around the wound site), recoil injury, or splitting of the entry when it is over hard bone. A wound to any other part of the body should be viewed with suspicion unless accompanied by other indications of suicide.

- **Victim's reach**

With the muzzle of the weapon in contact with the entry wound, the victim must be able to reach the trigger by hand or by using some other improvised means to extend his/her reach.

- **Condition of the firearm**

Must be consistent with the circumstances.

- **DNA/fingerprints**

Should be checked on the firearm.

- **Multiple wounds**

Are unusual although not entirely uncommon. They may occur when the first shot was not crippling, such as a shot to the body or where the weapon was semiautomatic and the second shot has resulted from the victim's finger being retained inside the trigger guard.

- **Other injuries**

The victim may have injuries to the hand holding the muzzle caused by the foresight or to the hand pulling the trigger, caused by the trigger guard.

- **Signs of struggle**

There should be no signs of a struggle.

- **Position of firearm**

Should be consistent with having been held by the victim at the time of the shooting. However, there are occasions when recoil can cause the firearm to land further away than expected.

DNA versus Fingerprints

DNA, like fingerprints, is now accepted by the courts as powerful evidence in criminal proceedings. However, examiners are often faced with a difficult decision as to which of these is more important relative to a particular exhibit. This situation often arises with live or spent cartridge cases.

Smaller cartridge cases such as caliber. 22 long rifle, do not have the surface area to hold a substantial fingerprint and so DNA swabbing is the preferred option. However, larger cartridge cases such as caliber 45 ACP do have sufficient surface area and so fingerprint examination & DNA swabbing must both be considered viable options depending on the circumstances.

With regards to firearms, DNA swabbing should be undertaken first to avoid further contamination. However, DNA swabs should only be taken from areas on the firearm that are unlikely to yield fingerprints, such as the trigger, cocking handle, and chequered or rough areas of the grips.

The issue of how best it is possible to collect both fingerprints and DNA from a given exhibit is thoroughly discussed in **Friction Ridge Skin: Interaction between Fingerprint Detection and DNA/Biological Material**.

Scene Reconstruction

There are occasions when reconstructing a crime scene, or aspects of it, are necessary to identify possibilities or test a given scenario. It is usually based on information provided by persons involved in the shooting incident. Scene reconstructions are particularly common in police involved shootings or major homicides. It is important to keep an open mind with respect to any reconstruction because witnesses' accounts may not be entirely accurate.

Interpretation

Accurate interpretation of a scene is usually only possible once all the available evidence has been found and examined. Interpretation is basically reconstructing the chain of events related to the shooting from the available evidence. It allows the examiner to form conclusions on the basis of fact and therefore confirm or negate scenarios that may be posed by investigators, victims, or offenders. Courts and coronial inquests often rely on the opinions of forensic firearms examiners when determining the weight of the evidence before them. Accurate interpretation generally comes with experience, but also depends on proper education and training.

Other Considerations

Ambient lighting has a considerable effect on the ability of a shooter to take an aimed shot. Open sights on firearms require both the firearm and the target to be illuminated, while a telescopic sight requires only

the target to be illuminated. Other considerations are as follows:

- features that may affect line of sight;
- features that could result in an unintentional discharge such as a loss of footing on uneven ground;
- background features; and
- intermediate targets.

The Shooting Victim

A vast amount of evidence can be gathered from an examination of the victim of a shooting, both in a suicide and a homicide or nonfatal shooting.

Wound Position and Trajectory

The wound position and direction through the body, if both entry and exit are visible, may assist in determining the attitude of the victim at the time of the shooting. Wounds to the hands and arms may be defense wounds, where the victim has tried to ward off the shot.

Powder Tattooing

This term refers to burnt and partially burnt propellant particles that are expelled from the muzzle of a firearm and embed themselves in the skin surrounding a wound. Tattooing is generally seen on uncovered skin out to a maximum of 2 m, but more often at distances far less than this. The pattern depends on the firearm ammunition and environmental conditions (eg., wind in outdoor situations). The distribution of this propellant residue can allow forensic firearms examiners to express an opinion as to the range of the shot, otherwise known as '*distance determination*'. This is usually achieved by subsequent test firings using the actual firearm and ammunition of the same type. Therefore, it is important the pattern is well documented.

Residues on Clothing

If the victim is shot through clothing, at close range, the cloth retains the propellant and primer residues. Depending on the color of the clothing, these residues may be visible or invisible. Infrared imaging and other filtered light source examination may help to enhance the contrast of the residues against the background. Chemical analysis is the best method of determining the extent of the pattern produced, so that a forensic firearms examiner can conduct subsequent test firings to determine the distance from which the shot was fired.

Preservation of the pattern produced on the clothing is paramount. To ensure this, the clothing item should be removed from the body, dried, and laid flat so that the portion of cloth with the bullet hole is sandwiched between two sheets of paper or cardboard. This minimizes abrasion with other parts of the garment, which may remove loose material.

Postmortems

Forensic firearms examiners attend postmortem examinations for two main reasons:

- to collect firearms evidence, which includes clothing; and
- to assist the pathologist in the interpretation of gunshot wounds.

The Shooting Suspect

Suspect Weapon

Any relevant firearm in the possession of the suspect should be seized and forwarded for examination by a forensic firearm examiner. It is possible to macroscopically compare cartridge cases and bullets recovered at a shooting scene to the suspect weapon/s using a comparison microscope and comparative analysis techniques. Safety tests can also be conducted to confirm or negate allegations of accidental discharge.

Ammunition

If a suspect has ammunition in his/her possession, this too should be collected. Examination of the brand and type may provide a link to any ammunition at the shooting scene or it may be needed in tests to be conducted by the forensic firearm examiner. Macroscopic comparison of the headstamps on live ammunition or fired cartridge cases at the scene can be compared with those of live ammunition found in the possession of the suspect, to determine if the headstamps were formed by the same bunter tool

at the time of manufacture. This evidence can be particularly useful if the type of ammunition used is uncommon.

Medical Examination

The medical examination of the victim is an integral part of any investigation and may reveal crucial information with respect to the wound, firing range, and other circumstantial information. A medical examination of the suspect can reveal injuries that may have occurred in a struggle over a weapon, or bruising that may indicate that a poorly shouldered shotgun/rifle was used.

Gunshot Residue Analysis

If a suspect is located within approximately four hours of a shooting and he/she has not washed their hands, swabs may be taken for analysis of gunshot residue (GSR). When a person fires a firearm, gaseous residues are created, which escape from it. These may deposit distinctive combinations of elements upon the hands of the shooter and sometimes other areas such as in their hair or on their clothing. Some firearms such as revolvers or semiautomatic rifles or pistols, emit substantially more gaseous residues than a bolt action or lever action rifle because of their operating system. A 'GSR kit' can be used to collect these residues. GSR is microscopic and mainly consists of primer residues often containing the principle elements of lead, barium, and antimony. They are enhanced using chemical techniques and examined with the aid of a 'scanning electron microscope'.

It should be noted that the results of GSR analysis are not a definitive answer to whether a person has fired a firearm or not, as there may be other explanations. GSR is at best corroborative evidence. See **Firearm Discharge Residue: Analysis of** for a thorough discussion of this topic.

Firesetting

Introduction

> *If all that changes slowly may be explained by life, all that changes quickly is explained by fire. Fire is the ultra-living element. It is intimate and it is universal. It lives in our heart. It lives in the sky. It rises from the depths of the substance and offers itself with the warmth of love. Or it can go back down into the substance and hide there, latent and pent-up, like hate and vengeance* [1] p. 7.

In the setting of legal proceedings, firesetting is included under the crime of arson and may be present in civil suits regarding fire damage (*see* **Fire: Scene Investigation**; **Arson Investigation: Misconceptions and Mythology**; **Fire Modeling and Its Application in Fire Investigation**; **Fire Debris: Laboratory Analysis of**) and self-incineration [2] as well. From a psychological perspective, however, fire captures a wider variety of meanings. A source of warmth and light, fire may provide satisfaction and comfort, a sense of community, and awaken feelings of desire or passion, even as it contains destructive power. Fire is thus a dialectical image [1], conveying opposites, contrasts, and contradictions.

The myth of Prometheus conveys the notion that human mastery of fire was a transgression. Freud interpreted the myth to indicate that "the acquisition of fire was a crime" [3] p. 188, because, through mastery of the instinctual impulse to quench the fire, humankind became more powerful than the gods, entering a process of civilization through the renunciation of instinct. Anthropologists who have attempted to study the acquisition of fire from an empirical perspective have been unable to determine the precise timing of this development [4], nor have they reached consensus about the nature of the initial uses of fire [5]. The transition from a passive use of fire available in nature to the active control of fire is likely to have required mental as well as technological development, involving "self-restraint and reduction of spontaneity" [4] p. 521. Some anthropologists have observed that this restraint resulted in effects as consequential as social organization and the development of rules as well as language. Although the acquisition of mastery over fire was an historical attainment for society, each individual must go through his own process of developing knowledge about the uses and dangers of fire [6] p. 194–203.

The setting of fires for personal gain has been with us for millennia. In contemporary society, firesetting for profit, arson, is frequent and underprosecuted for want of identifiable perpetrators, and it can be deadly in result without any such intent. Arson fires can be set for insurance fraud, welfare fraud, bankruptcy scams, burglary, building stripping, property improvement, business modifications, as well as for employment [7]. That said, we turn our attention to the more perplexing domain of firesetting behavior in which financial gain is not the primary motive.

Childhood Discovery of Fire

In contemporary Western society, many children play with fire at least once in the process of the acquisition of knowledge about societal rules [8]. Risk factors for firesetting in childhood include covert antisocial behavior [9], parental stress, conduct problems, and hyperactivity, and in girls, anxiety or depression [10]. In adolescents, firesetting has been associated with shyness, aggressiveness [11], severe antisocial behavior, severe drug use, and risk-taking behavior [12]. Across age groups, heightened curiosity about fire has been associated with an increased risk for firesetting, accounting for the severity and persistence of firesetting behavior above and beyond the presence of antisocial conduct [13].

Younger children may find fire fascinating and may not have the cognitive capacity to appreciate its dangers. This susceptibility to experiment with fire has been a major focus of prevention, due to the potentially serious consequences. Public education programs have been implemented for the prevention of childhood fire play. In the United States, a common intervention following an initial firesetting incident is a home visit by a firefighter, who educates the child and his family about fire safety. Although this intervention has been shown to be effective in reducing firesetting behavior, more intensive treatments such as fire safety education programs in a clinical setting and psychotherapy have shown more promising results [14].

Studies of psychotherapy for firesetting behavior have principally involved the use of cognitive–behavioral techniques. However, these treatments have been brief, and it is as yet unknown what components of firesetting are most strongly modified by the cognitive–behavioral approach and whether the treatment effect would be augmented by a longer duration of therapy [14]. Owing to the observed importance of the intensity of fire interest in guiding children's firesetting behavior, further development of treatment modalities and techniques is needed. Intense fire interest and repeated firesetting can be associated with an underlying psychiatric disorder that requires treatment.

A history of firesetting in childhood has been associated with future violence, including cases of serial homicide (*see* **Serial Homicide**, [15]). Treatment and prevention of future firesetting behavior in childhood and adolescence may be concomitant with the resolution of psychopathology that would otherwise evolve with greater severity into adulthood. This can be stated no more than as a hypothesis currently, as there is virtually no data on the relationship between childhood firesetting and adults who become repeat firesetters.

Pyromania

The diagnosis of pyromania originated in the nineteenth century to explain some acts of repeated arson [7]. In current classifications, notably the Diagnostic and Statistical Manual, Fourth Edition, Text Revision (DSM IV-TR) (*see* **Psychopathology:**

Terms and Trends), pyromania is defined according to the following criteria:

(A) Deliberate and purposeful fire setting on more than one occasion.
(B) Tension or affective arousal before the act.
(C) Fascination with, interest in, curiosity about, or attraction to fire and its situational contexts (e.g. paraphernalia, uses, consequences).
(D) Pleasure, gratification, or relief when setting fires, or when witnessing or participating in their aftermath.
(E) The fire setting is not done for monetary gain, as an expression of socio-political ideology, to conceal criminal activity, to express anger or vengeance, to improve one's living circumstances, in response to a delusion or hallucination, or as a result of impaired judgment (e.g. in dementia, Mental Retardation, Substance Intoxication).
(F) The fire setting is not better accounted for by Conduct Disorder, a Manic Episode, or Antisocial Personality Disorder [16].

These stringent criteria define pyromania very narrowly as a specific disorder of impulse control and thought, which alone cannot account for the wide variety of mental conditions that are found in association with arson or other firesetting behaviors.

Although rare, pyromania may cause severe impairment and mental suffering [7]. In a small study of 21 patients recruited from research treatment settings for impulse control disorders, individuals who met criteria for pyromania at some point in their lives had high rates of mood disorders, anxiety disorders, substance-use disorders, and other impulse-control disorders [17]. Of note, the authors found that only two of the 21 subjects had been arrested for firesetting, and that 12 of 21 reported that they set "controlled" fires that did not rise to the level of criminal charges. On this basis, the authors state that the prevalence of pyromania may possibly be greater than is stated in the current literature.

Studies generally indicate that the prevalence of pyromania is low in offenders convicted of arson. A review of medical records and forensic mental health examinations in 90 arson recidivists over a 20-year period in Finland revealed only three defendants meeting DSM-IV-TR criteria for pyromania [18]. Another study of a similar population of defendants referred for psychiatric evaluation found 23% of arsonists with prior nonviolent offenses had a diagnosis of pyromania, while 12% of arsonists with a history of violent offenses had the diagnosis. However, this sample included approximately 10% of arson offenders, those referred for psychiatric evaluation [19]. A study using a variety of sources, from the FBI Behavioral Sciences Unit, from a forensic hospital, and from military disciplinary barracks found the rate of pyromania to be 1.3% [20].

While heuristically useful as a diagnostic category that explains a small subset of firesetting behavior, pyromania should be understood as a highly disabling disorder that is nonetheless uncommon and does not account for the vast majority of cases of firesetting.

Psychopathology

The exclusion criteria noted above in the DSM-IV-TR definition of pyromania indicate numerous other mental pathologies and psychological motivations with which firesetting behavior may be associated. Firesetting occurs in the context of a variety of other disorders. In this sense, the choice of fire is opportunistic in that fire is not the focus of the individual's mental illness, as in pyromania, but is rather the means of choice for self-expression under particular circumstances, or when the person has worsening symptoms of another psychiatric disorder.

Many of the research surveys on arsonists have involved small samples, or samples that are selected from specialized populations, such as defendants who have been referred for psychiatric evaluation in the context of criminal proceedings, and have been retrospective reviews of data collected for other purposes. These studies have consistently demonstrated that over half of the arsonists evaluated were intoxicated with alcohol at the time of the crime [18, 20, 21] and that a substantial number of arsonists suffered from an affective [20] or psychotic disorder [18, 20, 21]. Personality disorders were also common [18, 20, 22], as were other substance-use disorders [20, 23]. Some studies have suggested a high level of mental retardation in populations of arsonists [18, 22].

Sociodemographic and situational features have been associated with firesetting behavior. A majority of arson offenders were living alone or unmarried at the time of the crime [20, 24], many were unemployed, and among women, nearly half had a history of sexual abuse [24]. These features cannot be considered elements of psychopathology *per se*, but are rather factors that may contribute to the impact of a mental disorder.

Communication

The concept of *communicative arson* was introduced by Geller in 1992 [25], and arose from the observation that, in the context of psychiatric deinstitutionalization, the firesetting behavior of many mentally ill patients could not be explained by the symptoms of their disorders nor by pyromania [25, 26]. Communicative arson refers to acts of firesetting that occur in the context of the individual's decreased ability to convey his wishes and needs to others, due to a lack of adequate social skills. Treatment of individuals who set fires to convey anger, dissatisfaction with housing, or a need for care has focused on their social-skills deficits and on assertion training [27, 28]. In their discussion of the existing theoretical models for adolescent firesetting behavior, Glancy *et al.* remark that

> Libidinal explanations of psychodynamic theorists have given way to alternative paradigms of firesetting behaviour. Social learning models hold that juvenile firesetting is the manifestation of interpersonal failures that lead to the deviant expression of aggression and control ... it is theorized that firesetting can be linked to modelling of aggression and inadequate social skills [8] p. 53.

Observations of mentally ill patients who set fires indicate that the same applies to adult firesetters [27].

Although arson is classified as a crime against property, the potential destructiveness of uncontrolled fire as a threat to individuals as well as to communities would suggest that it is a form of violence that may arise from interpersonal conflicts, perceived threat, or aggressive impulses. The most common motive for arson is revenge [20, 22], which is aggressively targeted to a specified victim. Although revenge can be classified as a motive unrelated to mental disorder [7], in one study of defendants interviewed at an outpatient forensic evaluation clinic, "The common finding among all diagnostic groups was the high frequency of vindictiveness as the principal motivation behind the fire" [21]. On the other hand, when psychiatric patients are studied, arson correlates with histories of suicide attempts and not with past homicidal behaviors [29, 30].

As noted throughout this article, the choice to set a fire can be opportunistic or impulsive, based on emotional states that would otherwise manifest under different circumstances as other forms of destructive behavior, including interpersonal violence. On the other hand, the choice of fire can also be perceived by a person with poor social and verbal skills as an effective way to communicate. Firesetting requires no face-to-face encounter with another person, thus avoiding all eye contact; the rate of success in conveying a message is higher than most past efforts to influence outcome may have been for the individual; and far more often than not, someone must respond and intervene as a result of the fire – thus the person with poor social skills who is often ignored is not ignored this time, when he communicates by way of fire.

Conclusion

Firesetting is a destructive act with high potential lethality and a wide range of motivations. The controlled use of fire is essential for human society to exist, and individual learning of the safe and appropriate use of fire is an attainment during childhood that requires attention and intervention. Adult firesetting is often associated with a variety of psychopathological conditions and is not limited to persons with a diagnosis of pyromania. There is as yet little consensus on a comprehensive classification of firesetting behaviors nor is there consensus on what the categories or variables should be in order to develop a valid and reliable nosology for these behaviors. In contrast with the field of interpersonal violence, systematic, prospectively designed studies of risk factors for future firesetting in adults are lacking, and existing research on treatment modalities for juvenile and adult firesetting has yielded limited results at this time. The challenges posed by firesetting behavior have yet to be met.

Footwear and Foot Impressions: Comparison and Identification

Introduction

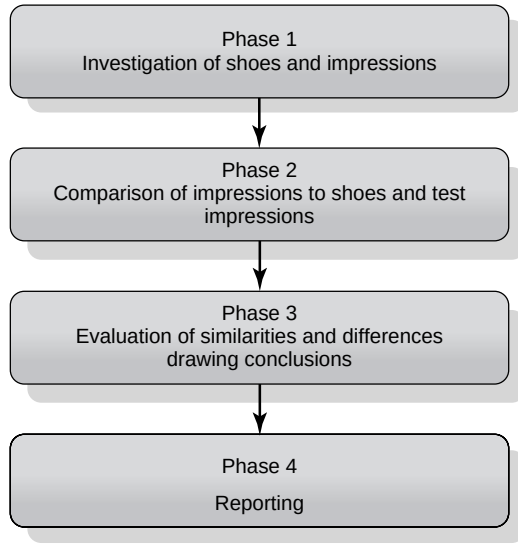
This article can be used as guidelines for comparing shoemarks and drawing conclusions. It is a major update of the "Guideline for drawing conclusions regarding shoeprint examinations" as presented in Stockholm, Sweden 1999.

The new guidelines are intended for shoemark and tire track experts at the Netherlands Forensic Institute (NFI), scene of crime officers, and for anyone working in the field of comparative shoemark examination.

Throughout the development of these guidelines, the most important goal was thoroughness. Considering the variety and complexity of shoemark examination, there will always be a need for amplification and detailing.

Fifty years of knowledge and experience of the NFI was drawn on for the composition of this article, and long experience in presenting cases to the judiciary was also a factor in its composition.

Objective of the Guidelines



The guidelines exclusively relate to drawing conclusions in comparative shoemark examination. They lay out a method for objective examination, which takes into account not only the similarities between a shoemark and a shoe but also any differences. Whether there are similarities or discrepancies in a comparison, the document gives universal guidelines on how to reach a conclusion. When similarities are found, some steps must be taken before reaching a conclusion, and these steps are diligently covered in the guideline.

Observation. If there is reason to deviate from these guidelines, the reader should keep in mind that this article only indicates the direction in drawing conclusions. However, any deviation from the guidelines should clearly describe why the deviation was made, so that another examiner can verify this point of view.

For the essence of the guideline, we refer to section: "Evaluation of similarities/differences, and drawing conclusions."

Short Description of the Examination Phases

A comparative shoemark examination consists of the following phases:

Phase 1. In phase 1, the shoes and impressions are examined for class characteristics (dimensions, form, and pattern) and accidental characteristics, and described.

Phase 2. Examination is done to determine whether the class characteristics, presented by the impressions, correspond or differ from those of the shoes:

- if there are no correspondences, but some differences, then a negative conclusion must be drawn.

In case there are differences in dimensions and shape, it is investigated if this could be the result of how the shoemark was produced, for example by running, jumping, or slipping.

If the class characteristics correspond, the next step is an investigation into acquired characteristics; i.e., whether

- the degree and pattern of wear and tear is similar or different;
- any damage is visible in the sole of the shoe that may have caused the irregularities in the shoemark.

Phase 3. In phase 3, the similarities encountered are analyzed.

Ascertained is

- the characteristic value of the similarities;
- the extent of similarity in shape between the damage of the shoe and the irregularities in the impression.

If any characteristics in the shoes are encountered that are not visible in the impression or characteristics in the impression are encountered that are not visible in the shoe, an explanation is sought.

A conclusion is drawn after the analysis of all similarities and/or differences. That conclusion depends on the extent of similarity or difference in

- class characteristics;
- wear and tear phenomena; and
- accidental characteristics.

If the type of shoe is not very common, an investigation can be performed to quantity the value of these findings. The findings of this investigation can be included in the examination as additional information.

If insufficient similarities or differences are encountered to state with certainty whether the impression *was caused* or *not caused* by the shoe, the conclusion must be expressed less forcefully.

In the Netherlands, the terms used to express a conclusion are

Affirmative:	*was caused;* *was very probably;* *probably;* *possibly;*
The question remains open:	*inconclusive;*
Negative:	*not plausible;* *probably not;* *not.*

Phase 4. In phase 4, a report about the comparative shoemark examination is produced in accordance to the laboratory procedures and national standards when (available).

Basic Assumptions of the Guideline

The following basic assumptions apply to the use of the guideline:

1. The similarities should, in principle, be visible to the naked eye. An enhancement tool, such as a magnifying glass, is generally only used to assess if the characteristics in the shoe were created during manufacturing or through usage of the shoe (for example, features caused by air trapped in the production process or damage due to use).
   If case magnification is used, attention must be paid to the fact that similarities smaller than 1.5 mm must be clearly distinguishable in size from the background noise of the impression. Should the dimensions of an irregularity be of the same magnitude as the noise, the characteristics that seem to be similar will not be considered as corresponding.
2. Background noise can be created by
   (a) the structure of the background on which the impression is placed (carrier);
   (b) the size of the particles of the material with which or in which the impression is made;
   (c) the surface structure of the shoe;
   (d) disturbance of the impression; and
   (e) retrieving or storing the footwear impression evidence incorrectly.
3. The guidelines apply to generally occurring wear and tear of shoes (for example, worn patches in the middle on the front of the sole and on the back of the heel).
   Similarities that are related to the following are not included in the guideline:
   (a) patterns of wear and tear that point to an unusual gait or to an abnormality in the feet of the person wearing the shoes and
   (b) damage to the shoes created in the manufacturing process.
   When such similarities are encountered, the values of these are ascertained separately and included in the final conclusion. For evaluation of this, more detailed investigation is

often necessary, focused on the statistic podiatric aspects and the manufacturing process in question, respectively.

Evaluating Similarities/Differences and Drawing Conclusions

In comparative shoemark examination, three situations can be distinguished:

- corresponding class *and* accidental characteristics;
- corresponding class characteristics, *but no* corresponding accidental characteristics; and
- class characteristics that are different.

It is possible for a shoemark to differ from a test print. This can occur in the following ways:

- through the way the impression was made – due to the height, weight, and the actions of the person while making the impression;
- through disturbance of the impression;
- because of damage caused to the shoe in the time between the shoemark being made and the shoe being seized;
- because of wear and tear obliterating earlier damage to the shoe in the time between the shoemark being made and the shoe being seized and
- the degree of wear or tear to the pattern may have increased, in the time between the shoemark being made and the shoe being seized.

If the differences between a shoemark and a test print cannot be explained by the above, they are indications that the shoemark was not made by the shoe.

Corresponding Class and Accidental Characteristics

If the class characteristics of the shoe correspond with the class characteristics of the impression, it is investigated if there is damage in the shoe that corresponds to irregularities in the impression. If there are damages, the following is ascertained about these similarities:

- **The number**

The number of accidental characteristics corresponding with irregularities in the impression (or, expressed less strongly, which shows similarities to irregularities in the impression).

The similarities encountered must be indicated and labeled in work forms.

- **The characteristic value**

After the indicated similarities have been given a label, the characteristic value of each similarity is determined by subdividing these into one of the six defined classes. These classes are listed in Supplement 1. The classification of a similarity depends on the size and complexity of the shape. This classification and the associated value are based on experience at the NFI.

- **The extent of similarity in shape**

The extent of similarity in shape of each labeled corresponding irregularity with the particular accidental characteristic is ascertained. There are two categories into which the extent of similarity in shape can be subdivided:

(a) location, size, and shape correspond and
(b) location and size correspond and the shape corresponds roughly.

If the location or the size is different, it is investigated whether this can be explained by the way the impression was made (standing still, walking, running, jumping, or sliding). If this is not the case, this irregularity and damage may not be considered to correspond.

Results of Characteristic Similarities. The results of the characteristic value determination are entered in the result table (Supplement 2). The characteristic value and the extent of similarity in shape are indicated for every similarity.

The results indicated in the result table are plotted in two conclusion graphs (I and II), which are based on experience. The graphs are presented in Supplement 2.

Graph I is for irregularities that correspond with accidental characteristics in location, size, and shape.

Graph II is for irregularities that correspond with accidental characteristics in location, size, and *roughly* in shape.

In the graphs, the number of similarities with the same characteristic value is plotted horizontally. The corresponding logarithmic value of the score "S" can be read on the vertical axis for the characteristic

value line in question. This is repeated for all similarities with an equal characteristic value. When the number of similarities with the same characteristic value increases, the "S" score will thus increase logarithmically.

Results of Corresponding Wear and Tear. The value of a possibly corresponding pattern of wear and tear is then added to the log(S) value obtained.

The following assumptions are applicable in this regard:

1. If the (general) pattern of wear and tear to the shoe is not present or minor, and this corresponds with what the impression shows, *nothing* is added to the log(S) value.
2. If the profile components of the shoe demonstrate clear occurrences of wear and tear (partially worn down), the log(S) value is increased *by 1, at most*, depending on the quantity and the extent of similarity with the impression.
3. If the wear and tear has advanced to such an extent that various profile components have taken on characteristic shapes and/or areas between the profile components that demonstrate wear and tear with clear characteristic shapes, the log(S) value can be increased by *3, at most*, depending on the extent of the similarity.

If the wear and tear indicates an abnormality of the foot of the person wearing the shoes, the value of this can be determined by a more detailed podiatric examination.

Conclusion. The separately obtained log(S) values are added together on the conclusion line, next to graphs I and II. The corresponding verbal conclusion is stated next to this line.

Depending on the number total of log(S) (Σ log(S), which represents the number of similarities, their characteristic value, the extent of similarity in shape and the possible corresponding wear and tear, a conclusion can be drawn that

- the impression was *possibly* made by the shoe ($0.75 \leq \Sigma \log(S) < 3.5$);
- the impression was *probably* made by the shoe ($3.5 \leq \Sigma \log(S) < 6.5$);
- the impression was *very probably* made by the shoe ($6.5 \leq \Sigma \log(S) < 8.0$); and
- the impression was *made* by the shoe ($\Sigma \log(S) \geq 8.0$).

Supplement 3 shows an example with sample data for filling in the result table and the graphs.

Note: Not all laboratories use this system, and such a system should not be seen as the panacea. However, the experience in our laboratory shows that it combines pragmatism and scientific rigor. More information about the value of shoemarks can be found in the Statistics section.

Corresponding Class Characteristics, but no Corresponding Accidental Characteristics

When corresponding class characteristics are encountered and accidental characteristics that correspond or differ are absent, the question remains open whether the impression was made or not made by the shoe.

Conclusion. Considering the corresponding class characteristics, the shoe qualifies for having made the impression.

Owing to the absence of corresponding accidental characteristics, it *remains inconclusive* whether the impression was made by *this* shoe or not.

Class Characteristics that Differ

When class characteristics that differ are encountered (most importantly differences in dimensions), it is investigated if these can be explained, for example by how the impression is made. This is backed up by making test impressions. If the differences in dimensions cannot be explained by the way the impression is made, if there are differences in shape or pattern, or if the impression shows more wear and tear than the shoe does, a conclusion of exclusion must be drawn.

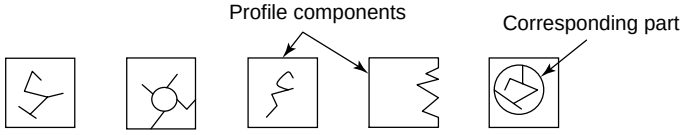
Conclusions. In these cases, depending on how clear the differences are, one of the following conclusions is drawn:

- it is *not considered plausible* that the impression was made by the shoe;
- the impression was *probably not* made by the shoe; and
- the impression was *not made* by the shoe.

Different Degree of Wear and Tear

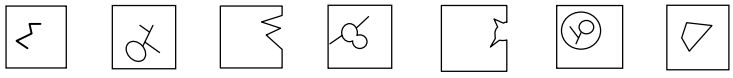
If the degree of wear and tear of the shoe does not correspond with the degree of wear and tear presented in the impression, it must be possible to explain why; for example by considering the period between the time the impression was made at the crime scene and the time the shoe was impounded. Should this not be the case, a negative conclusion must be drawn.

Conclusions. In this case, depending on how clear the difference is, one of the following conclusions is drawn:



- it is *not considered plausible* that the impression was made by the shoe;
- the impression was *probably not* made by the shoe; and
- the impression was *not made* by the shoe.

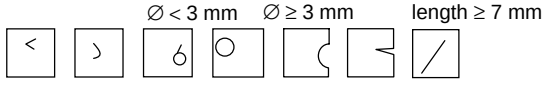
SUPPLEMENT 1 Evaluation of similarities



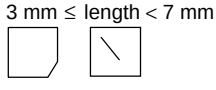
The value of a similarity between a particular accidental characteristic in the shoe and an irregularity in the impression depends on the number of corresponding components and the overall size of the similarity. The minimum acceptable size of a component is 1.5 mm. See also the explanatory notes on the next page. The similarity is subdivided into one of the following classes:

Similarity with "High Characteristic Value"

H1. Similarity consisting of six components, at least. One such similarity is necessary to ascertain that the impression was made by the shoe.

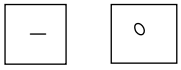


H2. Similarity consisting of four components, at least. Two such similarities are necessary to ascertain that the impression was made by the shoe.



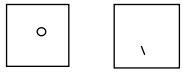
Similarity with "Medium Characteristic Value"

M1. Similarity consisting of two components, at least, or a line with a minimum length of 7 mm.
Note: a circle with a minimum diameter of 3 mm is considered as consisting of two components.
Three such similarities are necessary to ascertain that the impression was made by the shoe.



M2. Similarity consisting of one component with a size of 3–7 mm.
Six such similarities are necessary to ascertain that the impression was made by the shoe.

Similarity with "Low Characteristic Value"



L1. Similarity consisting of one component, a line or a round shape with a size up to 3 mm.
Eight such similarities are necessary to ascertain that the impression was made by the shoe.

1.5 mm ≤ size < 3 mm

L2. Similarity consisting of a line or a round shape with a size less than 1.5 mm.
Ten such similarities are necessary to ascertain that the impression was made by the shoe.
(the lower limit "x" depends on the magnitude of the background noise in the impression. It must be possible to distinguish the irregularity in the impression, as being a result of the accidental characteristic in the shoe, from the background noise).

x < size < 1.5 mm

Explanatory Notes

- **Minimum size of a component**

For the classes L1 and higher, components must have a minimum size of 1.5 mm.

- **Two- and three-dimensional impressions**

A three-dimensional footwear impression (such as a cast) *can* be compared with the shoe or with a test impression made with the shoe. The components of the similarity can extend in three dimensions.

A two-dimensional impression (e.g., a shoemark on a sheet of paper) *must* be compared with the shoe *and* the two-dimensional test impressions made with it. For an explanation, please refer to the examples in Supplement 4.

- **Too few components**

If the number of components in a similarity is too low to comply with the requirements of a class, a lower class must be selected. For example, a similarity with five components is classified in class H2.

- **Partial similarity in shape**

If an irregularity in the impression shows fewer components than the accidental characteristic in the shoe, or the other way around, attention must be paid to the fact that only the similarity is evaluated.

For example, if an accidental characteristic consists of six components and the irregularity in the impression shows four components of these, the similarity does not comply with the criterion of an H1. Only the corresponding components are counted, and the similarity is classified as an H2 (and noted as corresponding, in Graph I).

If parts of components in a similarity do not correspond entirely as far as shape and size are concerned or if they are presented vaguely, it will be classified as roughly corresponding (noted in Graph II).

- **Schallamach**

If an impression is made with or in a fine medium, very small details (smaller than 1.5 mm) in the shoe sole may be presented. Detailing of the impression may be so large that the fine details of a Schallamach pattern can be distinguished in comparison to the transfer medium.

A corresponding Schallamach pattern, with sufficient corresponding details (more than 10) may lead to identification. Should there be fewer than 10 corresponding details, an L2 value will be taken separately for each clearly corresponding detail.

SUPPLEMENT 4 Characteristic value of similarities in two-dimensional impressions

In comparative examination of two-dimensional impressions, determine the characteristic value of the similarities by the representations of the accidental characteristics in test impressions.

Figure 1 shows two studs from a shoe with one or two line-shaped damages (accidental characteristics), respectively, each with a length of 2 mm.

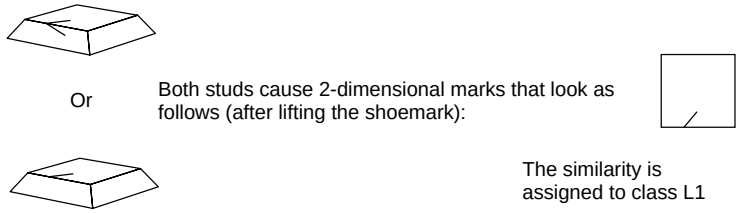

Figure 1 Two studs with one or two line-shaped damages

Figure 2 shows two studs from a shoe with, respectively, a circular damage of an approximate size of 3.5 mm, within which there are two other irregularities, each a length of at least 1.5 mm, and of a large circular damage with no further characteristics.

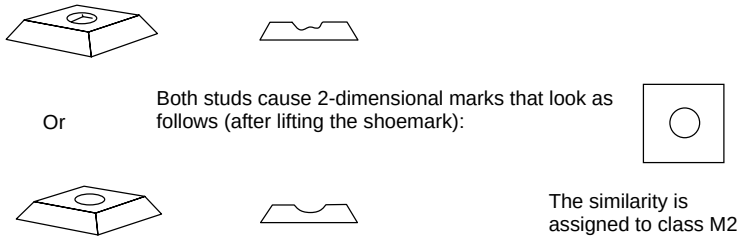

Figure 2 Two studs with two different circular damages

SUPPLEMENT 5 Definitions of terms used in this document

Accidental characteristics	See characteristics
Background noise	Disturbance of the footwear impression caused by the structure of the medium with which or in/on which the impression is made
Characteristics	Two types of characteristics are defined: Class characteristics These are features in footwear regarding the shape, pattern, and dimensions of the shoe as manufactured Accidental characteristics

	These are distinctive features of particular footwear caused primarily by general usage: wear and tear, and damage caused during use and secondarily by damage or imperfections caused during the manufacturing process
Characteristic value	A numerical value assigned to a similarity (of an irregularity in the impression with an accidental characteristic of the footwear), depending on its complexity
Class characteristics	See characteristics
Correspondence	This refers to similarities between a specific footwear impression and a specific shoe. Correspondence takes into account class and accidental characteristics.
Dimensions	The dimensions of shoe and footwear impressions are measured in millimeters The shoe sizes, used by manufacturers, are not considered accurate enough for investigative purposes Moreover, footwear impressions do not often show the size of the shoe that has made the impression
Footwear impression	The mark made by a shoe. The different types of footwear impression are Imprints in soft mediums (subsoil: sand, clay, snow, etc.) Marks standing out against hard or elastic surfaces, with or in a transferring medium. Mediums can include liquids, such as blood, mud, paint, and dust and any powdery material Note: when the term "footwear impression" is used, this refers to the original impression and also to any other acceptable reproduction of this, such as a photographic reproduction of a footwear impression on a negative or on paper, a digital photograph, a lifted footwear impression, a cast of a three-dimensional footwear impression
Form	The form is the basic outline of the sole of a shoe or a footwear impression
Impression	An impression is the mark made by a shoe as defined in "footwear impression", above
Mark	Another term for footwear impression
Pattern	The pattern refers to the ridges, lines, studs, and blocks of the tread of the sole of a shoe
Profile component	A distinctive part of a pattern (a ridge, line, stud, or block)
Shoeprint	Another term for footwear impression
Test impression	A test impression is made by the investigator for comparison with a footwear impression. A test impression is not always necessary, because when a cast of an imprint is available, the shoe can be directly compared with the cast. Test impressions are made when there is a lifted shoemark or a shoemark on a hard or elastic surface

Footwear and Foot Impressions: Databases

Introduction

Footwear impressions are recovered from all types of crime and over the past 20 years, considerable time and effort has been spent on the development of footwear databases. Their development has primarily been aimed at assisting an investigation by providing information about what possible footwear could have made the mark at the scene and provided background data to aid the evaluation of findings from a comparison [1–3].

Footwear sole databases have been developed by various forensic institutions and more recently, various commercial manufacturers have produced systems. It is the aim of this article to focus on the general principles and applications of footwear sole databases and the relationship with footwear impressions recovered from the scenes of crime.

The potential to gain useful intelligence through the use of footwear impressions is covered in article – **Footwear and Foot Impressions: Intelligence**.

The topics reviewed in this section are given as follows:

1. reference database of sole patterns from footwear
   (a) structure
   (b) coding
   (c) duplicate sole patterns
2. use of database to aid an investigation
3. use of database to aid evaluation of findings.

Reference Database of Sole Patterns from Footwear

There are several factories worldwide producing an enormous range of footwear including training shoes, casual footwear, traditional smart footwear, etc. The range of sole tread patterns as one would expect is even greater ranging from the plain leather sole on a smart dress shoe to tread patterns that are comprised of a single pattern component to footwear with tread pattern comprised of various complex geometrically shaped components.

The tread pattern on a specific brand and style of footwear may essentially be the same in appearance, but the size and spacing of the tread pattern components can vary depending on a number of factors. These include the size of the footwear, the method of manufacture, the number of moulds used by the manufacturer for a specific design, and the country of origin. Other footwear, especially training shoes, can have tread pattern components that change in appearance with wearing, an example being components that appears circular when new, can appear square when worn.

The primary function of the footwear sole database has been to provide a source of information that a footwear examiner can use, primarily to deal with two aspects:

1. To aid the investigative process by providing details of the possible footwear responsible for a mark at a crime scene.
2. To aid the examiners assessment of the evidential significance that the tread pattern makes to their final conclusion.

The sole reference database consists of a collection of sole tread patterns from items of footwear. The aim of the collection is to try and cover as many examples of footwear sole tread patterns as possible, although it is extremely difficult to deal with every available type and style of manufactured footwear. Therefore, most systems are based primarily on the most commonly encountered footwear. The collection of tread patterns means that it is possible to record features such as the manufacturer, the type and style, the size, and country of origin and a photographic record can be made about the appearance of the uppers. The database is made up of an image of the complete sole pattern. Every part of the tread pattern has to be present; otherwise, components may be missed when it is subsequently coded and may hamper any subsequent searches.

To actually record every pattern that could potentially be of interest during an investigation is extremely difficult and is generally unnecessary. This is due to the fact that the vast majority of crimes involve people wearing a limited number of footwear styles and in most instances of burglary, for example, in the United Kingdom, the footwear of choice is some form of training shoe.

The three main ways used to obtain sole tread pattern information are listed in the following section.

- **Direct from manufacturers.**

It is possible to obtain examples of new footwear patterns and relevant information by developing a direct relationship and agreement with the main manufacturers. It is difficult to have this relationship with all manufacturers, but any that can be established requires a lot of time and resources should be applied to make sure it is maintained. If it is not possible to deal directly, then another source of information can be to attend events organized by manufacturers where they present and market their goods to the trade buyers. It is normally possible on these occasions to record all required information including taking test prints and images of the uppers from the models of interest.

- **Footwear submitted to a laboratory or institute during casework.**

This refers to items of footwear that are taken from a suspect and submitted to a forensic laboratory/institute as part of the normal casework comparison process. Once it is submitted, it is possible to take test prints of the sole tread pattern and to take images of the uppers, plus details regarding the footwear such as size, country of origin, style number, and color. The footwear that will be encountered will provide examples of how certain patterns will look like during the various stages of wearing.

- **Footwear sole tread patterns taken by law enforcement agency in custody.**

Increasingly, an excellent source of information is obtained from the law enforcement agency. The police in the United Kingdom are authorized under the Police and Evidence Act (PACE) to take the footwear from a person arrested on suspicion of an offense. Various methods are available to make a record of the tread pattern on the sole of the shoe. The relevance of this source of tread patterns is that it is a record of what is actually being worn by people at that time and is more representative than the database made up entirely of tread patterns from submitted casework.

Coding of Tread Patterns

The main problem of how an examiner makes use of this potentially huge amount of information has been to develop a coding scheme of some form or another that allows different sole tread patterns to be differentiated from each other and allows small partial areas of the pattern to be identified.

The two main methods that have been developed and have obtained favor amongst examiners are provided in the following list:

1. use of generic pattern descriptors or icons and
2. use of a generic code name.

It is possible to describe a sole pattern fairly easily if the number of different components is small and their shapes fit a known descriptor. One of the problems associated with coding any footwear mark is trying to ensure consistency between the various people involved. This is important to ensure that all relevant impressions must be recovered from a search and everyone should talk in the same language. Consequently, there are normally rules associated with how the coding scheme is applied.

An example of a simple tread pattern, which can be coded easily and consistently, is the simple straight bar pattern illustrated in Figure 1.

It has therefore been possible to describe this generic pattern verbally as “a series of straight bars” or simply to use “straight”. This method has been used effectively in fairly simple databases based on Microsoft excel or a similar type software.

More sophisticated software and search algorithms have enabled the development of more complex and sophisticated software systems. By coding using icons, it is possible to code a mark from

Figure 1 This footwear has a simple pattern of evenly spaced straight bars

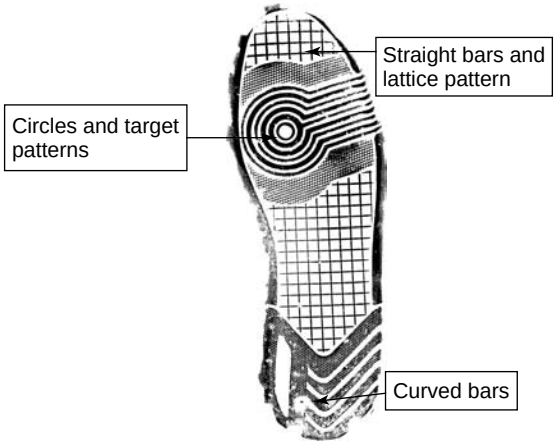

Figure 2 Complex pattern consisting of various tread components

the crime scene and search the reference collection to find any matches, search large numbers of footwear tread patterns for example, or to use icons to visually describe the pattern. By examining the various pattern components, it has been possible to build up a library of pattern descriptors and icons shapes that can be used to describe the various sole tread patterns and brand logos present on footwear.

Figure 2 shows an example of a complex tread pattern from an Adidas training shoe.

In this instance, it is possible to identify several pattern components than the straight bars in the example shown in Figure 1. It is possible to use random pattern, linked or lattice, straight, curved or wavy, circular, semicircular, oval, targets, lattice or linked pattern, complex, irregular, square, and logo. Of course, not all systems have the same descriptors or icons and it will depend on which patterns and shapes are used.

The following example shows a fairly complex pattern consisting of various components. A number can be identified in this example (Figure 2).

The use of icons allows for the use and development of computers to do all the hard work and the examiner identifies the most likely footwear contained in the database. There are rules and/or guidance to follow and to ensure consistency when more than one person is involved.

Use of a Generic Code Name

An alternative to the coding of footwear by using individual components as descriptors is to allocate a name to the tread pattern. This has an advantage in that everyone using the same coding system will know what the footwear looks like from the alpha numeric reference that has been allocated.

This is usually done in two ways. The first is to allocate the manufacturers name and a number. Usually, the number is based on something as simple as when it was first seen in the laboratory. An example would be Reebok 7; the seventh different tread pattern seen on the sole of Reebok footwear. The second alternative is to use the manufacturers name and the style name of the footwear as a reference; an example would be Reebok Classic.

In most commercially available systems, both elements will be utilized and the reference collection will have named tread patterns, with the ability to search using the various pattern components.

The reference database is therefore made up of complete sole tread patterns from footwear. It will be coded in some way and may contain more than one example of a specific pattern to show how the pattern changes in appearance with wearing. In some organizations, the reference collection is only the tip of the iceberg. The collection will additionally consist of test prints taken from all the footwear submitted. Of course, depending on the time the collection has been going and how often a particular pattern is encountered, there may be hundreds of examples of a pattern showing a whole range of sizes, moulds, and degrees of wear.

Use of Database to Aid an Investigation

At a crime scene, the perpetrator of the crime may leave footwear impressions. In some instances, these tend to be the more serious types of offense, and the law enforcement agency investigating this crime may need to address the following questions:-

- What does the complete tread pattern look like on the footwear responsible for the mark recovered at the scene?

- How manufacturer makes footwear with the identified tread pattern?
- What do the uppers look like in a footwear with the tread pattern?
- What is the size of the footwear responsible?

The information provided may give the investigators a lead or at least help when they have a suspect and are searching for clothing that they should submit for examination.

The process in this type of inquiry is for the footwear mark to be submitted to the footwear examiner who will examine and then code the tread pattern that is visible. Enhancement techniques may be used to ensure that the mark is clearly visible and that no other impressions are present. The mark will then be coded using the coding scheme most appropriate for the system. The database will be searched and "hits" will be found. These "hits" need to be considered against the submitted mark, but in many instances it will be possible to identify what type of footwear has the corresponding sole pattern, which manufacturer made them, and how the uppers will look like. With some partial impressions at a crime scene, the outcome will not be one single 'hit' but you are likely to get a list of potential "hits". This result is obtained due to the discriminating power of a coding scheme. If you make it simple, anyone will be able to use it after some training but it is likely that you will get lots of "hits", which will need further investigation. If you make a very complex coding scheme, then there is a need for more training, less people will be able to use it, it can introduce variation as people will have to make more decisions, but it is likely to reduce the number of "hits". Some common tread patterns are present on footwear produced by more than one manufacturer and the only visible difference between complete tread patterns may be the presence of a logo. This may mean that any feedback to the investigating officer is given with a "health warning".

The sizing of footwear impressions at crime scenes is normally an approximation at best and examiners will usually report a range of sizes. The underlying collection of the database can assist, as it may have a large number of different sizes and moulds of the appropriate sole pattern which can be used to estimate the size of the footwear responsible for the mark at a scene.

Use of Database to Aid Evaluation of Findings

This section does not elaborate the processes involved in doing a footwear mark comparison but provides general information regarding how an examiner uses the database to aid their interpretation [4–6]. Footwear mark comparisons are described more in detail in the article (*see* **Footwear and Foot Impressions: Comparison and Identification**).

In a footwear mark comparison to footwear submitted to an examiner for comparison, the examiner takes into consideration several aspects: pattern, size, mould, wear, and damage. In some forensic institutes/laboratories, examiners use the footwear collections that they hold to aid their evaluation of the evidence. They can estimate the commonality/frequency of the pattern being considered. It is also possible to gain useful information regarding the size, mould, and wear from the collection.

Ultimately, this information can assist the expert to express his or her opinion when a mark and a known sole cannot be differentiated.

Footwear and Foot Impressions: Foot Impressions and Linking Foot to Shoe

The forensic application of barefoot morphology involves the study of the physical features of feet and the impressions they make. This type of examination is used in cases when either an impression has been made at the scene of a crime or when the wearer of a shoe needs to be determined. However rare the application, in instances where it is needed to answer a question in a criminal case, barefoot impression evidence can become extremely important.

Barefoot Impressions as Physical Evidence

Barefoot impressions are a type of impression evidence that may be found at the scene of a crime. For example, if an individual involved in a homicide steps into a pool of blood with bare feet, they may track impression detail of the skin of the feet (friction skin and creases) that may be compared and identified in the same manner as fingerprints [1] (*see* **Friction Ridge Skin: Comparison and Identification**).

The shape and size features of the foot, defined as the morphology of the foot, may be examined and compared in barefoot impression evidence cases where the detail is insufficient to make a friction skin identification [2]. This type of examination is relevant when impressions have been made by a sock-clad foot, or when detail of the impression is limited due to a variety of deposition manner or surface type factors. It is also applied to the examination of the impressions found on the inner surfaces of footwear.

Barefoot impressions found on the insoles of footwear are analyzed to determine possible association or lack of association between a suspect and a particular shoe or boot. Scenarios in which this may provide important investigative information include cases in which discarded footwear has been associated to an impression from a crime scene, or in which footwear is found at a scene and may belong to either a suspect or a victim [3].

Accepted techniques for the comparison of footwear impression evidence include a side-by-side visual comparison, and the creation of an overlay tracing of the known item to be placed over the item in question to determine correspondence of features [4] (*see* **Footwear and Foot Impressions: Comparison and Identification**). The same techniques, side-by-side visual examination and overlay, are employed in the examination of barefoot impression evidence [5].

The Structure of the Foot and the Foot Inside a Shoe

A normal foot has 26 bones. Five metatarsal bones, which reach from the arch area to the metatarsal head area, are distinctly separated from one another. Phalanx bones are anterior of the metatarsal bones, forming five separate toes [6]. When a foot is placed inside a shoe, the forefoot and toes are most commonly constricted inward.

Barefoot impressions on the insoles of shoes are the result of pressure, heat, and sweat that occurs during the wearing of a shoe [3]. These impressions characteristically do not include friction ridge skin or crease detail, as socks are normally worn and the impressions result from repeated wearing of the shoe, with the foot constantly rubbing, rather than from a single touch of the foot inside the shoe. These impressions are often a clear recording of toes and the forefoot leading edge of the ball portion of the foot, referred to as the *metatarsal ridge* [2, 3, 5, 7]. In some footwear, impressions of the ball, arch, and heel areas may also be present (Figure 1).

In a barefoot comparison of shoe insole impression evidence, the recording of the features of the foot visible on the inner surface of the shoe are compared with the known exemplars taken from a person in question to include or exclude them as a source of the impressions inside the shoe. Comparisons also take place between the inside uppers of the shoes and the wear patterns as associated to the three-dimensional features of the foot which come into contact with the upper inside surface of shoes, such as toe nails, protruding toes, or toe joints [5].

As can be seen in Figure 2, an inked barefoot impression taken of a foot outside a shoe is wider in the forefoot and toe areas than is the impression of the same foot inside a shoe. A significant constriction

Figure 1 Foot impressions on shoe insoles

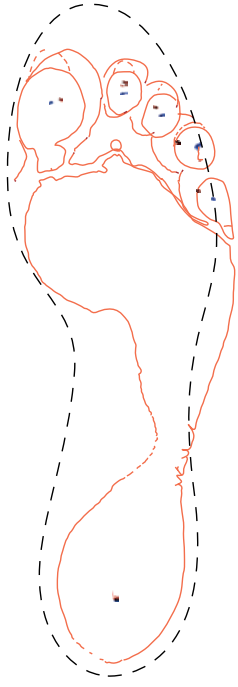

Figure 2 Tracing of a barefoot impression overlaid onto a tracing of the impression of the same foot inside a shoe

of the toes and metatarsal area is often observed when comparing a barefoot impression inside a shoe to one taken outside of a shoe. It is extremely important to take this constriction into consideration during an analysis of a barefoot impression inside a shoe.

Known Exemplars Used in Barefoot Comparison Cases

For the comparison of barefoot impression evidence, inked impressions are taken both walking and standing, both of naked and socked feet (Figure 3) [7]. Walking impressions involve the inking of the person's feet, and then having the person walk a length of paper approximately 15-feet long, down one side and back the other. This provides a series of naturally walking impressions for use in the comparison process. These successive impressions have been observed to "exhibit little or no change" from one another as they are made along the paper [8].

Known shoes of the person in question may also be seized for comparison to barefoot impressions found inside the shoes in question involved with a crime [8]. However, in practice, occasionally, only

Figure 3 Three barefoot impressions of the same right foot

inked impressions are available for comparison to the impressions of feet inside of shoes [9]. Thus, although it is generally recommended in forensic examinations to compare "like to like" exemplars, such as a shoe insole impression to another shoe insole impression, occasionally it is necessary to compare an inked bare foot impression to an impression inside a shoe.

Databases and Studies of Barefoot Impression

Some of the research in the area of foot morphology and forensic application has taken the form of the collection of large numbers of barefoot impressions from individuals and categorization of them to determine how variable the feet are.

The 1980 study of this type conducted in India collected footprints from 725 individuals. From the measurements taken, a series of indices were calculated to represent variation among the feet. These indices were combined to calculate probabilities. This appears to be one of the first applied databases using foot measurements and calculated statistics to estimate the variability of barefoot morphology in the human population [10]. Previous and subsequent similar studies have derived similar indices to one another, providing support for both the method employed and statistics demonstrating the high level of individuality of feet [11]. The five foot impressions in Figure 4 show the variability in shape of the features of the feet and toe positions between different individuals.

In 1986 and 1987, the FBI collected barefoot impressions from 500 individuals. Measurements, as described previously, were entered into a computer database and intercompared. It was noted that the size and shape features varied considerably and concluded that no left or right foot of any individual in the sample set was found to be identical. Further, results showed that only a few combined size and shape characteristics were required to discriminate a foot from this population [3].

The Royal Canadian Mounted Police (RCMP) has collected approximately 12 000 barefoot impressions for the study [12]. Two statistical analyses have been carried out on portions of these samples that have been entered into a database. The population used in the first preliminary study was 960, and for the second study it was increased to 5755 [13, 14].

Figure 4 Impressions of right feet from five different individuals

These studies concluded that measurements taken of the feet show a great degree of variability between the barefoot impressions of individuals, and a great degree of similarity between multiple impressions of feet taken of the same individual. The second study reports the statistical odds of a chance match of barefoot impressions, based solely on the positions and measurements of the characteristics of the feet recorded, with no ridges or creases considered, to be one in 1.27 billion. This number is not used in criminal cases, it is applied as an indication of the high degree of variability of barefoot morphological features for background and research purposes.

Both the footwear industry and military researchers have studied the population of human feet for the purpose of achieving comfort in footwear. Although not the goal of the studies, the results include comments which reflect upon the wide variety and differences in the structure of feet [3, 15, 16]. Although these are not to be considered forensic validation studies, they do support the concept of high degree of individuality of the morphology of the foot.

In addition to the construction and statistical analysis of databases, forensic texts that include sections on the examination and comparison of barefoot impression evidence, as well as articles specific to this discipline, have been published [2, 3, 17–19]. Through discussion, practice, peer review, and study, the development of forensic barefoot morphology impression comparison has been shaped over the last few decades. It is this process that has led to the current procedures and methodologies for the examination of this type of evidence. Both empirical and statistical studies validate the identifying nature of specific physical features of the foot, and that these features may be used to exclude an individual as the source of a barefoot impression, include them as a possible source of the impression or may lead to an inconclusive conclusion.

DNA Analysis Applied to the Insides of Shoes

It should be noted that DNA technology may be applied on samples taken from inside the shoes (*see* **DNA: Sources of**). This analysis could assist to assess if a contact occurred between an individual's feet and the shoes. However, in many circumstances, the chance of obtaining a profile may be small. Additionally, the DNA from more than one person is often found on the insides of shoes, not necessarily including the owner of the shoes [20].

Case Examples in the Comparison of Feet to Shoes

There have been many interesting cases in the past decade involving the examination and comparison of the insoles of shoes in determination of the wearer of the shoe, examples are mentioned later.

In 1948 in Canada, a shoe to foot comparison was conducted between a pair of shoes and two brothers who were suspects in a series of break and enters. One brother, Donald Kett, was convicted. The other brother, William Kett, claimed he was innocent and that all the shoes that were matched to the crime scene belonged to Donald. However, through comparison of the impressions inside the shoes, it was determined that William had worn the shoes, and he was also convicted [21].

In 1955, a burglar left his shoes at the scene of a crime in Surrey, England. Shoes were obtained from a suspect, and casts of the insides of the shoes were made and compared against one another. The shoes were found to have been worn by the same individual. This evidence was presented in court and a conviction was the result [22].

William Bodziak, a retired FBI Special Agent, describes a case in which a fleeing suspect lost his right shoe at the scene of a homicide. By comparing the sweat stains and depressions of the wearer's foot on the insole of the crime scene shoe to those found in the right shoe the suspect was wearing when apprehended, it was determined that there was a high probability that both the shoes were worn by the same person [3].

Robert Kennedy, a retired RCMP Officer, has conducted many cases involving the comparison of shoe insoles. One of his cases involved the homicide of a prostitute in Israel. A young man was the suspect, and when shoes were seized from his house, it was determined that his brothers and father also wore the same style of shoe. All the shoes were examined, and the victim's blood was found on the outside of one of the pairs of shoes. After the insole impressions of the shoes were examined, it was determined that the impression in one shoe did correspond to the suspect, but the impression in the other shoe did not. After

further examination of the insoles, it was determined that the insole that was different from the suspect's foot was not the original insole. Through a physical match of the glue residues on the bottoms of the insoles of all the shoes, the original insole was found in one of the other shoes. The impression on this insole was also found to correspond to the suspect, which linked the suspect to the pair of shoes on which the victim's blood had been found [23].

Another example of the use of barefoot morphology to link a suspect to a shoe associated with a crime in a series of break and enters in 1999 and 2000 that occurred in Manitoba, Canada. Similar shoe impressions were found at three crime scenes. When a suspect was located, and discarded shoes were found corresponding to the shoe impressions from the crime scenes, he denied ownership of the shoes. After examination and comparison it was determined that the suspect was likely the wearer of the shoes, and he was charged with the three offenses [24].

Footwear and Foot Impressions: Intelligence

Introduction

Over the past few years, there has been an increasing awareness among law enforcement agencies worldwide that footwear impressions have the potential to make a significant contribution to police intelligence.

The evidence from crime scene statistics suggests that footwear impressions are present at a large number of crime scenes, and its percentage is similar to DNA and fingerprints. Footwear impressions are routinely recovered from the scenes of crime by officers using a range of techniques, including photography, adhesive lifts, and gelatin lifts, which are the three most common methods. Clearly, the majority of footwear impressions are recovered from the scenes of more commonly occurring crimes, such as burglary, theft, and criminal damage. It is this type of offense that has been the focus for the establishment of intelligence systems. The previously established systems were fundamentally based on human input and effort. Today the databases are much more sophisticated and provide increasing opportunities to maximize the contribution that footwear intelligence can make. [1–8]

The following topics are reviewed in this article:

1. why can footwear impressions be used as intelligence?
2. structure of footwear databases
3. use of databases to provide footwear intelligence.

Why can Footwear Impressions be Used as Intelligence?

The majority of impressions are recovered from the scenes of more common offenses such as burglary, theft, and criminal damage. There is a general acceptance amongst police investigators that a small number of people is responsible for the majority of crimes. This means that by gathering forensic intelligence and using other information available to the police, such as type of offense, location, modus operandi (MO), it is possible to gain invaluable information about linking crime scenes and to potentially identify the person who is responsible for the crime. Fingerprints have been used to provide intelligence to police for many years and more recently, the National DNA Database (NDNAD) in the United Kingdom has shown how useful DNA can be to the police in providing thousands of "hits", either to link different scenes or to show that a specific person may be linked to a scene or scenes.

The value of footwear impressions has been recognized by the UK government when they passed changes to the Police and Evidence Act (PACE), which enabled sole prints to be taken from the footwear that were worn by the persons arrested by the police. Footwear has the potential to play a significant role in providing intelligence to law enforcement agencies.

There are limitations to the use of footwear and these are the same factors that are also applicable to any comparison work. The simple fact is that as an item of footwear is worn over a period of time, the appearance of the sole will change and the detail that it produces in an impression will also change. Some features such as the pattern gradually changes, whereas fine characteristic detail can change within hours or days.

In using footwear, there is always a need to consider the time between when an impression was made and when the footwear of interest was recovered as the examiner may have to consider the differences that they find and make a judgment as to the meaning and significance of any difference found.

Structure of Footwear Databases

A footwear intelligence system is primarily made up of the following essential elements:

- reference database and
- scene and suspect databases.

Reference Database

The reference database/collection provides a source of information that can be used by the people involved in providing the intelligence. The database normally consists of prints taken from the sole of known footwear, where it is possible to gather information with regard to the manufacturer, size, country of origin, etc. (*See* **Footwear and Foot Impressions: Databases**.)

The sole reference database consists of a collection of sole tread patterns from items of footwear. The database is made up of an image of the complete sole pattern and also normally contains images of the uppers that are associated with each pattern. Depending on the system, these tread patterns will be coded, either by the use of pattern component descriptors such as straight bars, wavy bars, circles, target, square blocks, logo etc. These descriptors codes can be in different formats ranging from a simple letter or a word code to represent a particular component to the use of sophisticated icons. The other alternative

is to have an alpha-numeric descriptor for a particular pattern, which is usually based on the name of the manufacturer and a name or number, e.g., Smith 100, Smith Classic. The importance of maintaining this reference database is to provide a universal descriptor of a specific pattern that enables examiners to assign a code or name to each footwear impression that is recovered from a scene and to each item of footwear recovered from a suspect who is arrested and comes into custody.

There are various systems available but almost all are computer based, which makes the coding and searching much easier. One feature that helps to improve the effectiveness of a system includes, regularly updating of the reference collection to ensure that new tread patterns are captured and included in the reference. It is also useful to have some indication of how often a particular sole pattern is seen, its commonality.

Scene and Suspect Databases

The other two parts of an intelligence system are the databases/platforms for the footwear impressions recovered from crime scenes and the footwear recovered from the suspects who are arrested for an offense by the police/law enforcement agency.

The law enforcement agency will have a lot of information and available data, and some of this will be fairly sensitive and may have restricted access. The general information, that is, stored for a scene mark will include such things as, date of offense, date of scene impression recovered, division, address of scene, other forensic evidence recovered, offense code, and of course the code of the footwear impression. A similar set of data will be recorded for a suspect's footwear but will be more specific about the individual and may include name and related reference numbers.

Use of Databases to Provide Footwear Intelligence

- coding of footwear impressions and suspect footwear;
- assessment of the evidential quality of a scene mark;
- scene-to-scene linking;
- scene-to-suspect linking and screening of footwear.

Coding of Footwear Impressions and Suspect Footwear

The recovered footwear impression from the crime scene will be examined and a code allocated for the tread pattern will be apparent in the impression. A pattern code will also be assigned to the footwear taken from a suspect. It is often the case that at a particular period of time, there will be specific footwear that occur most commonly and make up the majority of the marks recovered and the footwear taken from the suspects. Using the allocated codes, it is possible to search the suspect and scene databases to identify if there are any "hits" obtained which would indicate other scenes or suspects that may be linked and would warrant further investigation. There is of course the potential to use other parameters that can reduce the scope of the search.

Assessment of Evidential Quality of a Scene Mark

When examining the scene impressions, it is possible and useful to assess the quality of the impression and its intelligence and evidential potential. In undertaking footwear comparison, there are a number of factors that are taken into consideration; pattern, size, mould, wear, and unique characteristic damage features. It is therefore possible to assess both the intelligence potential of the footwear impression and the evidential potential of the footwear impression and allocate a point on a scale. It is accepted that any impression where it is possible to discern a possible pattern has some intelligence use, as it can be coded and used in a search to show potential links to other scenes. It is also true that a footwear impression consisting of a single pattern component such as a single square block may show sufficient characteristic detail to enable an item of footwear to be conclusively identified as the boot/shoe responsible. It could be said, however, to have limited intelligence value as it would be very difficult to assign the correct pattern code. A square block is found on a very large number of tread patterns.

An example of a possible quality scale is shown in Table 1.

A footwear impression is of "good quality" if the features of the mark, such as the pattern components and any other detail, are clearly apparent and well defined. Footwear impressions that are poorly defined and do not even show any pattern components

Table 1 Example of Intelligence/Evidential Assessment Scale

Point on scale	Intelligence/evidential value	Description
1	No intelligence or evidential use	Very poor quality impression with no clear pattern or detail
2	Potential to provide Intelligence only	Generally poor quality impression but has pattern components apparent but the mark does not show any other detail.
3	Potential to provide limited evidential support	Generally poor quality mark but with limited details present which may include, pattern, mould, and wear.
4	Potential to provide significant level of support	Fair to good quality mark with pattern, mould, wear and possible damage features
5	Potential to provide strong support or conclusive evidential result	Clear well-defined good quality footwear impression with characteristic feature present

are unlikely to be of any significant evidential or intelligence value. A footwear impression is of poor evidential quality if it is only possible to observe the most basic aspects of the tread pattern and there is no other detail present. Impressions that only show the basic tread pattern may be poor evidentially but do have an intelligence value. It should be noted that this description is valid only if no unexplainable/meaningful differences exist between the mark and the actual sole.

Scene-to-Scene and Scene-to-Suspect Linking

Law enforcement agencies have made the use of intelligence as one of the core activities. For many years, they have used fingerprints and DNA and combined the information supplied by these forensic disciplines together with all the other information that they use to aid investigation. By identifying potential suspects, they can also analyze the information generated to examine the areas such as crime trends and also help the police to target specific locations. Footwear is an additional forensic area that can contribute toward the picturethat is generated. It does not have the same potential to produce identification as fingerprints and DNA do but it can be very effective.

Scene-to-scene linking can be undertaken at the very simple level by using the pattern code to find potential links and then using other information to investigate the link further. The way in which this is undertaken will depend on the computer system used and the nature of any search engine. The integration of other case data such as modus operandi and time of the offense, for example, into the system may provide increased resources for intelligence and more generally crime analysis.

It is also possible to undertake a more detailed comparison of the "linked" scenes to determine if there is any other corresponding detail or features within the marks which would provide stronger evidence that the same footwear was responsible for both marks.

Scene-to-suspect linking is basically the same as that for scene-to-scene linking. The links can be

identified just by using the pattern code, and that is generated when a scene mark is first put on the database and when the suspects footwear is coded and then searched. It is also an option to do a degree of comparison between "hits" that may be generated from a search. The scene mark and a print of the sole tread pattern from the suspect footwear can be compared, and similarities and differences assessed will enable an examiner to determine what evidential potential a full one-to-one comparison may have.

Footwear and Foot Impressions: Overview

Comparison and Identification

Comparison is defined as "the process of ascertaining whether two or more objects have a common origin" [1]. In footwear and foot impression evidence, this occurs through the analysis of the impression in question from the scene of a crime and an evaluation of similarities and differences to a source in question. The source item and exemplar impressions made by the item are compared to the impression from the scene.

In the area of footwear comparison, impressions are made by the outsoles of the shoes or boots. A footwear comparison is conducted using both the actual shoe and test impressions made using the shoe in question (Figure 1). The characteristics that are compared range from class or manufactured characteristics, which are attributes of the design and manufacturing processes, to accidental or acquired characteristics, which are due to random occurrences. Class characteristics may include the item of footwear as a possible source of the scene impression or they may eliminate the item of footwear as a source of the impression. The presence of sufficient individualizing characteristics, as well as the absence of unexplainable/meaningful differences, in both a scene impression and an item of footwear may result in identifying a particular shoe as the source of an impression.

There are quantitative and qualitative elements involved in the comparison of shoe impression evidence. Physical size, shape, and relative position of both manufactured and acquired characteristics may be compared quantitatively through processes such as overlaying a test impression of a shoe on top of an actual size photograph of a crime scene impression or examining the exemplars side by side and using calipers. Differences, similarities, and value of associations and disassociations are interpreted qualitatively based on training and experience. Influences such as movement during impression deposition, effects of substrate material, and collection methods are studied during training and are continually evaluated through experience. Training and certification programs establish standards and expectations for footwear examiner experts. The International Association for Identification has established a recommended course of study for shoe and tire examiners and has a certification program in the area of footwear examination [2]. The Canadian Identification Society also has a footwear examination certification program [3].

It is noted that there are differences in the methods of reporting of comparison conclusions between agencies and between countries. However, comparison results commonly range from general correspondence of outsole design characteristics to an agreement of unique characteristics. More information about the interpretation of footwear impression

Figure 1 A shoe outsole and a test impression of the same shoe

can be found in the Statistics(Interpretation) section of the present Encyclopedia.

Foot impression comparisons are conducted by analyzing an impression of a bare or sock-clad foot from a crime scene and an evaluation of the similarities and differences to the foot of a person to determine if they may or may not have made the impression. If a barefoot impression includes the recording of skin detail, known as friction skin, then the impression is analyzed in the same manner as fingerprints and palm prints. However, if a conclusion based on the unique features of the skin is not possible, a comparison of the shape features of the feet may be conducted. This type of comparison may result in the inclusion or exclusion of a person as the possible source of the crime scene impression.

Foot impressions and linking foot to shoe

Foot impressions also may be present in the insides of shoes. This type of impression may be of value to determine who wore a particular shoe. A shoe may be compared to exemplar impressions of the foot of a person and/or to other items of their footwear. By comparing the size and shape of the features of the foot, with consideration for the possible effects of these features when inside of a shoe, a person may be included or excluded as the possible source of the impressions in an item of footwear (*see* **Footwear and Foot Impressions: Foot Impressions and Linking Foot to Shoe** for more information).

Footwear impressions

Footwear impressions may occur as a result of deposition of a material, removal of a material, or imprint into a surface or substrate (Figure 2). Impressions may be categorized as two- or three-dimensional based on the resulting depth of the impression. Deposition and removal of material usually results in a two-dimensional impression, and impressing into a substrate results in a three-dimensional impression.

An item of footwear may step into a material such as dirt, dust, oil, or blood. This material can transfer in subsequent steps to a relatively clean surface, leaving an impression of the outsole of the footwear. A clean footwear outsole may come into contact with a surface covered with material such as dirt, fine dust, or powder. This material may stick to the clean outsole as travel occurs across the surface.

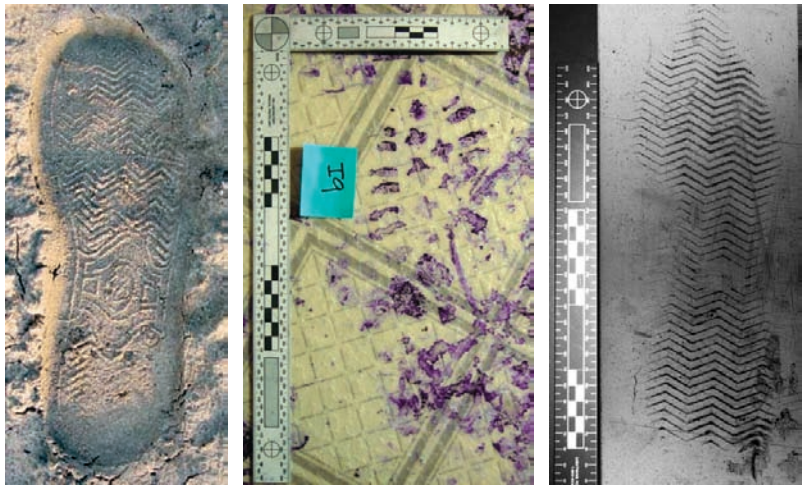

Figure 2 Examples of different types of crime scene footwear impressions (a) 3D impression in soil; (b) enhanced blood impression; (c) gel lift of a dust impression (color inverted)

This may leave an outline, or negative impression, of the outsole design behind.

A soft material, such as mud or snow, may hold an impression of a footwear outsole after a step into it has occurred. The condition of the material and the environment affects the quality of the impression over time. For example, the snow may melt, or wet mud may flow back into the impression, covering detail. If, however, the nature of the material is conducive to maintain the shape of the footwear outsole, a three-dimensional recording of the outsole will be recorded.

Detection and recovery techniques

The methods utilized for detection and recovery are dependant upon the condition and nature of the impression. Deposition or removal of material usually results in a two-dimensional impression and is usually photographed and lifted. A three-dimensional impression is usually photographed and cast.

Detection of footwear impressions may be accomplished by careful observation and through the use of lighting techniques, forensic light sources, application of chemicals, or lifting materials and equipment (Figure 3). The composition material of the impression will determine the method used for detection, possible enhancement and recovery. Dust and blood, for example, require a different series of processing techniques for two-dimensional impressions. There are also different casting materials and techniques utilized for three-dimensional impressions in dirt, mud, sand, and snow. Impressions on surfaces that may be removed from the scene may be collected, still attached to the original surface, such as a shoe impression on a piece of paper, or on flooring that may be cut out and removed.

Footwear outsole databases

Databases of footwear outsole impressions are utilized to search impressions from scenes of crime to determine what type of footwear may have left the impression. Once a possible source is determined, it may be possible through manufacturer information to determine a size or size range of shoes that made the impression. Outsole databases are created through the collection of footwear designs and entry into an electronic system, which allows searching and retrieval based on the patterns and designs of an impression.

Crime scene impressions of footwear may also be entered into database search and retrieval systems. Unidentified impressions may be compared to one another, potentially linking impressions from different crime scenes to one another (*see* **Footwear and Foot Impressions: Databases** for more information).

Forged and Counterfeit Documents

Introduction

While the terms *counterfeit* and *forgery* are often used synonymously, there exists a distinct difference between counterfeit and forged documents. A counterfeit document can be defined as one wherein

a genuine specimen is used as a template for the creation of a document that infringes on the property rights of the issuer and misleads the acceptor as to its true identity, validity, and/or authenticity [1]. Examples of counterfeiting include constructing a fraudulent identity card, generating spurious travel documents, or the unauthorized printing of money. Forgery, on the other hand, involves the illegal alteration of an existing genuine document and includes actions such as modifying the amount for which a check is written or altering the date of inception of a contract. Alternatively, rather than referencing components of a document that have been contrived, forgery can also relate specifically to an intent to deceive [2].

Counterfeit documents serve many purposes for those attempting to defraud, allowing them to assume identities, make purchases, obtain credit, and orchestrate illicit activities that would not otherwise be possible. The types of items that are counterfeited or forged are broadly encompassing and include travel documents, such as drivers' licenses, passports, and visas; business and personal checks; travelers checks; and resident alien or immigration cards. The negative impact of counterfeiting and fraud to society can be extensive. Consider the following excerpt taken from the 9/11 Commission Report:

> Fraud in identification documents is no longer just a problem of theft. At many entry points to vulnerable facilities, including gates for boarding aircraft, sources of identification are the last opportunity to ensure that people are who they say they are and to check whether they are terrorists [3].

The costs incurred as a result of counterfeiting and forgery are realized by private citizens, consumers, businesses, the financial services industry, and the justice system. It is estimated that credit card fraud costs to both cardholders and card issuers approximates hundreds of millions of dollars per year [4]. In the year 2000, Visa and MasterCard reported losses in the United States of an estimated $1.0 billion under the traditional definition of identity theft, a 45% increase over these losses reported in 1996 [5]. The American Bankers Association reported that 80% of banks cited losses due to check fraud in 2006 with a total of $12.2 billion attempted to be drawn against accounts [6]. The US Social Security Administration estimated in 2000 that reports of misuse of Social Security Numbers increased more than fivefold over the number in 1998, with 81% of these directly attributable to identity theft [5].

Virtually any type of document can be simulated or altered, and examinations are often conducted on business and personal contracts; employment, banking and medical records; vehicle titles and license plates; letters of credit or reference; insurance documentation; certificates of stocks or bonds; and even sports memorabilia. Certain documents are classified as breeder documents, those that enable an individual to obtain other records that can be used for identification purposes [7]. These documents are often targeted for fraudulent reproduction by counterfeiters with the final objective being the acquisition of a more generally accepted, secure document (e.g., passport). Breeder documents may include birth and marriage certificates, social security cards, utility bills, military identification cards, and library cards.

Instruction in constructing these fraudulent materials can be found in books, magazines, and on the internet; lack of standardization of documents within and among countries has served to facilitate the perpetuation of counterfeits and forgeries. The equipment and materials used in counterfeiting are typically easily obtained, and a functional system may be as basic as a computer with desktop publishing software, camera, scanner, printer, and laminator. Although the cost of these software and hardware components is relatively low, often counterfeiters use fraudulent means for acquiring goods; therefore, the true cost of the items to them may be negligible. A more elaborate equipment set is typically not necessary in that while these methods of producing counterfeit documents will differ from those used in the genuine standards, the finalized document need not be a perfect simulation; it need only be sufficient in quality to pass the scrutiny of the initial reviewer. These individuals who constitute the first line of defense against counterfeit documents may have diverse backgrounds and skill sets and represent a variety of professions, including cashiers, tellers, clerks, immigration officers, and aviation employees. They may have varied levels of training in document comparison and feature recognition, and these verification examinations may be conducted in environments in which both the time and equipment available for these inspections is limited. The increasing prevalence of counterfeited and forged documents in circulation equates to an increased necessity for the

capability of differentiating those that are spurious from those that are genuine.

The Role of the Forensic Document Examiner

One of the primary roles of the forensic document examiner (FDE) is to analyze documents in order to determine genuineness. If a fraudulent document is detected, the FDE will then gather information that can elucidate how the forgery or counterfeit has been achieved. This may allow the examiner to identify and compare materials and methods of manufacture with those discovered in relation to one or several suspects, as well as to link different cases.

While one might consider documents to be specimens comprised strictly of paper substrates, a document can be any object containing marks or symbols that convey meaning to someone [2]. These marks can include characters that are handwritten, electronically generated, etched, or transferred from other surfaces and can be found on substrates such as plastics, metals, rubber, wood, and textiles. The role of the FDE is not to establish intent, but rather to objectively examine evidence and impartially report findings. In federal courts in the United States, determining intent of a defendant is a responsibility that lies solely with a judge or jury; therefore, in this context, inclusion of the word "forgery" in the reports and testimony of the FDE is highly discouraged [2].

Cited in the American Society for Testing and Materials (ASTM) standard E444-07, entitled "Standard Guide for Scope of Work of Forensic Document Examiners", a primary responsibility entailed in the comparison, analyses, and examination of documents is to "establish genuineness or nongenuineness, or expose forgery, or reveal alterations, additions, or deletions" [8]. The standard outlines the definition of an FDE, typical work encountered in the field, types of equipment utilized, the range of expertise required to satisfactorily examine evidence, and the reporting of results. The scope of work of the FDE includes the identification of equipment utilized to print, copy, or fax a document; identification or exclusion of substrates, inks, and writing instruments; determination of age, sequence, source, and alterations to documents; isolation of relationships between documents; recovery of eradicated or obliterated components of documents; and examination of content for evidence of spuriousness or to ascertain the identity of a person. In order to accomplish these objectives, the FDE must employ a multitude of techniques and utilize a host of instrumentation in the process of deriving accurate conclusions. These types of examinations can be challenging, but, nonetheless, standardized methods and instrumentation exist that can be used to determine whether a document is genuine or counterfeit, or whether the integrity of a once genuine document has been compromised. At minimum, the equipment to which an examiner should have access includes a microscope, an electrostatic detection device (EDD), and an instrument equipped with filtered lighting in order to make these determinations.

Microscope

Compound and stereo microscopes are primary tools of the FDE for providing magnification necessary to visualize and examine minute details of a document. Sufficient magnification and lighting are often essential in determining the printing process(es) employed, identifying individual and class characteristics, and gaining an understanding of how the document was constructed. Comparison microscopes allow for the side-by-side comparison of a genuine and a questioned document. More sophisticated methods, such as polarizing light, fluorescent, confocal, and atomic force microscopy, may also be used to evaluate physical and optical properties of documents. Scanning electron microscopy (SEM), in which a beam of electrons is bombarded across a surface resulting in the generation of high resolution images capable of resolving fine detail, is often also useful in document analysis. The stage of these instruments can be adjusted along and rotated about the x, y, and z axes, allowing for the viewing of virtually any aspect of the sample. Using this method, micrographs of ink particles and substrate fibers can be obtained that allow for detailed comparisons between questioned and genuine specimens. Figure 1 demonstrates differences in the printing quality of a genuine and counterfeit document that are easily visualized using approximately $50\times$ magnification.

Electrostatic Detection Device

An EDD is an invaluable tool that provides FDEs with a method to visualize indentations present on

Figure 1 A split photomicrograph showing differences in the printing features of the same area on a counterfeit (left) and genuine (right) document using approximately 50× magnification

paper documents. When entries are made on documents, indentations may be created on underlying pages. First introduced to the questioned document field in 1978 by Foster and Freeman, Ltd. as the Electrostatic Detection Apparatus (ESDA), electrostatic detection methods are considered minimally destructive, having a slight potential for effects to paper substrates resulting from a brief humidifying process, and the potential removal of small quantities of pencil lead from a document [9, 10]. Foster and Freeman™ currently sells the ESDA^2 and ESDA-*Lite* systems, while Projectina™ offers the Docustat. The electrostatic detection process, in general, is based upon the premise that physical contact with a substrate, such as from a writing instrument, causes a perturbation in paper fibers on underlying sheets of paper. This paper fiber disturbance results in a difference in electrostatic potential from undisturbed regions of the substrate, which can then be realized when a document is covered with a Mylar film, and a highly negative voltage is applied across it. Subsequent exposure of the document to toner particles, which adhere to indented regions, then allows for the visualization of these perturbations [11–13]. In addition to indented writing, an EDD can be used to visualize alterations that have been made to documents. In Figure 2, the date on a document was abrasively removed and then modified. Although in this case the previous number was not able to be determined, significant evidence of abrasion exists.

Video Spectral Analysis or Filtered Light Examination

Video spectral analysis (VSA) and filtered light examinations (FLEs) are nondestructive methods that can provide valuable insight regarding the optical properties of inks and other materials found on a document. FLE allows the user to view specimens at different wavelengths of light using various barrier and excitation filters; however, VSA can also be used to examine items using forms of radiant energy other than visible light, such as ultraviolet (UV) and infrared (IR). Evaluation of near infrared reflectance

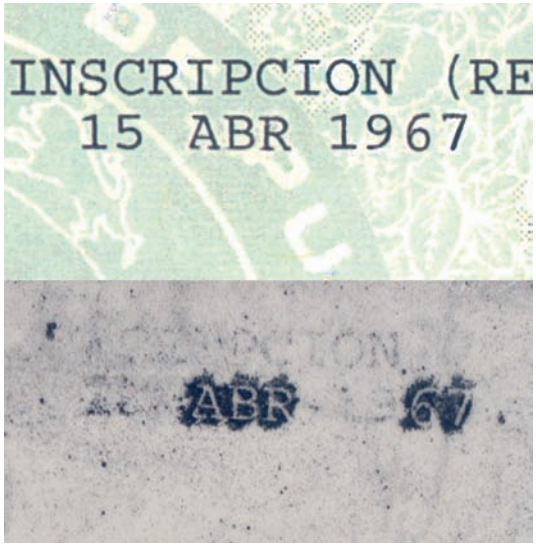

Figure 2 The examination of a suspected date change using an electrostatic detection device (EDD), with the original document (top) as compared to the EDD lift (bottom). Although an EDD can sometimes be used to visualize previous written entries, it was not possible to decipher the original date on this document; however, there is significant evidence of abrasion

(IRR) and infrared luminescence (IRL) properties can provide significant assistance when evaluating inks present on a document (Figure 3). VSA systems available on the market include the Video Spectral Comparator (VSC) from Foster & Freeman™ and the Docucenter and Docubox offered by Projectina™, all of which employ a combination of filters and photography to elucidate features of a document that may not otherwise be detected. Modern commercial equipment, including these instruments, typically has incorporated a charge coupled device (CCD) into the design, thereby providing users with the opportunity to examine and record images electronically.

Although the aforementioned instrumentation can be considered a minimum requirement for the FDE, other analytical methodologies can be used to conduct detailed chemical and physical analyses of materials used in the construction of counterfeit documents. Fourier transform infrared spectroscopy (FT-IR) is a technique that uses infrared radiation to excite bonds within molecules in order to isolate chemical functional groups. Using this instrumentation, components of documents can be analyzed to determine if they share the same chemical composition. Chromatography is an analytical technique used to separate individual components within a substance based on characteristics such as differences in solubility in a solvent. Depending on the material being analyzed, thin layer chromatography (TLC), gas chromatography (GC), or high-performance liquid chromatography (HPLC) can also potentially be used. In addition, mass spectrometry (MS) can be coupled with GC or HPLC to provide specific chemical identification of substances found in documents (e.g., colorants). Advanced methods of presentation of specimens to a mass spectrometer exist and include thermal desorption and direct analysis in real time (DART), which allows for noncontact sampling under ambient conditions of solid, liquid, and gas-phase specimens.

Other instrumental analysis methods can be used to assist in identifying inorganic compounds (e.g., metal complexes in pigments, minerals in paper, and plastics), such as X-ray fluorescence (XRF), SEM coupled with energy dispersive X-ray analysis (EDXA), and inductively coupled plasma mass spectrometry (ICP-MS). These are highly specialized techniques that can be used to detect trace components and/or identify unknown materials either found on or used in the construction of a document and can be invaluable tools in determining associations among specimens.

Irrespective of the request, the FDE must have a fundamental understanding of how documents are constructed. In order to determine if a specimen is counterfeit or forged, one should have an in-depth understanding of how the genuine was created, as well as a specimen file of known standards. This knowledge is critical for comparative examinations of suspect documents to be conducted objectively. Also, inherent limitations may exist that must be realized in order to derive accurate conclusions (e.g., manufacturers of components of documents may employ limited quality control measures in the production process, thereby resulting in variability in the genuine product). Following are discussed general examination procedures for questioned documents, along with some of the production methods and security features that are commonly utilized in the construction of genuine specimens. However, since there are numerous types of documents that can be counterfeited, this summarization should not be construed as an unabridged discussion of all possible

Figure 3 A split image showing differences in the infrared luminescence properties of a counterfeit (top) and genuine (bottom) document both printed using offset lithography

types of features that can be found in genuine documents.

Examination Procedures

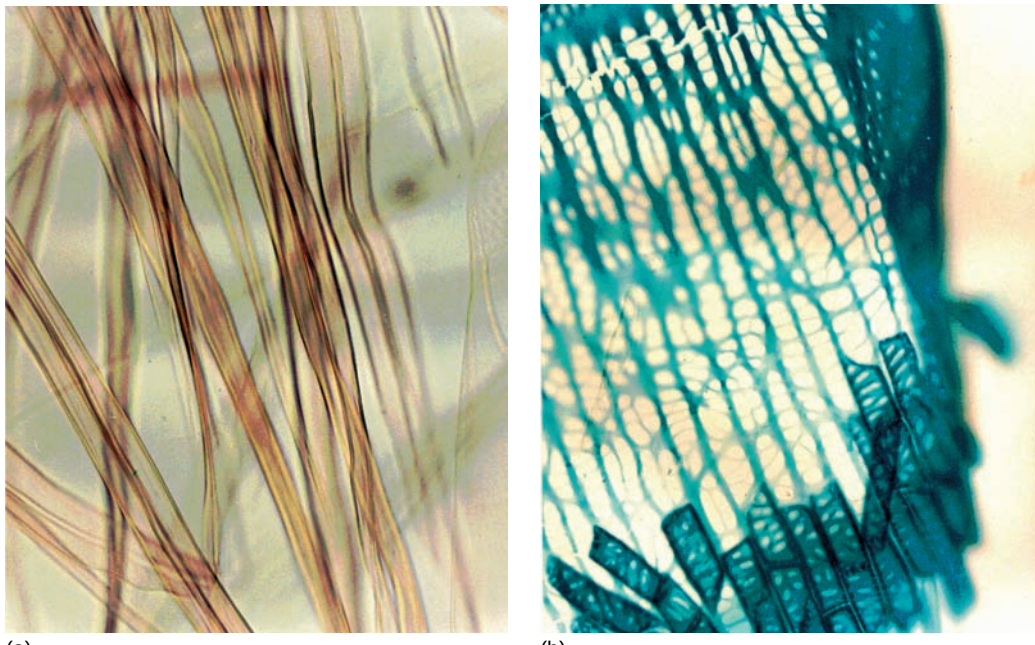
The successful forensic examination of suspected counterfeit documents is contingent upon the use of a nonbiased approach to scientifically demonstrate that the questioned document is either genuine or counterfeit. Ultimately, the soundness of the findings must be irrefutable in a legal proceeding. In order to accomplish this objective, it is considered best practice that the FDE reference a genuine standard either obtained from or approved by the issuer of the document. In the event this authentic standard is unavailable, the examination may be conducted using a listing of features contained within the genuine that has been obtained from the issuing authority. It should be kept in mind that some documents produced by counterfeiters, termed fictitious instruments, are completely fabricated and have no genuine counterpart. In the case of forgeries, the document itself is typically genuine, but has been altered in some capacity; therefore, those features present in the genuine standard will typically also be evidenced in the forged document.

An examination is then conducted in which the questioned document is compared to either the genuine standard or reference list of features, and the similarities and differences recorded. This is best conducted by evaluating four categories of attributes to include (i) physical characteristics, (ii) printing processes, (iii) security features, and (iv) electronic media.

Physical Characteristics

Observation of physical characteristics, such as the dimensions, color, gloss, and physical composition of a document, is typically the first step in the

examination process. Although examiners should not rely solely on manufacturers' specifications, because there can be inherent oversight in the quality control process, many secure documents have strict regulations and manufacturing tolerances with regard to these attributes. For example, the sizes of identification cards are specified by the International Standards Organization (ISO) in the standard ISO 7810, "Identification Cards–Physical Characteristics", in which is detailed four official formats, ID-000, ID-1, ID-2, and ID-3. The most common size used for financial and identity cards is referred to as *ID-1* or *CR80*, which is defined as being 85.60 mm (3.370 in.) in width and 53.98 mm (2.125 in.) in height, and having a nominal thickness of 0.76 mm (0.030 in.) [14]. The currently issued US currency is 155.956 mm (6.14 in.) in length, 66.294 mm (2.61 in.) high, and 0.109 mm (0.0043 in.) thick. The size of a document may be subject to extremely narrow production tolerances, on the order of tenths of a millimeter. Therefore, counterfeit specimens may be readily identifiable when deviations are found in measurements, even as little as 0.5 mm from the genuine standard [15].



Color and gloss differences can be key in distinguishing among counterfeit, forged, and genuine specimens. Differences in colorimetric values between the suspect document and a genuine standard may be measured using a spectrocolorimeter, a spectrophotometer designed for the quantification of minute color differences, as well as for the evaluation of properties such as metamerism in documents. Using a spectrocolorimeter or microspectrophotometer, values for various colorimetric indices may be calculated, such as whiteness index, paper brightness, and colorant strength, which can be of additional value in comparisons between and among documents. Gloss characteristics of a counterfeit document may differ from those of an authentic specimen and may be quantified using a gloss meter (typically measured at various angles, such as 25, 60, and 85, depending upon the level of reflectivity of the surface).

Examination of the various components of a document *via* physical, optical, and chemical means can allow one to determine source or establish associations with other documents. This may include the analysis of paper fibers present in a cellulosic document (Figure 4a, b), the identification of polycarbonate, or the structural composition of a multilayered polyvinyl chloride (PVC) document. Other physical attributes of a document can be examined and include embossing characteristics, omissions of symbols or text, misspellings, and the formatting of designs, logos, and text with respect to both their design and their relative positions on the document. Regional conventions not indigenous to an area may be commonly encountered, such as improper denotations of monetary amounts, dates, or telephone numbers. All of these attributes can serve as class characteristics to help associate multiple documents to a common source. The document in Figure 5 contains a misspelling that can assist an examiner in establishing that a document is a counterfeit and then potentially associating it with others.

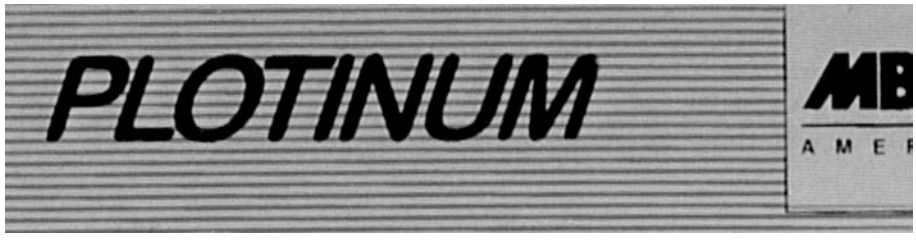
Printing Processes

Genuine documents are often designed such that fraudulent reproduction would be inherently difficult. One method for achieving this is to select printing processes that are not commonly available to the counterfeiter, and thus, would require time or expense that he or she would potentially be unable or unwilling to expend. The three most commonly utilized printing processes in creating genuine specimens, and most difficult to simulate by the counterfeiter, include offset lithography, intaglio, and relief printing (e.g., letterpress and flexography). When these processes are used in combination with one another, additional layers of security are then present, with the resultant composite product being a more robust document.

Offset Lithography Offset lithography is a planographic printing process wherein hydrophobic inks are applied to a plate containing hydrophilic nonimage areas that have been moistened using a dampening solution. As a result, the ink is repelled by the nonimage areas and adheres to only the hydrophobic image areas of the plate. The image is then offset to an intermediate blanket cylinder, and as the substrate travels between the blanket cylinder and an impression cylinder, the image is subsequently transferred. In security printing, a line offset method is primarily utilized rather than half-tone dots to create an image. The printed areas are typically comprised of fine lines that may form geometric patterns or other intricate designs. Spot colors are applied and may form a gradation of shades, gradually transforming from one color to another across the design, a technique referred to as *rainbow*, *split fountain*, or *iris*

(a) (b)

Figure 4 Photomicrographs of fibers used in the formation of paper: (a) eastern cottonwood fibers and (b) tupelo fibers



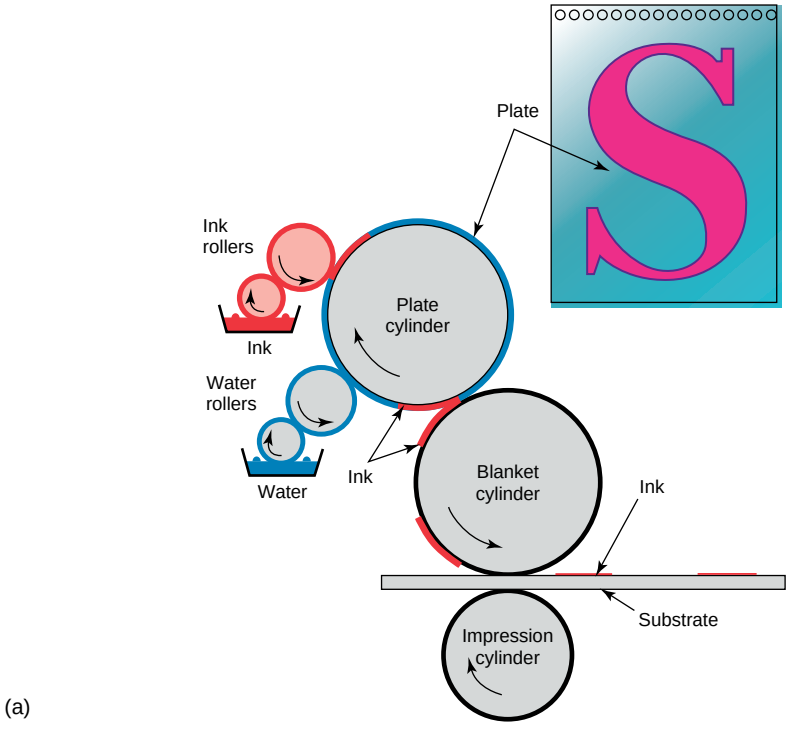


Figure 5 The word "PLATINUM" on a counterfeit credit card is misspelled and reads "PLOTINUM"

printing. The combination of this gradient coloration, resolution of the composite lines, and registration of components equates to an advanced degree of difficulty in counterfeiting documents prepared in this manner [15]. Figure 6 consists of an illustration of the offset lithography process, as well as a photomicrograph of the resultant print.

Intaglio Intaglio printing is a process wherein the image area of the printing plate or cylinder is etched or engraved. Once ink is applied, it subsequently fills the engraved areas, with the excess being removed by a doctor blade that is wiped across the surface. The plate then contacts the substrate under extremely high pressure, exceeding tens of tons per linear inch. Through capillary action, in combination with this high pressure, the ink from the etched image areas is transferred to the substrate, resulting in an embossed image on the document. A characteristic tactile quality is thus imparted to intaglio printed documents, which can serve as an additional security feature. Aged documents can lose some of this tactile character, and therefore, counterfeiters may attempt to artificially age documents to account for the lack of this property. Additionally with intaglio printing, ink is not entirely contained within the structure of the image upon removal of the plate, thereby resulting in a feathering effect that can be visualized

(b)

Figure 7 (a) A schematic representation of intaglio printing; (b) a photomicrograph of an image printed using intaglio

microscopically and is difficult to duplicate. Many intaglio presses afford an additional advantage of allowing the application of multiple colors, an arduous feat for the counterfeiter to attempt to duplicate with multiple passes of each individual color in that the registration will invariably be poor [15]. Figure 7 consists of an illustration of the intaglio process, as well as a photomicrograph of the resultant print.

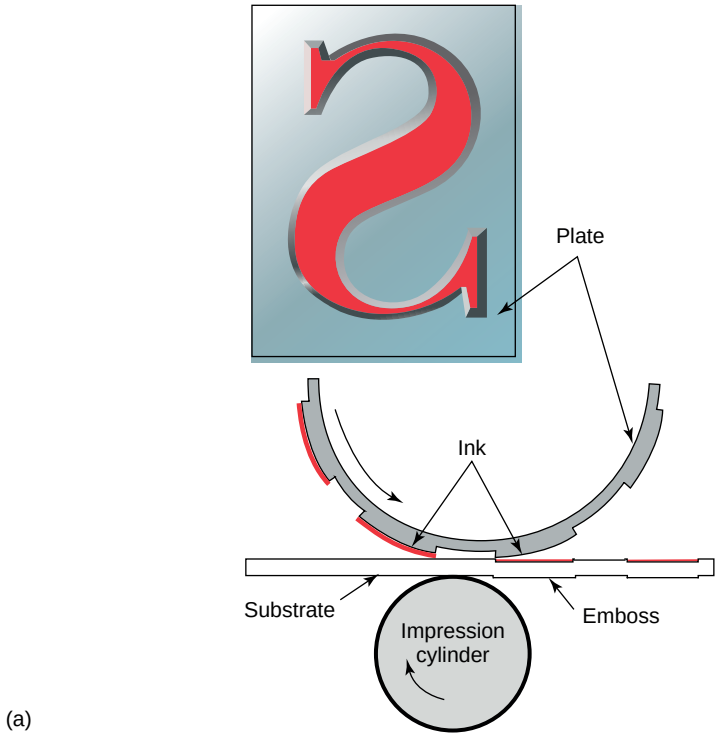
Relief Printing

Letterpress and flexography are processes wherein a plate containing a raised image area is inked and, *via* impact, the impression is transferred directly to the substrate. The differences in the processes are that flexography utilizes a flexible rubber or photopolymer plate as opposed to the rigid plates that are commonly incorporated in letterpress printing. Letterpress is primarily used to print unique identifiers on a document, such as a serial number, that align uniformly with inherent design elements. Use of other means of creating these often results in the digits being misaligned with respect to the rest of the document. The counterfeiter is forced to either attempt to simulate this process or to utilize the same number or limited number set repeatedly, which may then be counterproductive to the primary goal of escaping detection [15]. Flexography can be used on a variety of surfaces and is typically used in high speed printing, as the low viscosity solvent or water-based inks utilized in this process are formulated to dry quickly. Figure 8 consists of an illustration of the letterpress process, as well as a photomicrograph of the resultant print.

A point of commonality of all of these printing processes is that the effects imparted by them are virtually impossible to reproduce *via* digital means, the primary methods utilized by many counterfeiters. The printing processes most commonly available to the general public typically include electrophotography (e.g., laser printers, photocopy machines), inkjet, dye diffusion thermal transfer (D2T2), and thermal mass transfer, all having unique properties that differentiate them from those typically utilized in security printing. Other types of processes can be utilized in genuine documents, but may be more readily reproducible by the counterfeiter. These include screen printing, flexography, and thermography. Some forgers construct miniaturized versions of production presses; however, large quantities of work cannot be processed with this equipment, and the same properties imparted through use of a commercial press are typically not evidenced. Counterfeiters may even have access to production presses themselves, gained through either fraudulent means or provided by a government, organization, or individual wishing to defraud. This possibility must always be considered, and close attention to detail must be therefore applied in each comparison made.

Security Features

A vast array of physical, optical, and chemical security features can be incorporated into documents to ensure their integrity, the objective being to convert a printed document into an end product for which the validity and authenticity can be verified. It is, therefore, critical that the printer(s), supplier(s), and issuer(s) adhere to secure operating procedures during all manufacturing and distribution protocols. Without strict security regulations, a breach of information and/or materials security may result that could serve to compromise the integrity of the document.



Security features can be considered overt, covert, or forensic. Overt features are those designed to be either detectable by the unaided eye under normal viewing conditions or discernible by touch (e.g., an identification number or watermark). These features are often key in inspection processes in which the expeditious evaluation of documents for genuineness is vital, such as at congested security checkpoints. Covert features are those not visible to the unaided eye or not tactile in nature. They may require specialized light sources or equipment in order to be detected (e.g., ultraviolet source or barcode reader). For forensic purposes, sometimes considered an additional category, these covert features are disclosed on a need-to-know basis and typically require specialized expertise and/or instrumentation for identification, as with the detection of a unique ingredient incorporated into an ink. It should be emphasized that it is often not necessary to be privy to the forensic features that are incorporated into a document if authenticity can be definitively determined on the basis of overt and/or covert features.

While it is well beyond the scope of this article to provide detailed descriptions of all the various security features available for use in constructing a document, following are described those commonly encountered. These features can be generally categorized into those incorporated within the substrate, those involving the printing process, and additive features.

Security Features Incorporated into the Substrate.

Watermarks

An image or pattern found in paper that appears less dense than the paper itself when viewed with transmitted light. Watermarks can be created using two different processes: fourdrinier (dandy roll) and

(a)

(b)

Figure 8 (a) A schematic representation of letterpress printing; (b) a photomicrograph of an image printed using letterpress

cylinder mould. During the papermaking process, an image imprinted onto a wire is attached to a dandy roll and impressed at varying degrees of pressure into the wet paper. The cylinder mould process uses areas of relief on the roll, rather than a wire with an image, resulting in a three-dimensional image in the paper, having various shades of gray. The watermark from the cylinder mould process usually contains far more detail than a dandy roll watermark. Other legitimate artificial or chemical watermarks can be used; however, the end product of these processes does not result in a true watermark. Typically, counterfeiters will use simulated watermarks that can be easily created using faint printing, stamps, and specialty inks (e.g., UV fluorescent) (Figure 9a). These are usually detectable to a trained examiner due to the lack of detail, ability to visualize without the aid of transmitted light, and/or the presence of UV fluorescence properties. Figure 9b illustrates a genuine watermark utilized in a secure document.

Planchets

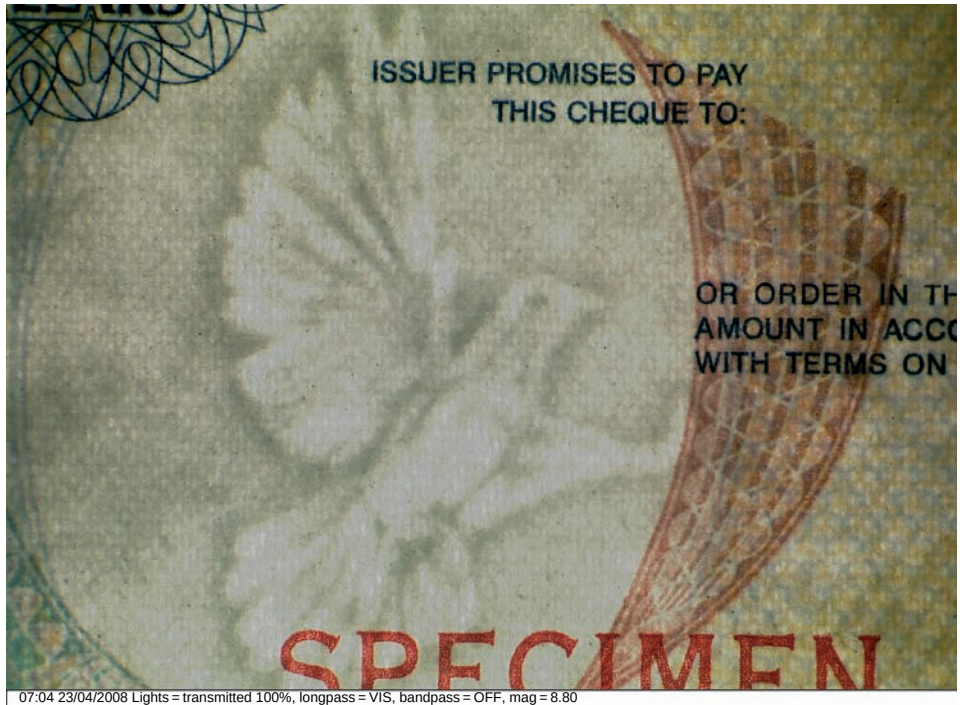
Thin pieces of paper or synthetic material integrated into the substrate of a document during manufacturing. Planchets typically are found randomly distributed within bands on a document and may be iridescent, fluorescent, chemically treated, thermochromic, or contain microtext. Simulations may include drawing or printing colored disks onto paper; however, a genuine planchet will be removable from the substrate using a sharp object and will leave a void in its absence. It should be noted that authentic documents that have been frequently handled may be devoid of planchets; however, the voids left by their presence will remain. The images of planchets on a counterfeit document, created *via* a reprographic process, can be used to associate multiple documents if they are shown to be in identical positions. Figure 10 demonstrates the nonrandom distribution of planchets found in counterfeit documents having a common source.

Window thread

A ribbon that is laced through the substrate in an alternating pattern of visibility (windowed) and nonvisibility when viewed in reflectance. One iteration of the pattern is typically 1 cm in length, and when viewed in transmission, the entirety of the reflective ribbon can be visualized. The threads may be holographic in nature or contain microtext printing as additional security measures. Counterfeiters may draw an approximation of a window thread or attempt simulation by utilizing foil printing to create a ribbon having alternating areas of opaqueness; however, in neither case will the ribbon appear continuous under transmitted light. Figure 11(a)–(e) illustrates some of the different types of window threads that are found in secure documents, along with a counterfeit simulation.

Security fibers

Embedded into the substrate, these randomly distributed, colored fibers typically must be evaluated microscopically in order to ascertain whether they are actually individual fibers, or whether they have been drawn or printed onto or adhered to the surface of a document. Genuine security fibers can often be distinguished from the latter category of counterfeits in that they will present as being partially below and partially above the surface of the document (Figure 12). Additionally, these fibers may be fluorescent, iridescent, or invisible except when viewed under certain conditions. Fibers may also exhibit unique chemical signatures, for which identification using FT-IR may be warranted.



Security Measures Incorporated into the Printing.

Intricate printing

Features that are generally difficult to reproduce and require sophisticated technology to create. These can include complex patterns created with fine line detail and variable line thickness, custom geometric patterns, guilloche patterns (consisting of two or more bands of continuous, overlapping sinusoidal lines), microtext (generally 15–90 micrometers in size, see Figure 13a, b), two-sided registration (splitting of a graphic image such that one-half is displayed on the front of the document and one-half is displayed on the back of the document), and rainbow printing (i.e., split fountain printing, where two or more ink colors in a single unit merge together as a result of oscillating ink rollers). Figure 14 depicts a document containing both a guilloche pattern and rainbow printing. Depending upon the sophistication of the counterfeiter and the type of equipment being used, simulated intricate printing patterns are often readily detectable using examination under an appropriate level of magnification. Other printing features serve specifically as antiphotocopying mechanisms, such as void pantographs, wherein images such as the text “copy” or “void” are produced at a higher

(a) 07:06 23/04/2008 Lights = 365nm ultra violet, longpass = VIS, bandpass = OFF, mag = 8.80
integration = 1/3, iris = 73%, gain = 12dB, brightness = 10, contrast = 30, imaged width = 41.82 mm

(b) 07:04 23/04/2008 Lights = transmitted 100%, longpass = VIS, bandpass = OFF, mag = 8.80
integration = 1/8, iris = 50%, gain = 6dB, brightness = 28, contrast = 30, imaged width = 41.82 mm

Figure 9 (a) A simulated watermark visualized with 365-nm ultraviolet source is compared with (b) a genuine watermark visualized using transmitted light. The simulated watermark is not visible when viewed with transmitted light and the genuine watermark is not visible when examined using an ultraviolet source

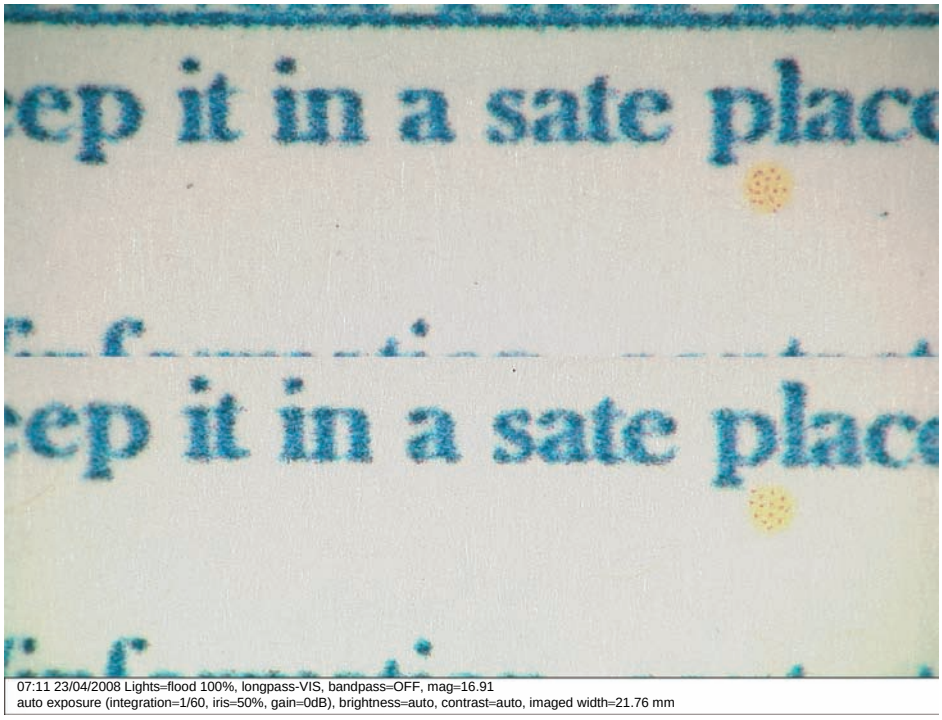


Figure 10 A split photomicrograph showing simulated planchets with the same relative placement and position. This would not be expected in genuine documents in that the planchets are randomly distributed in the substrate during the papermaking process. The top and bottom images are two counterfeit documents bearing different names that have been shown to be associated with a common production source. Also note that the word "sate" is misspelled and should read "safe"

screen ruling than that of the surroundings. Therefore, the pantograph is camouflaged in the original document; however, upon reproduction, it becomes readily visible.

Security inks

Numerous types of security inks are available, which exhibit various characteristics that can lend uniqueness to genuine documents. Iridescent or color-shifting inks exhibit different hues when viewed at varying angles and can be easily simulated for presentation to the untrained observer, but are very difficult to reproduce exactly. For example, counterfeiters often use metallic material sprinkled into the ink to give the perception that the ink is changing colors when tilted at different angles under a light source. Noniridescent inks include thermochromic (change in color due to a change in temperature), photochromic (change in color due to exposure to different wavelengths of light), fluorescent, infrared absorbent, and those exhibiting anti-Stokes shifts (fluorescence that is excited using a longer wavelength energy than that of emission). It is important to note that the changes that thermochromic and photochromic inks undergo when exposed to different temperatures or radiant energies are reversible. Metameric inks exhibit the property of appearing to be equivalent in color under one viewing condition, but perceptibly different under another. This phenomenon stems from the fact that the inks actually have different spectral properties. Despite this, the inks are matched under one illuminant or light source, such that the colorimetric difference derived from their spectra is below the threshold of detection by the human eye. An examination using some form of filtered light or VSA can be extremely helpful when characterizing both security and counterfeit inks. Also, GC/MS and FT-IR may be used to authenticate genuine security inks or link counterfeit inks in order to ascertain if they originated from a common source.

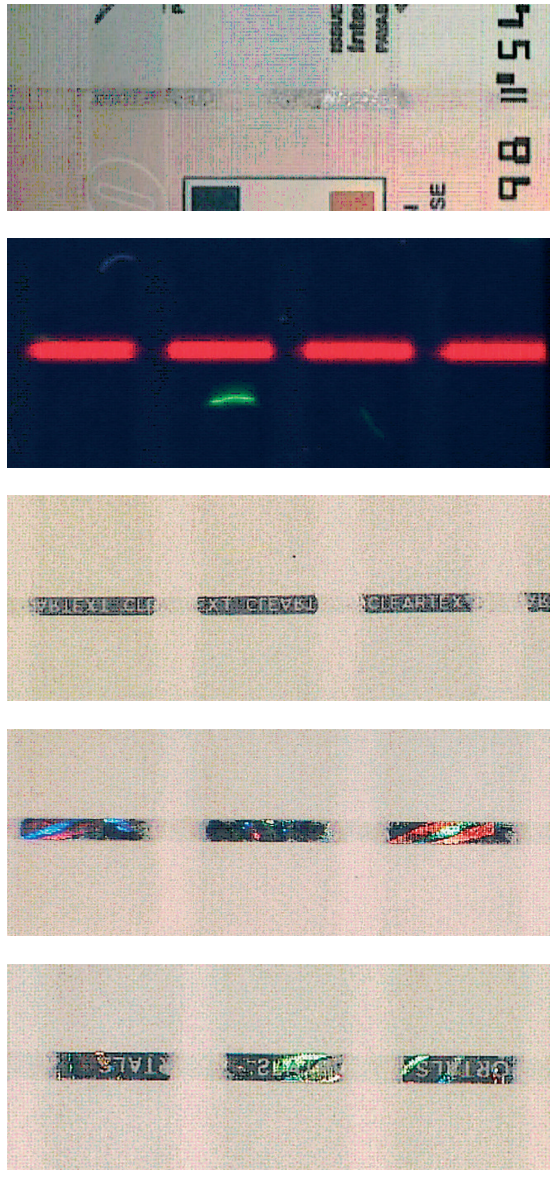

Figure 11 Examples of the different types of security threads from left to right: (a) demetallized, (b) holographic, (c) microtext, (d) fluorescent, and (e) a counterfeit

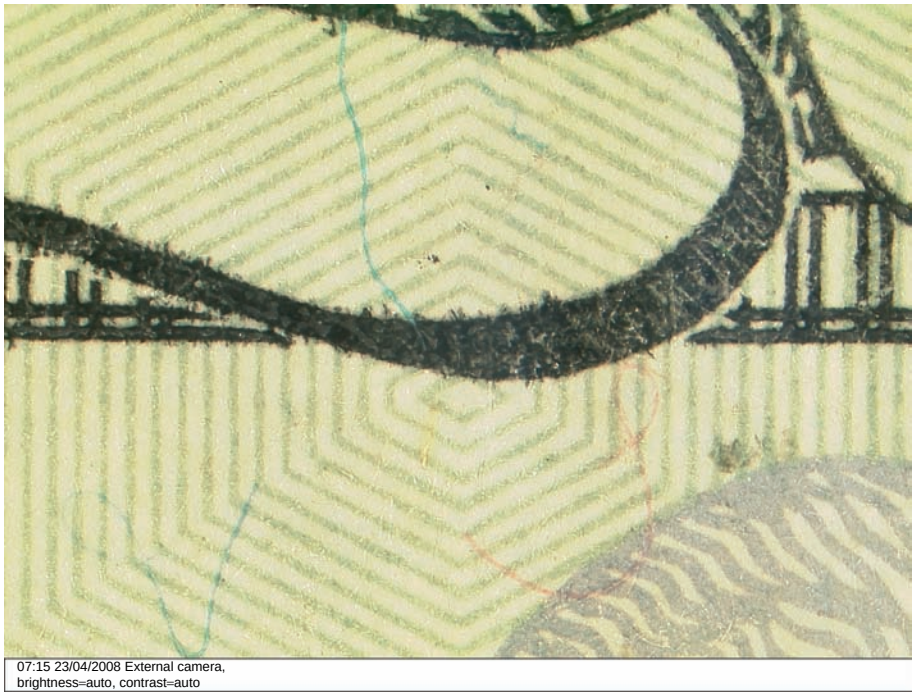

Figure 12 Red and blue security fibers found in a Federal Reserve Note

Security Features Added to a Document.

Optical variable device (OVD)
Optical variable devices (OVDs) can be either iridescent or noniridiscent in nature and include, among other structures, holograms and kinegrams. A hologram is a compilation of images, typically etched by laser into a photographic plate that forms a three-dimensional rendering of a photograph of an actual object, maintaining its original dimensions (Figure 15a, b). Color and conformational effects can be noted as the image is rotated through various angles of viewing. A kinegram is a two-dimensional vector image that appears to change in color and/or conformation when rotated and has the advantage of being visible at almost any viewing angle, even in low lighting conditions. OVDs are very difficult for the counterfeiter to successfully simulate and cannot be duplicated using electrophotographic methods.

Security laminate
– A coating, typically a foil or film, applied as a physical protective barrier for a document, as well as a means to ensure its authenticity. These coatings may involve the use of glass microbeads and thin interference layers of films that form a combination of varying refractive indices in order to produce a retroreflective effect. Retroreflective materials reflect light directly back at the source rather than diffusely, such that the angle of illumination must be equivalent to the angle of viewing for the feature to be visible. Therefore, retroreflective features that are integrated into a security design are not visible to the unaided eye and are best observed using a retroviewer, which allows the eye to be in alignment with the apparent angle of illumination, typically through the use of a semitransparent mirror [15].

Security threads
Thin ribbons, typically polyester, that may be metallized/demetallized or coated with pigments or other materials, resulting in their being rendered opaque, transparent, or fluorescent. Security threads may be designed such that they are only viewable using transmitted light or may contain microprinting. Inclusion of a security thread will result in a discernible increase in thickness of the document at the point of insertion. While optical properties may potentially be duplicated, simulated threads often are formed using

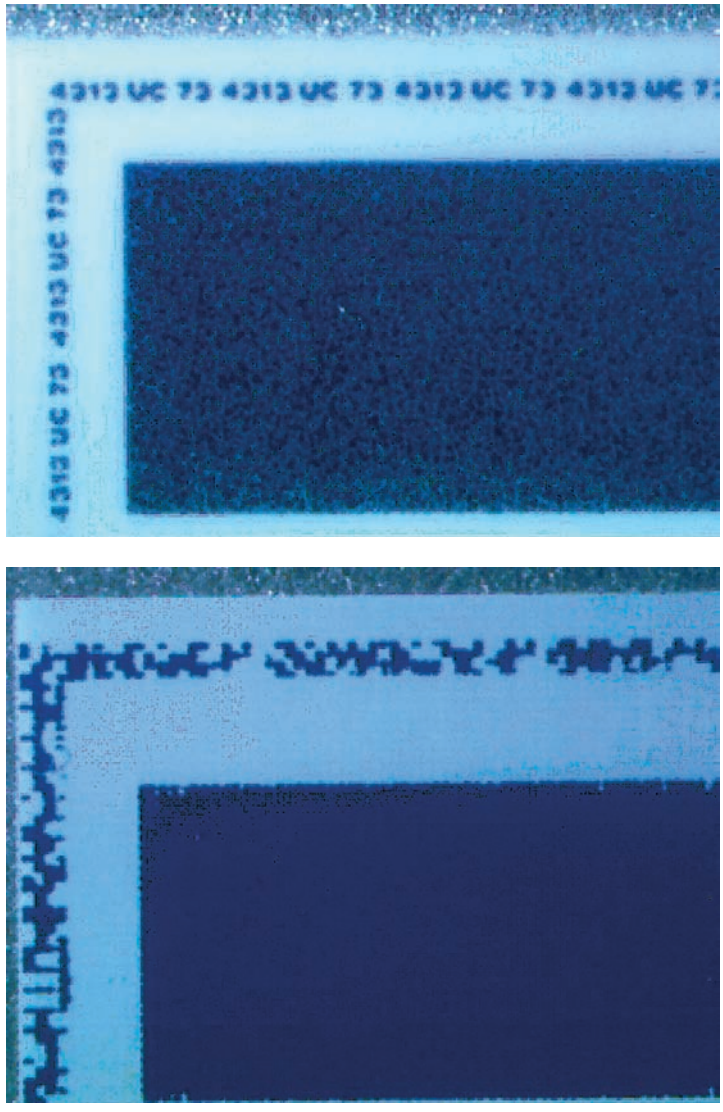

Figure 13 Microtext printing of the same area on (a) a genuine and (b) a counterfeit document

a different material, such as paper, or may be printed onto the substrate of a counterfeit document, which will not result in the perception of a difference in texture, key in the identification of a genuine security thread.

Perforations

Incorporating perforated printing, such as with serial numbers or images, in security documents can be especially useful in identifying page substitutions in a multiple page document if the holes are misaligned in one or more pages. The process involves physically creating holes through multiple pages in a single step and can be created *via* machine or laser.

Grommets or eyelets

Rings, eyelets, or rivets, typically metallic, used to secure a photograph to a document and may be engraved with information. Although not very common, grommets are used in some travel documents, such as passports, and are a very useful means of preventing photographic substitution. There may be

Figure 14 An intricate printing pattern, including guilloche and rainbow printing processes

evidence of tampering that can be visualized using microscopy. If the grommet has been substituted with a fraudulent replacement, an elemental analysis of the constituent metal may be warranted.

Security binding threads
Threads used to bind multiple page documents (e.g., passports) using stitching procedures that can be, in themselves, security features. In constructing these booklets, stitching methods more intricate than the conventional single, continuous stitch may be employed (e.g., locking stitches), which may be difficult for the counterfeiter to readily reproduce. When the integrity of the binding is in question, physical, optical, and chemical examinations can be conducted in order to determine the stitching method utilized, or if a thread has potentially been replaced or unbound.

Embossing and debossing
Processes used to create three-dimensional images in a substrate, typically formed using a die (and its counter die) with the application of heat and/or pressure. *Embossing* is a term that can be used to describe the formation of an image above the surface of a substrate (raised), while debossing results in an image inset below the surface (impressed). Embossed images may be coated in foil (e.g., tipping), as typically found with the raised numbers on a credit card. In some cases, the FDE may be requested to conduct an examination on embossing equipment as part of the analysis.

Foil stamping
Foil stampings may be colored, iridescent, or holographic and therefore serve as effective anticopying features. When observed with a microscope and sufficient oblique lighting, the foil should appear to be impressed below the surface of the document. The examination of counterfeit documents may reveal evidence of tampering, and, in many cases, foils are fraudulently constructed and attached to documents by means of an adhesive. In these cases, the debossing characteristic of this process will not be present.

Laser engraving
The beam emitted from a laser can be used to inscribe, or engrave, text or images into a document. Although laser engraving is not an etching process, which requires chemicals or machinery, it employs the same basic concept and can be used on a variety of substrates, such as plastics and metals. The effect is generally achieved using a computer-controlled operation, capable of precise engraving in three dimensions, a process termed *vector engraving*. This type of laser engraving results in a tactile quality being imparted to the document that can serve to be as distinct a component of the feature as are the contents inscribed. Pixel mode engraving can also be utilized, which allows for very high resolution characters or images to be imbedded in a document, without imparting the three-dimensional quality.

Chemical reactions
Involve the impregnation of a substrate with chemical substances that yield a reaction that can serve to prove either that a document is genuine or that it has been altered. A common method employed in altering documents involves the use of a strong oxidizing agent, such as sodium hypochlorite, which when combined with certain chemically treated security papers, results in the irreversible formation of a brown stain. Use of other chemical agents to remove inks can result in the development of other colors that are solvent-specific. Optical examinations, especially using a filtered light source, generally allow the FDE to detect such alterations.

(a)

(b)

Figure 15 Images of (a) a genuine and (b) a counterfeit hologram. Note the misspelling of MasterCard as "MasteCard" in the fraudulent version

Electronic Media

Electronic media is an all-encompassing term used to describe information on a document that can be authenticated using a machine-readable source. The more common electronic media include magnetic stripes, barcodes (one-dimensional and two-dimensional) optical memory stripes, optical character recognition, machine-readable zones, smart chips, and radio frequency identification devices (RFIDs). These are becoming more common in various types of security documents (e.g., passports, drivers' licenses) and will likely become far more ubiquitous in the future. The forensic examination of

(c) 2011 John Wiley & Sons, Inc. All Rights Reserved.

these features does require the appropriate reading device. For example, electronic information that has been fraudulently encoded into one of the tracks on a magnetic stripe may not correspond to the information embossed on the card. If this is the case, the encoded information should be reported to investigators to determine if the fraudulent information can be linked to an originating source.

Digital watermarks are a form of electronic media and may be categorized as invisible or fragile; these security features serve to protect the integrity of a digital image. Invisible watermarks are designed to be robust, such that information may be embedded in an image without detection. While virtually any electronic data may be contained within the watermark, this is typically restricted to less than 120 bits in size and used for applications such as copyright protection or to identify specifics of origin. Fragile watermarks are also invisible and reside in every pixel of an image. However, these serve to identify regions with which have been tampered, and altering the image results in the localized breakdown of the watermark, such that upon its extraction, areas that have been modified are readily apparent [16].

Biometrics, as they relate to security, pertain to electronic records of physiological or behavioral attributes that can be used to verify the identity of an individual. Biometric data can be placed on or encoded into a document and compared with information in a database in order to authenticate one's identity. Fingerprints and handwritten signatures are two of the more commonly recognized biometrics that can be encountered on documents; however, DNA, speaker identification, hand geometry, as well as iris and facial recognition technologies have all received significant attention, of late. While these features are not necessarily incorporated into modern documents, this does not preclude the potential for their future use. Biometric verification typically occurs in inspections conducted at the point of presentation of the document (e.g., by airport security personnel) and does not normally fall under the guise of a questioned document examination. However, the forensic examiner should be aware of these developing technologies in that biometrics are security features that may serve to establish the genuineness of a document or the identity of an individual. Fundamentally, all biometric authentication systems operate by using a software-based algorithm to match relative points of commonality between known standards and a questioned specimen. The overall patterns of the relative positions of the points within a biometric are then statistically evaluated on the basis of their uniqueness. If needed, these biometrics can be evaluated by a trained expert, and the FDE may have to determine if a signature is an original or digital reproduction, and if so, how the reproduction is printed. Oftentimes, multiple individuals who obtain a counterfeit document from the same source will have the same fingerprint pattern printed on their identity documents. This can occur if an original fingerprint image was scanned, copied, and incorporated into the document as an electronic file. For an extensive review of biometrics, the authors recommend Wayman *et al.* [17].

Conclusion

Fraudulent documents pose some of the greatest threats to modern society in terms of physical security, the integrity of our financial system, and our personal identities, themselves. With the escalating value of personal and financial data to a counterfeiter, along with the rapid evolution of technology and the increased amount of information available *via* the internet, corrupt individuals are becoming increasingly motivated to perpetrate these crimes for the purpose of financial gain. Security, in terms of both the physical document and the electronic information it contains, should be a major concern for governments and private entities alike, in that the impact of document fraud to society is extensive. Although the submission of counterfeit documents for forensic analyses usually takes place after the documents have been used and the crime has been committed, this function serves a particularly important role in combating fraud. Forensic examinations can allow for the detection of fraudulent documents, as well as provide investigative clues regarding the perpetrator(s), how the documents were constructed, if they are associated with other counterfeits, and if they were produced using materials seized from a suspect(s). Also, an FDE is sometimes called upon to provide expert testimony in a court of law to convey the findings of an examination. Indeed, this is a critical stage in the legal process and, therefore, it is incumbent upon the FDE to have a solid foundation in the examination of counterfeit materials so that he or she can provide unbiased and accurate information to the courts.

Acknowledgment

The authors would like to thank Jeffrey A. Payne, Forensic Document Examiner, of the US Secret Service for his review of and contribution to this article.

Foundation Testimony

In systems of justice where the admission of evidence is highly regulated, as is the case in the United States of America and some other adversary systems of jurisprudence, there often exists a requirement that, prior to the admission of a category of proof, testimony be adduced to show that the evidential prerequisites for admission of that type of proof have been satisfied. This is referred to as *laying the foundation* for admissibility, or authentication of the evidence. The necessary foundational testimony differs according to the type of evidence that the witness is expected to give. The admission of forensic evidence is often subject to such foundational prerequisites.

Thus, before a witness will be permitted to give opinion testimony as an expert, the court must be satisfied that the witness has the qualifications needed for giving the opinion testimony. This is part of laying the foundation for opinion testimony by an

expert witness (*see* **Chain of Possession of Tangible Evidence**).

When it comes to documentary evidence, or proof based on physical objects that have been examined by an expert, there are also special rules that specify the type of foundation testimony that the law requires (*see* **Documents: Authentication of**).

Similarly, any evidence to which objections on hearsay grounds may be raised, but which the proponent asserts comes within an exception to the rule against hearsay, must be shown to have been obtained under circumstances that justify its admission (*see* **Hearsay Evidence**; **Best Evidence Rule**; **Learned Treatises as Evidence**).

The required foundation testimony is explained in the separate articles referred to above.

Friction Ridge Examination (Fingerprints): Interpretation of

Introduction

This article concentrates on the interpretational issues associated with fingerprint evidence or, more generally, evidence obtained from friction ridge skin comparison. The basic premises of the field, namely, the fact that [1] friction ridge skin arrangements are *extremely discriminating* and reflect the variability between donors, and that [2] friction ridge skin arrangements are *persistent*, have been covered elsewhere (*see* **Friction Ridge Skin: Comparison and Identification**). The same apply to the protocol analysis, comparison, evaluation and verification (ACE-V) used as a comparison methodology by most examiners. Only the main decisions of the ACE process will be discussed here.

Main Decisions Sought after During the Comparison Process (ACE)

Analysis allows an assessment of the quality of the mark and factors such a distortion, pressure, amount of residue, and the nature of the substrate and of the detection technique used. These factors can help set the *tolerances* that the examiner will have to allow when considering a potential correspondence. The analysis stage also leads to a decision regarding the capacity of the mark to be *compared* against known prints. In some instances, this conclusion is limited only to whether or not the mark is expected to be identified should the corresponding source be available. This decision is not within the scope of this article.

The comparison stage is essentially factual and leads to a documentation of the features that have been found in correspondence and the features that have been described as dissimilar.

Evaluation is the fundamental inferential step of the process, and is the topic of the present discussion. It will lead to the formulation of a conclusion, which may take three forms in the discipline: *individualization* (generally also referred to as *identification*), *exclusion*, and *inconclusive* [1].

Exclusion means that the mark and the print(s) do not have the same source. Observed differences in ridge flow (for example, the mark being a loop and the print showing a whorl pattern) will enable an examiner to exclude the print from being from the same friction ridge skin area as the mark. In fact, as soon as a difference is observed between the mark and the print that cannot be reconciled in the light of the tolerances defined during the analysis stage, an exclusion conclusion will be reached. The examiner would logically come to the deductive conclusion of exclusion upon assessing that the probability of a

match is zero, if the mark under consideration truly had been left by a designated friction ridge skin area. How an examiner assigns a probability of zero to the observation at hand is sometimes without debate (e.g., when the general pattern between the mark and the print cannot match). Sometimes, owing to, for example, a lack of clarity, the decision is more difficult to substantiate. Hence, a one-unexplained-discrepancy rule is not a standard. In fact, this rule is ill defined by a circular argument [2].

The absence of any irreconcilable discrepancy is a prerequisite for identification. In that case, the examiner will weigh the corresponding features in reference to the standards for identification (see below). An individualization conclusion is commonly understood to mean that a mark has been attributed to a particular individual to the exclusion of all others [3]. "Others" refers often to any human in the world living or dead. When that was the examiner's express or implied assertion, he obviously operates by tradition within the *earth population* paradigm. The relevance of such a paradigmatic posture has been discussed elsewhere (*see* **Identification and Individualization**). Another way to describe this approach, *borrowed from the practice of toolmarks examination*, is by saying that individualization will be reached when the examiner observes a level of agreement (across all legible features) that exceeds the highest level of correspondence he observed through his/her training and experience in comparisons involving *nonmatching* entities. An identification is then concluded when the mark shows sufficient quality (clarity) of friction ridges in agreement with the print so that the probability for such a match to happen if a print from another source is submitted is deemed to be impossible [4].

For all other cases, the comparison will be declared as "inconclusive" – indicating that none of the previous conclusions (individualization or exclusion) has been reached – even if there are significant and perhaps highly probative correspondences between the mark and print. Corroborative evidence of this type (i.e., less than "certain") based on friction ridge skin impressions is rarely brought to the attention of the Judiciary despite its potential to address the issue of identity. A policy (and essentially unscientific) resolution of the International Association for Identification (IAI) has enforced that view [5]. Unfortunately, such a cautious approach precludes the fact-finder from potentially very strong corroborative evidence [6, 7]. This situation arises from the misconception that fingerprint evidence must be categorical and from the unwillingness of the majority of examiners to accept the relevance of probabilistic evaluation.

Standards for Identification

There is variability regarding the identification standards applied by law-enforcement agencies. In a nutshell, we can distinguish between the empirical and the holistic approach (according to the distinction made in [8]).

The Empirical Approach

This practice calls upon the examiner to require a minimum number of minutiae (or points) in the agreement (without discrepancies) between a mark and a print before concluding on an individualization. The practice is still widespread, but with the number of points required varying from one country to another. Table 1 (updated from [9]) lists a few options.

None of these standards have a meaningful scientific or statistical underpinning (see [10] for an analysis of the 16-point standard). They represent an adopted, often dogmatic, practice used by fingerprint examiners. The 12 (or 8–12)-point rule can be traced to the pragmatic guidance given by Locard in 1914 [11]. The 16-point rule is associated with the very early and premature statistical work by Balthazard [12] and the misleading interpretation of a paper by Bertillon [13, 14].

Table 1 Numerical standards adopted in a selection of countries

Numerical standard	Country
16–17	Italy
8–12	Germany
10–12	Holland
12	Belgium, France, Israel, Greece, Poland, Portugal, Romania, Slovenia, Spain, Turkey, and South American countries
7	Russia

From a logical perspective, there is no argument to recommend any predetermined minimum number of features for the following main reasons (see [15] for additional statistical data):

- The relative frequency of general flow varies greatly from class to class. The empirical approach makes no distinction between general patterns.
- Minutiae frequency varies greatly as a function of their type and their position. Hence any system suggesting a fixed addition of points cannot be supported from a statistical perspective.
- When quality allows, features (frequently referred as level three features) such as pore positions and shapes (including edges) add to the identification process. No numerical standard accounts for them.

Such numerical standards are not an objective standard for identification, but rather an ill-defined and locally adopted quality control measure. In fact, while facing the same set of images (marks and prints from the same source), examiners differ extensively in the total number of annotated corresponding features [16, 17]. As stated by a group of European experts working under the auspices of Interpol: "The decision whether the total volume is sufficient for individualization may differ according to the approach. It is not the calculation of a number of points that automatically leads to identification. It is the total constellation of all the information, as a coherent complex of which the relations are the same, and the details, as far as present, fit within tolerances, which constellation is weighed and referenced with individual knowledge with or without an empirical standard" [18], p.28. That leads to the holistic approach.

The Holistic Approach. Following a three-year review, the IAI took a resolution that set the scene for the holistic approach since 1973. The resolution, slightly modified in Ne'Urim, states: "No scientific basis exists for requiring that a predetermined minimum number of friction ridge features must be present in two impressions in order to establish a positive identification." [19]. The examiners from the United States of America, Canada, Switzerland, the United Kingdom, and Nordic countries (Norway, Finland, Sweden, and Denmark) follow this approach.

The approach calls for an assessment by the examiner of each comparison based on its own merit (in terms of quality and quantity as revealed by the mark and the print). The expert concludes on an individualization when he/she is satisfied that there is "sufficient" correspondence (or sufficient discordance in the case of an exclusion) between the compared images. This informed judgment is based on training, experience, and expert knowledge. Allowing the whole range of features to be accounted for in the identification process is referred to as *ridgeology* [20].

The inferential steps taken by fingerprint examiners to reach their conclusions remain unclear and there is an important risk in this "opinionization" of the fingerprint field [21]. The main one is the lack of transparency in the inferential process.

It must be stressed that the inferential process is probabilistic in nature [6]. Currently there is no scientific way to substantiate probabilities of an adventitious match on an order of magnitude that would prevent a discussion about the probability of a coincidental match. Hence categorical conclusions of individualization (within this *earth population* paradigm) cannot be substantiated (*see* **Identification and Individualization**). The fingerprint profession has to recognize that conclusions of identification to the exclusion of all others are essentially outside the realm of the expert witness. His/her testimony should limit itself to expressing the contribution of the findings in favor of one proposition (identity of sources) versus another (nonidentity of sources). Here lies the first element of a "paradigm shift," to take the expression of Saks and Koehler [22].

From Identification to Activity Issues

The examination of marks allows the association of an individual with a particular surface or item. A contact between the donor and the surface or item is a prerequisite. At present, there is no scientific method that allows a reliable estimate of the timeframe in which the mark was left on the surface. Also, there is currently no reliable means of assessing the significance of the absence of the detection of marks on a given surface to indicate whether or not the object has been touched with bare hands. However, consideration of the position of the detected marks on the objects may help a court in assessing how

an object was handled, thereby providing potential information on the nature of the activities involved.

Bias, Errors, and Challenges

An analysis of the issues of bias associated with image comparisons is given by Thompson (*see* **Interpretation: Observer Effects**). Empirical studies have confirmed that observer effects can influence the interpretation and conclusions associated with fingerprint examination (see [23] and associated references). The misattribution of a mark recovered in the conduct of the Madrid bombing has been attributed in part to confirmation bias [24].

The fingerprint profession has claimed for many years that a misidentification was not a possible outcome (with the exception of intentional or fraudulent evidence). A recent publication provides accounts of 22 cases of misidentifications [25, 26]. Although Cole [25] suggests that these cases represent the tip of the iceberg, the accuracy of this statement remains nonvalidated. Error rates estimated through proficiency testing suggest that the case of a wrong individualization is a rather rare (although existent) event [26–29].

US court challenges (following the impact of the *Daubert* decision and its progeny) (*see* **Expert Opinion: United States**) have been well covered by Langenburg (*see* **Friction Ridge Skin: Comparison and Identification**). Associated with the court cases is an important body of scholarly publications questioning the reliability of fingerprint identification and its underpinning process, ACE-V (see [30] with discussions [31–34]). A recent paper by Cole can serve an excellent source for the relevant references [35]. Most of the arguments by these scholars are have merits and will be resolved partly when fingerprint evidence will adopt a reporting practice based on a probabilistic approach substantiated through adequate statistical research.

Statistical Models

Although probabilistic research has been sporadically present in the forensic literature associated with fingerprints (see [36, 37] for critical reviews), the fact that the practitioners ruled out probabilistic statements from their practice has led to the more and more untenable situation of a field claiming individualizing power without any firm statistical backing. However, systematic research on the selectivity of fingerprint features has always pointed toward an extreme selectivity of these features, even when partial and limited information is considered (e.g., [38–40]). Such models can serve readily to assess the weight of evidence (in terms of likelihood ratio) associated with fingerprint evidence. This is the second element of a paradigm shift: promoting systematic research on the selectivity of the fingerprint features, and hence moving from the sole examiner's informed judgment to the actual statistical selectivity that fingermarks may provide. As Saks and Koehler aptly put it: "Forensic identification scientists can help themselves immediately by forswearing exaggerated, definitive conclusions in favor of humbler, scientifically justifiable, and probabilistic conclusions" [41, p. 219.]

CHRISTOPHE CHAMPOD

Friction Ridge Skin: Comparison and Identification

Introduction

The comparison of fingerprints, and more specifically, the friction ridges that compose a fingerprint, has been a mainstay of forensic science for 100 years. It is perhaps one of the quickest, cheapest, and easiest ways to reliably identify an individual.

The basic premise of fingerprint comparison is rather straightforward. Humans (and simians [1]) bear a series of ridges and furrows on the palmar and plantar surfaces of their epidermal layer of skin. The arrangement of the ridges and the features of the ridges have significant variation, which allows for identification. Furthermore, the fact that the ridge arrangements remain constant throughout our lifetime, makes fingerprint identification a useful technique for personal identification.

With respect to forensic application at scenes of crime, the principles remain the same, but the application can be more difficult. Sweat, secreted from the pores, and other contaminants, such as oils, blood, or dirt, form a residue on the ridges. When we touch a surface, this residue is transferred to a surface, leaving an impression of the friction ridges. This residue is typically not visible to the naked eye and must be developed using a chemical or physical (e.g., fingerprint powder) process. These "invisible" impressions are known as *latent-prints*, or *fingermarks* (or sometimes just "*marks*"). The unknown fingermarks obtained at scenes of crime are compared to fingerprints taken from a known source. Known standards are obtained by applying black ink to friction ridges and recording the ridge detail in a controlled fashion. In more recent times, this has been done electronically by scanning the ridges and creating a digital image.

While there are some differences between North American and European terminology, for the sake of consistency in this entry, the term "fingermarks" refer generally to unknown impressions developed at scenes of crime and "fingerprints" refer to the known standards. The same principles that are discussed apply equally to the ridges of the palms, toes, and feet.

History

There is evidence that fingerprints have been used as a means of personal identification in ancient cultures [2, 3]. Most notably the Chinese and Japanese have used finger and palm prints as a means of "signing" contracts and Chinese artists used their fingerprints as a personal mark of authenticity. Cultures in the Middle East practiced similar behavior. It is unknown what depth of understanding these cultures possessed regarding the nature of friction ridge skin.

Early pioneers of friction ridge skin dotted the sixteenth through eighteenth centuries [4]. However, it was not until the nineteenth century that two individuals, Sir William Herschel and Dr Henry Faulds, first explored the use of friction ridge skin as a means of personal identification and thus recognized its value [5]. Sir William Herschel was an employee of the civil service of India in 1858. He instituted the use of inked finger and palm prints as a means of signing contracts with local natives. He promoted the use of friction ridge identification throughout his civil service career. Courts, jails, and civil offices under Herschel were using friction ridges as a means of personal identification. Simultaneously, thousands of miles away in Japan, Dr Henry Faulds was systematically studying friction ridges. He too realized their value as a means of identification, but also studied (as did Herschel) their persistency. Faulds also recognized that the patterns of fingerprints would allow for classification, and fingermarks left by criminals at crime scenes could identify the perpetrator of the crime. Years later, Sir Edward Henry developed a classification system for the storage and retrieval of fingerprints.

It was Sir Francis Galton, however, who after writing the seminal friction ridge text "Finger Prints"

in 1892, earned the distinction of the father of fingerprints [6]. Galton expounded, through systematic study of friction ridge detail, upon the works of Herschel and Faulds. Galton is credited with the first (albeit quite crude) probability model for fingerprint individuality. Galton continued to study and publish on the topic of friction ridges for many years.

Further study throughout the twentieth century led to an increased understanding of friction ridge skin formation and structure. It is the mechanism of *formation* (morphogenesis) that explains the unique arrangements of friction ridge skin and it is the *structure* of friction ridge skin that explains the persistence of friction ridge skin. Noted scientists such as Drs Bert Wentworth, Harris Wilder, Inez Whipple, Harold Cummins, Charles Midlo, Alfred Hale, Michio Okajima, Sara Holt, and William Babler [7–13] all contributed significantly to the modern understanding of friction ridge skin formation and structure.

Features of Friction Ridges

The features of friction ridges can be categorized into Level 1 detail, Level 2 detail, and Level 3 detail [14, 15]. These levels refer, respectively, to ridge flow, ridge path, and ridge shape.

Level 1 detail is the flow of the ridges. In the fingers, the flow of the ridges can be classified into a pattern type. There are three major pattern types: loops, whorls, and arches (see Figure 1). There are many subclassifications for further pattern refinement as well. The flow of the ridges (and pattern type) are useful class characteristics, but lack strong discriminating power. Therefore, Level 1 detail is useful for exclusion, but not for statements of identity. Furthermore, because of the flexibility of skin, Level 1 detail can be grossly distorted and appear quite different in a fingermark than in the comparable fingerprint. For this reason, one must use caution when utilizing Level 1 detail, even when excluding (see Figure 2).

Level 2 detail is the path of the ridges. If one examines the fingerprint carefully in Figure 3, it can be observed that the ridges are not continuous. They split into two ridges, end abruptly, vary in length, or sometimes appear as a single dot. The occurrence of these events are known as *minutiae*. Minutiae are sometimes referred to as *points of identification*, *Galton points*, *dactyloscopic points*, or just colloquially as *points*.

Traditionally, identification of a source of a fingermark has sprung from a focus on the minutiae. Essentially the more minutiae one found in agreement between a fingermark and fingerprint, the more certain one could be that the impressions shared a common source. Today, examiners recognize that each minutia contains additional information useful in the comparison process, such as the rarity and clarity of the minutiae [16].

Each minutia has four components that must be considered during a comparison. When minutiae in a fingermark and fingerprint are compared, they are said to be in correspondence if all four of the components agree. The first component is the type of minutiae. There are three basic types of minutiae: bifurcations, ending ridges, and dots (Figure 3). There are combinations of these minutiae that are useful as well, such as short ridges and enclosures. The frequencies of minutiae types have been recorded and are useful [17–19]. When a minutia type is rare, it possesses more discriminating power. The second and third components of a minutia are angle and orientation. Minutiae in correspondence must be

Figure 1 Three major classes of fingerprint patterns. (a) Whorl pattern, (b) loop pattern and (c) arch pattern

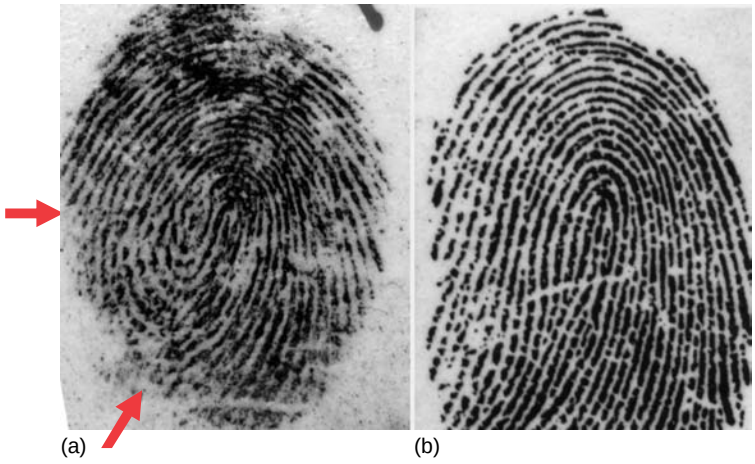

Figure 2 Distortion of pattern type. The fingermark in (a) was developed with black powder. The area between the red arrows is a distortion. The resulting effect gives the appearance of a whorl pattern, when in fact, it can be identified to the loop pattern in (b). [Image courtesy of Michella Snyder, Bureau of criminal Investigation, Richfield, Ohio USA]

oriented in the same direction along a ridge, with the same angle to be in agreement (Figure 4). The final component is ridge count. Minutiae in correspondence must have a similar spatial arrangement. Spatial distances can be distorted due to the flexibility of skin. However, the number of intervening ridges between minutiae is quite robust and cannot typically be altered, even under extreme distortional pressures. Thus the number of ridges between minutiae is counted. It is important that the path of each ridge is followed during a comparison and that the totality of the arrangement of the ridges is considered.

Level 3 detail can be represented by the shapes of the ridges and the relative location of the pores within the ridges (Figure 5). The use of pores for purposes of identification was first proposed by Edmond Locard [20, 21]. He noted that the relative relationships and positions of the pores varied significantly from person to person, and thus could be used to identify the source of a mark. The size and shapes of pores, however, did not vary significantly between persons, nor was this feature robust, since the pores constantly dilate and constrict. Locard did not recommend the use of pore size and shape for identification. Salil Chatterjee first suggested that edge shapes could be used for comparison purposes [22]. Chatterjee categorized edge shapes into eight classifications. These shapes can be compared when the clarity is sufficient and they are reproduced in the

Figure 3 Three major types of minutiae. In this inked fingerprint impression, the ridges are black and the furrows are white. The ridges end and split in various places. These are minutiae. The basic types of minutiae are dots (1), ending ridges (2), and bifurcations (3). Combinations of these three basic types are possible. For example, a spur (4) is an ending ridge in combination with a bifurcation. [Photograph courtesy of Ashley Boone, Bureau of Criminal Apprehension, Saint Paul, Minnesota, USA]

mark and the print. However, due to the flexibility of the skin and the three-dimensional nature of the

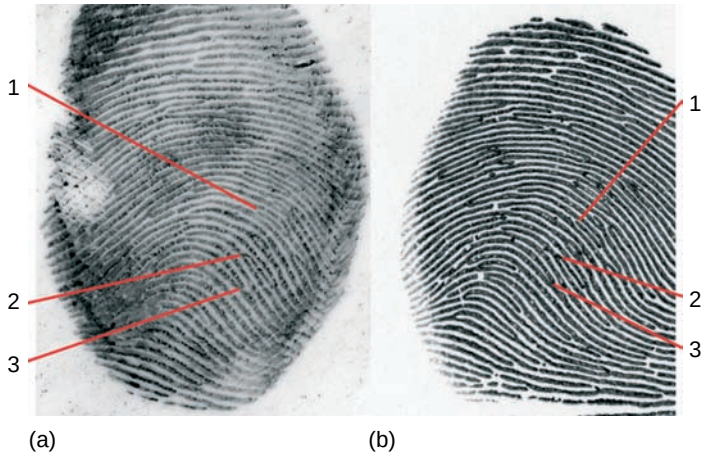

Figure 4 An example comparison of a developed latent fingermark and an exemplar. The image in (a) is a fingermark developed with black magnetic powder. It can be compared to the inked exemplar in (b). Friction ridge features present in the fingermark are sought in the exemplar. When comparing minutiae, they should correspond in location, type, orientation, and angle. For example, compare the minutiae that are marked as "1", "2", and "3" in the fingermark with their respective mates in the exemplar. Note the ridge count between them. [Images courtesy of Jennifer Kostroski, Bureau of Criminal Apprehension, Saint Paul, Minnesota, USA]

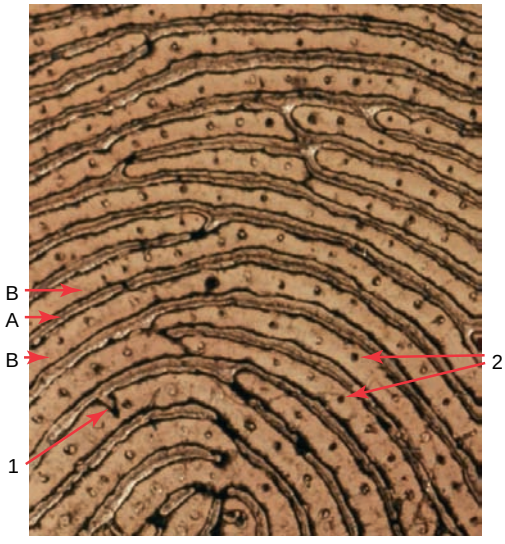

Figure 5 The presence of Level 3 detail: sweat pores and ridge shapes. The above image was produced by applying ink to the friction ridge skin and then pressing the finger against a clear glass plate. The furrows (A) appear slightly darker and thinner than the ridges (B). The ridges are not smooth along the edges, are not necessarily uniform in thickness, and occasionally bear distinct shapes (1). Sweat pores (2) can be seen dotting the ridges as well. [Photograph courtesy of Joshua Bergeron, Bureau of Criminal Apprehension, Saint Paul, Minnesota, USA]

friction ridge edges, it can be problematic to use edge shapes, as their presence can be intermittent or the shapes appear differently due to distortion of the skin from pressure and movement. Similar problems can occur when comparing pores as well. Level 3 detail can be powerful to use when present, but only a small percentage of actual case work contains such fingermarks bearing the highest clarity possible.

There is a class of additional features, sometimes referred to as *occasional features* or *accidental features*, in the friction ridge skin that are useful for identification purposes if present. These include incipient ridges (nascent ridges halted during development), creases and wrinkles, scars, and other skin damage (Figures 6–8).

The levels of detail present will be determined by the clarity of the impressions. The more clarity found in a mark, the more levels that can be observed. Thus, when a mark possesses minimal clarity, all that might be available is Level 1 detail, and perhaps only statements of exclusion can be made. When a mark possesses exceptionally high clarity, the amount of discriminating information contained in the ridges is also very high, and statements of identity can be made with very small areas of friction ridge skin (see Figure 9).

Figure 6 The presence of incipient (nascent) ridges in a fingerprint. Incipient ridges are undeveloped ridges that can be seen in the furrows. They generally lack sweat pores and are thinner than a fully developed ridge

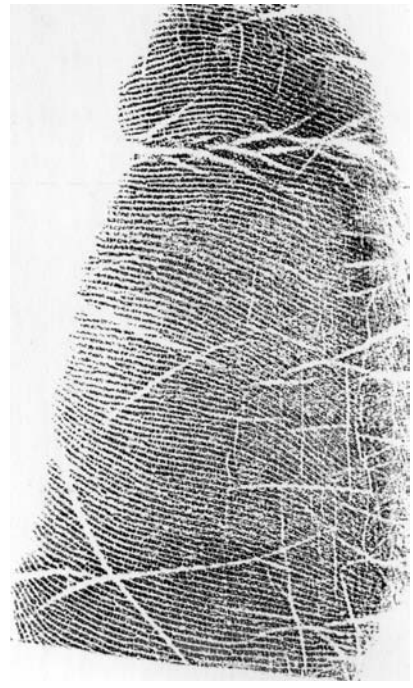

Figure 7 The presence of creases in a palm print. The above image is an inked palm print of the author's right palm (from the hypothenar region, commonly referred to as the "writer's palm" area). Palms typically bear a large number of creases which can be used for identification purposes

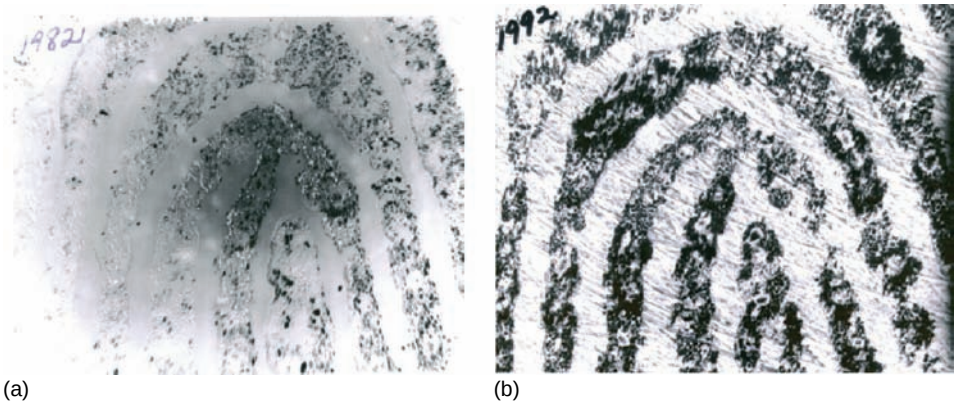
ACE-V

Analysis, comparison, evaluation, and verification (ACE-V) are the four stages that represent the overall examination of two friction ridge images (for example, a fingermark from the crime scene and a fingerprint from a suspect). During an examination, a friction ridge specialist first performs an analysis of the fingermark, followed by an analysis of the known exemplar. The purpose of the analysis is to assess the quantity, quality, and specificity of the features present in the fingermark. During the analysis, the specialist typically tries to assess the evidentiary value of the mark (i.e., its intrinsic value for discriminating a unique source). If the mark is determined to possess sufficient value, and the known exemplar is also sufficient for comparison purposes, then the specialist proceeds to the comparison phase. The comparison is the side-by-side comparison of the images. Features present in one image should be found in the other image, in the same relative position, orientation, and number of intervening ridges. Level 1, Level 2, and Level 3 details should all be in agreement given the quality and tolerance of the images. After the side-by-side comparison is complete, the specialist must formulate an opinion about the source of the images. This decision making process is the evaluation stage. While terminology may differ between agencies or countries, fingerprint specialists currently report one of the three general categorical conclusions: individualization (identification), exclusion, and inconclusive opinion [23]. A specialist reports an individualization if he or she has declared a match and believes the images originated from the same source. An exclusion is reported when the images could not share a common source of friction ridge skin. An inconclusive opinion is reported when the examiner could not determine an individualization or an exclusion. Finally, a specialist has another specialist (and in some agencies, multiple specialists) verify his or her conclusion. This check is a quality assurance mechanism and is the final phase of ACE-V known as *verification*. It is recommended by the standards of Scientific Working Group for Friction Ridge Analysis, Study, and Technology (SWGFAST) that at a minimum, all individualizations must be verified by at least one other specialist trained to competency [15]. However, some agencies will have

Figure 8 The presence of permanent scarring in a fingerprint. Fingerprint with a scar. Notice how the ridges pucker inwards, toward the scar. [Image courtesy of Kasey Wertheim, USA]



all conclusions, including exclusion and inconclusive opinions, verified.

The ACE-V approach was first suggested by Roy Huber, of the Royal Canadian Mounted Police (RCMP) in 1959 as a protocol for forensic examinations [25]. Michael Cassidy and Harold Tuthill, both of RCMP, adopted ACE-V for footwear examinations [26–27]. David Ashbaugh of RCMP suggested the use of ACE-V for friction ridges soon after [14]. However, wide spread knowledge and articulation of this approach really did not gain notice until the 1990s. In 1999, David Ashbaugh and Stephen Meagher of the Federal Bureau of Investigation (FBI), both testified in the first *Daubert* evidentiary hearing on the admissibility of fingerprint evidence [29]. In this hearing, they stated that friction ridge identification specialists utilize the ACE-V method as a means of comparing friction ridges and that this is the generally accepted method for doing so.

Probability Models

As previously noted, current practice by fingerprint specialists is to report a categorical opinion as a result of ACE-V examination of two images. It should be observed that there are two common practices to reach this opinion: minutiae thresholds (also called *the empirical* or *numerical standard*) and the holistic approach [30].

Many countries employ a minutiae threshold. This is a static number of minutiae that must be observed in correspondence to declare a positive match. The application of this approach can vary from country to country. For example, until recently, sixteen corresponding minutiae were needed to present an identification in court in England and Wales, but a match could be declared for “investigative purposes”,

(a) (b)

Figure 9 A comparison with a low number of minutiae, but a high level of clarity. The image in (a) is a fingermark deposited 10 years before the exemplar in (b) was taken. A high degree of clarity in the images reveals ridge shapes, edge shapes, and sweat pores. [The images above were presented by Stephen Meagher, FBI Latent Print Unit, in the first Daubert hearing for fingerprint evidence (*U.S. v. Byron Mitchell, 1999*)]

if a specialist found less than sixteen, depending on the circumstances of the evidence and the experience of the specialist. Those employing minutiae thresholds may only count minutiae towards the final opinion and these features must be true dactyloscopic minutiae (i.e., not produced by scars, include incipient ridges, etc.) [16].

With respect to the holistic approach, the specialist declares an individualization (or exclusion) opinion when he or she is personally satisfied that there is "sufficient" correspondence (or sufficient discordance in the case of an exclusion) between the compared images. This threshold of sufficiency is said to be based on training, experience, and expert knowledge. The expert evaluates the quantity, quality, and specificity of the ridge details present, utilizing all three levels of detail and any occasional features that may be present (e.g., scars, warts, creases, etc.). The evaluation of all of the features present determines whether "sufficiency" is reached to declare a definitive opinion. Ultimately, the specialist must be convinced that the chance of finding the examined features in someone else, *other than* the person against which the mark has been compared and identified, is so small that it may be discounted [32]. Whilst one cannot refute the importance of expertise, this opinion is subjective and not based *per se* on a statistical calculation for the corresponding features in the compared images.

In fact, the probabilistic approach as a means of reaching a conclusion has been rejected wholesale by profession, while simultaneously applauding the use of probabilities to support the individuality of friction ridge arrangements. The International Association for Identification (IAI), which is the professional organization representing the majority of fingerprint specialists in the world, declared the following resolution in 1980:

> Whereas the delegates of the IAI ... state unanimously that friction ridge identifications are positive, and officially oppose any testimony or reporting of possible, probable or likely friction ridge identifications found on hands and feet. Now therefore be it resolved that any member, officer or certified latent-print examiner who initiates or volunteers oral or written reports or testimony of possible, probable or likely friction ridge identification, or who, when required in a judicial proceeding to provide such reports or testimony, does not qualify it with a statement the print in question could be that of someone else, shall be deemed to be engaged in conduct unbecoming such member ... and charges may be brought [33].

Historically, probability models were explored as a means of providing statistics for a static minutiae threshold. This threshold was a "safe region" above which, once x number of corresponding minutiae were found, an individualization could safely be declared without possibility of duplication within the earth's population. Early models by Galton [6], Henry [35], and Balthazard [36] explored the probabilities of duplication of an entire fingerprint [6, 35,36]. In fact, the work of Balthazard led to the adoption of a 16–17 minutiae threshold, which was adopted by the French and Italian courts, and remains still to this day in France and Italy. More sophisticated models were proposed by Roxburgh [37], Amy [38, 39], Santamaria Beltran [40], Kingston [41], Gupta [42], Osterburg *et al.* [17], Sclove [44] and Stoney and Thornton [45–47]. However, all these models dealt with relatively small sets of fingerprints – the largest was Stoney and Thornton at 412 fingerprints (distal thumb tips). Champod and Margot [19, 48] reported statistical analyses for minutiae from nearly 1000 fingerprints (loop and whorl patterns from fore and middle fingers) using a computerized database [48]. Pankanti *et al.* [49] explored false match probabilities for minutiae in automatic fingerprint identification systems (AFIS databases and their matcher algorithms) [49]. Most recently, Neumann *et al.* [50, 51] reported on the use of likelihood ratios as a means of objectively assessing the evidential weight of corresponding minutiae between a mark and a fingerprint [50–51].

Current work on the validation of this model by Neumann *et al.* has led to the development of software that would allow a fingerprint specialist to annotate corresponding minutiae between two images [52]. The software calculates a likelihood ratio assessing the strength of the evidence, based on the minutiae annotated by the specialist. This statistic represents the probability of the corresponding minutiae under two competing hypotheses: the mark was made by the individual or the mark was made by another individual. Following recent challenges in US courts, government funding agencies in the United States such as Technical Support Working Group (TSWG) and National Institute of Justice (NIJ) supported the development of similar models. A nonexhaustive list of individuals currently developing models includes Champod and Egli at the University

of Lausanne (UNIL) in Switzerland, Meuwly at the Netherlands Forensic Science Institute, and Srihari at the State University of New York (SUNY) in Buffalo, New York. However, even as these models become available, current attitudes from fingerprint specialists have ranged from mild resistance to abject hostility towards the use of probabilities in fingerprint comparison [53].

It is very possible, in parallel developments in the underlying theories and computing power, that such models will be increasingly used by research scientists and practitioners in the near future. In fact, the courts may eventually require it. Note the dissenting opinion of a US appellate judge in *U.S v. Crisp* [54]:

> Fingerprint identification may also be seen as reliable because the examination community prevents its experts from testifying to a match unless they are certain of the match. Fingerprint experts, in other words, refuse to hedge their testimony in terms of probability .... This practice seems to have hastened the technique's acceptance by courts, which have been attracted to its seeming infallibility .... Professions of absolute certainty by an expert witness, however, seem out of place in today's courtroom. Even a DNA match has a small chance of being an error [54].

Legal Challenges

Fingerprint evidence has enjoyed widespread acceptance and use in the courts worldwide for approximately 100 years. However, the 1993 US legal decision in *Daubert et al. v. Merrill Dow Pharmaceuticals* raised the bar for admissibility of scientific evidence [55]. The *Daubert* decision required trial judges to assess the reliability of a scientific principle or method based on five factors. These five factors are:

1. General acceptance: Is the method or principle generally accepted within the relevant community?
2. Testing and validation: Has the method or principle been subjected to testing or validated through testing?
3. Known standards: Does the application of the method adhere to published and accepted standards?
4. Peer review: Has the method or principle been published and subjected to peer review?
5. Rate of error: What is the known or potential rate of error for the method?

Trials judges were asked to assess the proffered evidence under these factors. They were given a wide berth in their application and these are general recommendations for admitting the evidence and not a strict checklist.

In 1999, fingerprint evidence was put to the *Daubert* test in *U.S. v. Byron Mitchell* [56]. After a five day evidentiary hearing, Justice Curtis Joyner ruled to allow the presentation of fingerprint evidence. Upon appeal in 2004, the appellate court upheld the decision [57]. Since the decision, fingerprint evidence has been challenged hundreds of times in the United States. Stricter scrutiny and concerns have been raised by some courts and dissenting opinions, but fingerprint evidence has been mostly accepted.

There are a few exceptions to the admissibility of fingerprints at the time of this writing. In *Massachusetts v. Patterson* [58], the court recognized the reliability of ACE-V methodology as a standard for fingerprint comparison, but did not allow the evidence in the instant case because it was used for the individualization of a simultaneous impression [58]. In this instance, a cluster of fingermarks were observed that appeared to have been deposited simultaneously by the defendant. None of the marks stood alone and could be considered "identifiable" on their own; however, as an aggregate, the features were combined to effect an individualization. The Patterson Court rejected this notion stating that such an application of ACE-V had not been sufficiently tested. In *New Hampshire v. Langill* [59], the trial judge did not allow the fingerprint evidence because the judge found the examiner's documentation to be insufficient to demonstrate the accurate application of the method and because the conclusions of the initial examiner were not verified as a blind test by the verifying examiner (i.e., the second examiner was aware of the conclusions of the first examiner) [59]. The judge rejected the evidence until the analysts could demonstrate that ACE-V had been reliably conducted. The most recent rejection occurred in *Maryland v. Rose* [60], a death penalty case resulting from the shooting of a man during a carjacking [60]. The judge rejected the prosecution's assertion that the reliability of the ACE-V process has been demonstrated during 100 years of operational practice. The judge

also expressed concern about experts testifying to "an infallible method" that when applied correctly has an error rate of zero. This was particularly troubling because no evidence of systematic study of error rates or the possibility of chance duplication of fingermark fragments was presented by the prosecution. The judge felt that since it was a death penalty case, the assertion of 100% certainty, with a zero chance of error simply could not be demonstrated given the lack of research and data.

Future Directions

It is rather remarkable that two of the most important, direction-changing events have occurred nearly simultaneously (relatively speaking) in the fingerprint discipline's century of existence. These two events are the *Daubert* challenges in the United States, followed by the FBI's very public erroneous identification of Brandon Mayfield in the Madrid Train Bombing case [61]. These events have brought new scrutiny from commentators, courts, and academics upon fingerprint specialists and other forensic identification specialists as well.

In turn, forensic professionals have responded with an increased focus on conducting research, improving standards, and moving towards transparency. The Interpol European Expert Group on Fingerprint Identification (IEEGFI) in Europe and the SWGFAST are recognized for developing and promoting international standards. Furthermore, research solicitations and funding by US research groups such as the TSWG and the NIJ have led to important research that is advancing the field.

While the advancements in the field are welcome, they are, in our opinion, severely overdue. They have followed a long period of stagnation and it has taken *Daubert* and the *Mayfield Incident* to stir the pot. There will likely be a period of rapid change and progression in this discipline. These changes may result from the accurence of a series of events that are similar to what occurred within the forensic DNA community in the 1990s. Forensic DNA practices were subjected to significant academic debate and legal scrutiny that ultimately led to the formation of a blue ribbon panel of experts to evaluate the state of the science of forensic DNA. The result led to two reports by the National Research Counsel (NRC) that was sponsored by the National Academy of Sciences in the United States [62]. The recommendations of the NRC led to rapid implementation of standards and international cooperation and consensus to improve forensic DNA practices. Observing the successes of the forensic DNA model, the National Academy of Sciences has formed a new committee, called the *Committee for the Evaluation of the Needs of the Forensic Science Community*, to assess the state of the science in other forensic disciplines, including fingerprints. It is sincerely hoped that the recommendations of this committee will have the same positive effects experienced by the forensic DNA community and open the door for improvements in the fingerprint discipline.

GLENN LANGENBURG

Friction Ridge Skin: Fingerprint Detection and Recovery Techniques

Introduction

This entry presents an overview of the most common methods used to detect and enhance fingermarks in relation to forensic investigations. The list of techniques presented here is not exhaustive. For a comprehensive review of the subject, including further information on the properties of light and fingerprint chemistry, the reader should consult the publication by Champod and coworkers [1].

Detection of Visible Fingermarks

Visible fingermarks are those in which the papillary ridges are distinct from the substrate when observed with the naked eye. A positive image of the papillary ridges can be produced when the finger has been contaminated with a substance of contrasting color (e.g., blood, wet paint) that is then transferred to the substrate, and a negative image can be produced when the papillary ridges remove material (such as dust or soot) from the surface. Indented fingermarks can be produced when a finger comes into contact with a malleable substance that retains a three-dimensional image of the fingerprint ridges (e.g., window putty, candle wax).

Visible fingermarks can generally be detected without any treatment as long as there is sufficient contrast between the fingermark and its substrate. Weakly visible fingermarks may be enhanced using colored, oblique, or episcopic light illumination. Indented fingermarks can be difficult to visualize or photograph; therefore, good lighting conditions, powdering, or the use of a casting material (such as silicone) can be used to enhance the contrast.

Detection and Enhancement of Latent Fingermarks

Latent fingermarks are those that cannot be readily seen with the naked eye. They are created from the natural secretions and contaminants on the finger that are deposited onto the substrate in the shape of the papillary ridges – in much the same way as a rubber stamp deposits ink in the shape of its raised profile.

In order for a latent fingermark to be visualized, it must be given properties that differentiate it from its substrate. Usually, this is done by giving color or luminescence properties to the fingermark through either optical, physical, or chemical processing, or a combination of these. The most effective approach is to use a sequence of techniques that is appropriate for the type of substrate and the environmental conditions that the fingermarks have been exposed to.

Substrates are generally classified as being porous, nonporous, or semiporous. Porous substrates such as paper and cardboard absorb fluids, including natural secretions that have been deposited on the surface. Nonporous substrates such as glass and most plastics do not absorb such secretions, and thus the fingerprint deposit remains on the surface of the substrate. Semiporous substrates such as expanded polystyrene, latex gloves, or polymer banknotes possess both porous and nonporous characteristics. Substrates can be further divided into those that have been exposed to water, and those that have not. This factor determines the types of secretions that have potentially

washed or diffused away from the fingermark, hence defining the development techniques that can still be effective. In each particular scenario, the most appropriate sequence of reagents and techniques may be different.

Detection Techniques

Optical Techniques

All types of evidence must first be examined using optical techniques because they are nondestructive and can be performed relatively easily either in the laboratory or at the crime scene. In order to understand how optical techniques work, it is necessary to understand some of the basic properties of light.

Light Properties. The perception of color and luminescence is due to the interaction of light with matter. Light is a form of electromagnetic energy that comprises the ultraviolet (UV), visible, and infrared (IR) regions of the electromagnetic spectrum (Figure 1).

The human eye can only see the visible region of the spectrum, which is within the wavelength range of approximately 400–700 nm. Color perception is dependent on the wavelength of radiation; for example, radiation at 450 nm is observed as blue light, 550 nm is green, and 650 nm is red. When all colors of the visible spectrum are present with the same relative intensity, the result is white light (Figure 2).

Light in the visible region can be polychromatic (many colored), or monochromatic (single colored). When a single wavelength is present, there is pure monochromatic light. When a narrow range of visible wavelengths is present, there is a monochromatic band of light.

When a light beam is directed onto a surface, certain wavelengths are reflected from the surface, absorbed by it, or transmitted through it. The reflected wavelengths produce the color that an object appears to have. For example, an object that appears blue under white light reflects light around the wavelength 450 nm, while absorbing most other wavelengths. The same object under monochromatic green light (around 550 nm) appears black if it absorbs all the radiation at 550 nm.

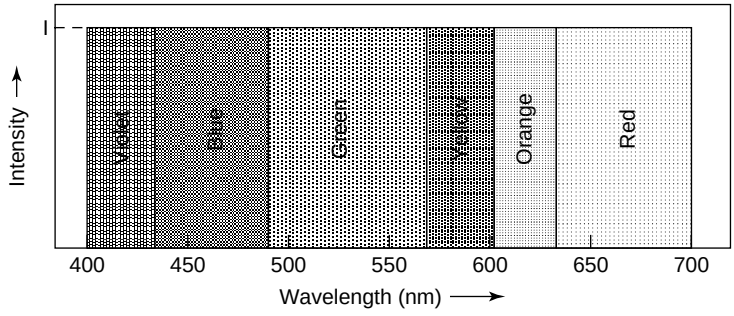

Figure 2 When each color of the visible spectrum is present with the same relative intensity, white light results [Reproduced from Ref. 1. © Taylor & Francis Group, 2004.]

Light Properties and Fingermark Detection. The absorption properties of light can be exploited when enhancing fingermarks. A forensic light source (FLS) that generates strong white light can be trained on the object, and filters can be used in the light path to block certain wavelengths in order to differentiate a contaminated or treated fingermark from its substrate. Laser light sources or alternate light sources (ALS) such as the Polilight® lamp are examples of FLSs used for fingermark detection. The application of UV light can be used in the same way if the substrate and fingermark possess different absorption properties in the UV region; however, a UV imaging system is required to capture the results.

Episcopic coaxial illumination can be effective for the detection of latent fingermarks on smooth, shiny surfaces. This technique relies on the diffused reflection from the fingermark ridges as opposed to the specular reflection from the substrate.

Some substances also possess photoluminescence properties that can assist in fingermark enhancement. This phenomenon occurs when matter absorbs a photon of energy in the visible or UV region and then emits the energy as a photon of light at a longer wavelength. During this complex process, some energy is lost in the form of heat and movement (molecular vibrations), and thus the light emitted is at a lower energy (longer) wavelength. Photoluminescence is a reproducible property, and, with FLSs, it is possible to use filters at particular excitation and observation wavelengths to increase contrast between a photoluminescent fingermark and its nonluminescent substrate. Images of the fingermark can be easily captured using standard photographic equipment and the correct filters. Where the substrate and the fingermark both possess luminescence properties and cannot be readily differentiated using traditional photographic techniques, more advanced imaging techniques can be employed such as fluorescence lifetime imaging (FLIM) [2–6] or chemical imaging [7–9].

In general, latent (or invisible) fingermarks – by their very nature – require additional processing rather than optical techniques alone. It is generally necessary to treat the evidence with a physical or chemical process that imparts color or luminescence to differentiate the fingermark from its substrate.

Preliminary optical examinations can assist in observing contaminants in a fingermark and determine whether a substrate possesses inherent properties that preclude treatment with a particular reagent. For example, if a certain reagent produces fingermarks that fluoresce at a particular wavelength, then the technique is redundant if the substrate strongly fluoresces at the same wavelength (this results in a lack of contrast and the fingermark remains invisible). After treatment with an appropriate reagent, optical techniques can be used for further enhancement.

Further information on light, chemistry, and fingerprint detection principles can be obtained from the publication by Champod and coworkers [1].

Detection Techniques at the Crime Scene

Fingerprint Powders. At the crime scene, fingerprint powders are traditionally used to develop fingermarks on smooth, nonporous substrates. The process of fingerprint development is a physical one, with the powder adhering to the moist, sticky, or greasy substances present in the latent fingermark deposit. Developed marks are photographed and can then be collected using adhesive tape or gel lifters.

While the application of powders is relatively easy and inexpensive, the technique generally lacks sensitivity. Only relatively fresh fingermarks are usually developed because, over time, latent fingermarks dry out and lose their stickiness, making it more difficult for the powder particles to adhere. The technique is also not suitable for developing fingermarks on porous surfaces as the latent deposit is quickly absorbed, making it unavailable to the powder. Items that can be transported back to the laboratory are not usually powdered as more sensitive techniques are available that should be applied where possible.

There are a multitude of different powders and brushes available for fingerprint detection, and the choice is often made according to experience or personal preference. Brushes are usually classified by the types of fibers used to make them (e.g., synthetic fibers, natural fibers, glass fibers, etc.). Traditional fingerprint powders consist of a resinous polymer for adhesion and a colorant (black, white, or gray) for contrast. Many different types of colored, metallic, or luminescent powders are also available commercially [10], and various pigments and dyes have been evaluated for use as fingerprint powders [11–16]. The selection of a powder must take into account the color and luminescence of the substrate. Aluminum flake powder is generally considered to be the most effective powder for general fingerprint development on smooth, nonporous surfaces [17].

Care must be taken when powdering, as excessive contact between the brush and the fingerprint destroys fragile fingermarks, and may result in the transfer of DNA to subsequent articles being powdered [18]. Magnetic powder, applied with a magnetic wand, can minimize such problems [19, 20]. The powder itself forms a "brush" in the magnetic field and the fingermark is developed when the finer powder particles adhere to it.

The Home Office Scientific Development Branch has conducted an extensive study on the most effective combinations of powders and brushes, and have prepared a flow chart to assist crime scene officers to select the most appropriate combination, depending on the type of surface encountered [21].

Small-Particle Reagent (SPR). Small-Particle Reagent (SPR) is a wet powdering technique that can be used to develop latent fingermarks on a wide variety of nonporous items. The process involves immersing or spraying the item with an aqueous suspension of an insoluble powder and then rinsing it with water to remove the excess reagent. The powder suspension, which also contains a low concentration of the detergent, is sensitive to the water-insoluble portion of the latent fingermark and is therefore effective on surfaces that are wet. Conventional SPR is a suspension of molybdenum disulfide particles [22], which gives a dark gray image of the treated fingermark. Particle size is a critical factor in achieving optimum results.

A modified SPR containing iron oxide instead of molybdenum disulfide has been proposed [23]. While it can improve contrast in some cases, comparative tests have shown that the modified formula was not as sensitive or selective as the original formulation [24]. A white SPR formulation based on zinc carbonate powder has also been developed [25]. As with molybdenum disulfide, the particle dimensions of the zinc carbonate affects fingerprint development. A fluorescent SPR powder using basic yellow 40 (BY40) in the original formulation is also available [26]. In this case, fluorescence visualization can best be achieved with excitation at 450 nm and observation using a barrier filter at 550 nm.

Powder suspensions similar to those used for the detection of latent fingermarks on adhesive surfaces (discussed later) have also been investigated for their potential to be applied to other nonporous surfaces [27]. Preliminary results suggest that these types of suspensions work differently from the conventional SPR technique.

Detection Techniques for Porous Surfaces

Ninhydrin. Ninhydrin (2, 2-dihydroxy-1, 3-indandione) reacts with primary and secondary amines to produce a dark purple compound known as *Ruhemann's purple* (Figure 3) [28]. Latent fingermarks generally contain amino acids as they are present in natural skin secretions. When ninhydrin is applied to a porous substrate carrying a latent fingermark, the compound reacts with the amino acids. If the fingermark contains a sufficient amount of amino acids, it becomes dark purple and can be readily viewed under white light. The mechanism for the reaction of ninhydrin has been well studied [29–31], and is given in Figure 4 [1].

Ninhydrin is usually made up in a solution that is applied by dipping or spraying the evidence. The solution contains a small amount of polar solvent (such as methanol or ethanol) to dissolve the ninhydrin, acetic acid to slightly acidify the reaction, and a carrier solvent. Chlorofluorocarbon (CFC) based carrier solvents are ideal for the ninhydrin development of latent fingermarks; however, the CFC ban worldwide has led to various replacement solvents being tested. Formulations based on hexane, heptane, or

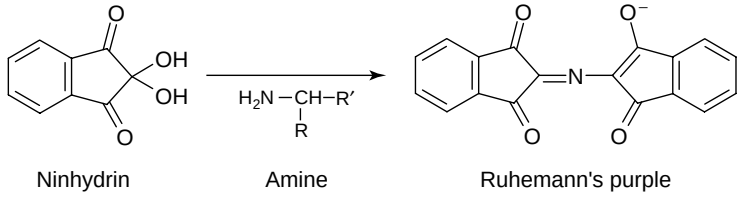

Figure 3 The chemical reaction of ninhydrin and a primary or secondary amine produces Ruhemann' s purple [Reproduced from Ref. 28. © RSC, 1910.]

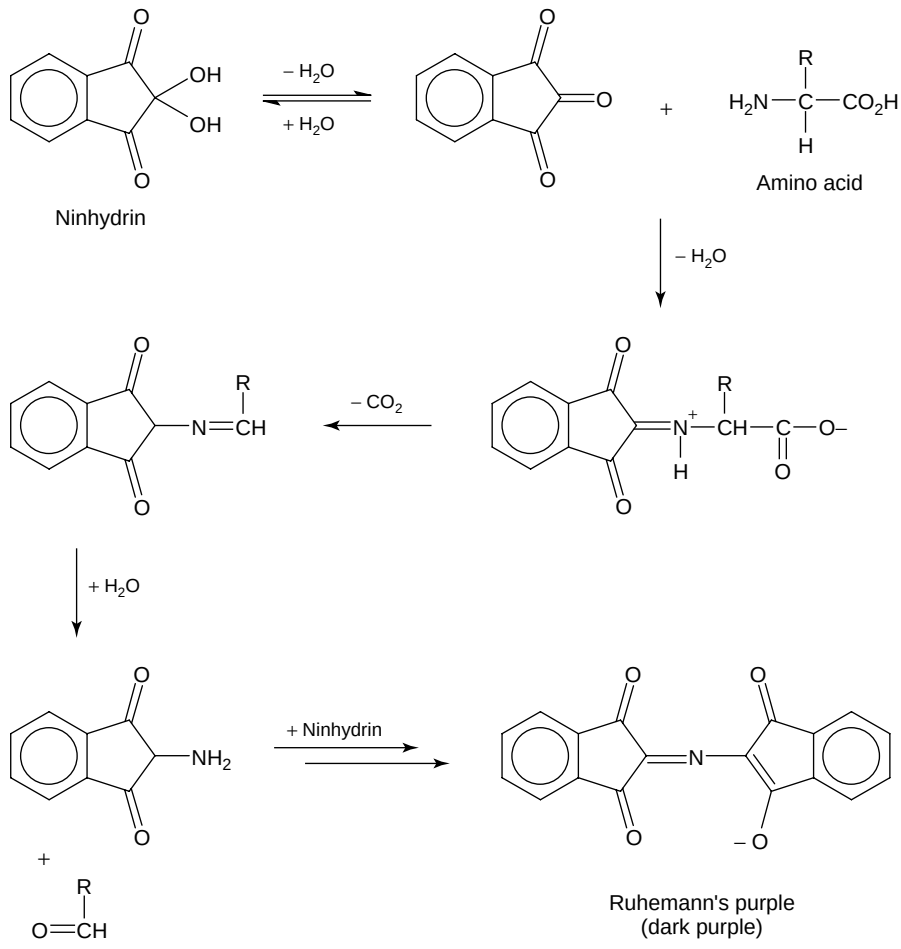

Figure 4 The mechanism of reaction between ninhydrin and amino acids [Reproduced from Ref. 1. © Taylor & Francis Group, 2004.]

petroleum ether have been proposed and have been successfully employed despite the high flammability of these formulations. Currently, the two most used formulations are based on hydrofluoroether (HFE) and hydrofluorocarbon (HFC) solvents.

Treated fingermarks are usually stored for 24 h at room temperature to allow optimal development to be achieved. Visualization is then undertaken in the absorption mode with white light illumination and a green–yellow bandpass barrier filter in front of the camera (e.g., 540–580 nm).

Secondary Metal Salt Treatment. If a fingerprint that has been developed with ninhydrin shows poor contrast, it can be further enhanced by treatment with a zinc or cadmium metal salt solution. The metal salt forms a fluorescent 1 : 1 coordination complex with the Ruhemann's purple (Figure 5) [30, 32]. Zinc nitrate treatment changes the color of the fingerprint to orange, while cadmium nitrate treatment changes the color to red. If the relative humidity is low, exposure to steam may be necessary to complete the reaction.

Visualization in the absorption mode is best achieved for zinc with a 490-nm bandpass filter in front of the camera (or the equivalent illumination from a FLS), and for cadmium with a 505-nm bandpass filter in front of the camera (or the equivalent illumination from a FLS). The fluorescence emissions for both complexes is very weak at room temperature,

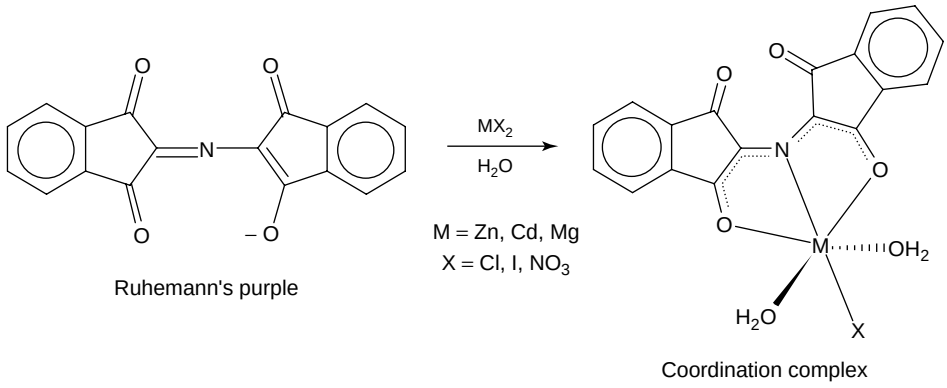

Figure 5 Treatment of Ruhemann's purple with certain metal salts produces a coordination complex [Reproduced from Ref. 32. © Blackwell Publishing Ltd, 1987.]

but this can be significantly augmented by cooling the fingermarks with liquid nitrogen (−196 °C, 77 K). The sample is placed in an insulated container and covered with a thin layer of liquid nitrogen. The luminescence can be seen by illumination in the blue–green (490 nm) region for the zinc complex and illumination in the green (505 nm) region for the cadmium complex, combined with a green–yellow (550-nm) bandpass barrier filter for the zinc complex and an orange (590-nm) bandpass barrier filter for the cadmium complex.

Diazafluorenone (DFO). The compound 1,8-diazafluoren-9-one (DFO) reacts with amino acids to give a product that is pale purple in color (Figure 6). While the color obtained is lighter than that of Ruhemann's purple, the advantage is that the product shows strong room-temperature luminescence without secondary treatment [33]. The reaction product [33] and mechanism [34] for the reaction between DFO and the amino acids present in the latent fingermark deposit appears to be similar to that of ninhydrin with amino acids (Figure 7).

DFO is generally applied by dipping the evidence into a solution of the compound and then heating at 100 °C for 20 min in an oven. Alternatively, it is possible to heat at 160 °C for 20–30 s or at 180 °C for 10 s in an ironing press [35]. Since the CFC ban, DFO formulations based on petroleum ether [36] and HFE7100 [37] have been evaluated. In each case, methanol was found to be an important component of the formulation because it contributes to the formation of a hemiketal that is the reactive species. Alternatively, DFO can be applied using a "DFO-dry" procedure, which involves placing DFO-soaked filter papers onto the evidence and heating it at 100 °C with a steam iron filled with a 5% acetic acid solution. The advantage of this technique is that ink running, damage to the documents, and background staining of the evidence is minimized.

The luminescence of DFO-treated fingermarks may start to diminish around 30 min after heating if they are kept in humid environments due to moisture absorption. However, the luminescence intensity can be restored by reheating (in an oven at 100 °C or in a press at 180 °C). Visualization can be achieved

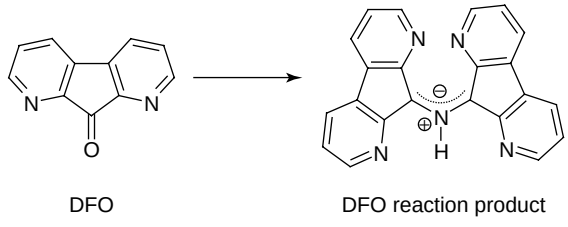

Figure 6 Suggested reaction product between DFO and amino acids [Reproduced from Ref. 35. © Elsevier, 1993.]

over a broad excitation range ($\lambda_{ex.} = 430-580$ nm) with an observation filter selected, depending on the excitation wavelength ($\lambda_{em.} = 560-620$ nm). The best results are generally obtained with excitation between 530 and 570 nm.

1,2-Indanedione (IND) and 1,2-Indanedione-Zinc (IND-Zn). 1,2-Indanedione (IND, Figure 8) is a relatively new reagent that also reacts with the amino acids present in the latent fingerprint deposit. The resulting image is a bright pink color with strong luminescence at room temperature. While the color development with IND is inferior to that obtained using ninhydrin, it is an improvement on the color achieved using DFO. The luminescence produced by IND is also far stronger than that produced by DFO, giving it a distinct advantage for the development of fingermarks on porous substrates [38–41]. Other researchers, however, have reported that IND does not perform as well as DFO [42, 43] (Wilkinson, D. *Personal Communication,* 2007). This may be due to the use of different reagent formulations, the impact of different paper substrates, or the inherent sensitivity of IND to certain environmental conditions encountered around the world [40]. Recent studies have highlighted the fact that IND development is affected by both humidity and the nature of the substrate [41].

Excellent results have been reported for an IND formulation that contains zinc chloride [44]. This

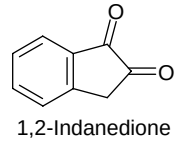

Figure 8 Chemical structure of 1,2-indanedione

combined indanedione-zinc formulation (IND-Zn) does not change the color of the development, as is the case with ninhydrin fingerprints that have been posttreated with metal salts, but allows the treatment to work more reliably, and, in some cases, can significantly improve development. Owing to the similarity in structures between ninhydrin and IND, it was originally hypothesized that the role of zinc was to form a coordination complex with the reaction product. However, recent studies suggest that the zinc is more likely to be a catalyst for the reaction between IND and amino acids [45] (Spindler, X. and Shimmon, R. *Personal Communication,* 2007).

Several formulations for IND [40] and IND-Zn [44] have been evaluated. In contrast to DFO, alcohols are detrimental to the reaction [46]. IND or IND-Zn is applied by dipping or spraying the item, then heating it using a dry heat press at approximately 165 °C for 10 s. Fluorescence visualization can be achieved by using various filter combinations, for example: (i) excitation at 500–520 nm

and observation using a 550-nm long-pass filter; or (ii) excitation at 520–540 nm and observation using a 590-nm bandpass filter.

Genipin. Genipin is a natural product obtained from the Gardinia fruit that reacts with the latent fingermark deposit to produce a dark blue image and room-temperature fluorescence (using excitation at ~590 nm and observation at ~620 nm) [47]. Development of genipin into a viable reagent for latent fingermark detection on paper is being investigated [48]. The potential advantages that genipin may have over ninhydrin and DFO include the following: the combination of color and fluorescence in a single reaction; the excitation and emission properties of genipin, which may give a better signal-to-noise ratio than DFO on paper surfaces that have an inherent fluorescence emission in the 500–600 nm range; and, the very low toxicity of the genipin compound, which is currently used as a food colorant and natural medication.

Physical Developer (PD). Physical developer (PD) targets the water-insoluble portion of the latent fingermark, which makes it suitable for use on porous items that have been wet or previously treated with amino acid–sensitive reagents such as those presented above. The PD reagent is an aqueous solution of silver ions containing a ferrous/ferric redox (reduction/oxidation) system, a citric acid buffer, and a cationic surfactant (usually *n*-dodecylamine acetate). This solution is relatively unstable, and, when a document is placed in the PD reagent, silver ions (Ag^+) are reduced to silver metal (Ag^0) (Figure 9). The silver preferentially deposits on the fingerprint deposit to produce dark gray to black ridges on a light gray background. The ferrous (Fe^{2+}) ions participate in the reduction of the silver ions, while the ferric (Fe^{3+}) ions slow the reaction down. Citric acid is necessary to complex with the ferric ions and to maintain a low pH. The surfactant traps randomly generated silver particles to inhibit further premature deposition of silver. While the mechanism of fingerprint development with PD has not been conclusively elucidated, several theories have been proposed [49, 50].

$$Fe^{2+}_{(aq)} + Ag^{+}_{(aq)} \rightleftharpoons Fe^{3+}_{(aq)} + Ag^{0}_{(s)}$$

Figure 9 The redox reaction that forms the basis of fingermark development by PD

Once immersed in the PD reagent, fingermarks take anywhere from 10 to 60 min to develop on the substrate. It is important to remove the item and rinse off the excess reagent as soon as good contrast is observed as it is not possible to reverse overdevelopment. Some paper substrates contain alkaline binders and fillers that react strongly with PD, resulting in high background development. In this case, an acid prewash (typically a solution of maleic acid) can be used to neutralize these alkaline components and improve fingermark development [49–52]. A systematic study of acid prewashes has demonstrated the influence of paper pH on successful fingermark enhancement with PD [53]. In some cases, PD-developed fingermarks on dark paper substrates (e.g., brown paper) can be further enhanced by treatment with a sodium hypochlorite solution (dilute household bleach). This lightens the background and darkens the fingerprint due to the formation of silver oxide [49, 50, 54].

The PD technique presents a number of challenges that make its use unfavorable in many operational laboratories. It is time consuming to prepare and employ. PD is also very sensitive to environmental factors and contamination, which means that good-quality reagents and clean glassware must be used, and the technician preparing and applying the technique must to be experienced in its use. It is relatively expensive because the working solution has a short half-life (generally less than two weeks). The PD process is also destructive, which means that no further fingerprint treatments can be used, and other forensic evidence such as inks and handwriting are also likely to be compromised [1].

Several modifications to the PD formulation have been proposed [55–57]; however, the new formulations are still subject to the same robustness issues that plague the traditional PD [58]. Despite its limitations, PD remains the best technique to detect latent fingermarks on porous surfaces that are or have been wet. In addition, on substrates that have not been wet, PD can sometimes develop fingermarks that go undetected using amino acid reagents.

Oil Red O (ORO). While PD has long been considered the only routine technique that is able to develop latent fingermarks on items that have been wet, promising research has been conducted using a relatively new reagent based on the lipid dye Oil Red

O (ORO). ORO stains the lipid (sebaceous) component of the latent fingermark deposit to produce a dark red to brown image on a light pink background. Treated fingermarks begin to appear on substrates after 5 min, with the best results being obtained if the item is agitated in the solution for up to 1 h. Despite the development time involved, the technique is less labor intensive than PD as the item can be left immersed in the solution and an automatic rocker used to agitate. Overdevelopment does not readily occur with ORO. This reagent has the potential to be used in conjunction with PD for the development of fingermarks on items that have been wet or items that have been previously treated with amino acid-sensitive reagents [59–61]. Several attempts have been made to improve the original ORO formula; however, the original formulation has so far proven to be superior [61, 62].

Salama and coworkers [61] conducted an extensive study where latent fingermarks on a variety of paper types were immersed in water for varying lengths of time and aged over periods up to eight weeks. For fingermarks aged up to four weeks, ORO development was as effective as PD, sometimes more effective. However, better results were achieved with PD for eight-week-old latent fingermarks.

ORO can be used after amino acid–sensitive reagents, provided their formulations do not contain solvents with a dielectric constant of less than 24, as such solvents appear to remove the lipid fraction targeted by ORO [63]. ORO does not replace PD but can be used before PD treatment to maximize the exploitation of any latent fingermark evidence that may be present [61].

Detection Techniques for Thermal Paper. Thermal paper is a porous surface that presents particular challenges for latent fingermark development. The active coating that gives this paper its thermosensitivity reacts with polar organic solvents that are present in traditional reagents such as ninhydrin to produce a dark gray or black color that obscures any developed fingermarks [64]. While acetone can be used to remove the active layer of the paper [65], the results are still not optimal and the technique is very destructive. Promising results have been obtained using a modified 1,2-indanedione formulation that contains a lower concentration of polar components that are in a nonpolar carrier solvent [66]. Preliminary experiments with low heat from a hair dryer [67] or acetic acid fuming [68] have produced good results on certain types of thermal paper.

An extensive study [65] has compared the development of a printed alanine standard with several different solutions: NPB (15 g ninhydrin dissolved in 100 ml ethyl alcohol and made up to 2.5 l with petroleum ether), INON (4 g 2-hydroxy-2-(3,5,5-trimethyl-hexyl-oxy)-indan-1,3-dione which is a hemiketal of ninhydrin and isononanol dissolved in 1 l petroleum ether), ThermaNin (4 g ThermaNin dissolved in 1 l petroleum ether), and DFO (50 mg DFO in 2 ml glacial acetic acid and 4 ml methyl alcohol made up to 100 ml with HFE7100). Various whitening methods were also tested. The best results were obtained with a combination of NPB with a whitening mixture "G3", which contains 12.5 mmol each of 4-pyrrolidino-pyridine, oenantholactam, 1-octyl-2-pyrrolidone, and 1-cyclohexyl-pyrrolidone.

Recommended Detection Sequence. The recommended sequence for porous surfaces is given in Figure 10 [1, 40]. This should be used as a general guide, and modified sequences or the integration of other techniques should also be considered.

Detection Techniques for Nonporous Surfaces

Cyanoacrylate Fuming. Cyanoacrylate fuming is the most common technique applied to smooth, nonporous surfaces that are dry. It is also possible to treat items that have been wet as long as they are dried first. Cyanoacrylate esters (generally the ethyl ester) are sold commercially as rapid, high-strength glues like "superglue". Cyanoacrylate vapors react with certain components in the latent fingermark deposit (e.g., moisture and some sebaceous components) to produce a hard, white polymer known as *polycyanoacrylate* (Figure 11). Recently, several studies have been conducted in an attempt to more clearly elucidate the chemistry behind the reaction and the factors that contribute to the process [69, 70].

Generally, the fuming technique involves placing or suspending the item in a sealed chamber and heating a small amount of the cyanoacrylate liquid to around 80–100 °C to produce a sufficient concentration of vapor. The development of fingermarks needs to be closely monitored to ensure that overdevelopment does not occur.

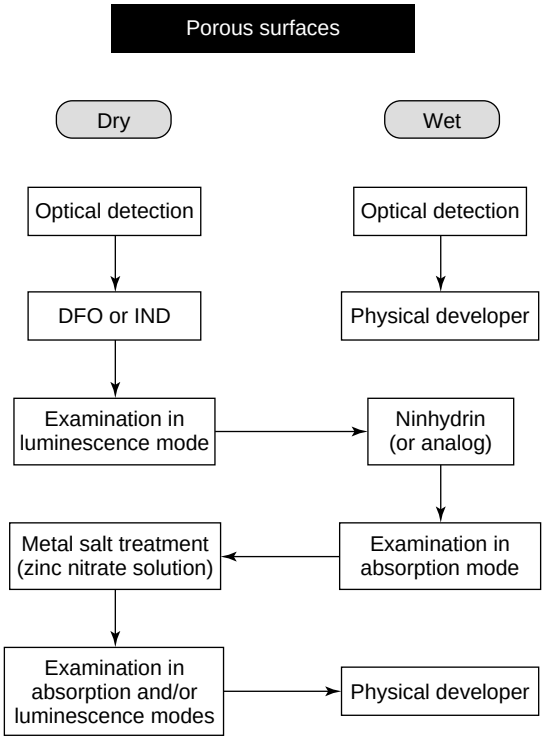

Figure 10 The recommended sequence for fingermark development on porous surfaces [Reproduced from Ref. 1. © Taylor & Francis Group, 2004.]

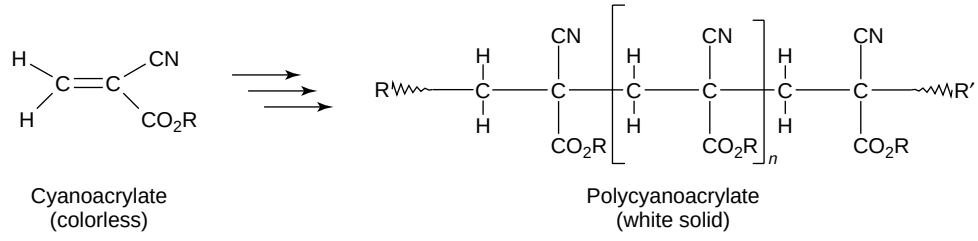

Figure 11 The polymerization of cyanoacrylate to give polycyanoacrylate [Reproduced from Ref. 1. © Taylor & Francis Group, 2004.]

Many commercial fuming units are available to automate the process, resulting in more effective control of temperature and vapor circulation, and the safe purging of the chamber of cyanoacrylate fumes before the items are removed. Some systems also control the humidity within the chamber. Portable cyanoacrylate fuming kits have also been investigated for use in the field. For example, when fuming large areas such as the inside of motor vehicles, a portable case can be used to generate cyanoacrylate fumes. These fumes are then pumped through a hose into the vehicle being processed [71]. A similar system can be employed to fume large items by building a plastic tent around the item and pumping the fumes into the tent. Commercial cyanoacrylate fuming systems are now available that can be safely and reliably used to process evidence in the field.

Vacuum cyanoacrylate (VCA) fuming involves placing the items in a chamber with a small amount of liquid cyanoacrylate and reducing the pressure

to approximately 200 mTorr using a rotary pump [72, 73]. The resulting treated fingermarks are more evenly developed and overdevelopment is unlikely. The developed fingermarks also have sharper ridge and pore detail than those developed by the conventional procedure [74–77]; however, the marks are less visible to the naked eye than with atmospheric pressure systems. Items such as unopened cans and bottles of soft drink are not suitable for VCA fuming as they may explode under reduced pressure.

Fingermarks treated with cyanoacrylate can be recorded using oblique lighting or coaxial illumination for white or multicolored surfaces. A reflected ultraviolet imaging system (RUVIS) can also be used. The contrast between cyanoacrylate-treated fingermarks and the substrate can be enhanced by powdering or applying a colored or luminescent stain once the cyanoacrylate polymer has been allowed to harden overnight. Many stains have been evaluated for the posttreatment of cyanoacrylate-developed fingermarks. Gentian violet is a colored stain that is useful for enhancing fingermarks on light colored substrates. However, luminescent stains are generally preferred, with the most popular being rhodamine 6G (luminescence excitation at 450–550 nm, observation at 550–600 nm) [78], Ardrox 970-P10 (luminescence excitation at 250–500 nm, observation at 450–650 nm) [79–82], and basic yellow 40 (luminescence excitation at around 445 nm, observation near 495 nm) [83, 84]. Other stains that have been evaluated include basic red 28 (luminescence excitation at 495 nm, observation at 585 nm) [85], safranine O (luminescence excitation at 520 nm, observation at 560 nm) [84], 4-(4-methoxybenzylamino-7-nitrobenzofurazan) (MBD); luminescence excitation at 350 nm, observation at 614 nm) [86], Nile red [87], and thenoyl europium chelate [88–90]. Combinations of various dyes have also been proposed for certain surfaces [85, 91, 92]. Cyanoacrylate stains are generally applied by dissolving the colored or luminescent material in a solvent mixture and then dipping or spraying the evidence. Background staining is then removed by washing with water. For substrates that are not suitable for staining (for example, semiporous substrates that cannot be effectively destained), fingerprint powders should be used to enhance cyanoacrylate-treated fingerprints. Black magnetic powder is the recommended powder, although luminescent powders can also be used. These powdered fingermarks can then be lifted, or simply photographed.

Vacuum Metal Deposition (VMD). Vacuum metal deposition (VMD) is a technique that can be used to develop latent fingermarks on a variety of nonporous and semiporous substrates [93–95]. Under vacuum, gold is evaporated and subsequently condenses on the substrate in a layer so thin that it is invisible to the naked eye. Zinc is then applied in a similar way and preferentially deposits on the areas of exposed gold where there is no fingermark deposit (Figure 12). Cadmium could also be used instead of zinc; however, cadmium is rarely used because of its toxicity. This technique generally produces negative fingermarks where the ridges remain transparent while the background is metalized (i.e., opaque); however, for certain types of polymer substrates and under particular conditions, reverse development occurs where the zinc deposits on the fingermark ridges and not on the background [94, 96, 97].

Jones and coworkers have extensively studied VMD development of fingermarks on a variety of polymer surfaces [98–101]. They found that VMD development is dependent on the type of polymer substrate and the amount of gold deposited; and that no one set of conditions is universally applicable. Guidelines for optimizing VMD development on various substrates, including problematic polymer banknotes, have been provided by this

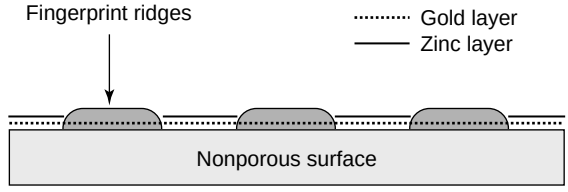

Figure 12 Fingermark development by vacuum metal deposition [Reproduced from Ref. 1. © Taylor & Francis Group, 2004.]

research group [100, 101]. More recent studies have investigated the gold agglomerates formation during the VMD process using transmission electron microscopy (TEM) imaging [102].

Levin Elad and coworkers [103] studied the surface properties of different polymers and examined their correlation with VMD development of latent fingermarks. The surface energy did not affect fingermark development; however, there was a correlation with the degree of roughness of the surface.

VMD can be used successfully after cyanoacrylate development and before the application of a luminescent stain [104–108]. Some studies have suggested that VMD may, in fact, be a more sensitive technique than cyanoacrylate, particularly for older latent fingermarks [109]. Despite the advantages of using this technique, the high cost of purchasing a VMD unit and the expertise required to obtain optimum results means that its application is generally limited to major cases [109] and, in particular, those involving "difficult" surfaces such as leather, smooth fabric, and polymer banknotes [101].

Recommended Detection Sequence. The recommended sequence for nonporous surfaces is provided in Figure 13. Where possible, a wet nonporous item should be dried at room temperature before being treated as a dry item. If this is not possible, SPR should be applied.

Miscellaneous Techniques

Multimetal Deposition (MMD). With multimetal deposition (MMD), the item to be treated is immersed in a colloidal gold solution (pH approximately 2.7) followed by a modified physical developer (MPD) [110]. The negatively charged gold colloids (prepared by treating tetrachloroauric acid with sodium citrate and a detergent) are attracted to organic residues in the fingermark deposit that are positively charged because of the strongly acidic conditions. The colloids then acts as nucleation sites that induce the precipitation of silver from the MPD solution. Developed fingermarks are visible as light gray to black ridges against a gray background. MMD can be used to develop fingermarks on many types of substrates, including "difficult" semiporous surfaces

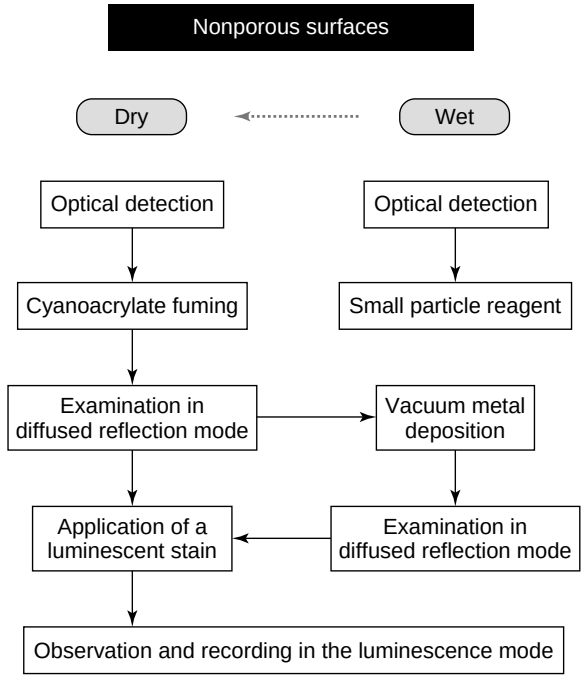

Figure 13 The recommended sequence for fingermark development on nonporous surfaces [Reproduced from Ref. 1. © Taylor & Francis Group, 2004.]

such as masking tape, glossy bottle labels, and rubber gloves [111].

Multi-metal deposition II (MMDII) is an optimized version of the technique that was developed to improve the reagent's sensitivity and specificity of latent fingermark enhancement [112, 113]. With MMDII, the use of silanized glassware and 14 nm colloidal gold particles is recommended, and the PD is based on silver acetate and hydroquinone rather than silver nitrate and a ferrous/ferric redox system. MMDII produces consistently better results than the MMD formulation and can be successfully applied to semiporous surfaces such as latex and nitrile gloves, polystyrene, and waxed paper [98]. However, MMD (and MMDII) still suffers from some of the disadvantages of conventional PD: the procedure is laborious, the reagents are delicate and expensive to prepare, significant experience is required for optimum results, and the technique is destructive.

Other Techniques Based on Nanoparticles. Becue and coworkers [114] have investigated modifications to the MMD method to reduce its operational limitations, namely cost, shelf life of reagents, and the labor-intensity nature of the process. Recently, a single-metal deposition (SMD) technique was proposed as another alternative to MMD (and MMDII) [115]. The method involves keeping the original gold colloid deposition and replacing the silver PD step with a gold-based amplification process. Results obtained with SMD were largely comparable to MMD, with the benefits of reduced cost, longer shelf life of reagents, and a simplified application procedure.

Choi and coworkers [116] have investigated nanoparticle binding to latent fingermarks in the MMDII process using scanning electron microscopy (SEM). They confirmed that the gold nanoparticles bind preferentially to the fingermark ridges under standard MMDII conditions, and that surfactant concentration influences background deposition but not ridge development. Conversely, pH variation influences ridge binding but not background development [116]. This research group has developed gold and silver nanopowders using oleylamine as a stabilizer and studied the fingermark development obtained by brushing the powder over latent fingermarks deposited on various surfaces. The long alkyl chain stabilizing groups were found to impart a lipophilic character to the gold nanoparticles, which increases the selectivity of the technique. Further studies will involve developing a water-dispersive gold nanoparticle to improve the MMD technique and investigating other nanoparticles that may improve latent fingermark development on different surfaces [117].

Almog and coworkers [118] investigated the enhancement of fingermarks treated with silver PD using various nanoparticles. Gold nanoparticles stabilized by *n*-alkanethiols and CdSe/ZnS nanoparticles stabilized by *n*-alkaneamine were found to adhere preferentially to the ridges of latent fingermarks on nonporous surfaces. CdSe/ZnS nanoparticles have fluorescent properties under UV illumination.

Iodine/Benzoflavone. Iodine fuming can be applied to a wide variety of porous and nonporous substrates. The iodine vapor is absorbed by the lipids in the latent fingermark deposit to produce a yellow–brown image. The process is simple, rapid, and economic; however, the fingermark development is a reversible physical process, which means that, unless the image is captured or chemically fixed, the contrast is generally poor and transitory. The technique is also only sensitive enough to develop latent fingermarks that are less than one week old.

Several methods have been proposed to capture or fix the image produced by iodine development, including silver plate transfer [119–121] (which is limited in application but has been proposed for the detection of fingermarks on human skin). The best results have been obtained with a solution of 7,8-benzoflavone (α-naphthoflavone), which chemically fixes iodine fumed fingermarks as a relatively stable dark blue–purple image [122, 123]. A system that involves mixing a solution of iodine with a solution of 7,8-benzoflavone immediately prior to use, and then spraying the mixture onto the surface of interest, has proven to be the particularly effective for fingermark detection at the crime scene [119, 120, 124].

Osmium Tetroxide and Ruthenium Tetroxide (RTX). Osmium tetroxide (OsO_4) is an oxidant that reacts with the unsaturated organic components of the latent fingermark deposit to give a dark gray–black product. As OsO_4 is volatile, the item to be treated is exposed to the vapor given off by crystals of the reagent in a closed glass container until a gray–black image of the fingermark is formed [125]. Development times range from 1 to

12 h. The technique can detect fingermarks on both porous and nonporous surfaces; however, exposure to OsO_4 can be fatal if inhaled, ingested, or absorbed through the skin. For this reason, the technique is no longer considered a viable alternative for fingermark detection.

Ruthenium tetroxide (RuO_4) reacts in the same way as OsO_4; however, it is not volatile at or near room temperature. The compound decomposes explosively at 108 °C, therefore fuming methods are extremely hazardous [125]. A safer method of generating RuO_4 vapor (known as *RTX*) involves reacting equal volumes of 0.1% ruthenium(III) chloride hydrate solution and 11.3% ceric ammonium nitrate solution at room temperature in a closed container [126]. The fumes generated produce a dark gray image in around 10–20 min or longer, depending on the surface. The fumes can be directly applied in a chamber enclosing the evidential items or by placing the reactants in a wash bottle and gently squeezing the generated RTX vapors through the nozzle that is directed onto the surface of interest. Nonporous items can also be directly immersed in the RTX reaction mixture for almost instantaneous development [127].

RTX works well when the latent fingerprint deposit contains oily material from the sebaceous secretions, but is generally ineffective on eccrine deposits. A modification of the procedure involves preparing a developing solution of 0.25% (w/v) RTX dissolved in a HFC solvent [124]. The item is sprayed or immersed in the solution, and fingermarks appear as brownish-black images. Fingerprints developed with RTX can be removed with a 4% hypochlorite solution. RTX is toxic by inhalation or skin contact [128], and must be used with great care.

A less expensive version of RTX solution that uses HFE7100 as a carrier solvent was proposed and compared with conventional RTX and iodine-benzoflavone for the development of latent fingermarks at the crime scene [129]. Recommendations are made in this study for the best sequencing of methods on various surfaces and for various ages of fingermarks.

Detection on Semiporous Surfaces

Fingerprint detection on semiporous surfaces such as waxed paper, glossy paper, matte-painted surfaces, and some rubber/latex gloves can often be difficult as the techniques available are generally suited to either porous or nonporous surfaces. Iodine/benzoflavone and MMD are excellent techniques for specific nonporous surfaces; however, the best approach for general fingermark detection on semiporous surfaces is to use a combination of techniques (Figure 14).

Detection on Human Skin

Human skin is an extremely challenging substrate to develop latent fingermarks on because the natural secretions comprising the latent deposit are also found on the surface of the skin. Therefore, when a detection technique is applied, the background develops along with any fingermarks, resulting in a very poor signal-to-noise ratio. Fingermarks on warm skin are particularly difficult to detect because the deposited secretions remain in a liquid state and diffuse very quickly. Despite the inherent difficulties, in certain cases, an attempt to develop latent fingermarks on human skin may be justified. For example, in a case of manual strangulation, fingermark development should be attempted on the neck of the victim.

Cadavers should ideally be processed for fingermarks at the crime scene to maximize chances of detection and recovery. As with all fingermark examinations, the sequence should begin with a thorough optical examination using different lighting conditions. Visible fingermarks should be photographed (and a silicone cast made if a molded impression is observed) before applying any other detection method. The appropriateness of subsequent techniques will depend on the time delay and whether the body has been stored in a cold room. Common techniques include the following: powdering [130, 131], iodine or iodine/benzoflavone [119, 120, 131, 132], RTX [124, 126, 131, 133], cyanoacrylate fuming [88, 134–136], and various transfer techniques [131, 137–142]. Cyanoacrylate fuming is precluded if it is more than 24 h after death or in the case of a cadaver that has been stored in a cold room because of the moisture that is present on the skin surface.

Sampson and Sampson [143] have published a review based on personal experience, published accounts, interviews, case reports, and student questionnaires and suggest guidelines for the processing of human skin for latent fingermarks. In addition to these recommendations (Figure 15), experience and experimentation should be used to determine the best sequence for a particular set of circumstances.

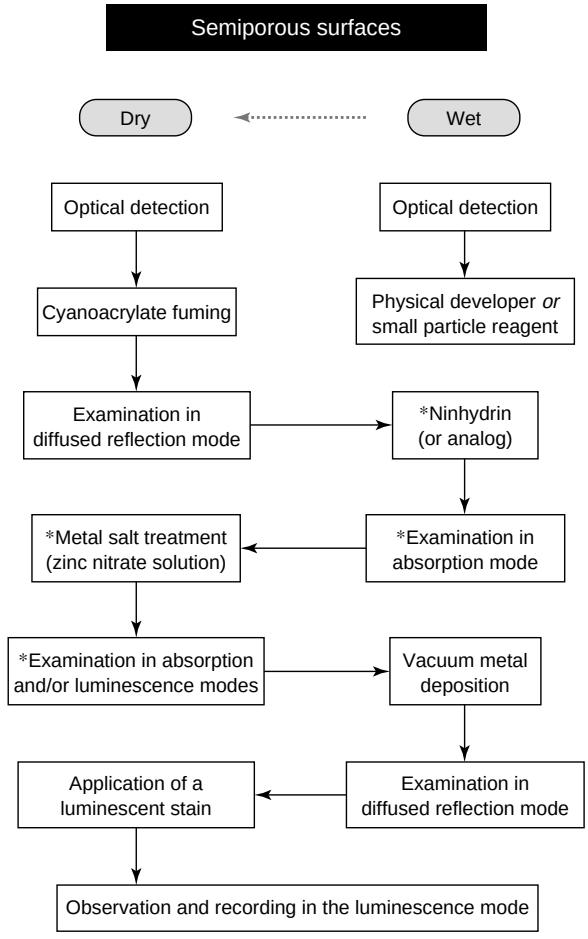

Figure 14 The recommended sequence for fingermark development on semiporous surfaces (*skip if item has been wet) [Reproduced from Ref. 1. © Taylor & Francis Group, 2004.]

Detection on Adhesive Surfaces

Adhesive surfaces such as the sticky side of adhesive tapes and labels are promising substrates for the development of fingermarks because such surfaces essentially pull secretions and skin debris from the finger when contact is made. In addition, a perpetrator is likely to remove their gloves to more easily manipulate the adhesive tape.

It is often necessary to remove adhesive tape from another surface (or from itself) before processing. Several techniques have been proposed for achieving this, including freezing, heating, and the application of a solvent [144–146]. Schwartz and coworkers [147] have shown that labels and stamps can be successfully removed with the product Un-Do® (a heptane-based adhesive neutralizer) without adverse effects on subsequent fingermark detection.

A range of techniques is available for the development of latent fingermarks on adhesive surfaces, and these have been extensively reviewed by Midkiff and coworkers [148–150]. Techniques used to develop latent fingermarks on adhesive surfaces must be combined with methods used to process any nonadhesive surface that is also present. For example, an adhesive tape must be examined on both the adhesive and nonadhesive sides, and the techniques used for each side must be compatible (i.e., not mutually exclusive). Normally, the best approach is to develop

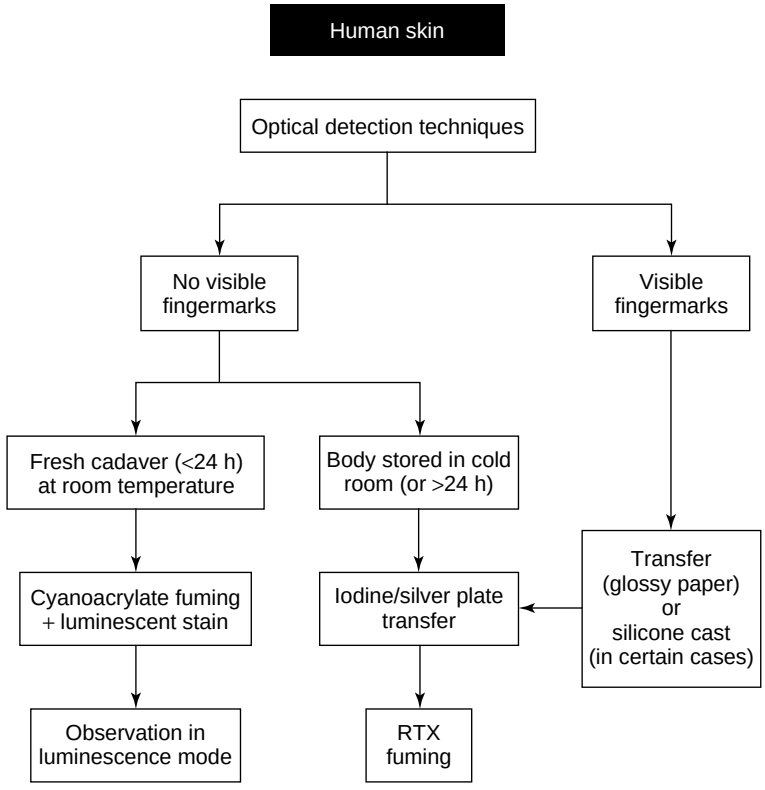

Figure 15 The recommended sequence for fingermark development on human skin [Reproduced with permission from Ref. 133. © IAI, 1994.]

and photograph fingerprints on the nonadhesive side before treating the adhesive side.

Gentian violet (crystal violet) is a reagent that stains the sebaceous material in the latent fingermark deposit to produce a dark purple image against a light purple background. The technique is very effective for the treatment of pressure-sensitive adhesive tapes such as clear Sellotape, paper masking tape, and polyvinyl chloride (PVC) insulation tape. The reagent is a stain solution that generally contains phenol, which facilitates the absorption of the stain into the fatty fingerprint deposit. It can be applied by dipping or using a pipette; or, alternatively, floating the tape (adhesive side down) on the surface of the reagent. The tape is then washed with water to remove excess stain. Observation of the treated fingermarks is generally made in the visible region, with coaxial illumination [151] or capture of the deep red to near-IR luminescence [152] being other options for enhancement. Fingermarks developed on dark-colored adhesive surfaces (e.g., black electrical tape) can be transferred onto fixed and washed photographic paper. Owing to the extreme toxicity of phenol, some phenol-free gentian violet formulations have been developed.

Sticky-side powder is a suspension of black fingerprint powder in a detergent solution that produces dark gray to black fingermarks on adhesive surfaces [153, 154]. A slurry is prepared by mixing equal parts of Photoflo® detergent (Kodak) and water with a small amount of black powder. This is then painted onto the adhesive surface using a soft brush (e.g., a camel-hair fingerprint brush) and gently rinsed off after 10–15 s under running tap water. The process can be repeated if only weak development is obtained the first time. Sticky-side powder produces good results on a range of adhesive surfaces, including duct tape, masking tape, surgical tape, paper-backed labels, clear plastic tapes, and reinforced packing tapes [154].

Black electrical tape is a particularly difficult surface to develop latent fingerprints on due to its dark coloring. White or ash gray powder can be used to replace the black powder in the sticky-side powder formulation to overcome this difficulty [155]. Fluorescent or white fingerprint powders can also be combined with Liqui-nox™ and water [156]. In fact, a variety of conventional fingerprint powders can be used in suspension to process adhesive surfaces for latent fingermarks [157]. Titanium dioxide has been proposed as a white pigment that can be used in sticky-side powder [158] or SPR [159] formulations to detect latent fingermarks on dark surfaces. An evaluation of the different methods that may be used to develop latent fingermarks on black electrical tape was conducted by Schiemer and coworkers [160]. Their recommended sequence is cyanoacrylate fuming and a BY40/BR28 combined fluorescent stain followed by a white powder suspension (1 ml Photo-Flo, 1.5 ml Citron detergent, and 2 ml water). Gentian violet can then be used followed by a transfer onto photographic paper.

The recommended sequence (Figure 16) does not include MMD; however, MMD may be considered as it is capable of developing fingerprints on both adhesive and nonadhesive surfaces. Again, experience and experimentation should be taken into consideration before applying techniques to evidential items as there is no universal procedure for adhesive surfaces.

Detection on Cartridge Cases and Firearms

While latent fingermarks may be developed on unfired cartridge cases using a variety of techniques, fired cartridge cases present a much greater challenge. This is most likely due to friction between the surface of the cartridge case and the chamber at the moment of ejection, although other contributing factors include friction at other stages of the firing process (e.g., loading of the magazine or of the live round into the chamber), the high temperature and pressure generated in the cartridge case at the time of firing, and exposure of the surface of the cartridge case to combustion gases and discharge residues generated at the time of firing [161]. The friction causes

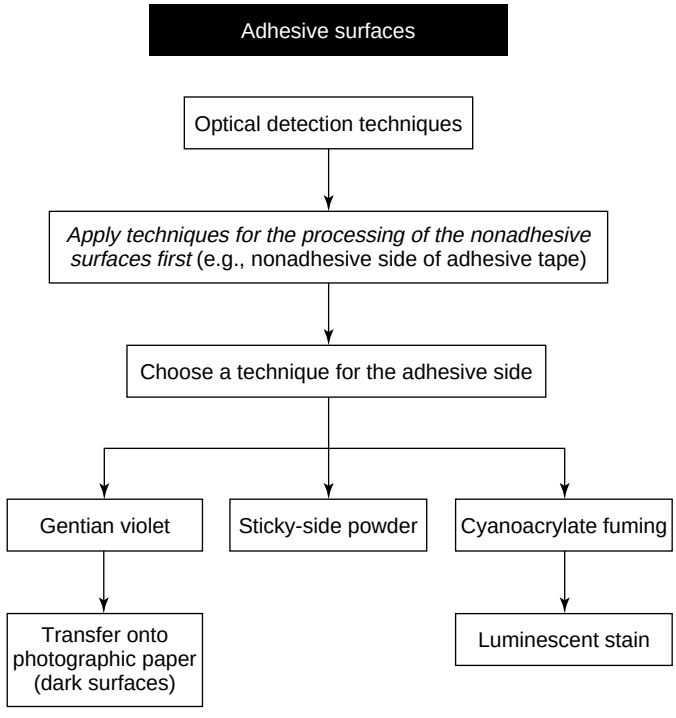

Figure 16 The recommended sequence for fingermark development on adhesive surfaces [Reproduced from Ref. 1. © Taylor & Francis Group, 2004.]

smearing of the fingermarks and, therefore, regardless of the detection technique employed, detection success rates on fired cartridge cases are generally low.

Latent fingermarks on brass cartridges may develop spontaneously due to a process of differential tarnishing; therefore, a thorough visual examination should be conducted before any other technique is applied.

Firearms can also present difficulties for latent fingermark development because of the nature of the surface (e.g., metal, wood or plastic), the presence of surface finishes and patterns, or surface contamination (e.g., gun oil and discharge residues), as well as the way that the firearm has been handled and packaged. Despite these inherent problems, identifiable fingermarks may be developed around 10% of the time [162].

Cyanoacrylate fuming produces mixed results on cartridge cases according to the type of material they are comprised of. Good results have been obtained on nickel casings treated with cyanoacrylate, while poor results are generally obtained on brass casings [163]. Satisfactory results have been achieved on plastic shotgun cartridges, with limited results on metallic casings [164]. Fingermark detection using VCA was investigated on a variety of different firearms. Conventional cyanoacrylate fuming was found to produce a whiter, more visible polymer than that obtained by the vacuum method. However, overdevelopment can be avoided with vacuum fuming, and therefore it is considered a better choice for processing firearms [165].

Gun blue is a reagent containing the active ingredients selenious acid (H_2SeO_3) and a cupric salt in an acid solution. The selenious acid and cupric ions oxidize certain metals (e.g., zinc, aluminum and iron) to form a black copper-selenide coating. The reagent selectively reacts on clean metal substrates, so the presence of greasy or oily material (such as a latent fingermark contaminated with sebaceous material) inhibits the reaction [166, 167]. A dilute gun blue solution can therefore be applied to metal surfaces such as brass cartridge cases to develop latent fingermarks as transparent images against a dark background. It is important to consider toolmark evidence before using gun blue, as the technique can destroy the fine detail present in such marks [168].

A comparison of etching (dissolution of the metal surface with an acid), blueing (dissolution of the metal with an acid and formation of a dark metal complex), and MMD showed that gun blue was the most effective treatment for the development of latent fingermarks on brass cartridge cases and that MMD was the best technique for aluminum cartridge cases. Lacquered steel cartridge cases were found to be a problematic surface, and cyanoacrylate fuming was recommended in this instance [169].

Other techniques that can be used to develop latent fingermarks on cartridge cases include palladium deposition techniques [166, 170, 171] and camphor fuming [172].

Enhancement of Fingermarks in Blood

Fingermarks in blood are often present at scenes of violent crime. Such marks can be very powerful evidence when the offender's fingermarks are found in the blood of the victim (as determined by DNA profiling). It is therefore important to preserve the DNA evidence present when enhancing fingermarks in blood. Nondestructive techniques such as optical enhancement should be used before other more destructive techniques. Heavily bloodstained areas that are unlikely to produce clear fingerprint detail should be sampled for DNA testing before fingermark development techniques are applied.

Fingermarks in blood should be considered at the same time as latent fingermarks, as the enhancement techniques for one type of evidence are not necessarily compatible with the other. For example, techniques that develop only fingermarks in blood, such as amido black or diaminobenzidine (DAB), are likely to destroy latent fingermarks.

In some instances, it may be useful to determine whether a fingermark in blood was formed by a contaminated finger (i.e., blood on the finger) or if it was a latent fingermark already on the surface that was subsequently developed by the blood. A number of studies have been conducted to determine whether this is in fact possible. Creighton [173] found that, when blood was allowed to flow over a series of latent fingermarks, the tendency was for the fingermark to repel the blood. Huss and coworkers [174] found that blood does not develop a previously deposited eccrine (sweaty) fingermark, whereas it is possible for blood to develop sebaceous (greasy) fingermarks, although the development is reversed because the greasy ridges

repel the blood, which consequently accumulates in the furrows.

Fingermarks in blood created by a contaminated finger can also occur as a negative image, where the furrows are stained with blood and the ridges are clear. This phenomenon was originally assumed to be a function of the pressure and contact involved during deposition of the fingermark; however, recent studies have refuted this [175]. Reverse development actually occurs when there has been a time lapse between contamination of the finger and deposition of the fingermark. When the blood present on the ridges is dry, it is not transferred. Rather, the fluid blood remaining in the furrows is deposited, resulting in a negative image.

Untreated blood can be enhanced in the absorption mode (recommended for lightly colored or luminescent surfaces) or in the diffused reflection mode (recommended for dark or shiny surfaces). The best conditions for visualization in the absorption mode are created with a strong band of light at around 415 nm (band width approximately 40 nm) in a dark room, as blood exhibits a strong absorbance at this wavelength [176]. Under these conditions, the fingermark appears almost black, creating good contrast with a light colored or luminescent background. Fingermarks captured on film or using a digital camera have better contrast than those perceived with the human eye due to our relative insensitivity in the violet region of the light spectrum.

For diffused reflection, an illumination wavelength other than the violet region is employed. For a colored surface, the best contrast is obtained with a wavelength that is opposite to the substrate color. The fingermark in blood is observed perpendicular to the surface, without the use of a barrier filter, while working under dark conditions. The incident light angle is varied until the best contrast is obtained. The incident light is strongly absorbed for dark surfaces or specularly reflected for shiny surfaces, while the blood itself exhibits diffuse reflectance. The end result is light ridges observed against a dark background.

UV luminescence techniques can be used where excitation is in the short-wave UV region with observation in the long-wave UV region to enhance blood, semen, and saliva marks [177]. However, short-wave UV light may be detrimental to subsequent DNA profiling, so care must be exercised when using this method (*see* **Friction Ridge Skin: Interaction between Fingerprint Detection and DNA/Biological Material**). In addition, UV imaging systems are expensive and the technique labor intensive when large surfaces are being screened.

Fingermarks in blood must be "fixed" to prevent the blood from diffusing or washing away when a chemical treatment is applied. For example, items can be immersed in either methanol or 5-sulfosalicylic acid solution for 5 min (or longer for heavier deposits) to fix the blood [178, 179].

Protein stains such as amido black [83, 178, 179], coomassie blue [180], and Hungarian red [181], or chemicals such as DAB or ABTS (2,2′-azino-di-(3-ethyl-benzthiazolinesulfonate) diammonium salt) [182] can be subsequently employed to enhance weak fingermarks in blood.

DFO is effective for the enhancement of both bloody and latent fingermarks on porous surfaces to give strong room-temperature luminescence [176]. The use of DFO or ninhydrin does not preclude the use of protein stains such as amido black; however, the converse is not true. DFO or ninhydrin is recommended as the first treatment because latent fingermarks are not developed by protein stains.

Leuchomalachite green, phenolphthalein, fluorescein, tetramethylbenzidine, and leuco rhodamine 6G are heme-reacting chemicals, which have been proposed for the enhancement of fingermarks in blood [183–187]. Reagents that react with heme are generally extremely sensitive. Fixed black-and-white photographic paper can be successfully used to transfer fingermarks in blood, which have been treated with either leucomalachite green (LMG), leucocrystal violet (LCV), but not DAB) [188]. This could be useful where the fingermarks are situated in locations that are difficult to photograph or where the contrast is poor.

Sears and coworkers [189] have systematically studied a number of techniques for the development of fingermarks in blood and have provided recommendations for the best sequences on a variety of surfaces. A recommended sequence for the detection and enhancement of fingermarks in blood is provided in Figure 17. Techniques for the development of latent fingermarks should be integrated appropriately in such sequences for the maximum exploitation of any fingerprint evidence that may be present.

Bleay and coworkers [190] investigated the development of fingermarks in blood that have been

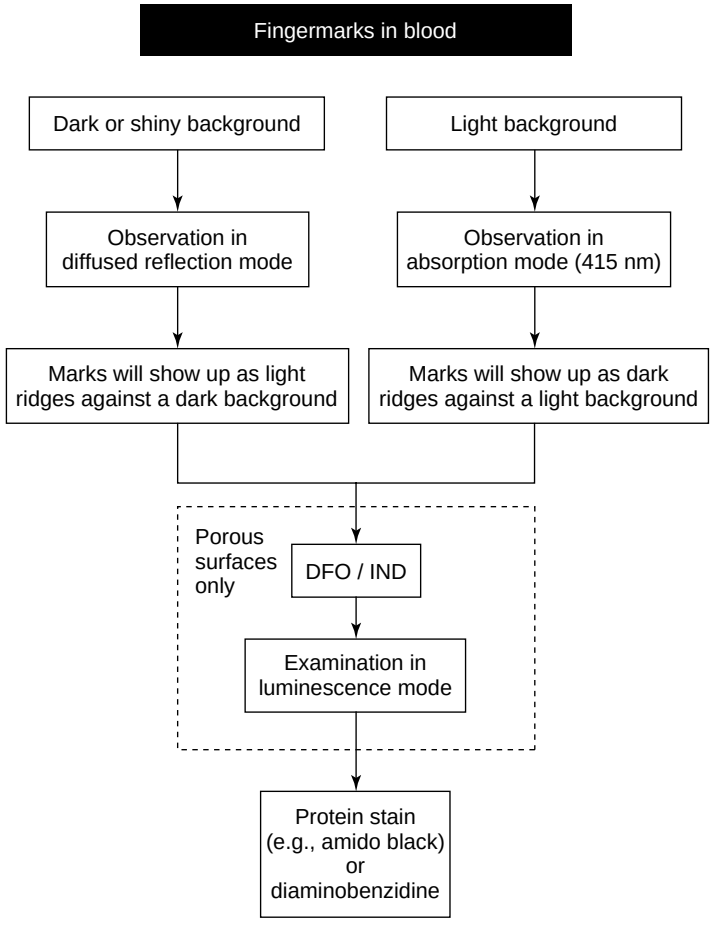

Figure 17 The recommended sequence for the enhancement of fingermarks in blood [Reproduced from Ref. 1. © Taylor & Francis Group, 2004.]

exposed to the conditions associated with fire scenes. They found that blood fingermarks could survive high temperatures and fume-filled environments. Protein dyes are ineffective on blood fingermarks that have been exposed to temperatures above 200 °C; however, black powder suspensions, cyanoacrylate fuming, and VMD can still be used.

Friction Ridge Skin: Interaction between Fingerprint Detection and DNA/Biological Material

Introduction

A single exhibit can hold many forms of forensic evidence. For example, a knife used as a murder weapon may hold blood and fibers from the victim on the blade, fingerprints and trace DNA of the offender on the handle, and soil and pollen traces when it was discarded in a garden bed as the offender fled the scene. A forensic examiner will employ a sequence of methods to exploit all available information from the exhibit.

DNA and fingerprints are considered to be two of the most valuable forms of forensic evidence, given their potential to individually link a person to a trace. Researchers demonstrated the ability to recover DNA profiles from fingerprints and skin traces in 1997 [1]. This development highlighted the importance of combining fingerprint enhancement and DNA analysis from the same piece of evidence. Given that DNA sampling methods would destroy any fingerprints present, the effect, if any, that fingerprint enhancement methods have on subsequent DNA profiling becomes a concern.

Numerous fingerprint enhancement techniques have been investigated to assess their impact on DNA profiling of fingerprints and biological stains exposed to the reagents used. These techniques are discussed in the following sections, and guidelines provided as to the sequencing of fingerprint and DNA evidence. Detailed explanations of DNA profiling or fingerprint reagents are not discussed in this section. This information can be found in **DNA**; **Short Tandem Repeats**; **DNA: Sources of**; **Friction Ridge Skin: Fingerprint Detection and Recovery Techniques**; **Friction Ridge Skin: Morphogenesis and Overview**.

Fingerprint Enhancement Techniques

Light Sources

Alternative Light Sources and Lasers. Argon ion lasers at up to 9 W for 20–30 min have been applied to bloodstains, and no difference in the restriction fragment length polymorphism (RFLP) DNA profiles between treated and untreated samples was detected [2, 3]. Other alternative light sources such as the Polilight (Rofin, Australia) have been successfully tested, showing no deleterious effects on the DNA profiling of biological stains and fingerprints [3–5].

UV Light. Ultraviolet (UV) light can be divided into two types: shortwave, with wavelengths below 300 nm, and longwave, with wavelengths between 300 and 400 nm. These two types have vastly different effects. When fingerprints or other biological fluids are exposed to longwave UV, successful DNA profiles have been achieved [3, 4, 6]. Shortwave UV, however, was found to prevent DNA profiling of bloodstains exposed for more than 30 s [3]. The DNA molecule is a strong absorber of UV radiation, which leads to gene damage and mutations [7], and at a wavelength of 254 nm, UV light will break the molecular bonds in the DNA. Given the short exposure time limits, which are not feasible for forensic examinations, shortwave UV light is not recommended if DNA profiling is required.

Powders and Physical Methods

Powders: Black, White, Magnetic, Metallic, and Stickyside. The application of powder is the most ubiquitous method in fingerprint development, given its ease of use, low cost, and effectiveness at crime scenes. The types of powders available are consequently numerous, from basic carbon and titanium granular powders to metallic flake and magnetized powders, each with different benefits and applications.

Many research groups have tested the effect of various powders on DNA recovery [6, 8–12]. All were able to recover profiles from powdered fingerprints or biological stains; however, one study found a decline of approximately 25% in the amount of DNA recovered from saliva stains powdered with white or black powder. An extensive study of 11 different powders found that most allowed DNA recovery; however, two metallic powders (BVDA special silver and Faurot aluminum bronze) totally inhibited DNA analysis [8]. However, the Home Office Scientific Development Branch (United Kingdom) [13] has recovered DNA from aluminum powdered prints up to one year after their deposition. For any use of powder, it is recommended that DNA extraction methods

are chosen so as to completely remove the powder prior to amplification. This is particularly important for metallic and magnetic powders.

Adhesive Lifters. After powdering fingerprints, a crime scene examiner may choose to "lift" the developed fingerprint with adhesive tape for preservation. DNA can be recovered from both the tapelift and from the remnants of the fingerprint on the surface [13, 14]. This may be useful for cold cases, where lifted fingerprints have been archived.

Small Particle Reagent (SPR), Physical Developer (PD), and Iodine/Benzoflavone. Small particle reagent (SPR) and physical developer (PD) are useful methods for developing fingerprints on surfaces that have been wet, as they react to the insoluble components of fingerprints. The physical developer method utilizes the preferential deposition of silver onto the fingerprint ridges.

Iodine fuming is one of the oldest methods of fingerprint development, and operates by the absorption of iodine by the fatty material in the fingerprint to create a brown deposit. The absorption is transient, but can be fixed by 7,8-benzoflavone application.

Iodine and SPR have been found to have no negative effects on the profiling of bloodstains [6, 15], provided adequate cleanup is employed during the extraction. Iodine, however, was found to reduce the quantity of DNA recovered from fingerprints [16]. Conversely, physical developer has been found to adversely affect the chance of recovering DNA, in that after 48 h profiles may be recovered, but the chance declines rapidly the longer a sample is left posttreatment [13]. Physical developer involves the use of silver nitrate and washing steps that could contribute to the loss of the DNA in fingerprints.

Chemical Reagents

For Use on Porous Surfaces (Paper and Cardboard)

Ninhydrin, 1,8-Diaza-9-Fluorenone (DFO), and 1,2-Indanedione. These reagents chemically react with the amino acids present in fingerprint traces to produce a colored and/or fluorescent deposit. Ninhydrin was the first to be employed in fingerprint development, and its effect on the recovery of DNA profiles from treated fingerprints and blood or saliva prints has been investigated [6, 16–19]. This research shows that ninhydrin does not significantly affect the recovery of profiles; however, the quantity of DNA may be reduced after treatment. Given the negligible effect it has on the recovery of DNA, ninhydrin has been tested as a screening tool to determine if swabs of skin cell traces contain sufficient DNA for a profile [19]. While 120 of the 158 swabs that gave a reaction to ninhydrin also produced a DNA profile, several false negative results led to the conclusion that this method may be useful in volume crime investigations rather than serious offenses.

The effect of 1,8-diaza-9-fluorenone (DFO) and 1,2-indanedione on the subsequent DNA profiling of treated fingerprints, blood prints, and saliva has been examined by various researchers [6, 11, 18, 20–22]. DFO produced results similar to ninhydrin profiles may be obtained; however, the quantity of DNA recovered will be lower. DNA profiling after indanedione treatment was also successful; however, samples should be extracted quickly after treatment, as those left for six days proved negative [21].

For Use on Nonporous Surfaces (Glass and Plastic)

Cyanoacrylate fuming (CAF) and subsequent staining. The action of cyanoacrylate fuming (CAF) in the presence of fingerprints causes the ester to polymerize as a white residue layer. This layer can then be stained to enhance the visibility or fluorescence of the fingerprint. Several studies have tested whether CAF and various combinations of stains will affect DNA recovery. Full profiles were recovered after CAF and, variously, Basic Yellow 40, Crystal Violet, and Rhodamine 6G staining [5, 6, 10, 11, 23, 24]. However, cyanoacrylate has been found to inhibit the polymerase chain reaction (PCR) process in at least one study [24]. Extraction methods must therefore adequately remove the fingerprint reagents prior to amplification. It should also be noted that the layer of polymer must be adequately removed during sampling, so that the DNA-containing cells can be collected. Vigorous swabbing, or, if possible, cutting the substrate into pieces may assist this process.

Gentian Violet. Gentian violet is used to develop fingerprints on the adhesive side of tape. It has been found to have some affect on DNA recovery from

fingerprints with partial profiles resulting [13], but no affect on DNA recovery from saliva or bloodstains [6]. Phenol in the gentian violet formulation may be a reason for the DNA degradation; however, Paraben K has been proffered as an alternative [6].

Vacuum Metal Deposition (VMD). Vacuum metal deposition (VMD) is considered to be the most sensitive method for developing fingerprints on nonporous and semiporous surfaces, for example, polymer banknotes and leather [25]. The method is a two-stage process under vacuum, where a monolayer of gold is deposited on the surface but does not cover the fingerprint ridges, followed by a thicker layer of zinc, leaving the ridges clear against a silver-colored background. VMD may follow cyanoacrylate fuming in a sequence, and full profiles have been recovered from fingerprints on plastic treated in this sequence, indicating that VMD does not inhibit DNA analysis [4].

Other Examination Methods

Reagents for the Enhancement of Blood. Leucocrystal Violet (LCV), Amido Black, Coomassie Blue, Diaminobenzidine (DAB), Luminol, Fluorescein, Hungarian Red. It is often necessary at a crime scene to enhance marks (fingerprints, shoemarks, spatter patterns) in blood. The above-listed chemicals can increase the contrast between the blood and the substrate by producing a dark color, luminescence, or fluorescence when in contact with blood. These reagents, with the exception of diaminobenzidine (DAB), do not prevent the recovery of DNA profiles from treated bloodstains [6, 13, 18, 26, 27]; however, they can reduce the amount of DNA recovered, and may cause the need for extra purification during the extraction process. DAB has been found to inhibit DNA analysis, particularly if left in contact with the stain for longer than a few minutes [13]. The research indicated that DAB may have a degradative effect on the DNA molecule rather than inhibiting the extraction or amplification.

Electron Beam Irradiation. The use of pathogenic organisms such as anthrax as a terrorist weapon has become an issue in recent years. Items believed to be contaminated with a biological agent may be exposed to electron beam irradiation to neutralize the organism and render the item safe. The item would then be subjected to standard forensic examinations. DNA may still be recovered after this irradiation process, as profiles were recovered from licked envelopes exposed to 51.6-kGy irradiation, up to 56 days after the treatment [28]. Some evidence of DNA degradation was observed in the treated samples in terms of lower recovered quantities.

Powder Brush DNA Transfer. It is possible to recover DNA profiles from the applicators used to brush the powder over fingerprints and biological stains, which may be present at crime scenes [8, 12, 29–31]. Conceivably then, it would seem plausible that DNA could be transferred from one scene to another via the powder applicator. This phenomenon has been demonstrated in research [12, 30], but would seem less likely to occur in casework, given that the proportion of contaminant DNA "added" to a biological trace would be small and difficult to detect. However, the possibility exists and should be considered at every crime scene. To prevent such a chance the following recommendations are given [12]:

- For serious cases, consider the use of disposable or cleanable brushes, and smaller aliquots of powder.
- Use magnetic powder, whereby the "wand" applicator does not touch the surface. It should be noted that additional cleanup methods may be required during DNA extraction to remove all magnetic powder prior to amplification.
- Powdering wet areas and biological stains facilitates DNA transfer and should be avoided.
- Swab areas of an object unsuitable for fingerprints prior to fingerprint examination.
- Consider the use of other fingerprint methods, such as CAF.

Summary

Given the random nature of trace DNA sampling, definitive answers to the factors affecting its successful profiling can be difficult to give accurately. However, due the volume of research on the subject, certain guidelines can be offered with respect to the sequencing of fingerprint and DNA examinations.

With a few exceptions, fingerprint reagents will not prevent the subsequent DNA profiling of the treated substrate. The exceptions include shortwave UV light, physical developer, and DAB. Although,

the examiner must be aware that the quantity of DNA recovered will be lower after any treatment, potentially because of physical actions during the fingerprint treatment such as washing steps. Fuming with cyanoacrylate may protect DNA-containing skin cells with a layer of polymer and therefore lower the chance of loss; however, this may also make the cells difficult to remove during sampling.

Care should be taken by staff performing the DNA extraction to ensure that all traces of the fingerprint reagent have been removed before amplification. Extra cleanup methods may be required. Just 5 μg of fingerprint powder in the amplification mix can inhibit the PCR reaction [32].

Therefore, if DNA and fingerprint analysis is required of the same item, the following actions are suggested:

- Consider swabbing areas on the item that are unsuitable for fingerprint examination, for example, rough areas of a gun, the edge of a trigger, or the rim of drinking glass.
- If fingerprints that have been powdered are lifted, consider swabbing the remainder of the mark left on the substrate.
- Conduct one single treatment for fingerprints first, preferably a method with fewer steps. The single treatment can include the use of CAF followed by one stain.
- Do not use shortwave UV light, DAB, or physical developer where possible.
- Limit the time the item is in contact with the reagent.
- Use caution to avoid contamination during the fingerprint examination. For example, use fresh solution or a spray method, use fresh powder and brushes, and wear face masks and protective clothing.
- Sample and extract the DNA as soon as possible after the fingerprint treatment.
- Clearly detail on laboratory submission forms in which treatments have been applied, for the information of the DNA analysts.
- Laboratory staff should employ an extraction method that will adequately clean up treated samples.

Friction Ridge Skin: Morphogenesis and Overview

Anatomy

Outer Morphology of the Skin

The friction ridge skin occurs on the palmar sides of the hands and the plantar sides of the feet of all primates, including humans. As the name implies, the skin is ridged to produce friction. The friction aids in grasping and walking. The friction ridge skin also contains numerous sweat glands, and the pore openings are located along the tops of the ridges. The friction ridge skin does not contain sebaceous (oil) glands or hair follicles. In addition to the ridges, creases are found cress crossing through the friction ridge skin. These creases, in addition to the furrows between the ridges, permit flexibility of the skin. Figure 1 shows the friction ridge skin on a foot, palm, and finger; arrows point to ridges (R) and creases (C).

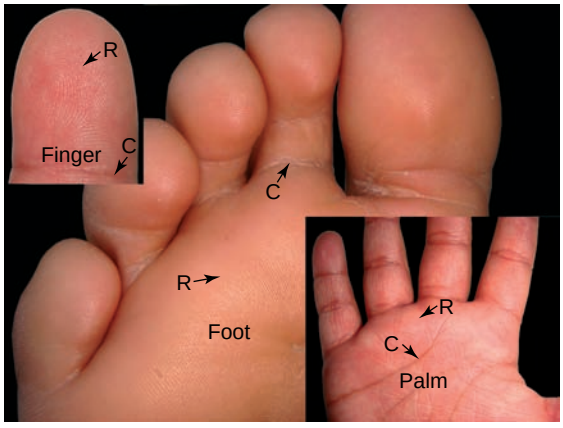

Figure 1 Friction ridge skin of the foot, palm, and finger showing the ridges (R) and creases (C)

Regions of the Hands and Feet

Areas of the hands and feet are described in relation to their orientation to the body. Proximal describes an area located toward the core of body while distal describes an area located away from the center of the body. For instance, when describing the hand, the wrist is located proximally (closer to the core of the body) and the tips of the fingers are located distally (further from the core of the body). The sides of the hands and feet are described relative to the bones of the forearm and lower leg, respectively. The thumb side of the hand is referred to as the *radial side* and the little finger side (blade of the palm) is referred to as the *ulnar side*. The great toe side (instep) of the foot is called the *tibial side* and the little toe side (outer edge) is called the *fibular side*.

The palmar side of the hand and soles of the feet are divided into different regions and contain prominent ridge flows delineated by deltas. A delta is the triradius formed where three ridge fields meet (Figure 2).

Regions of the Hand. The hand is divided into three main regions: interdigital, thenar, and hypothenar. As shown in Figure 3, the radial side of the palm is called the *thenar* (includes area labeled I) and the ulnar side of the palm is called the *hypothenar*. At the base of the palm, between the thenar and hypothenar, is the carpal (proximal) delta [1]. The interdigital region of the palm lies proximal to the fingers and contains the areas labeled II, III, and IV in Figure 3. The interdigital region also contains the digital deltas; there are typically four digital deltas (a, b, c, and d in Figure 3). The fingers are composed of three phalanges: distal, medial, and proximal. The thumb lacks a medial phalange. The phalanges are delineated by creases, which correspond to the underlying joints of the fingers.

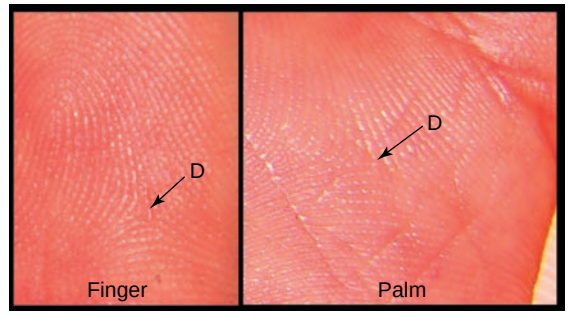

Figure 2 Deltas (D) on a finger and a palm

Regions of the Foot. The foot is divided into five primary regions: interdigital, hallucal, thenar, hypothenar, and calcar. The foot typically contains five digital deltas and a proximal delta. As shown in Figure 4, the interdigital area includes the areas marked II, III, and IV and digital deltas a, b, c, and d. The hallucal area corresponds to the ball of the foot and contains digital delta e. The interdigital and hallucal areas are demarcated from the rest of the foot by the ridge flows established by the proximal delta. The tibial side of the foot is called the *thenar* and the fibular side of the foot is called the *hypothenar*. The heel of the foot is called the *calcar area* [1]. Like the thumb, the great toe has a proximal and distal phalange. The remaining toes have proximal, medial, and distal phalanges.

Creases of the Hands and Feet

The general position of major creases is very robust between individuals due to their purpose – affording the hands and feet mobility. The major creases occur on all individuals with normal hand and foot morphology [2]. Figure 5 shows the normal configuration of the major creases of the hand. The only major creases of the foot are the creases associated with the toes. Additional creases on the hands and feet exist; however, these may not be present in all individuals.

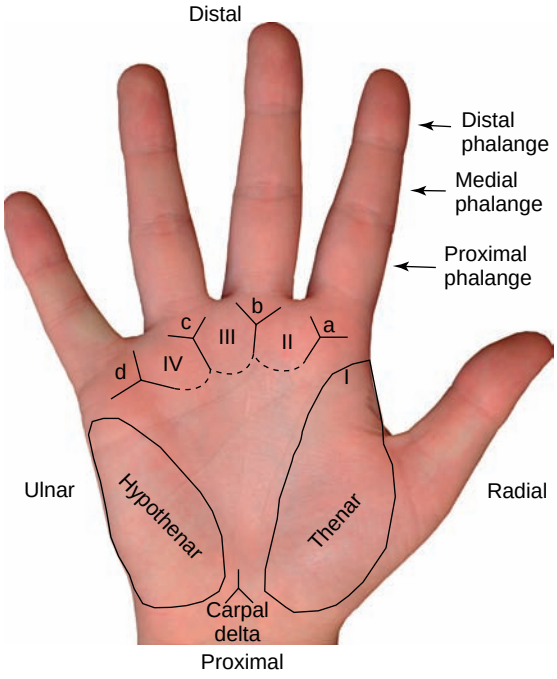

Figure 3 Areas of the palm showing the primary digital deltas (a, b, c, and d) and the carpal (proximal) delta. The thenar area is on the radial side of the palm and includes the region marked I; the hypothenar is on the ulnar side of the palm. The interdigital region contains areas II, III, and IV and the digital deltas. The phalanges of the fingers are marked as the distal, medial, and proximal

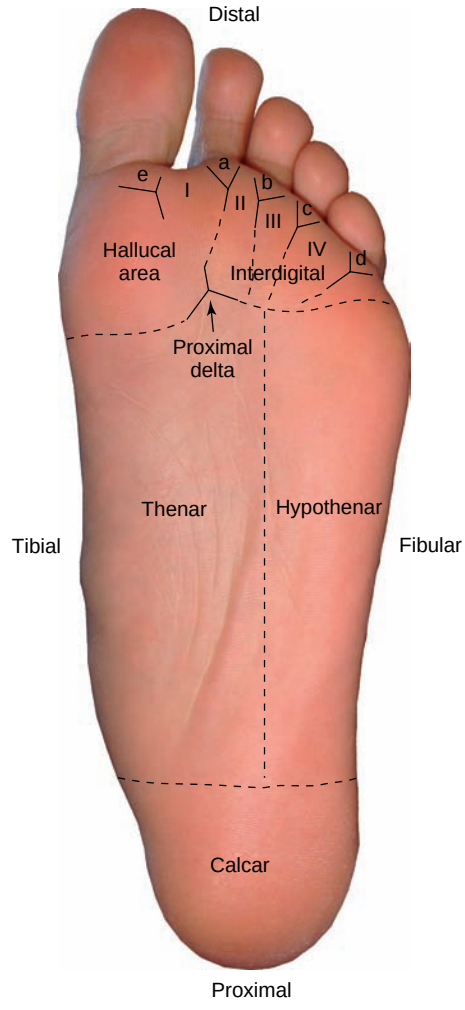

Figure 4 Areas of the foot showing the primary digital deltas (a, b, c, d, and e) and the proximal delta at the base of the ball of the foot. The hallucal region is the area under the great toe (including digital delta e); the interdigital region includes areas II, III, and IV and digital deltas a, b, c, and d; the fibular side of the foot is called the *hypothenar*; the tibial side of the foot is called the *thenar*; and the heel is called the *calcar area*

Anatomy of Friction Ridge Skin

The skin is composed of three principle layers: epidermis, dermis, and hypodermis. The superficial epidermis is a rapidly regenerating layer composed of stacked cells. The dermis is a supportive layer of connective tissue providing flexibility to the skin. The inner hypodermis is an insulating layer that cushions the skin.

The ridges and furrows seen on the outer surface of the epidermis reflect the complex structure beneath the surface of the skin (Figure 6). While the surface of the epidermis has alternating ridges and furrows, the bottom of the epidermis (where it is attached to the dermis), has alternating primary and secondary ridges. The primary ridges of the epidermis correspond to the surface ridges. The secondary ridges of the epidermis correspond to the surface furrows. The areas of dermis between adjacent primary and secondary ridges are called *dermal papillae.*

The sweat glands are appendages of the epidermis. As shown in Figure 6, the sweat glands are located in the primary ridges of the friction ridge skin. The coiled, secretory portions of the sweat glands are buried in the dermis. Sweat passes from the

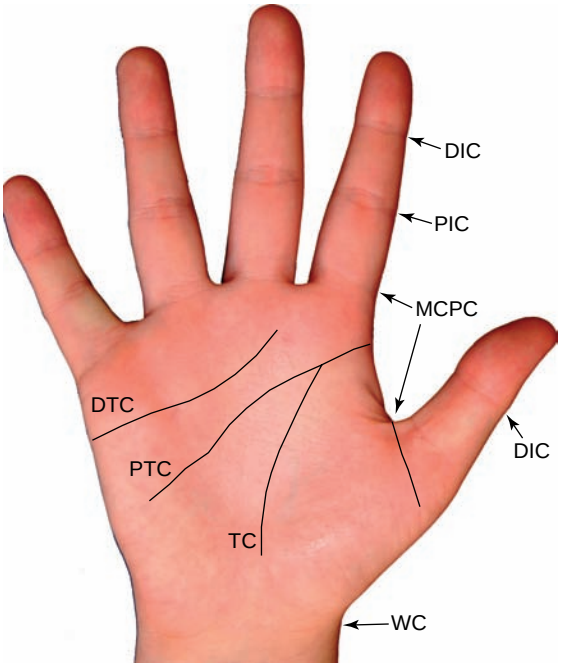

Figure 5 Major creases of the hands. Digital creases include the digital interphalangeal crease (DIC), the proximal interphalangeal crease (PIC), and the metacarpophalangeal crease (MCPC). The palmar creases include the distal transverse crease (DTC), the proximal transverse crease (PTC), thenar crease (TC), and the wrist crease (WC)

coiled portion, through the ducts in the primary ridges, and onto the surface of the ridge via a pore (Figure 7).

A fibrous sheet called the *basement membrane* tightly binds the primary and secondary ridges of the epidermis to the underlying dermis. This tight bond ensures that the ridges and furrows are locked into their configuration over the life of an individual, barring injury or disease.

Epidermis. The epidermis is a layered tissue composed primarily of skin cells called *keratinocytes*. The layers of the epidermis represent the biochemical changes that keratinocytes undergo as they are pushed from the bottom of the epidermis to the surface. As shown in Figure 8, the primary layers of the epidermis include the following: stratum basale (generating layer), stratum spinosum, stratum granulosum, stratum lucidum, and stratum corneum. There is also a specialized population of rapidly dividing cells in a suprabasal layer in the primary ridges. The

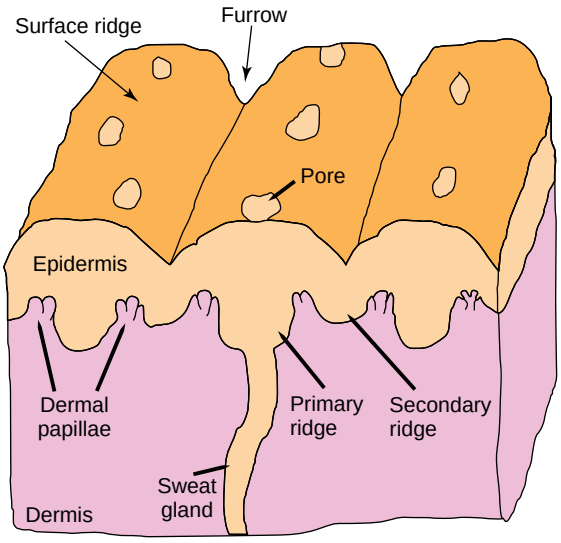

Figure 6 Cross section of the friction ridge skin

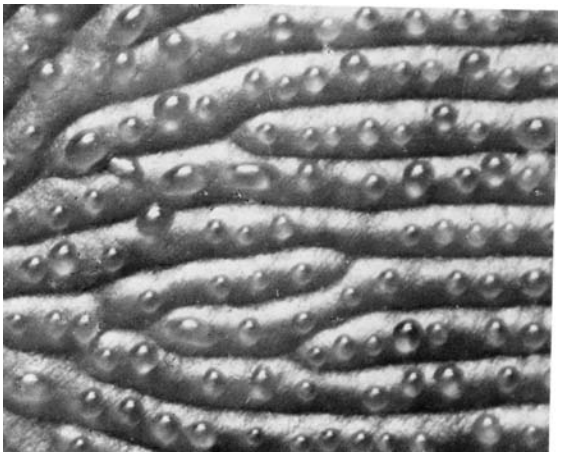

Figure 7 Pores of the friction ridge skin emitting sweat. [Reprinted from Montagna, p. 381) [3]

keratinocytes of the stratum basale are responsible for generating all the new cells that are pushed toward the surface to maintain the protective outer stratum corneum.

The keratinocytes of the epidermis are tightly bound to one another via intercellular junctions called *desmosomes*. This network of intercellular attachments prevents the cells from migrating laterally; the cells can only be pushed toward the surface of the skin. Movement toward the surface without lateral

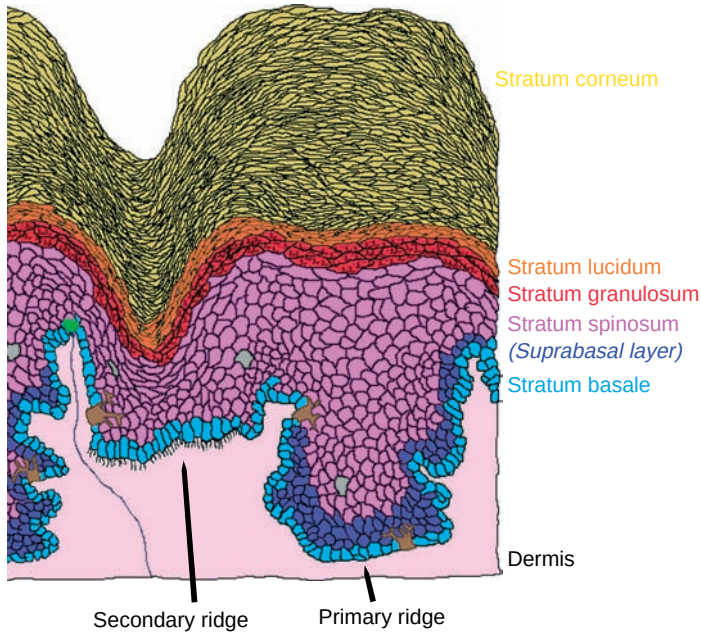

Figure 8 Layers of the epidermis

migration ensures that the configuration of ridges and furrows persists.

Other cells of the epidermis include melanocytes, Langerhans cells, and Merkel cells. The melanocytes provide pigmentation to the skin. The Langerhans cells are an extension of the immune system and Merkel cells are an extension of the nervous system [4].

Dermis. The dermis is the connective tissue layer that supports the epidermis. The dermis is composed primarily of fibers (collagen and elastin) and a gelatinous ground substance. The primary cell of the dermis is the fibroblast; it is responsible for maintaining both the fibrous and gelatinous structure of the dermis. Several immune response cells also populate the dermis: monocytes, macrophages, dermal dendrocytes, and mast cells [4]. The dermis contains capillary loops to provide nourishment to the epidermis and neural networks to provide sensitive touch discrimination.

Hypodermis. The hypodermis is the innermost layer of the skin. The hypodermis is composed primarily of subcutaneous fat. This fat cushions the skin, insulates the body, and serves as an energy reserve. It also permits mobility of the skin over underlying muscle and bone [4].

Physiology

Keratinization

The sheet of keratinocytes forming the stratum basale is responsible for dividing and pushing cells toward the surface of the epidermis. As the newly generated cells are pushed from the basal layer toward the surface, they undergo a process called *keratinization*. Keratinization prepares the cells for their ultimate purpose: providing a protective layer of dead, cornified cells on the exterior of the body. Figure 9 shows the cornified keratinocytes on the outer surface of the skin. The layers of the epidermis previously described represent the various stages of keratinization as the cells progress toward the surface of the skin.

Keratinocyte Proliferation

The keratinocytes of the stratum basale (basal cells) are responsible for continually dividing; pushing previously generated cells toward the surface to

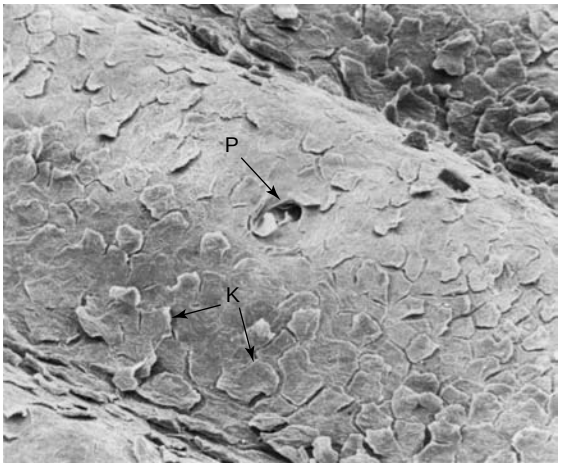

Figure 9 Surface of the friction ridge skin showing cornifed keratinocytes (K) and a sweat pore (P). [Reprinted from Montagna, p. 25]

replace those lost at the surface during exfoliation. The rate at which the basal cells divide must be equal to the rate at which cells are sloughing at the surface to maintain the appropriate skin thickness. The basal cells rely on chemical signals from the upper layers of the epidermis and from the dermis below. These signals either induce or inhibit cell division, enabling the skin to maintain the outer protective barrier [4]. If there is too much abrasion at the surface (resulting in a thinning of the stratum corneum), the basal cells will divide faster to provide additional replacement cells. If the skin is too thick, the cells will slow down the rate of division until enough cells at the surface slough off and the proper thickness is achieved. The skin's inherent drive to maintain the epidermis (ridges and furrows) contributes to the persistency of the friction ridge skin.

Persistence

The configuration of the friction ridge skin persists due to a combination of physical attachments and constant regulation of basal cell division in the epidermis. The basal keratinocytes proliferate in unison and are a template for the surface ridges and furrows. The intercellular attachments of the keratinocytes ensure that the cells migrate to the surface in concert, faithfully reproducing the surface features. The structure of the primary and secondary ridges of the epidermis and the protective dermis and hypodermis also provide durability to the skin.

Embryology

The friction ridges and major creases of the hands and feet develop on the growing fetus from approximately 8–18 weeks estimated gestational age (EGA). The shape and growth stresses of the fetal hand at the time of formation of creases and ridges have a direct impact on the position of creases and the general ridge flows (patterns) in the different regions of the hands and feet. While the shape and growth stresses of the fetal hand certainly guide the ridges and creases across the volar surface, the actual paths and shapes of the ridges and creases are left up to random events. This randomness imparts the friction ridge skin with its unique features. Figure 10 shows several ridge paths and a crease path.

Hand and Foot Development

The hands and feet undergo a similar developmental sequence; however, the development of the feet typically lags 0.5 week behind the development of the hands [5]. Between 6 and 13 weeks EGA, the hands and feet transform from flat paddles to recognizable hands and feet [2]. From 8 to 12 weeks EGA, however, there are special transient structures on

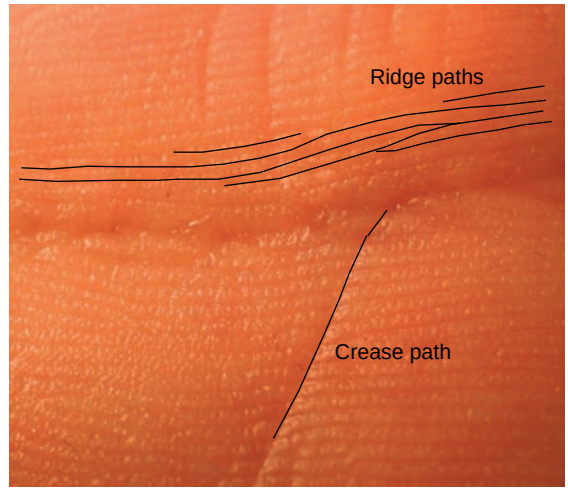

Figure 10 Ridge paths and a crease path on the palm of a hand

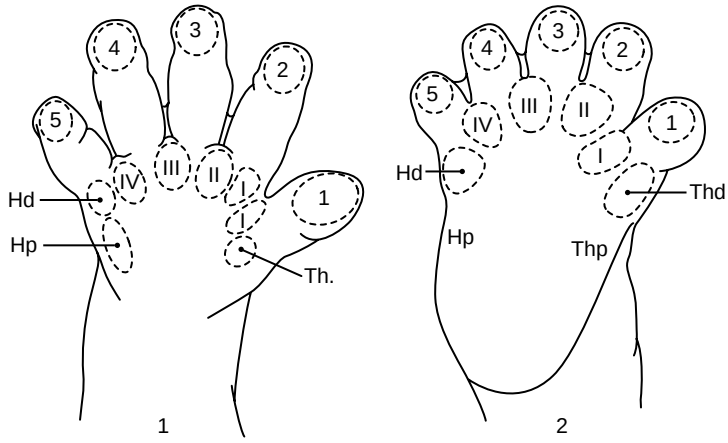

Figure 11 The volar pads of the hands and feet. The digital pads are marked as 1, 2, 3, 4, and 5. The interdigital pads are marked as I, II, III, and IV. The hypothenar pads are Hd (hypothenar distal) and Hp (hypothenar proximal). The thenar pads are marked as Th. (thenar), Thd (thenar distal), and Thp (thenar proximal) [Reprinted from Cummins 1929, p. 114.] [6]

the hands and feet that have a significant impact on the ridge flows and major creases seen on the hands and feet; these structures are called *volar pads*. The volar pads are localized swellings that occur on the hands and feet. As shown in Figure 11, there are prominent volar pads associated with distal phalanges, the interdigital regions, the hypothenar regions, and thenar regions of both the hands and feet [6].

Crease Formation. The major creases of the hand form concurrent with the volar pads, beginning at approximately 8 weeks EGA [2]. The thenar crease encircles the thenar pad (Th.) and the proximal portion of digital pad I. The proximal transverse cuts through the center of the palm and typically ends at the hypothenar pad (Hp). The distal transverse crease follows along the proximal edge of the interdigital volar pads III and IV and typically ends at interdigital pad II. The digital creases form at the joint locations of the fingers and thumbs. The digital creases of the feet start forming at approximately 9 weeks EGA [2].

Volar Pad Formation. The volar pads reach their maximum size at different times across the hands and feet. The volar pads of the palm peak in size at approximately 10 weeks EGA; the volar pads on the fingers (distal phalanges) peak at approximately 11 weeks EGA; and the volar pads of the feet peak at approximately 12 weeks EGA [5]. After the maximum size is attained, the volar pads discontinue growth and begin to disappear into the rapidly growing hand or foot. The size and shape of any volar pads present at the time of formation of the friction ridges have a direct impact on the general ridge flows in the hands and feet [5].

Friction Ridge Formation

The friction ridges typically form on the hands of the fetus at approximately 10 weeks gestation, and on the feet shortly thereafter. The general flow of ridges across the hands and feet is established by the growth stresses present on the hand or foot at the time of formation of the friction ridges. The predominant growth stress of the hands and feet is longitudinal (wrist to fingertip and heal to toe, respectively), causing the main ridge flows to cross the hand and foot laterally (side to side). If the developing ridges encounter a volar pad, the ridges are redirected based on the growth stresses established by the volar pad [7].

The fingers and toes tend to have intense patterns, as the volar pads are often quite prominent when the ridges are forming. Figure 12 shows the three primary pattern types that develop on the fingers: whorls, loops, and arches. These patterns reflect the size and shape of the volar pads at the time of formation of the friction ridges. Whorls tend to form on very high, rounded volar pads. Loops tend to form on

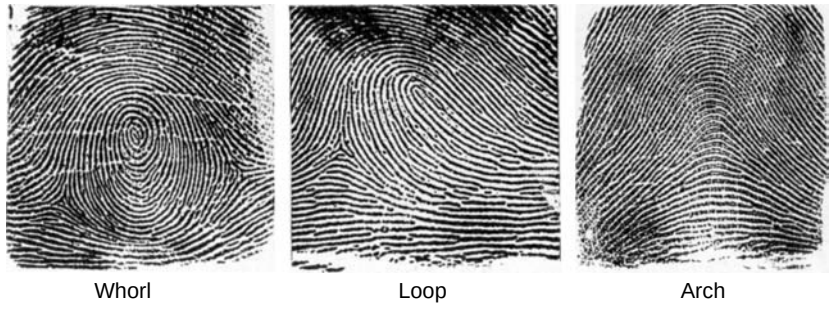

Figure 12 Three primary finger pattern types [Reprinted from Cummins 1943, p. 32 [8].]

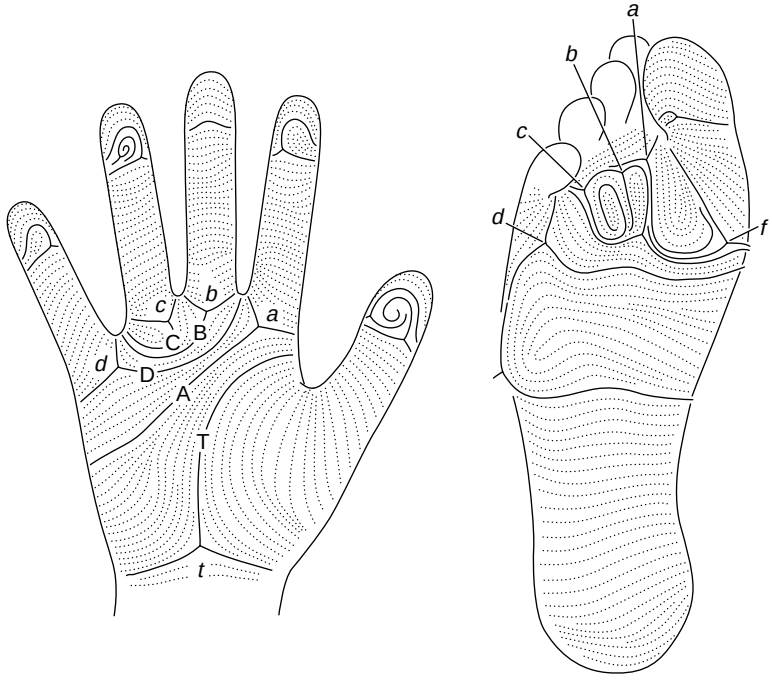

Figure 13 Predominant ridge flows on the hands and the feet. Digital deltas of the hands and feet are marked a, b, c, and d. The proximal delta of the hand is t and the proximal delta of the foot is f. On the hand, A, B, C, D, and T are the main ridge flows [Reprinted from Holt pp. 16, 24, respectively [1].]

asymmetrical volar pads that lean to one side. Arches tend to form on very low volar pads [5].

The palms and the feet may also have prominent volar pads when the friction ridges form. The palms and feet tend to have looping patterns in the interdigital region, including the hallucal area of the foot, that correspond to the interdigital pads. Occasionally, the thenar and hypothenar areas of the hands and feet have patterns; these patterns occur if the hypothenar or thenar pads are still prominent at the time of formation of friction ridge. Figure 13 shows the common ridge flows on the hands and feet.

Uniqueness

Although there is certainly variation to the general flows (patterns) of ridges on the palms and feet, this variation is limited by the general growth stresses

on the hands and feet. For instance, one would not find a hexagonal pattern of ridges since there is no fetal hand structure that would permit such a pattern. Within these general ridge flows, however, the specific paths and shapes of the ridges show infinite variability. This variability exists because the final path of each ridge and final three-dimensional shape of each ridge is not dictated during development.

During the development of any organism, the genetic code is responsible for ensuring that the organism has the proper body plan; genes are turned on and off in a regimented sequence to ensure that the limbs and organs have the appropriate form and functionality. There are many fine details of an organism; however, that are not programmed in the genetic code. For instance, the human body is programmed by the genetic code to develop hands and feet containing friction ridge skin on the volar surfaces. The overall ridge and crease patterns vary in a limited manner because the shape and function of the hand or foot is consistent between normal individuals.

The exact placement of each ridge and crease, however, is left up to the chance events that take place during development. These chance events are referred to as "developmental noise" [9] or "noise in gene expression" [10]. Essentially, during the developmental process of an organism, there are features that are not hardwired into the genetic code. Consequently, these features are at the mercy of random formation. The ridges and creases of the friction ridge skin are such features. The classic example is identical (monozygotic) twins who share the same genetic code but have different finger, palm, and footprints. Figure 14 is the left middle and index fingers from monozygotic twins.

As the ridges are formed on the fetal hands and feet, the hands and feet continue to grow, pulling existing ridges apart. As the ridges reach a critical separation distance, new ridges form in between to ensure the skin is continually ridged [11]. The process is dependent upon the growth of the fetus and the stresses on the epidermis during the development of the friction ridge skin. As a result, the length and path of each ridge is not determined by the genetic code of an individual, but instead by the unique forces at play on any particular area of the hand or foot during development.

The ridges continue to form until the fetus is approximately 18 weeks EGA. At this time, the friction ridge system stops adding new ridges. The ridges are locked into their configuration. The hands of an adult are obviously much larger than the hands of a fetus, but the relationship of the ridges to each other is conserved during growth to adulthood.

ALICE V. MACEO

Frye v. United States

Importance of the Opinion

This case is one of the landmark decisions on the admission of novel forensic opinion evidence in the United States. It was also the first well-reasoned court decision on that issue. Handed down in 1923, *Frye* dealt with the admissibility of testimony based on the purportedly scientific systolic blood pressure deception test developed by Dr Marston. The systolic blood pressure deception test was, thus, the forerunner of the modern polygraph. The *Frye* principle requiring (*see* **General Acceptance Test for Novel Expert Evidence**) came later to be used as the polestar for admissibility of a wide variety of other types of expert opinion evidence.

While it was nominally deprived of its vitality in 1993 when the US Supreme Court held, in (*see* ***Daubert v. Merrell Dow Pharmaceuticals***), that the 1975 passage of (*see* **Federal Rule of Evidence 702**) superseded the *Frye* decision's requirements of general acceptance in federal trials, it remains important for several reasons. First, one of the *Daubert* mandates on admissibility retains, as factor in judging "reliability" of the evidence, whether a test is generally accepted in the profession wherein it belongs. Second, *Frye* remains the law in a significant number of American states that have decided to remain faithful to it and have eschewed an opportunity to follow the federal model of *Daubert*. Despite the importance of the decision, its text is relatively brief and the opinion does not contain citations to other authorities or precedents.

To this day, when the admissibility of opinion testimony is challenged in a pretrial hearing on a motion (*see* ***In Limine*** **Motions and Hearings**) asking the court to exclude the evidence for lack of reliability, forensic scientists may be required to testify in a special hearing to establish the reliability of techniques or methodologies on which they have based their opinion. While being purely a rule of American legal jurisprudence, the *Frye* decision has also been cited on the issue of expert opinion testimony by courts in other countries. All forensic scientists should be cognizant of its existence.

Text of the Opinion

Frye v. United States
Circuit Court of Appeals for the
District of Columbia
54 App. D.C. 46, 293 F. 1013 (Decided
December 13, 1923)

Before Smyth, Chief Justice, Van Orsdel, Associate Justice, and Martin, presiding Judge of the United States Court of Customs Appeals.

Van Orsdel, Associate Justice.

Appellant, defendant below, was convicted of the crime of murder in the second degree, and from the judgment prosecutes this appeal.

A single assignment of error is presented for our consideration. In the course of the trial counsel for defendant offered an expert witness to testify to the result of a deception test made upon defendant. The test is described as the systolic blood pressure deception test. It is asserted that blood pressure is influenced by change in the emotions of the witness, and that the systolic blood pressure rises are brought about by nervous impulses sent to the sympathetic branch of the autonomic nervous system. Scientific experiments, it is claimed, have demonstrated that fear, rage, and pain always produce a rise in systolic blood pressure, and that conscious deception or falsehood, concealment of facts, or guilt of crime, accompanied by fear of detection when the person is under examination, raises the systolic blood pressure in a curve, which corresponds exactly to the struggle going on in the subject's mind, between fear and attempted control of that fear, as the examination

touches the vital points in respect of which he is attempting to deceive the examiner.

In other words, the theory seems to be that truth is spontaneous, and comes without conscious effort, while the utterance of a falsehood requires conscious effort, which is reflected in the blood pressure. The rise thus produced is easily detected and distinguished from the rise produced by mere fear of the examination itself. In the former instance, the pressure rises higher than in the latter, and is more pronounced as the examination proceeds, while in the latter case, if the subject is telling the truth, the pressure registers highest at the beginning of the examination, and gradually diminishes as the examination proceeds.

Prior to the trial the defendant was subjected to a deception test, and counsel offered the scientist who conducted the test as an expert to testify to the results obtained. The offer was objected to by counsel for the government, and the court sustained the objection. Counsel for defendant then offered to have the proffered witness conduct a test in the presence of the jury. This also was denied. Counsel for defendant, in their able presentation of the novel question involved, correctly state in their brief that no cases directly in point have been found. The broad ground, however, upon which they plant their case, is succinctly stated in their brief as follows:

"The rule is that the opinions of experts or skilled witnesses are admissible in evidence in those cases in which the matter of inquiry is such that inexperienced persons are unlikely to prove capable of forming a correct judgment upon it, for the reason that the subject matter so far partakes of a science, art, or trade as to require a previous habit or experience or study in it, in order to acquire a knowledge of it. When the question involved does not lie within the range of common experience or common knowledge, but requires special experience or special knowledge, then the opinions of witnesses skilled in that particular science, art, or trade to which the question relates are admissible in evidence".

Numerous cases are cited in support of this rule. **Just when a scientific principle or discovery crosses the line between the experimental and demonstrable stages is difficult to define. Somewhere in this twilight zone the evidential force of the principle must be recognized, and while courts will go a long way in admitting expert testimony deduced from a well-recognized principle or discovery, the thing from which the deduction is made must be sufficiently established to have gained general acceptance in the particular field in which it belongs**.

We think the systolic blood pressure deception test has not yet gained such standing and scientific recognition among physiological and psychological authorities as would justify the courts in admitting expert testimony deduced from the discovery, development, and experiments made thus far.

The judgment is affirmed.

General Acceptance Test for Novel Expert Evidence

The "general acceptance test" is a legal principle that requires expert opinion evidence of a novel nature to have been generally accepted as a reliable method in the scientific or technical field in which it belongs. When such general acceptance has been shown to exist, expert testimony based thereon then may become admissible as evidence in a court of law.

The principle finds its origin in American jurisprudence in the case of *Frye v. United States* (*see* ***Frye v. United States***) [1], 293 F. 1013 (D.C.Cir. 1923). While the *Frye* case was concerned solely with the admissibility of opinion evidence based on systolic blood pressure (*lie detector*) test, the *Frye* principle of *general acceptance* became, thereafter, the polestar to guide courts in arriving at a decision on whether to admit opinion testimony based on almost any form of other novel scientific evidence in court.

While the principle became general legal authority in the United States for some time, the *Frye* decision has also been referred to in some court decisions in Canada, the United Kingdom, and in other countries as well, including some civil law system court decisions. The universal appeal of the rule of general acceptance as a test for admissibility became eroded in some jurisdictions after the 1993 decision in *Daubert v. Merrell Dow Pharmaceuticals* (*see* ***Daubert v. Merrell Dow Pharmaceuticals***) [2, 3], because *Daubert* demoted it to a mere factor in the making of the admissibility decision rather than as an absolute requirement.

While conceived as a legal standard, the *Frye* principle of general acceptance has found widespread recognition as an appropriate standard among forensic scientists as well.

ANDRE MOENSSENS

General Electric v. Joiner

Facts and Issues Summarized

An electrician (Joiner), employed by a public utility who suffered from lung cancer brought an action against the manufacturer of polychlorinated biphenyls (PCBs) and the manufacturers (General Electric) of electrical transformers for job-related exposure to PCBs. The trial court determined that plaintiff's expert testimony on the causal connection between PCBs and lung cancer was unconvincing under *Daubert* criteria and excluded the evidence.

The intermediate appellate tribunal – the Court of Appeals for the Eleventh Circuit – reversed the trial judge's ruling. It held that the Court should have applied a more lenient standard of review because the Federal Rules of Evidence exhibit a clear preference in favor of admitting expert testimony.

A further appeal was taken by the defendants to the United States Supreme Court, which had to decide whether the Court of Appeals, in reversing the trial court's *Daubert* decision, applied the correct standard of review. The Supreme Court held that "abuse of discretion" is the proper standard of review of the district court's ruling excluding expert evidence on *Daubert* grounds. The trial court was found not to have abused its discretion in this case. The Court of Appeals was said to have applied overly stringent criteria in reviewing the trial judge's ruling; in so doing it "failed to give the trial court the deference that is the hallmark of abuse of discretion."

Importance of the Opinion for Forensic Science

This case was the first one after *Daubert* (*See* ***Daubert v. Merrell Dow Pharmaceuticals***; **Expert Opinion: United States**; **Federal Rule of Evidence 702**) in which the Supreme Court dealt with issues of admissibility of scientific evidence. *Joiner* reiterated the Court's admonition in *Daubert* that the trial judge is allowed considerable discretion.[a] As long as the judge's decision is supported by the evidentiary record, the appeals court should affirm the decision to admit or exclude evidence. Only if the trial court's opinion is wholly unsupported by the record – an "abuse of discretion," the lower court's ruling ought to be reversed by the reviewing court.

The Supreme Court found that the trial court had followed the *Daubert* guidelines properly while rejecting expert opinions based on studies proffered by the plaintiff's experts. The witnesses, according to the Supreme Court, cited animal studies that "were so dissimilar to the facts presented ... that it was not an abuse of discretion for the District Court to have rejected the experts' reliance on those studies" [1].

In the process of developing the reasons for its holding, the Court inserted some comments that are of particular importance to all forensic scientists. The first one of these is that the Federal Rules of Evidence allow trial courts "to admit a somewhat broader range of scientific testimony than would have been admissible under *Frye*." Thus, *Daubert* is to be read as admitting some scientific evidence that might not be admissible under *Frye*'s more rigid "general acceptance" test.

Despite this more lenient admissibility posture, the Supreme Court also issued the warning that trial courts cannot abandon their "gatekeeping" function. While the focus of the *Daubert* opinion was on the principles and methodologies used by experts in arriving at their opinions, and not on the conclusions that they have generated, the distinction between principles, methodologies, and conclusions is not always easily drawn. The Court stated [2]:

> [C]onclusions and methodology are not entirely distinct from one another. Trained experts commonly extrapolate from existing data. But nothing in either *Daubert* or the Federal Rules of Evidence requires a [trial] court to admit opinion evidence which is connected to existing data only by the *ipse dixit* of the expert. A court may conclude that there is simply too great an analytical gap between the data and the opinion proffered.

The trial court had found that the gap between data and conclusions was too wide, and its finding that the studies offered by plaintiff's experts did not support their conclusions that Joiner's exposure to PCBs contributed to his cancer was not an abuse of discretion.

End Notes

[a.] While *Joiner* was the first article to expound on the meaning of *Daubert*, it is not the only one. Two other Supreme Court cases are noted. (*see* ***Kumho Tire v. Carmichael***; ***Weisgram v. Marley***; **General Acceptance Test for Novel Expert Evidence**).

Genomics and Behavioral Evidence

Genetics and Behavior

It has been thought for hundreds of years that human behavior is driven by some combination of nature (heredity, family history, genetics, genomics), nurture (parental upbringing, influence of peers, good and bad life experiences), and free will. Scientists, philosophers, mental health professionals, and lawyers debate the relative importance of nature, nurture, and free will, but the answer may be, "It depends." In some cases, it depends on the specifics of a particular individual and a particular set of circumstances to know whether the person's behavior was determined by heredity, life experience, or a personal decision – or, more likely, some interaction among these three forces. In general, the relationship between nature and nurture is that environment affects the way genes express themselves; for a detailed discussion of this topic see reference [1].

Brief History of Genetics and Crime

Physicians since the eighteenth century thought that criminal and violent behavior was caused partly by one's family background, partly by unfortunate life experiences, and partly by purposeful malicious intentions. For example, Benjamin Rush, the "Father of American Psychiatry," published *Medical Inquiries and Observations upon the Diseases of the Mind* in 1812. He thought a predisposing cause of mental illness was "a peculiar and hereditary sameness of organization of the nerves, brain, and blood vessels [that] sometimes pervades whole families." However, the more immediate causes of mental illness included traumatic life experiences such as "terror from fire," "earthquakes," and "shipwreck."

In 1881, the trial of Charles Guiteau for the assassination of President James Garfield highlighted the debate among alienists and neurologists regarding the concept of moral insanity. The proponents of moral insanity thought that some forms of antisocial behavior were inherited. However, the jury rejected Guiteau's insanity defense and he was hanged. Sigmund Freud published "Heredity and the Neuroses"

in 1896. Freud said that some mental illnesses were the result of an interaction among hereditary preconditions, "concurrent causes" such as exhaustion and trauma, and "specific causes" such as harmful sexual experiences.

The relationship between a person's physical characteristics and criminal behavior was studied systematically. Cesare Lombroso, sometimes called the "Father of Criminology," published *L'Homme Criminel* in 1895. Lombroso's thesis, influenced by Charles Darwin, was that "primitive" physical characteristics such as a strong jaw, heavy brows, thick lips, and projecting ears predicted criminality. William H. Sheldon published *Varieties of Delinquent Youth* in 1949. Sheldon thought the mesomorphic or muscular body type was predictive of criminal behavior.

The eugenics movements in the United States (about 1910–1935) and in Europe were popular but misguided attempts to apply new knowledge regarding genetics to social engineering. More than 30 states in the United States adopted laws providing for forced sterilization of individuals who were thought to carry a serious hereditary disorder. This practice was approved by the US Supreme Court in the 1927 case of *Buck v. Hall*, in which Justice Oliver Wendell Holmes said that an allegedly retarded woman should be subjected to forcible sterilization because "three generations of imbeciles are enough." In 1934, the Nazi government in Germany used the eugenics movement as the basis for the Law for the Prevention of Genetically Diseased Offspring, which provided for forced sterilization on individuals with diseases that were presumed to be hereditary such as schizophrenia, manic-depressive illness, epilepsy, blindness, and deafness. The horrible consequences of the eugenics movements of the early twentieth century have continued to worry mental health professionals and legal scholars in the twenty-first century. There are concerns that government will use behavioral genomic testing to limit or control individuals because of their genetic makeup.

Although the three-dimensional structure of DNA was discovered by Watson and Crick in 1953, it was not until 1956 that Tjio and Levan announced that the correct diploid count for human chromosomes is 46, including sex chromosomes that are usually either XX (in females) or XY (in males). After the karyotyping of chromosomes became both feasible and accurate, a theory developed that men with an XYY karyotype were predisposed to violence. In the 1970s, there was a good deal of interest in the legal community and also in popular culture about the proposal that there was a genetic explanation for criminal behavior. When more detailed studies were conducted, it was found that XYY men were more likely to be arrested and incarcerated than typical or XY males, but were not more likely to be violent. It was suggested that XYY men were more likely to be arrested because of their learning disabilities or low intelligence [2].

Since the 1920s, there has been much research regarding the relationship between heredity and antisocial and violent behavior. The traditional genetic epidemiological research – based on family, twin, and adoption studies – was summarized by Anderson [3]. Although the studies are not always consistent, there is evidence that both antisocial behavior and violent behavior are heritable. For a more detailed discussion of the philosophical and legal aspects of genetics and criminal behavior, see Reference [4]. For an overview of behavioral genetics and a discussion of its future prospects, see Reference [5].

Traditional genetic research has been helpful in establishing the heritability of psychiatric conditions and certain types of behavior, but it is not very helpful when it comes to testifying about a particular individual. Testimony regarding behavioral genomics will be more meaningful when it is known that a particular gene or a group of interacting genes combined with particular types of life experiences are highly associated with violence or some other specific behavior. Then, the defendant being evaluated can be assessed for the relevant gene(s) and life experiences and testimony will be based on the genetic and environmental interactions for that individual.

Types of Genomic Information

Regarding terminology, the word "genetic" has traditionally referred to a person's genetic makeup or genotype at a specific locus. For example, "Huntington's disease is a genetic disorder." "Genomic" is currently used to indicate how all the DNA material in a cell, both nuclear and mitochondrial, interacts over time to influence biological pathways and physiology. For example, "The more we learn about the human genome, the more complex and dynamic it becomes." Also, "chromosomal" refers to circumstances in which entire chromosomes are missing

or duplicated. For example, "Down's syndrome is a chromosomal disorder caused by the presence of all or part of an extra chromosome 21."

There are three ways in which a specific individual's genetic makeup may be relevant to his or her behavior: (i) the person's genotype may exactly designate a psychiatric or medical diagnosis that clearly explains the person's abnormal behavior. (ii) The person's genotype may support a psychiatric diagnosis that has been made on clinical grounds. (iii) The person's genotype may help to explain a person's violent or criminal behavior.

Genotype Designates the Diagnosis

In some circumstances, the introduction of genetic information at a trial is easy to understand and readily fulfills *Daubert* and *Frye* criteria for reliability and acceptance in the professional community. That is the case when the genetic information is used to show that a specific individual has a specific genetic or chromosomal disorder. For instance, evidence regarding two well known disorders – Down's syndrome (a chromosomal disorder) and Huntington's disease (a genetic disorder) – may arise in a legal context. There are highly specific and reliable methods for genotyping individuals who may have these conditions. Of course, simply having a diagnosis is usually not sufficient all by itself to justify a legal conclusion. In addition to making the diagnosis, it is necessary to show that the defendant's mental functioning or behavior was impaired to a significant degree. The nature of the impairment depends on the legal issue being addressed – which might be competency to stand trial, the insanity defense, diminished capacity, or mitigation.

Most genetic disorders that directly cause cognitive and behavioral symptoms – such as mental retardation and violence – are identified in childhood. For example, Down's syndrome occurs in about one out of 800 live births. Individuals with Down's syndrome may be severely retarded and may commit a criminal offense out of ignorance or naïveté. These individuals may become irritable and frustrated and commit a violent act. Persons with Down's syndrome have a serious mental defect that affects their ability to appreciate the wrongfulness of their behavior, and may lack the mental capacity to participate in legal procedures because of their mental retardation. For example, they may not be competent to stand trial or testify as a witness at a trial.

Some individuals are born with a genetic disorder but the diagnosis is not made until adulthood. It may be that the person's genetic condition is first manifested by some form of aberrant behavior, which leads to his arrest. In this set of circumstances, it is possible for the mental health professional who conducts the pretrial forensic evaluation to be the first person to accurately diagnose the person's medical and psychiatric condition. Huntington's disease is an adult-onset, autosomal, dominant, neurodegenerative genetic disorder. Huntington's disease causes psychosis, dementia, and sometimes violence. The diagnosis of Huntington's disease – based on the defendant's genotype – may have a bearing on the outcome of a criminal case. In this circumstance, the genotype determines the diagnosis and there is a distinct causal relationship between the genotype and the behavior.

There are other genetic or chromosomal disorders that may be manifested by psychological or behavioral symptoms. For example: fragile X syndrome, Prader–Willi syndrome, Wilson's disease, and velocardio-facial syndrome.

G × E Interaction May Support Diagnosis

The inheritance of most psychiatric disorders – including schizophrenia and bipolar disorder – is not mediated by single genes or Mendelian genetics. Investigators of complex human behaviors have proposed complex genomic models such as: interaction among several genes; interaction among genes and epigenetic and other intracellular factors; and interaction among genes and the environment. The interaction between genetic and environmental factors has been called *G × E interaction*. Forensic psychiatrists and psychologists can evaluate defendants in terms of G × E interactions and their findings may be appropriate for testimony in criminal trials. A G × E interaction may support the diagnosis that has been made on clinical grounds and may help explain the defendant's behavior [6].

For example, in some criminal trials, there is a dispute over whether the defendant had a specific mental illness or perhaps any mental illness at the time of the alleged offense. For instance, the defense may assert that the defendant had major depressive disorder, severe, with psychotic features, and that was

why he killed his baby. The prosecution may claim the defendant did not have a significant mental illness at all, but simply pretended to have severe depression and command hallucinations after his arrest in order to avoid responsibility for the baby's death. In this circumstance, the forensic psychiatrist or psychologist may want to evaluate the defendant for a particular G × E interaction because this finding may support the diagnosis of major depressive disorder. A person who is homozygous for the short allele of the *SLC6A4* gene is more likely to become depressed and suicidal after stressful situations than a person who is homozygous for the long allele of that gene. If a person has this genotype and stressful life experiences, it would support the contention that the person had a predisposition to a major depressive disorder and suicidal states at the time of the alleged offense. In this circumstance, the genotype does not "make" the diagnosis of severe depression, but it "supports" the diagnosis that was made on clinical grounds.

Avshalom Caspi and his colleagues were the first to demonstrate psychiatrically relevant G × E interactions [7, 8]. In one of their studies [8], the genetic factor was the polymorphism of the serotonin transporter gene, which is referred to as *5-HTT* or *SLC6A4*. The environmental factor was severe psychosocial stressors. Caspi *et al.* [8] addressed "why stressful experiences lead to depression in some people but not in others." The authors found that a particular allele of the serotonin transporter gene appeared to protect individuals from the harmful biopsychosocial impact of multiple stressors. For this research to be usable in expert testimony in the US legal system, it must be replicated. Thus far, the work of Caspi *et al.* [8] has been replicated by several other research teams, which used varying definitions of psychosocial stressors, psychological distress, and genetic risk. Also, a few published studies did not replicate the findings of Caspi *et al.* [8]. Research regarding the *SLC64A* polymorphism, stressful life events, and depression was summarized by Zammit and Owen [9].

G × E Interaction May Explain Behavior

In some circumstances, the defendant's genotype may help to explain his violent or criminal behavior. For example, a man who has the low activity allele of the monoamine oxidase A (*MAOA*) gene and who experienced serious child maltreatment is more likely to manifest violent and antisocial behavior as an adult than a man who has the high activity allele of this gene. The concept is that these genetic and environmental factors may interact and, later in life, predispose a person to have antisocial, violent behavior. In this kind of case, the genotype does not make a specific diagnosis or support a specific diagnosis, but it does help to explain that a particular person may have a predisposition to maladaptive behaviors.

Avshalom Caspi and his colleagues also studied this type of G × E interaction. In the study of Caspi *et al.* [7], the genetic factor was the *MAOA* gene and the environmental factor was severe childhood abuse. They "studied a large sample of male children from birth to adulthood to determine why some children who are maltreated grow up to develop antisocial behavior, whereas others do not." In selecting the *MAOA* gene, the Caspi team knew that both humans and mice that lacked the gene altogether (*MAOA* "knockouts") became violent and aggressive, respectively. The *MAOA* gene, located on the X chromosome, encodes the MAOA enzyme, which metabolizes neurotransmitters, such as serotonin, norepinephrine, and dopamine. Regarding subsequent research, the work of Caspi *et al.* [7] has been replicated by several other teams that used varying definitions of child maltreatment, violent behavior, and genetic risk. Also, a few published reports failed to replicate the research of Caspi *et al.* [7].

Applications of Forensic Genotyping in Criminal Trials

The relevance of this testimony regarding behavioral genomics to criminal trials depends on the exact nature of the genetic findings and their role in the person's case, that is, whether the genotyping is intended to establish a specific diagnosis, to support a diagnosis made on clinical grounds, or simply to explain a person's criminal acts. Also, the significance of this testimony depends on what legal issue is being addressed, that is, whether it relates to competency to stand trial or engage in some other aspect of the legal procedures, sanity, capacity to achieve the mental state required for particular offenses, or mitigation. Information regarding the defendant's genotype might be relevant in several ways, as summarized in this section of the article.

Insanity Defense

Most jurisdictions in the United States have some version of the insanity defense, although there are various definitions of what constitutes insanity. A typical definition is that "at the time of the commission of the acts constituting the offense, the defendant, as a result of a severe mental disease or defect, was unable to appreciate the nature or wrongfulness of such defendant's acts." In some cases, genetic testing may help to establish that the defendant has one of the criteria for an insanity defense, i.e., "a severe mental disease or defect." For example, Huntington's disease is considered a severe mental disease or mental illness within the psychiatric community. Down's syndrome typically causes a severe mental defect or mental retardation. The diagnosis of a genetic condition does not, however, prove the second criterion for an insanity defense, i.e., the defendant's inability "to appreciate the nature or wrongfulness of such defendant's acts." To determine if the defendant had the capacity to appreciate the wrongfulness of his actions at the time of the alleged offense, a forensic evaluator must collect information regarding the person's functional abilities by relying upon: interview and psychological testing of the defendant; interviews of collateral sources, such as family members, who observed the defendant around the time of the alleged offense; and the investigation by law enforcement personnel regarding the circumstances of the crime and the defendant's behavior and statements when he was arrested.

Diminished Capacity

Most crimes are defined by a particular *mens rea* (guilty mind) and *actus reus* (guilty act). For example, the *actus reus* for first degree murder is the killing of another person. Typically, the *mens rea* for first degree murder is that the killing of another person was done in a premeditated and intentional manner. "Diminished capacity" refers to a defendant's inability to achieve the mental state required for a particular crime. For example, a person who is very intoxicated on cocaine or a person who is extremely depressed might not be able to exercise reflection and judgment and might lack the capacity to commit first degree murder.

Some states allow for the introduction of testimony by mental health professionals regarding diminished capacity, so information regarding the defendant's genotype might be relevant. As in the discussion regarding the insanity defense, the diagnosis of Huntington's disease or Down's syndrome help to explain why a defendant's mental abilities were severely impaired at the time of the alleged offense. The diagnosis by itself would not prove diminished capacity, but it would be part of the testimony to show why the person lacked the capacity to form a particular mental state.

Also, suppose that a defendant who is accused of first degree murder had a history of severe child abuse and a genotype that included the low activity allele of the *MAOA* gene. Because of his genetic makeup and life experiences, the defendant is at a high risk to commit violent acts. Suppose the circumstances of the alleged offense were such that the defendant might have been in a state of excitement or passion. Suppose also that the defendant was using cocaine and marijuana at the time of the alleged offense. One can see how all of this information – including the *MAOA* genotyping – could be considered by the trier of fact to decide that the defendant did not have the mental capacity to commit first degree murder.

Mitigation

In the guilt phase of the trial, the jury or the judge decides whether the defendant committed the crime. If the defendant is found guilty, additional evidence is presented in the penalty phase of the trial and the jury or the judge decides what the defendant's sentence will be. During the penalty phase, the defense attorney can present a very broad range of information to influence the jury and judge to be lenient toward the defendant. If the defendant was found guilty of a capital crime such as first degree murder, the jury may forego the death penalty and sentence the person to life in prison.

In the penalty phase of the trial, the defense often presents testimony about the defendant's difficult childhood, such as experiencing chronic illness, child maltreatment, or poverty. It may be relevant to present testimony that a person's genetic makeup – along with other factors like physical or sexual child abuse – predisposed a person to commit a violent, antisocial act. The defense attorney would argue that the defendant did not ask to have a particular genetic makeup. He did not ask to be physically or sexually abused as a child. But these factors – without

his desire, knowledge, or awareness – made it more likely he would commit a violent act later in life.

Dangerousness

The prosecution also has an opportunity at the penalty phase of a trial to present additional evidence. In some circumstances, the prosecution may argue that behavioral genomic testimony is not mitigating, but is an aggravating factor that should increase the length of a sentence. For instance, the prosecution may say that because of his genetic makeup and his childhood experiences, the defendant has violent tendencies and should have a longer sentence in order to protect society for a longer time.

Whether testimony regarding behavioral genomics favors the defense or the prosecution depends on the circumstances. In a case of aggravated robbery, for instance, it may be logical for the prosecution to argue that a person's genotype and bad life experiences mean he should be imprisoned longer in order to protect society. In a case of capital murder, on the other hand, the defendant is never going to live outside prison and threaten society. In that situation, it may be logical for the defense to argue that the person's genotype and bad life experiences mean he should have a life sentence rather than the death penalty.

Malingering

In some trials in which psychiatric or psychological testimony is offered, there is a dispute about whether the defendant is malingering mental illness. If the prosecution can show that the defendant was malingering, the jury is less likely to find the person insane or eligible for a reduced sentence. The defense may be able to use behavioral genomic testimony to bolster the argument that the defendant has an actual mental disorder.

In the future, it is likely that researchers in behavioral genomics will show that groups of genes or various G × E interactions greatly increase the risk that a particular person will have a serious psychiatric condition, i.e., schizophrenia, bipolar disorder, obsessive-compulsive disorder, autism, etc. It is likely that this kind of information will be one aspect of what the forensic psychiatrist or psychologist considers in assessing whether a defendant is malingering. It would raise suspicions of malingering if a person had no genetic or environmental risks for schizophrenia, but sometimes manifested symptoms that seemed consistent with schizophrenia. Of course, genetic testing would only be one part of a comprehensive evaluation, and not determinative all by itself. It is possible for a person to have the genetic risk factors for schizophrenia, but not have the illness. Also, it is possible for a person with actual schizophrenia to also be malingering.

Competency

Mental competency is a very important issue in many aspects of the criminal justice system. Mental health professionals are frequently asked to assess whether a defendant was competent in the past when he waived Miranda rights and made a statement to investigators. They are asked to evaluate whether a defendant is currently competent to stand trial or competent to waive his right to have an attorney represent him at the trial. After conviction, there may be an issue of whether an inmate is competent to waive his appeals or even competent to be executed.

In conducting a competency evaluation, the mental health professional would ordinarily assume the person is competent unless there is some reason to think otherwise. To conclude that an individual is not competent, the evaluator would have to identify some mental disorder that is causing the impairment in mental functioning. As in the previous discussion – regarding insanity, diminished capacity, and malingering – genetic testing may help establish that a person has a mental illness that would cause enough impairment to compromise the individual's competency. Of course, making the diagnosis of mental illness or mental retardation does not in itself mean the person is not competent, and that conclusion would require additional assessment of the person's actual functioning.

Juvenile Court

Since most juvenile courts are organized around the principle of rehabilitation, juvenile court judges are usually very interested in having a full understanding of the youngster's biological, psychological, and social background. Juvenile court judges – in order to arrive at an appropriate disposition of each case – take into consideration lengthy social histories, the

results of psychological testing, and psychiatric evaluations. There is a search for why this particular boy or girl got into so much trouble in the past, and then an effort to devise an intervention or corrective action to reduce the likelihood of more trouble in the future.

Preliminary research regarding G × E interactions has started to explain why some children manifest oppositional defiant disorder and conduct disorder, while others do not. Of course, juvenile court judges are not interested merely in research and theories, but they want solutions, interventions, and rehabilitation that actually works. As both genetic and environmental risk factors and their interactions become better understood, practitioners will develop more specific and more effective treatments. For example, it will be determined that some forms of adolescent violence are treatable with medication, while other forms of violence require lengthy residential treatment. In the future, an assessment of a youngster's risk factors based on G × E interactions will be a common feature of biopsychosocial evaluations conducted for juvenile courts.

Causation and Correlation

This article discusses a wide range of testimony regarding behavioral genomics. In some of the examples cited (such as Down's syndrome and Huntington's disease), there is an obvious relationship between the genetic abnormality and the behavioral outcome that is universally accepted by the scientific community. Both scientists and legal scholars would agree that having three copies of chromosome 21 is a sufficient cause for the clinical phenotype known as *Down's syndrome*.

The relationship between the G × E interactions (*SLC6A4* and psychosocial stressors; *MAOA* and childhood maltreatment) and behavior discussed in this article is not so obvious. There certainly is a correlation between the G × E interactions and the behavior, but one cannot say definitely there is a causal relationship. On the basis of the replicated research, the interaction of the *SLC6A4* gene and psychosocial stressors is a probabilistic cause of depression and suicidality, which means the G × E interaction increases the chance that depression and suicidality will occur. Likewise, the interaction of the *MAOA* gene and childhood maltreatment is a probabilistic cause of violence.

Implications for the Future

The goal of future research is to establish linkages along the following lines: individuals with a combination of allelic polymorphisms and certain life experiences have specific changes in brain functioning, manifested by functional magnetic resonance imaging (fMRI); there is a physiological relationship between these changes, such as modification in the activity of a particular neurotransmitter; these changes in the brain cause specific alterations in emotional and/or cognitive functioning; the functional alterations cause a consistent pattern of behavior; and the pattern of emotional, cognitive, and behavioral changes may constitute a diagnosis.

Genotyping is not a test that can be interpreted or presented all by itself. If genotyping is conducted on a criminal defendant, it should be part of a comprehensive psychiatric or psychological forensic evaluation. A pretrial forensic evaluation typically consists of many parts including a review of medical records, a review of the investigation of the crime, interviewing the defendant, psychological testing, neuropsychological testing, interviewing family members and other collaterals, and sometimes other investigations such as brain scans, electroencephalograms, and consultation with other medical specialists. As a small part of this elaborate evaluation, genotyping for *MAOA*, *SLC6A4*, and other genes might included.

Studying G × E interactions with behavioral and psychiatric implications is a popular topic and this type of research will flourish in coming years. It is likely that many G × E interactions will be highly correlated with major depressive disorder, bipolar disorder, schizophrenia, posttraumatic stress disorder, obsessive-compulsive disorder, panic disorder, substance abuse, and violent sexual predation. These interactions will usually not prove that a person has a particular diagnosis, but they will support and explain the diagnosis that has been made through traditional evaluation methods. Also, if the defendant is suspected of malingering, an investigation of the person's genetic makeup and relevant life experience may be used to support the claim that he or she actually has a serious mental disorder.

Geographical Identification by Viral Genotyping

Geographical Identification by Viral Genotyping

Introduction

Major genetic differences between human populations must have evolved when they expanded, originating from Africa, across the Earth in the course of the last 100 000 years [1, 2]. The theory of isolation by distance, i.e., the decrease of genetic similarity with increasing geographic distance has been supported by data on genetic polymorphism [3, 4]. In the course of this evolution, humans have carried many parasites that have coevolved with humans resulting in different types of relationship, i.e., commensal, mutualistic, or pathogen to humans [5]. Therefore, also evolution and genomic diversity of viruses has been used to gain better insight into patterns of ancient human migration [6]. Studies with human papillomavirus (HPV-16), polyomavirus JC (JCV), and also the bacterium *Helicobacter pylori* have shown a similar pattern of evolution to humans with origins in Africa and subsequent migration of ethnic groups to the other continents in prehistoric times [7–10].

This association of parasitic genomic diversity with geographic area has also attracted forensic scientists. Recently, Ikegaya *et al.* reported a novel method applying genetic diversity of the JC virus to forensic case work [11]. After that report, several other parasites have been examined to find out whether their genotype and geographical region correlate to such an extent that would allow them to be used as aids to the process of human identification.

Relations between Parasitic Genotype and Geographic Area

JCV, a member of the *Polyomaviridae* family, was first isolated in 1971 from the brain of a patient with progressive multifocal leukoenchephalopathy (PML) and was eventually found to be ubiquitous in the human population [12, 13]. After primary asymptomatic infection in childhood, JCV persists in the renal tissue of most adults, excreting its

progeny virus in urine. JCV strains worldwide can be classified into more than 30 genotypes from 18 main genotypes by phylogenetic analyses [14] of viral 5100p DNA sequences [15]. Each genotype is distributed in relatively small distinct areas of different parts in the world (Table 1).

BK virus (BKV) belongs to the same family of *polyomaviridae* as JCV, and was first detected from a renal transplant patient in 1971 [16]. Primary infection with this virus usually occurs in childhood and the seroprevalence rate reaches the adult rate (65–90%) at the age of 5–10 years [17]. BKV is also known to persist in the kidneys and to excrete progeny virus in urine [18]. BKV strains worldwide can be classified into seven main genotypes according to phylogenetic analyses of viral DNA sequences [19, 20]. Each genotype occupies distinct areas of distribution in different parts of the world (Table 2).

So far, a correlation between the geographic area and genotypes has also been noted in other parasites, such as Epstein Barr virus (EBV) [20], human herpes virus type 1 (HHV-1), *Helicobacter pylori* [21], and *Candida albicans* [22]. Figures 1 and 2 show the phylogenetic tree of the JC virus and HHV-1 virus, respectively. These phylogenetic trees, constructed from worldwide isolates, show close correlations to

the geographic areas; however, the relation between the area and genotypes is much closer in JC virus than HHV-1 virus. The reason for this is that the evolutional history of JCV is almost synchronized to the history of humans, whereas HHV-1 is not, as a host change may have occurred; therefore, not only geographic correlations but also evolutional history of the parasite in question has to be analyzed.

Detection of Parasitic Genotypes from Forensic Samples

Polymerase Chain Reaction (PCR) amplification of a 610 bp region (VT intergenic region: IG region) of the viral genome was used for JCV detection from forensic autopsy cases. The detection rate was 45% when 200 mg of renal tissue was used as template and somewhat lower, 33%, from 5 ml urine. The detection rate was higher (>50%) with elderly subjects. Multiple samples taken from the same kidney and the contralateral one from the same cadaver showed identical sequences. The JCV detection rate was not related to the cause of death and was hardly affected by postmortem decomposition [23]. Detection of JCV from formalin-fixed and paraffin-embedded tissue has also been reported [24]. In formalin-fixed, paraffin-embedded samples, not only the original sequences but also those with 1% of base substitution were detected and no genotype change was found. In formalin-soaked samples, the original sequences and those with more than 1% of substitution causing genotype change were detected; thereafter, genotype was determined only using specimens in a frozen state or that had been formalin-fixed for a short time. However, JCV was detectable from 50 μl of urine [25]. When 200 μl of urine was used for

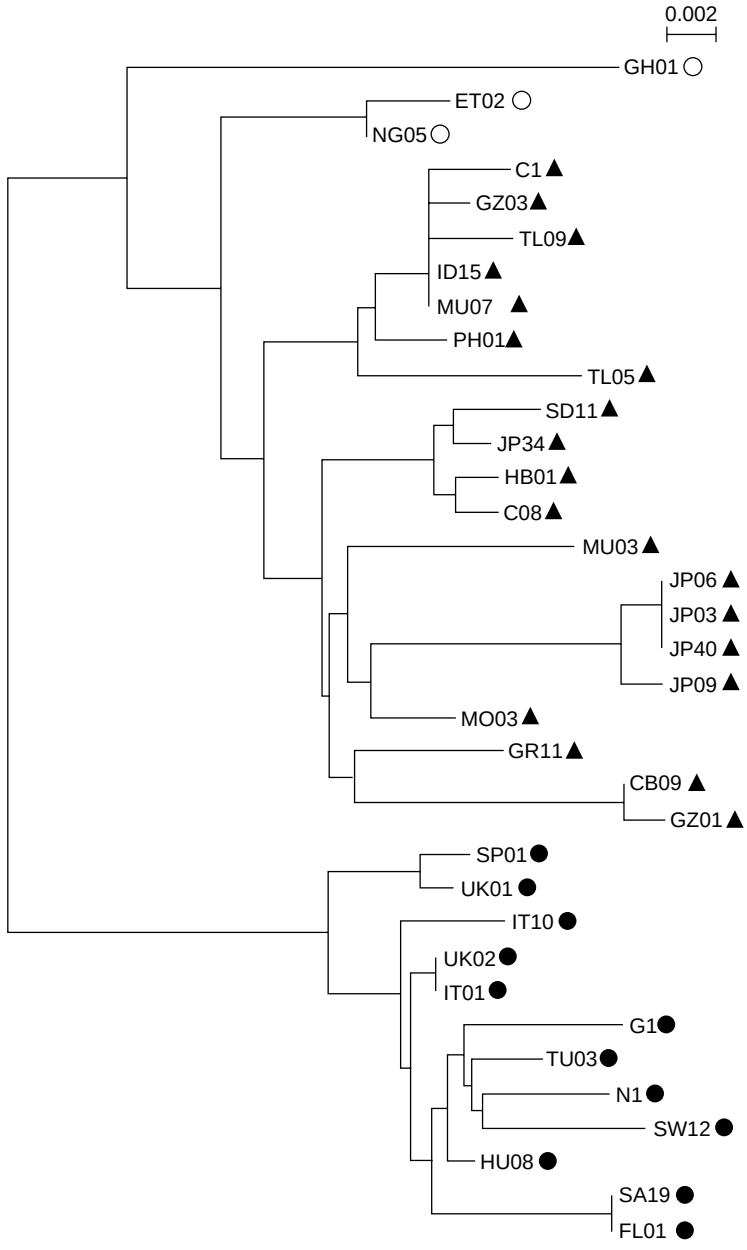

Figure 1 Phylogenetic analysis of JCV genome. 610 bp hypervariable region (IG region) of JCV genome was phylogenetically analyzed. Open circle, African isolates; closed circle, European isolates; and closed triangle: Asian isolates

detection, 54.9% was JCV positive, and JCV DNA was highly detectable from minute urine stains prepared 3 months earlier using 100 μl of JCV-positive urine. These findings show that this method could be used for urine stain samples left at the scene and small amounts of urine taken from autopsies. Although there are several chemical or immunological methods to identify urine stains, it can be problematic to confirm that they are of human origin. However, detection of JCV or BKV from urine

Figure 2 Phylogenetic analysis of HHV-1 genome. 666 bp hypervariable region of HHV-1 genome was phylogenetically analyzed. Open circle, African isolates; closed circle, European isolates; and closed triangle: Asian isolates

stains automatically confirms that they are human, because these viruses only infect the human urinary tract.

BKV DNA was also detectable in 30.5% of postmortem cases [26]. In addition, JCV DNA was detected in 47.2% of the same postmortem cases. Overall, BKV or JCV was detectable in 69.8% of postmortem cases.

As EBV infects human leukocytes, it might, at least in principle, be a good tool to identify

using blood samples, however, the detection rate from postmortem blood samples was only 16% [20]. Also HSV-1 DNA has been detected postmortem in forensic cases from the trigeminal nerve by PCR method with a detection rate of 61% [27], as well as Helicobacter Pylori from gastric mucosa, with a detection rate of 56% [28].

Estimation of Geographic Origin

After JCV infection, the same viral strains are maintained in the kidneys and urine throughout life, irrespective of the host's relocation; therefore, the estimated geographical origin from the JCV genotype is closely related to the area where the host grew up. Among all the parasites described above, the JCV genotype has been classified in most detail. The applicability of these methods depends in particular on the distribution of the genotype, subtypes, and subgroups within the geographic area in question. Especially in Asia, many genotypes and their subtypes are found in small domains; for instance, mainly two genotypes are found in Japan, with one genotype prevailing in the north and the other in the south. We can therefore estimate from which area a cadaver originated from and the probability of a cadaver originating from the place where it was found. Japanese police started to use JCV method in 2005 and BKV method in 2007. So far, these methods have been applied to more than 10 cases and in some of them with good results. For other parasites, it is not clear whether double infection or genotypic change might occur during life, therefore, further studies are necessary.

Potential New Approaches toward Geographical Identification Using Human Parasites

In addition to the genomic diversity of human parasites, another approach that may have potential to be used in similar way in the future, but has to our knowledge not been investigated, is the impact of antibiotics. The widespread use of antimicrobial agents worldwide has led to an increasing prevalence of drug-resistant strains of bacteria that can show distinct patterns both geographically and over time. In 1992 established Alexander Project is a continuing surveillance study examining the antimicrobial susceptibility of bacterial pathogens of community-acquired respiratory tract infections with participating centers in many countries in Europe, Africa, Latin America, Middle East, Far East, and the United States [29]. As this type of bacterial resistance is under continued evolution, it would presuppose the existence of a global online database for comparison and additionally a sufficient stability of the bacterial strains to be detected in postmortem material.

Glass

Introduction

Glass is ubiquitous and has been used for many centuries in a range of objects such as jewelry, drinking vessels, vases, and windows. The success of glass and its use can be attributed to its robust, inert, and decorative qualities.

Glass Technology

Glass is a noncrystalline or amorphous mixture of compounds, which when combined in the molten phase and cooled, exhibits a solidified version of its liquid structure. Hence, it can be regarded as being a supercooled liquid [1]. The main constituent of glass is silicon dioxide or silica (SiO_2). To reduce the high melting point of the silica [2] and to improve its properties, such as transparency when solid, several oxides can be added to it and heated. Typically, sodium oxide or soda (Na_2O) and calcium oxide or lime (CaO) are added to form the basis of the "soda–lime–silica" glasses used in most modern windows and containers [3]. Many other oxides are also added to alter the properties of the glass, such as iron oxide (Fe_2O_3), which is added to the mixture to produce a brown or green tint [3].

Nowadays, the molten mixture is molded, shaped, or blown to form container glassware, or drawn through rollers to produce patterned window and wired glasses [3, 4]. However, most modern windows are manufactured by the float process, whereby the molten mixture is poured onto molten tin, left to cool in a controlled atmosphere, to produce flat distortion-free panes [3, 4]. Methods can be used to strengthen glass. For example, glasses can be toughened or tempered by reheating and cooling rapidly, which creates a strong type of safety glass that forms cubes on breaking rather than shards [3, 4]. This type is used in the side windows of vehicles and glass doors. Laminated glass is another type of safety glass, which comprises two or more layers of plain flat glass with a thin sheet of plastic in between each layer [5]. This is used in vehicle windscreens and provides the basis of bulletproof screens used in banks and building societies.

Window glasses have been manufactured by various methods over the years. For example, the molten glass mixture was passed through rollers, cooled, and polished to create plate glass or a "gob" of molten glass was spun on the end of a rod to form a large flat disc as in the case of Crown glass [4]. Evidence of a type of manufacture can often be seen by the forensic scientist when examining the physical and chemical properties of a glass sample in the laboratory.

Breaking Glass

While glass is an inert and robust material, if enough force is applied the glass may crack and completely shatter, creating many hundreds and thousands of fragments, some of which may land on the clothing, footwear, and hair of the individual breaking it or to an individual standing close by. This aspect is important to forensic scientists. In the late 1960s, Nelson and Revell demonstrated the backscatter or backward fragmentation of glass fragments on to a person breaking a window [6]. They found that a large number of fragments were propelled in the direction of the force, away from the breaker, however, a large number of fragments were scattered back toward the origin of the force. Subsequent studies have confirmed this process [7–10]. In addition, researchers have attempted to estimate the number of fragments transferred to an individual breaking a window under varying conditions [7–11]. In summary, the number of fragments transferred by backward fragmentation is very variable, and can range from none to many tens, as this can depend upon how the window is broken and how far an individual is from the breaking

glass. Particles of glass can also be transferred by other means. For example, if the person leans in or walks through, a hole created in the broken glass [12], or by secondary transfer, via an item, that is, exposed to the breaking glass and is subsequently handled [13, 14]. While many studies tend to consider the transfer of glass from a breaking or broken window, other glass objects, such as bottles, vehicle windows and lenses, and drinking vessels, can also be broken at the scene. As a consequence, fragments from these broken objects can also be transferred to the victim or perpetrator, although the number of fragments involved, tend to be lower than that for a breaking window.

Research has shown that once fragments of glass are transferred, to the surfaces of clothing, these can be lost over a matter of hours with normal wear [9, 15, 16]. Typically, the larger fragments are lost first with the smaller, microscopic particles being lost later. The type of garment can also affect how long glass fragments may be retained on the surfaces [9, 15, 16]. For example, particles tend to remain on the fibrous surface of a fleece jacket longer than that of a smooth cotton tee-shirt.

In the laboratory, the forensic scientist may recover any particulate material by initially examining the exhibit by eye and picking off larger pieces using forceps. However, in the majority of cases, because most glass particles tend to be invisible to the naked eye, items are shaken vigorously over brown paper, or a large inverted cone, so as to dislodge any fragments. The resulting debris is collected into a small pot, which is examined under a low-power stereo microscope for any particles, the number and appearance of which are recorded.

Analysis and Comparison

A comparison is usually made of a sample of fragments of glass recovered from the suspect's (alleged perpetrator) or victim's clothing, footwear, or hair, with a control sample of the broken glass item from the crime scene. Several methods of comparison are used by forensic scientists. Two of the most commonly employed techniques have been considered here. These and others are usually performed in a sequence or stepwise process. Thus, if recovered fragments are found to be different from the broken window or object (i.e., the control glass sample), at any stage, then the examination will be stopped and an interpretation relating to any differences made accordingly.

The measurement of refractive index (RI), an optical property of glass (and other materials), is used extensively. The RI is a measure of the bending of light as it moves from one medium (e.g., air) into another (e.g., glass). The theory of RI and the technology relating to the measurement of fragments of glass can be found in several publications [17, 18]. In essence, a fragment (usually <1 mm) is immersed in silicone oil on a glass slide, which is then placed on to a hot stage, sited under a microscope. The RI of the oil changes with temperature, whereas the RI of the glass remains stable. The hot stage is controlled by a computer to heat and cool the fragment in the oil. During the heating and cooling cycles, there will be a temperature at which the RI of the oil matches that of the glass and the fragment disappears momentarily. The computer records these temperatures, which are averaged and converted to RI. The RI is determined for a sample of the control glass and a selection of fragments recovered from the suspect or victim. The refractive indices of any recovered fragments should be within certain parameters in order to ascertain if these are indistinguishable (match) from the control glass sample. These parameters may include comparing each individual recovered value against the range of the control glass values, or extending the range of the control by ± 3 standard deviation. Other methods used involve "grouping" the recovered results and comparing the mean of these with the mean of the control glass sample values, using statistical methods [16]. If the recovered values fall outside the parameters selected, then the fragments may be regarded as being different. Most modern window glasses have an RI in the range of 1.45–1.53 [18], although some other glass objects may fall outside this range.

If the recovered fragments are found to be indistinguishable from the control glass sample these are analyzed further, often by an analytical technique that will examine elemental composition. Many techniques can be used, such as scanning electron microscopy with energy dispersive X-ray detector (SEM-EDX) [19, 20]. A sample of the matching or indistinguishable recovered glass, and a sample of the control glass are analyzed and the chemical components determined, and compared to one another. The

elemental composition of any recovered fragments should also be within defined parameters, such as plus or minus standard deviation of each element or other statistical/multivariate limits of the control glass sample [16], in order to ascertain if these are indistinguishable in composition from the control glass sample. If not, then the fragments may be regarded as being different. As only one or two recovered fragments are analyzed elementally, the results will impinge on all the recovered fragments whose RI has been determined previously.

Once the recovered fragments have been examined and compared with the control sample, the results can be reviewed by the scientist, from which he can draw certain conclusions about the findings. While the determination of RI and elemental composition are highly discriminating techniques, it is not currently possible to determine conclusively that a recovered fragment, with a matching RI and composition, has come from the control or broken item at the scene.

Interpretation of Findings

Studies have shown that the presence of glass fragments on the surfaces of clothing of an individual from the general population is highly unusual [21, 22]. Moreover, glass particles matching a control glass sample is also significant, even in the presence of nonmatching glass [23, 24]. Therefore, if the scientist has found a group of recovered fragments that are indistinguishable from (matching) the control sample in the tests performed, then he is able to conclude, depending upon the circumstances that there is "some support" for the proposition that the individual has smashed the window concerned. The type of phraseology used and the strength of the evidence will depend upon the circumstances of the case, the findings, and any assessment made. In the United Kingdom, scientists tend to use Bayesian inference for the interpretation of glass evidence, which incorporates the use of at least two competing propositions and the estimation of the likelihood ratio (LR) [16, 25]. The strength of the evidence is usually conveyed in cases involving glass (and other evidence types) using a logarithmic verbal scale [26] going in stages from 'no support' to 'extremely strong support' for a proposition (e.g., LGC Forensics uses a scale comprising inconclusive, no support, limited support, moderate support, moderately strong support, strong support, very strong support and extremely strong support).

Glass Evidence: Bayesian Approach to

Introduction

Glass examiners are often asked to answer questions such as “Does the glass recovered from the suspect come from the crime scene window?” or “Did this person break that window?”. Such questions deal with unknown events and therefore their answers are inherently probabilistic or statistical in nature. For this very reason the analysis will never answer such questions definitively. However, statistical treatments do provide a framework which can ensure objectivity and consistency. Excluding DNA, glass is considered by some to be the field of evidence interpretation which makes the most use of statistics [1]. It is a forerunner of many ideas applied to other evidential material [2]. It is therefore not surprising to find that glass is the field, after DNA, where one can find the most publications showing how probabilities and statistics can help the scientist’s assessment of the significance of the evidence.

Glass is one of the most common types of trace evidence: in New Zealand, for example, in 2005, 18.6% of all physical evidence casework in NZ involved glass (Curran personal communication). The most common scenario where glass evidence may arise is when a window is broken in order to gain entry to a building or vehicle. In this chapter, we will assume that a window has been broken, for illustrative purposes. However, the methodology can be used in any investigation involving broken glass, such as a “hit and run”, assault or even laboratory accidents. If a window is broken, tiny fragments of glass may be transferred to a person’s clothing, footwear and headgear. If there are suspicious circumstances, the crime scene examiner will take a sample from the broken window. This sample can be referred to as the *control sample*, the reference, the known, the source, the bulk, or the crime sample [2]. If the police arrest a suspect, clothing, footwear, and headgear may be seized to search for glass fragments (*see* **Short Tandem Repeats: Interpretation** or [3]). The clothing will be examined for fragments if the case preassessment indicates that useful evidence is likely to be obtained. The fragments recovered from the suspect’s

clothing or person have been referred to as *unknown*, *questioned*, *transferred*, *recovered*, or *suspect* fragments. Here, we will use the terms *recovered* and *source* fragments. We will show how the case can be preassessed (formally or not), how to sample the evidence depending on the case, how examination results can be interpreted and how the value of evidence using the two-stage and continuous approaches can be assessed.

Establishing Working Propositions and Preassessment

Suppose that a witness sees a man break a house window with some sort of tool and attempt to enter. The witness shouts and scares off the breaker before he enters the premises. Half an hour later, Mr G, who fits the witness's description, is arrested in the vicinity of the crime scene. He denies any involvement. His clothing is seized and glass from the broken window is taken. In order to preassess (and assess) the case, the expert needs to evaluate the scientific evidence given two (or more) propositions. The importance of establishing working propositions cannot be overstated: it is a very critical stage, and is probably the most difficult stage of evidence interpretation. One has to be careful to work propositions rather than explanations [4]. Three key principles help the scientist [2, 5, 6]:

1. The scientist must interpret findings in the light of the nonscientific evidence. That is why the scientist needs to know something about the *circumstances* of the alleged incident.
2. The scientist, given *two mutually exclusive* propositions, must consider the findings: here they will be denoted H_p and H_d (for propositions proposed by prosecution and defense).
3. The scientist, *given* the *proposition*, should address the probability of the *evidence*.

A classification (or *hierarchy*) of the different kinds of propositions has been proposed [6]: level 1 (source level), level 2 (activity level) and level 3 (offense level). In order for the uncapitalise Court to address questions at the offense level, assistance from the forensic scientist will be needed. He/she will, depending on the circumstances, address level 1 or level 2. Propositions for glass evidence evaluation at different levels could be the following:

Level 1

H_p : The glass recovered on the jacket of Mr G. came from the broken window.

H_d : The glass recovered on the jacket of Mr G. came from some other source.

Level 2

H_p : Mr G. is the person who broke the window.

H_d : Mr G. had nothing to do with the incident.

Level 3

H_p : Mr G. is the offender.

H_d : Mr G. had nothing to do with the incident.

An example of explanation could be:

Mr G. has been in recent contact with broken glass.

It must be remembered that in order to go from level 1 to level 3, level 2 needs to be addressed. The higher we go in the hierarchy, the higher the value, the greater the requirement for expertise and the greater the need for background information. It may be a difficult task, but we believe that the best person to address this level is the forensic glass examiner (as opposed to a scientist in general or the court).

Once the propositions have been established, the glass examiner can preassess the case either informally or formally [7]. The first option will consist of thinking about what we would expect to find if the propositions were true. For example, would we find matching and/or nonmatching glass, how many fragments would we expect given each proposition? Formal preassessment [7] using the likelihood ratio (LR) approach (see [5] or Section "Interpretation: Source Level 1") consists in assessing six different probabilities using published or subjective data, before even looking at the evidence:

1. The probability of finding no matching glass fragments if the suspect is the person who broke the window.
2. The probability of finding a few (1–2) matching glass fragments if the suspect is the person who broke the window

3. The probability of finding many (3 onwards) matching glass fragments if the suspect is the person who broke the window
4. The probability of finding no matching glass fragments if the suspect had nothing to do with the incident
5. The probability of finding a few (1–2) matching glass fragments if the suspect had nothing to do with the incident
6. The probability of finding many (3 onwards) matching glass fragments if the suspect had nothing to do with the incident.

It should be noted that all of these statements contain level 2 propositions. This is for convenience only. These probabilities are not always easy to evaluate because of the lack of information and because of the variability of the different parameters. Sensitivity analysis [5, 8] with, for example, Bayesian Networks ([9]; Section by Taroni) can be used in order to estimate the influence of the uncertainty on the available parameters. Once the propositions have been established and the case preassessed, a discussion between the forensic scientist and the person asking for the analysis should take place in order to evaluate the case and its possible contribution. It is also possible (e.g., [8]), if and only if expectations regarding the number of fragments to be found given each proposition have been made, to search the suspect items for glass and then only address two of the six probabilities above. If we recover six fragments for example, we would then preassess the case using probabilities *3* and *6*. This would give the customer more value for a little additional cost.

In conclusion, as shown by [2], preassessing the case involves collecting all relevant information, discussing the propositions, identifying the parameters necessary to evaluate the evidence, discussing the search strategy, [3] and estimating the overall value of a case.

Interpretation: Source Level 1

When addressing source level propositions, such as H_p: The glass recovered on the jacket of Mr G. came from the broken window and H_d: If the glass recovered on the jacket of Mr G. came from some other source, then one is interested in determining if the recovered and the source fragments are different (or how different or similar they are) and how common/rare the analyzed characteristics are. The analyzed characteristics can be univariate (a good example would be refractive index measurements, for information on glass analysis, see Section on or [3]) or multivariate (e.g., results of elemental analysis). The evaluation can take place in one stage (the continuous LR approach, see [3, 10]) or two stages. As presented earlier, a very useful approach to interpretation is the so-called Bayesian Approach. This approach is not new Aitken (*see* **Interpreting Expert Opinions: History of**) and has been applied in many different areas such as DNA, disputed paternity or uncapitalise Court presentation. Let E denote the evidence, H_p and H_d the propositions and I the background information we have on the case (e.g., breaking method, time elapsed ...). The odds form of Bayes theorem states:

$$\underbrace{\frac{\Pr(H_p|E,I)}{\Pr(H_d|E,I)}}_{\text{Posterior odds}} = \underbrace{\frac{\Pr(E|H_p,I)}{\Pr(E|H_d,I)}}_{\text{Likelihood ratio}} \times \underbrace{\frac{\Pr(H_p|I)}{\Pr(H_d|I)}}_{\text{Prior odds}} \quad (1)$$

The odds form of Bayes theorem lends itself to a very simple method for updating prior belief: we may rewrite (1) as

$$\text{Posterior odds} = \text{likelihood ratio} \times \text{prior odds} \quad (2)$$

This formulation is convenient because it separates the probabilities relating to the evidence from those relating to the propositions. As mentioned earlier, the former usually concerns the forensic scientist and the latter the court. The LR approach can be applied at the comparison stage [10, 11] or after comparison. The continuous LR approach is more complex but more efficient than the two-stage approach. However, it is useful to begin with the two-stage approach [12] in order to understand the LR thinking.

The Two-Stage Approach

Let's take our example where a window was broken, and say that, after case preassessment, the decision was made to search for glass on Mr G's jacket and that six fragments were recovered. The refractive indices (RIs) of each of those six fragments were measured, as well as the RIs for a selection of fragments from the window broken at the crime scene.

Interpretation Based on Refractive Index Measurements. The first stage of the two-stage

approach consists in determining if the measurements made on the two samples are statistically different or not. Not surprisingly, early statistical interpretations of glass refractive index measurements used formal hypothesis tests for the difference of two population means [13, 14]. Before that, glass experts either used graphical displays of their results, range tests or the so-called 2 or 3 sigma, or standard deviation (SD) tests. An example of those tests with real measurements is given below: it is shown here and it has been shown before that the performance of these tests is poor compared to other methods. These methods have been superseded. A traditional statistical test for the difference in two population means with unknown variances is Student's t-test. Evett [13, 14] proposed the use of Student's t-test for comparing the mean RIs of the recovered and source samples. Walsh *et al.* [15] suggested that Welch's modification of Student's t-test was perhaps more appropriate as it allows the unequal variances in the two populations. This relaxation is quite useful, as it has been shown that measurements on recovered fragments present an SD larger (often 50% larger) than measurements made on a large sample of a window [3]. Both tests require measurements to be grouped before testing. Several grouping algorithms have been presented (divisive and agglomerative grouping methods, [3]). The divisive methods [16] out-performs agglomerative methods [17]. However, the main point is not so much *how* refractive index measurements are grouped but *that* they are grouped at all.

Once, the RI measurements of the recovered fragments have been grouped and the significance level chosen, one can proceed with the test. Let us assume that as in our example, all recovered fragments are grouped and that there has been only one window broken (one source only). If the fragments do not match, then the LR at source level is 0 (this is precisely one of the limitations of the two-stage approach!). If the fragments match, the LR is as follows:

$$\text{LR source level} : \frac{1}{f} \tag{3}$$

The forensic scientist will then estimate the frequency f (which could also be called *match probability*) of the analyzed characteristics. It goes without saying that the frequency must be estimated using the same procedure that was used for comparison.

Table 1 RI Measurements from casework (Courtesy of the Forensic Science Service, FSS London Laboratory Glass Workshop, January 2003)

Hat	Jacket	Window
1.51827	1.51826	1.51828
1.51826	1.51821	1.51828
1.51820	1.51826	1.51826
1.51827	1.51827	1.51827
1.51824	1.51819	1.51825
1.51826	1.51824	1.51826
		1.51827

Example : Comparing RI Measurements. As an example we will take casework data shown in Table 1 (Courtesy of the Forensic Science Service, *FSS London Laboratory Glass Workshop, January 2003*) from fragments recovered on a jacket and on a hat. We will not present the range test and the 3SD test as these have serious limitations and flaws.

If the fragments on each garment are grouped together and then compared using the t-test or the Welch test, the P-values using Student's t-test are respectively 0.14 and 0.04 for the hat and the jacket. With the Welch test, the P-values are 0.19 and 0.07. If our significance level is 0.01, then we would fail to reject the null-hypothesis using either test. That is we would say that we were unable to determine any significant difference between these samples on the basis of their means and that the observed differences can be explained by random measurement error alone. Therefore using the Student's t-test or the Welch test, the samples are not differentiated. To estimate the frequency of occurrence, the expert will then search the relevant database with the same tests that were used for comparing the data. Examples and formulae for this procedure can easily be found (e.g., in [3]). The means, SD and critical value of the Student's t-distribution (using Welch's formula for the degrees of freedom) are used along the appropriate-formula (e.g., in [3], p.151) to give a "match window", which can then be used to determine the frequency. In our example case, using a significance level of 0.99, gives us a match window from 1.51821 to 1.51829. Using this window with the Lambert *et al.* survey [18], yields a frequency of 2%. The corresponding LR would be 50.

Interpretation Based on Elemental Analysis Measurements. Researches have found that elemental

analysis enables to differentiate glasses with a similar RI (see Section on Trace Evidence). Traditional treatment of the data involves determining the mean concentration and the SD for each element. The 3 sigma rule can then be used to determine if the fragments match or not. If any of the range fails to overlap, the fragments are considered not to match. This approach suffers from two problems: the multiple comparison problem (approximately the false rejection rate of 0.1% is multiplied by the number of elements tested, so for 10 elements the false rejection rate would not be 0.1% but 9.6%, [3]) and the fact that this rule fails to take into account any estimated correlation between the elements. As a solution, a multivariate analog to Student's t-test – Hotelling's T^2 – has been suggested [3, 19] and is highly recommended. Hotelling's T^2 may be used on its own as a hypothesis test, or combined into a continuous LR approach. Aitken [20] proposed a formulation based on kernel density estimation. One advantage of Aitken's approach is that it drops the (untestable) assumption of multivariate normality (MVN) of the elemental concentration means. This advantage is perhaps more psychological than practical. The assumption of MVN is actually guaranteed by the Central Limit Theorem. However, Aitken and Lucy [21] and Aitken *et al.* [22, 23] proposed an aesthetically appealing way of looking at the evaluation of trace evidence. They take a "variance components" (or random effects if you are Bayesian) approach to the treatment of the measurements. Aitken *et al.* explicitly model three sources of variation. The first source of variation is the variation that arises from the measurement process. For example, if you buy a digital thermometer or set of scales, you'll usually find in the accompanying documentation a statement like, "this device is accurate to $\pm 2\,^{\circ}\mathrm{C}$ or $\pm 0.5\,\mathrm{g}$". This variation is purely an artifact of the measurement device. The second source of variation is the variation that is inherent in the item itself. For example, if we are interested in the measurement of the concentration of calcium in a piece of glass, we might regard it as being homogenous throughout. This does not mean however, that if I measure the concentration at two different sites on the glass I will get exactly the same concentration (ignoring measurement error). What it means is that the concentration varies uniformly throughout the piece of glass. By explicitly modeling this we attempt to understand the natural variation within the same source. Finally, the third source of variation is the variation that arises between items from different sources. This variation is the one that forensic scientists naturally focus on. The Bayesian approach also focuses on the first and second sources (either separately or together). Aitken *et al.* provide software for the computation of their statistic, as does Curran *et al.* It is probably safe to say that the statistics for elemental concentration caseworks are underdeveloped and could withstand substantial improvement (*see* **Glass**).

Disadvantages of the Two-stage Approach. The two-stage approach suffers from several drawbacks: first it assumes that if the fragments come from the broken window, then they would match with probability 1. There is however a possibility that certain fragments would not match the crime scene sample, for example because of the float manufacturing process or/and sampling procedures [15]. Another disadvantage of the two-stage approach is the significance test and the so-called fall-off-the cliff effect (label given by Ken Smalldon). If we imagine a situation where the P-value is 0.009, the samples would be declared to not match. However, if the P-value changed by $0.002-0.011$, then the samples would be declared to match. Such a reversal would be difficult to justify to the court, and would certainly trouble the forensic scientist if multiple matching fragments, with a rare RI close to the window, had been recovered in that case. Hypothesis testing fails to incorporate relevant evidence such as the relative frequency of the glass and the number of glass fragments that have been recovered.

The Continuous Approach

Abandoning a match/not match approach [10] is one of the greatest advances in interpretation. It enables to give a different value to a good match (close) and a "poor" match, there is no fall-off-the cliff effect, and it allows the scientist to weigh all the evidence in one process rather than in a step-by-step fashion. Moreover, it is less prone to be influenced by departures from normality [Bennett *et al.* [24], [1]] than significance testing is. The approach is described in several books (e.g., [1, 2]) and has been applied to different evidence type (e.g., inks, speaker recognition, fingerprints). To distinguish the LR applied for the assessment of evidence and for assessing the value of a comparison, we will use

LR for the global assessment of glass evidence and lr continuous for the assessment of the value of a comparison.

Interpretation Based on Refractive Index Measurements. In 1996, a case was presented [15] where a pharmacy window was broken. Fragments recovered on two suspects were compared to the broken window based on refractive index measurements followed by a t-test. According to the test, the samples did not match. There were however contradictory elements: a lot of glass fragments (rare event), some coming from a float surface (rare event), were recovered from the suspects' clothing. The refractive index measurements of the glasses were close. And, paint flakes, indistinguishable from the crime scene window frame had also been found on one of the suspects. Thus, despite the results of the t-test, the evidence supported the proposition that the suspects were at the crime scene when the window was broken. It was therefore suggested to replace the match/non match approach with a continuous likelihood based scale. This involves replacing $1/f$ with

$$lr_{\text{cont}} = \frac{f(\bar{X} - \bar{Y}|S_X, S_Y)}{\hat{g}(\bar{Y})} \tag{4}$$

where $\hat{g}(\bar{Y})$ is the probability density for float glass measured at the mean of the recovered sample. This value is usually obtained from a kernel density estimate. $f(\bar{X} - \bar{Y}|S_X, S_Y)$ is the value of the probability density for the difference of the two sample means. This is approximated by an unscaled t-distribution using Welch's modification to Student's t-test. Aitken [20] also showed that the assumption of normality could be dropped and the numerator of the LR could be replaced by a univariate kernel density estimate.

Interpretation Based on Elemental Analysis Measurements. When glass evidence is quantified by elemental composition, an analogous equation proposed by Curran [3, 19, 25] can be used. As previously noted, Aitken *et al.* [21, 23] (200x) have a treatment based on kernel density estimation.

Interpretation: Activity Level 2

When addressing activity level propositions, important forensic parameters such as the number of glass fragments, where they have been recovered (e.g., hair, garments, shoes), and the method of breaking are taken into account. As mentioned earlier, we think that the expert should always try to address activity level propositions: the higher in the hierarchy the greater the value added by the evidence. And for the Court to address the offense level, these parameters have to be taken into account and who is the best person to evaluate these parameters, if it is not the forensic scientist?

Example: One Group, One Control

Consider a case where the fragments have been grouped and where one window has been broken. When preassessing the case the following propositions have been chosen:
H_{p} : Mr G. is the person who broke the window.
H_{d} : Mr G. had nothing to do with the incident.
To evaluate the evidence E, two questions have to be answered:

> *What is the probability of the evidence given that the prosecution proposition is correct and given the background information.* (background information is a key element, if information changes, probabilities have to be reassessed, (*see* **Evidence Interpretation: a Logical Approach**).

And

> *What is the probability of the evidence given that the defense proposition is correct and given the background information.*

These two probabilities form the numerator and denominator of the LR.

$$LR = \frac{\Pr(E|H_{\text{p}}, I)}{\Pr(E|H_{\text{d}}, I)} \tag{5}$$

If we consider the denominator first, the question, in more detail, is:

> *What is the probability that one would find a single group of m matching fragments on the surface of the fleece jacket if Mr G. has not broken the window at the scene, given what is known about the incident and the suspect.*

As mentioned earlier, the information that we have on the suspect's activities is provisional and may change. Regardless of what we know about Mr G, it is inarguable that he has come to the attention

of the police in connection with a breaking offense. Casework clothing surveys (see below) are surveys of people who have also come to police notice in that way. Thus, it is believed that this is the most relevant survey in this case. If Mr G had said that he worked on a demolition center, then the most relevant survey would have been surveys done on persons working on demolition centers. But, in this particular case, he has given no explanation. If, using this information, we rephrase our question it becomes:

> *If we examine the fleece jacket of a man who has come to police's notice on suspicion of a breaking offence, yet he is unconnected with the offense, what is the probability that one would find a single group of m fragments which matches the control in that particular case?*

Casework clothing surveys distinguish between groups of glass that match the casework crime scene samples and those that do not. If we assume that the matching glass did come from the incident investigated, then the nonmatching glass can be considered as the background.

Let $b_{g,m}$ be the probability of g groups of size $(m_1, \ldots, m_g) = m$ being found. (In the literature, the terms P_i and S_j have been used to denote the probabilities relating to the number of groups P and the size S of the groups. This is equivalent to the one term $b_{g,m}$). Let f denote the probability that a group of glass fragments on the surface of such a person's clothing will match in RI the window in this particular case (lr continuous will be used instead of f if using the continuous lr to assess the value of a comparison). We make two assumptions:

> *A1: There is no association between the number of groups of glass found on a person's clothing and the size of these groups and*
> *A2: There is no association between the frequency of a given RI on clothing with either the number or the size of the group.*

It is unlikely that either of these assumptions is exactly true, but it is believed that they are correct at least as any first order approximation [3]. By invoking these two assumptions, we can estimate the denominator and answer our question *what is the probability that one would find a single group of m fragments which matches the control in that particular case on a person unconnected with the crime?*

$$\Pr(E|H_{\mathrm{d}}, I) = b(1, m) \cdot f$$

or if using the continuous lr

$$\Pr(E|H_{\mathrm{d}}, I) = b(1, m) \cdot lr_{\mathrm{cont}} \quad (6)$$

Estimating the numerator is slightly more complex as we have to allow for at least two possible explanations (actually, there are $m + 1$ explanations, see [3]) for the evidence given H_{p}.

1. Either, the group of fragments was transferred from the scene window, and Mr G had no glass beforehand.
2. Or no glass was transferred from the window and/or recovered, but Mr G had already one group of glass on his fleece.

If we invoke the assumptions A1 and A2, and let t_m denote the probability that given H_{p} and I, m glass fragments would be recovered on Mr G's fleece, then the denominator is:

$$\Pr(E|H_{\mathrm{p}}, I) = t_0 \cdot b(1, m) \cdot f + t_m \cdot b(0) \quad (7)$$

Now that we've defined the numerator and denominator terms, we can calculate the LR:

$$LR = \frac{\Pr(E|H_{\mathrm{p}}, I)}{\Pr(E|H_{\mathrm{d}}, I)} = t_0 + \frac{b(0) \cdot t_m}{b(1, m) \cdot f} \quad (8)$$

If we are using the continuous approach to glass comparison then this becomes

$$LR = t_0 + \frac{b(0) \cdot t_m}{b(1, m)} \cdot lr_{\mathrm{cont}} \quad (9)$$

There are infinite variations around this scenario [2, 3], however this example shows how probabilities can help the forensic scientist to assess the value of glass. This framework allows taking into account all factors that are intuitively important.

Estimation of Background and Transfer Probabilities

To assess the value of glass evidence at activity level, in addition to the lr continuous (or f), the expert has to estimate background and transfer probabilities. Clothing surveys enable the estimation of the former. Two types of clothing surveys have been performed: some on general population [26–31], and some on suspects [8, 18, 31]. Depending on the case and on the defense proposition, the expert will use one or the other. For example, when the suspect does not

have any explanation for the presence of glass on his/her clothing, the surveys on suspects' clothing will be used. If the recovered glass has been found on a victim, then general clothing surveys may be more relevant. Surveys have shown that more glass is recovered as background on persons suspected of breaking offenses, than on general population. When, choosing the relevant survey, it is important to consider the population of interest, as well as where and how the fragments have been searched for and on which garment. For instance, if the fragments have been recovered from the pockets of a person who is the victim of a crime, then a survey of a general population (e.g., [26]) where the scientists looked for fragments on pockets and turn-ups should be used. If the fragments were recovered from the outer surfaces of the clothing of a suspect, then surveys on suspect populations (e.g., from casework) ought to be used [8, 18, 31]. There are also surveys which looked at the question of background glass on shoes [32], Harrison *et al.* [33], [30] or in hair [34]. Curran *et al.* [3] have a comprehensive chapter on background surveys which includes all of the references here except for [31]. This latter study is a combination of survey data and extensive modeling of the $b_{(g,m)}$ terms and should be regarded as an important contribution to this subject. "Transfer probabilities" incorporate three distinct processes: the initial transfer, persistence and recovery. It has been argued that they depend on too many factors and are too difficult to estimate. Whereas it is true that transfer is a variable phenomenon, it remains essential to estimate transfer probabilities and a lot of research has been dedicated to fill in the gaps in our knowledge (for a review, see [3]). Experiments have been performed on glass transferred onto the ground in order to identify the parameters involved in initial transfer [35–40]. Researchers have studied transfer [38, 39] and persistence of glass recovered on garments [28, 41–47]. And last, but not least, because of the modular nature of transfer and persistence, graphical models (a superclass of Bayes Nets) have been suggested as a tool for the estimation of transfer probabilities [48]. As transfer is a variable phenomenon, we suggest that before searching the garments (when preassessing the case), the forensic scientist estimates a range of transfer probabilities. This will allow him/her to perform sensitivity analysis and show how uncertainty on transfer probabilities influences the overall value of glass evidence in that particular case.

Concluding Remarks

Many of the statistical techniques presented here are very difficult to implement without the aid of computer software. Commercial and noncommercial packages exist: some allow the estimation of transfer probabilities (TRANSFER), others measurement comparisons using a two-stage and/or a continuous approach (statistical analysis of glass (STAG) and fragment data system (FDS) allows grouping and comparing RI data, ELEMENTAL allows to compare data from elemental analysis). The computer aided glass evaluation (CAGE, CAGE2000) software allows the expert to assess glass evidence as a whole. It provides an interactive guide to estimate transfer and background probabilities by storing experimental and survey data (*see* **Use of Knowledge-Based Systems in Forensic Science**). The UK Forensic Science Service is considered as a pioneer in this field and is at the origin of FDS and CAGE. However, recently most products have been developed during PhD researches ([25], TRANSFER, STAG, ELEMENTAL; [8], CAGE2000).

In conclusion, we would like to say that there are very few alternative approaches to glass interpretation and that even if the LR approach is not a panacea, it provides a very good framework. It could be argued that because glass characteristics change a lot, then one should not attempt to estimate its frequency of occurrence. The same argument has been applied to transfer or background probabilities because they are hard to estimate. Proponents of such arguments believe that the solution is to analyze the glass with more discriminating techniques so that the glass would become "unique". However, we do not believe that such considerations will answer the Court's question. Assessing the strength of the match at source level is only one part of the process. As we have seen it is essential to address questions relative to activity level. Statistical tools enable us to deal with the uncertainty inherent in these questions and those uncertainties will remain regardless of whether we can determine a "match" between two samples of glass with 100% accuracy.

GSM Analysis and PDAs

General Introduction to Cellular Phone Networks

Cellular Phone Network Global Architecture

Cellular phone networks (*see* **Analysis: Computer Network**) may be based on various technologies and standards, but they all share a common philosophy: to allow users to have wireless phone calls (and advanced services) while being able to move on wide distances without being disconnected.

Cellular phone networks are wide: they may extend over a country or even over several continents. They rely on both an air interface (radio link between cellular phone and a base station) and a terrestrial interface (edge and core network equipment). Area covered by a single radio base station is called a *cell*, hence the name "cellular network/cellular phone". Cell shape and cell area vary depending on emitted radio signal strength, air condition (rain, snow, etc.), physical obstacles (such as hills, forests, and buildings), wave-reflecting or wave-absorbing surfaces, (lake, clouds, etc.), and various other factors. Distance between a cellular phone and its radio base station may extend up to several dozen kilometers.

"Handover" is the ability for a cellular phone to switch from one radio base station to the next radio base station[a] without being disconnected from the network. "Roaming" is the ability for a cellular phone to use different cellular networks (e.g., when traveling abroad).

Other Radio Communication Networks

Cellular phones should not be confused with plain cordless phones (such as digital enhanced cordless telecommunications (DECTs) phones). The latter may be considered only as cordless extension to wired phones (such as public switched telephone network (PSTN) phones). They allow users to have wireless phone calls only in a geographically limited environment (e.g., within a building, at home, or at the office), though distances can go up several hundred meters thanks to additional "relays". Coarsely compared to Internet Protocol (IP) networks, cellular phone networks may be considered autonomous system (AS)[b] within the Internet, while cordless phones may be considered part of a (wireless) local area network (W)LAN.

Cellular phone networks shall neither be confused with terrestrial trunked radio TETRA[c] networks (radio terminals such as walkie-talkies used in professional emergency networks such as police forces, fire brigades, etc.) nor with satellite phone networks (where terminal connects to a satellite constellation – such as Iridium, Inmarsat, or Globalstar – *via* the air). Note, though, that satellite phone handsets may share similarities with cellular phone handsets (functions and services, potential use of a chip card to connect to the network, etc.).

Cellular Phone Network Technologies

In order to allow several users accessing the network from the same place at the same time, cellular phone networks must use radio resource-sharing technologies. Main technologies used are TDMA (time division multiple access), FDMA (frequency division multiple access), CDMA (code division multiple access), or combinations of these.

- In TDMA, each user is given a time-slot.
- In FDMA, each user is given a frequency spectrum portion.
- In CDMA, each user is given a code.

This article does not intend to give further details, so interested readers may look for books on radio technology.

Cellular phone networks shall convey voice, data, and signals. Voice and data are both user defined, and user data might be anything from text messages to pictures. Signaling is nonuser-defined data (technical data/service data) that is required to establish a communication channel between user A and user B. Note, though, that user data (such as short message service (SMS)) may be conveyed in signaling channels.

Since user data may also be website-browsed content, streamed videos, or streamed television, it may not be (strictly speaking) user defined, but rather user dependant.

On a historical perspective, cellular phone networks are commonly classified into three categories:

- 1G (first generation): first generation cellular phone networks were based on analog standards (such as Nippon Telegraph and Telephones (NTT) in Japan; Nordic Mobile Telephones (NMT), C-Netz, Radiocom 2000, and Total Access Communication System (TACS) in Europe; Advanced Mobile Phone System (AMPS) in the United States, etc.). Nowadays, they have almost completely disappeared, even though some operators have not yet discontinued their service.
- 2G (second generation): second generation cellular phone networks shifted to digital standards (such as personal digital cellular (PDC) in Japan; Interim Standard-95 (IS-95) in South Korea and in the United States; Global System for Mobile (GSM) in Europe; Digital Advanced Mobile Phone System (D-AMPS) and Integrated Digital-Enhanced Network (iDEN) in the United States, etc.).
- 3G (third generation): third generation cellular phone networks are supposed to offer higher data rates and enhanced compatibility, along with multimedia services. Freedom of mobile multimedia access (FOMA) (in Japan), CDMA2000 (such as in the United States) and Universal Mobile Telecommunication System (UMTS) (such as in Europe) are all compliant with the International Mobile Telecommunications-2000 (IMT-2000) standard issued by International Telecommunication Union ITU.

Some intermediate technology networks (such as general packet radio service (GPRS)) are commonly referred to as *2.5G networks*, since they offer extended capacities compared to 2G networks, while not fully complying with 3G standards. Future "full-IP" networks, which would be even more

Internet-linked and with enhanced roaming capabilities, are commonly referred to as *4G networks*, though no standard has yet been defined.

Compatibility between the aforementioned standards (PDC, IS-95, GSM, iDEN, D-AMPS, FOMA, CDMA2000, UMTS, etc.,) varies and depends upon several factors (among which are frequency used, need for a subscriber identity module (SIM) card, etc.). This article does not intend to give a full compatibility chart to cellular phone users traveling abroad.

The following points may be noted:

- In spite of common beliefs, a user has no need for a 2.5G or 3G network to be able to send data (such as binary data) through a cellular phone network: "GSM-data" subscription (e.g.), based on circuit switched data (CSD) technology, may be sufficient. Bank card counterfeiting based on skimming sometimes uses "GSM-data" subscription to send card numbers abroad.
- Wireless data protocols such as I-mode or Wireless Application Protocol (WAP) should not be considered on the same level as 1G/2G/2.5G/3G/4G technologies: they only allow web-content presentation on cellular phones; they do not define any underlying (physical) transportation technology.

Mobile Phone Handset Architecture

Some handset manufacturers have a worldwide market share (such as Nokia, Sony Ericsson, Samsung), while others cover a narrower geographical area (such as Alcatel and Sagem – mainly in France, Siemens – mainly in Germany, Motorola – mainly in Northern America).

Hardware Architecture

Hardware architecture may be divided into three parts: handset itself, data storage memory card, (optional), and SIM card (depending on network technology).

Much like many other mobile devices, a handset may be considered a small-size computer. It is composed of a motherboard with a processor, random access memory (RAM), mass memory storage device (MMSD), power source, and additional modules, all interconnected through a bus and packaged in a case. The case bears the keyboard, screen, and connectors (power, data storage memory card, etc.).

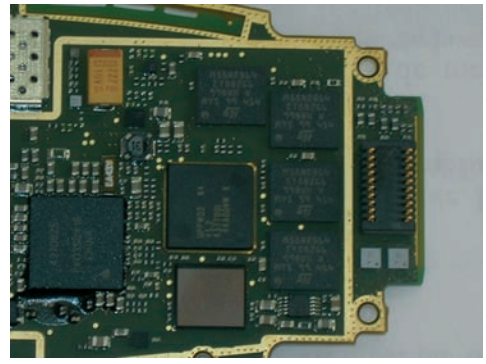

Figure 1 Nokia mobile phone embedding four flash memories

Mass storage generally relies on Flash memory (either NAND or NOR). There may be one single Flash component or several of them (up to four on some Nokia phones, for example (Figure 1)). Some handsets embed both NAND Flash and NOR Flash: in such cases, NOR Flash is used to store firmware (because it allows execute in place), and NAND Flash is used to store user data (because more read/write cycles are possible). On the most recent handset models, Flash memory is sometimes replaced by 1-in. microsize hard-disk drive (Hitachi and Cornice[d] are major manufacturers of such microdrives).

Power is supplied by main the battery, which is removable and rechargeable. Without such main battery, handset cannot be powered on without any external power supply (e.g., cable and plug). Many modern handsets also use an additional microsize button battery, used to avoid date and time setting erasure when main battery is removed (Figure 2).

On modern handsets, the antenna (and the whole radio module) is embedded in motherboard and cannot be disconnected easily.

Apart from the GSM connectivity module, additional modules are optional. Most of the time, they consist of optics (digital still camera or video camera) (*see* **Image Processing and Analysis**) or they offer extra wireless capabilities, such as infrared data association (IrDA) or Bluetooth; some handsets even have WiFi capabilities (Institute of Electrical and Electronics Engineers (IEEE) 802.11 standard), such as Nokia

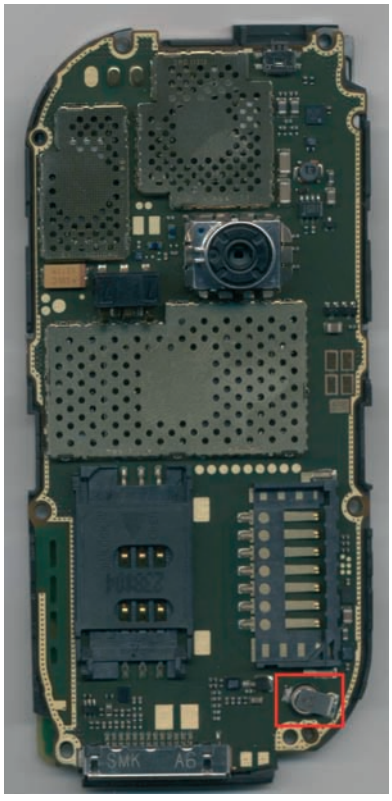

Figure 2 Additional microsize button-battery on a Nokia 7610 mobile phone

6136, which can be used along with a "Unik subscription" from the French operator Orange, to switch seamlessly from a voice over Internet protocol (VoIP) phone call through a WiFi access point to a GSM network. Global positioning system (GPS) may also be found (such as on Pharos handsets, or on some Hewlett Packard iPAQ models).

Data storage memory card is optional, though quite common. Card format may be virtually anything existing on the market (dozens of different format exist). Nevertheless, most common formats are Multi Media Card (MMC) (MMC and MMC micro), Secure Digital (SD), (SD, miniSD, and microSD) and Memory Stick (MS) (MS and MSmicro/M2), because microsize versions of these formats exist, which fit well the mobility and light-weight requirements. Such memory cards rely on Flash memory.

One interesting feature of the MMC system specifications is password protection: using the CMD42 LOCK_UNLOCK command, one can totally prevent MMC card access (either writing or reading). Since SD derives from MMC and is supposed to partially comply with MMC system specification, some SD cards also support password protection. Password protection on MMC and SD, though, is largely vendor dependent and remains quite rare in the mobile phone world. At the time of writing, it seems that Symbian S60 phones supported memory card password protection, as well as Windows Mobile 5.0 (or higher) phones embedding BSquare SDIO Now 2.0, or higher application.

According to various fora,[e] it seems that the following phones would support memory card password protection at the time of writing: Nokia N71/73/75/80/93, Nokia 6230/6230i/6233/6265i/6270/6275/6280/6600/6670/7373/7610/9210i/9300, Nokia E-series, Motorola A780, and Motorola ROKR E6.

SIM chip card comes from GSM standard. Its role is to authenticate the user on the network so as to check his/her credentials (using Ki cryptographic key), and to provide Kc cryptographic key to allow voice encryption over air interface. One single SIM card may be used in different handsets by same user, so that one does not have to shift telecommunication operator subscription when shifting handset (and vice versa). When no SIM card is used (as in PDC networks in Japan), users have to buy a new handset when swapping telecommunication operators.

SIM cards have data storage capacities, but those are mostly standardized: user with no technical knowledge can only store specified sets of data (such as text messages, address book, etc. see section "In Mobile Phone Handset"). Storage size is rapidly increasing.

Some SIM cards look like one single physical chip card, whereas they actually embed several SIM card data (including several sets of cryptographic keys). A legacy application for such SIM cards is to allow using one single SIM card with both a personal phone number and a corporate phone number (with separate billing), or to have a two-in-one SIM card for domestic use and roaming use. SIM Max[f] software can be used to "build" such "multi SIM" cards, if not proposed off-the-shelf by telecommunication operator (such as Tele2 in the Netherlands, or the Tunisiana "switch service"[g] in Tunisia).

Mass-storage SIM cards have been created recently: a memory card and a SIM card incorporated into a single case. Addressed via MMC or SD protocol,

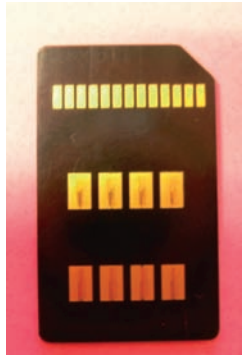

Figure 3 Orange SIM+card

the card behaves like an MMC/SD memory card; addressed via ISO7816 interface, the card behaves like a SIM card. A compatible phone is needed to fully support both features. Examples of such cards are "multimedia SIM" (jointly produced by Gemalto, Oberthur Card Systems, and Sagem Orga), "SIM+" (by Orange) (Figure 3), "MegaSIM" (by Msystems), "S-SIM" (by Samsung).

Software Architecture

As with any other "active device" (either mobile or not), a cellular phone handset has an operating system (OS), often called *firmware*. Data (either OS or user data) is stored as files according to a file system, which may or may not be OS-specific.

Various OS exist in the mobile phone market as follows:

- Created jointly by Nokia, Motorola, and other manufacturers, Symbian OS now equips most Nokia, Sony Ericsson, Motorola, Panasonic, Sharp, Siemens, LG, and other phones. Symbian OS supports FAT32, as well as other file systems.
- Microsoft Windows CE shall not be confused with Microsoft Windows Mobile (which is a platform including Windows CE OS and many applications). Companies such as HTC, Hewlett-Packard, and Acer produce Windows CE mobile phones. There was no dedicated file system initially (user data was stored in RAM), before the Persistent Storage file system was introduced in 2002.
- Linux-based mobile phones abound, even in major manufacturer catalogues: Motorola (e.g., A-series), Samsung (e.g., SGH-i858), NEC, and Panasonic all produce several Linux mobile phones. Trolltech Qtopia Linux stack for mobile devices is worth mentioning. Interested readers may refer to www.linuxdevices.com. Examples of file systems are Yet Another Flash File System (YAFFS), Journalized Flash File System (JFFS2), Samsung Robust File System (RFS), etc.
- Palm OS history is quite difficult to follow and may cross the Linux one. Handspring/Palm (Treo and Tungsten), Sony (Clié), Kyocera, and Samsung have all produced Palm OS mobile phones. There was no dedicated file system initially (user data was stored in RAM), before Nonvolatile File System (NVFS) was introduced in version 5.4 of the OS.
- Nucleus RTOS is used in various Motorola, Samsung, LG, Nec, etc. mobile phones. Nucleus RTOS supports FAT file systems.
- Research In Motion (RIM) OS has become very popular with Blackberry phones. RIM OS file system is proprietary.
- Mac OS X has been introduced in the phone market since mid-2007 with Apple iPhone.

As opposed to hard disk drives, where sector 0 always remains sector 0,[h] data stored in Flash memory follow a two-level structure as follows:

- "Upper level" is logical: this is the file system. It may be FAT, FAT-like (e.g., transactional file system (TFS4) on some Samsung mobile phones) or any other file system (see above), documented or not.
- "Lower level" is physical: this is the (electronic) block organization. By designing, each block has a limited read/write cycle lifetime. As a consequence, frequently used data tend to speed up their storage block aging. This led Flash manufacturers to imagine block-supervision features. Block supervision often means bad block management and wear leveling: when a block is more used than others, the Flash controller flags it as "used" and moves data to another block to force the used block "to have a rest"; when other blocks have filled their "age delay", the used block is flagged back to "normal", which means data may be stored there again. When a block is definitely overused, it is flagged as "bad" and it cannot be

reused anymore, and data is moved to another block to avoid loss.

Briefly, (logical) sector 0 may not always be stored on (physical) block 0. It may be stored on block 123 at time t_1, then on block 456 at time t_2, then again on block 123 at time t_3, then on block 789 at time t_4, and so on, though OS does not see any of these modifications and always address sector 0.

A Flash Translation Layer (FTL) is needed to operate such block shifts without interfering with file system. FTL is manufacturer dependent and may or may not be documented; Samsung XSR (eXtended Sector Remapper) is a well-documented FTL.

Where and How to Find Data?

In Mobile Phone Handset

As hinted in section "Hardware Architecture", useful data may be found in several locations: in mobile phone handset embedded Flash memory, in additional Flash memory removable card and in SIM card (when applicable).

In SIM Card. GSM standard defines hundreds of specifications for the SIM card. Shortly said, data is stored on SIM card according to files ("elementary file" – EF) and directories ("dedicated file" – DF). Each of these has read/write access rights[i]. Almost all investigation-interesting data on SIM card is read-protected through a code:

- PIN (personal identifying number) may be considered first-level code; after three failed PIN attempts, SIM card is locked, and PIN unlocking key (PUK) is needed.
  (GSM standards allows for several PIN codes (e.g.: PIN1 and PIN2), though "additional" PIN codes (e.g., PIN2) are seldom used.)
- PUK may be considered "master code"; after 10 failed PUK attempts, SIM card is totally "frozen". (As for PIN, GSM standard allows for several PUK codes (e.g, PUK1 and PUK2), directly linked to the PIN codes (e.g., PIN1 and PIN2); since "additional" PIN codes (e.g., PIN2) are rarely used, so are "additional" PUK codes (e.g., PUK2).)

Critical data, such as cryptographic keys or International Mobile Equipment Identity (IMSI) number cannot be read or modified without additional privileges: an administrator code is required.

Without knowledge of any code, it is still possible to retrieve data, though Integrated Circuit Card Identifier ICCID might be the only piece of data really interesting (printed ICCID may also be read on SIM card plastic media, though some telecommunication operators will print a number slightly different from ICCID[j]). ICCID is standardized and gives indication about mobile phone operator. Depending on local jurisdiction, mobile phone operator may be required to release PUK code to investigators, allowing further SIM card analysis.

Among standardized files, the most interesting ones are the following:

- address book: name, phone number, and additional info (such as email) in "extensions"
- call registry
- SMS messages: sent SMS and received SMS. Erased SMS may often be retrieved, since they are most of the time only "flagged as erased". Many types of SMS messages exist, including acknowledgement of receipt, multisegmented SMS, Enhanced Messaging Service (EMS), etc.
- Geographical information, such as the last location area code (LAC) used, forbidden Public Land Mobile Network (PLMN), last broadcast control Channel BCCH used. Note, though, that some mobile network operators have SIM cards with prestored PLMN (in France in 2004, some Orange SIM cards had a Hungarian network and a Thaï network as prewritten Forbidden PLMN).
- According to GSM standard, a UMTS SIM card (USIM card) is able to store MMS messages; at the time of writing, no real case had been found with MMS on SIM card.

Nonstandard files may also be retrieved, using the "SELECT" command and browsing through the entire hierarchical SIM card structure on a "brute-force" process. Totally mobile-network-operator dependent, such nonstandard files may be difficult to decode or to interpret; note, though, that technically aware users may hide personal data in such nonstandard zones.[k] SIMbrush[l] application claims to retrieve all files on a SIM card, including such nonstandard files.

Mass-storage SIM cards (see section "Hardware Architecture") shall follow a two-step analysis: one

using ISO7816 interface and GSM standard, one using MMC/SD protocol and computer forensics tools (*see* **Computers**).

"MultiSIM" cards remain difficult to identify and may present a risk for investigators: typing in PIN A allows access to SIM card A, giving investigators the false impression "there is nothing else to look at"; actually typing in PIN B allows access to SIM card B, typing in PIN C allows access to SIM card C, and so on.

In Additional Flash Memory Removable Card. Additional Flash memory removable cards should be analyzed through standard computer forensics process (*see* **Computers**). When password protected, MMC/SD cards might be unlocked:

- On Symbian S60 third edition and Nokia ESeries phones, using remote lock code: remote lock option locks the phone remotely with a password by sending a dedicated SMS from a third-party mobile phone, as well as it locks memory card with same password.
- On older Nokia phones, using password stored in MMCstore file on the mobile phone handset used along with memory card; such a file may be accessed through FExplorer application (see above), which may not be considered forensically sound depending on local jurisdiction. Another option is to spy data sent by the phone to the memory card using a MMC/SD bus analyzer (password is sent clear).
- Depending on the make and model, more advanced techniques might be used, such as clock attacks.

In/On Mobile Phone Handset. International Mobile Equipment Identity (IMEI) is handset serial number. Unless scratched or erased, it can be read on a sticker at the handset rear, and it can also be retrieved from user interface by typing a dedicated command (most of the time *#06# – note some handsets such as some Motorolas use different commands). IMEI may bring useful information if handset is supposed to have been stolen, and it can be used to get the list of SIM cards that were once inserted in the phone (see "IMEI/IMSI association" in section "In Cellular Network Core (telecommunication operator premises)".

Data found in handset itself ranges from address book to call registry, SMS, MMS, pictures, videos, etc. (*see* **Image Processing and Analysis**). New applications and services available on the most recent handsets, such as Internet browsing, emailing, push-to-talk (GSM handsets are used both ends as walkie-talkies), instant messaging (e.g., Yahoo Go Mobile for Symbian), peer-to-peer (P2P) applications,[m] Voice over Internet Protocol/Telephone over Internet Protocol (VoIP/ToIP) on 3G networks (e.g., Skype for Windows Mobile), etc., may quickly broaden the range of data to be retrieved.

Classical methods to retrieve such data are connecting the phone to a computer using data cable, IrDA interface, or Bluetooth interface, and launching a synchronization application. Dozens of such tools exist: Micro Systemation. XRY, Forensic Science Service CellDek, CelleBrite UME-36 Pro Forensics, MobilEdit Forensics, Oxygen Phone Manager, DataLifter Cell Phone Analyzer, Paraben Device Seizure, Guidance Software Neutrino, Wellphone, etc. Most of them are commercial tools, with the notable exception of open-source TULP2G,[n] originally developed by the Netherlands Forensic Institute.

All these solutions require powering on handset and booting it up, which may either not be possible if handset is broken, or which may not be considered forensically sound in some jurisdictions. As explained in section "Software Architecture", bad block management and wear-leveling may rearrange physical blocks anytime when phone is on, thus modifying evidence and raising the risk of overwriting erased data. In addition, some phones have event logs: Samsung A800, for example, creates a new logfile each time the OS is booted up and turned off.

When connecting a computer to the phone, Bluetooth ID of computer may appear in phone Bluetooth device history, thus modifying evidence.

Another limitation of synchronization solutions is the need for a SIM card inserted in the phone (at least in a GSM environment): in most cases, application cannot access phone content if SIM card is not inserted and SIM card PIN/PUK typed in; reprogramming a "blank" SIM card with same IMSI and ICCID is a way around, provided one knows last IMSI used (which may not be always possible, especially when a foreigner's handset is seized: foreign telecommunication operators may not be forced to release their International Mobile Equipment Identity/International Mobile Equipment Identity (IMEI/IMSI) association logs). The latter prevents phone connecting to the network, which

would modify telecommunication operator logs and possibly modify evidence (e.g., if voice calls or SMS are received while analyzing phone); using a Faraday cage or a network jammer (depending on local jurisdiction) also prevents the phone connecting to the network.

When a handset security code is set up by user, or when multimedia directory is password-protected, synchronization solutions generally fails to retrieve data.

At the time of writing, no synchronization solution could claim fully supporting 100% of the past and present existing phones. In some cases, it is still necessary to perform a manual analysis, browsing phone menus through normal user interface.

Lastly, most of these synchronization solutions only allow "active" data retrieval (i.e., data that can still be browsed and seen through normal user interface). As for computer forensics, deleted data are generally not really deleted: they still remain physically present for some time (depending on the handset use and further data overwriting "deleted" data).

More advanced methods such as the following allow circumventing many of the limitations presented above:

- File system "explorers" (such as FExplorer[o] for Symbian 60 Series phones, totalcmd[p] with various phone file systems plugins, etc.) may allow to browse phone file system freely, even when handset security code or multimedia directory password is set up. Nevertheless, such applications are often closed-source and not commercial products, so they may not be validated in some jurisdictions.
- "Dump software" and "Flashboxes" (such as RedBox, Vygis, Alibababox, Tornado, etc.) are tools originally designed by hackers to flash handset firmware or modify handset IMEI. They also provide unlocking codes, display various codes set up by user, and allow dumping (copy) embedded Flash memory. Once dumped, Flash memory can be analyzed with an hexadecimal editor or various forensic tools: that way, it may possible to retrieve erased data, as well as IMSI lists. They are often closed-source and are not industrial products, so they may not be validated in some jurisdictions. SIM card does not have to be inserted.
- Test and maintenance Joint Test Action Group (JTAG)[q] interface may be used on some mobile phone handsets to access and dump embedded Flash memory, through specific Boundary-scan description language (BSDL) commands. A JTAG interface card has to be installed on the forensic officer computer, and a JTAG interface cable has to be connected between the computer and the mobile phone Printed Circuit Board (PCB) (provided mobile phone PCB has JTAG plots).
- Dismantling handset, desoldering Flash memory, mounting it on a component reader, dumping it, and analyzing raw hexadecimal result (see above) are probably the ultimate solution. It does not require the handset to be fully functional and it does not have the handset powered on; submerged phones, crushed phones, or burnt phones might be analyzed following this method. This may be the most forensically sound solution, but also the most expansive one and the most difficult one! Solder is either Thin small-outline packages (TSOP) or Ball grid array (BGA): in the latter case, a dedicated desoldering station is needed (either hot-air, infrared, or laser). If desoldering is not processed properly and carefully by specifically trained staff, risk of breaking or over-heating Flash memory is nonzero (thus corrupting or erasing data), and there is no guaranty that the mobile phone will function properly after resoldering.

In Cellular Network Core (Telecommunication Operator Premises)

Depending on local jurisdiction, telecommunication (*see* **Analysis: Computer Network**) network operator may be forced (by way of subpoena or court order) to disclose various logs and information they keep for technical as well as financial and legal reasons. Content of such logs and duration of preservation may vary, but they generally include the following:

- subscriber identification (identity, bank details, and subscribed options);
- telephone number portability (i.e., when subscriber has changed operator while keeping his previous phone number);
- PUK code (when SIM card PIN is unknown/undisclosed);

- extended call registry (full dialling and dialled numbers, calls timestamping and duration, and used Cell ID, IMEI/IMSI associations, etc.);
- WAP/Internet gateway logs generated at the Gateway Mobile Switching Center (GMSC) level.

Lawful interceptions are generally conducted with the assistance of the suspect's telecommunication operator, at the Mobile Switching Center (MSC) level.

In addition, some telecommunication operators provide address book and SMS directories (web)storage services to their customers.

In Mobile Phone Handset User Computer

Since many mobile phone users transfer data from mobile phone to computer, one should not forget to look for mobile-phone-related data on the suspect's computer. Dedicated software may be used to operate such transfers, so one should focus on directories created and used by such applications. Looking for phone make/model like directories may also help, as well as investigating Bluetooth-related directories (Bluetooth is often used to transfer data from phone to computer).

On Windows systems, investigating registry may help find previously computer-connected Bluetooth devices (and mobile phones in particular).

Last, analyzing potential mobile-phone-generated JPEG pictures for EXIF metadata or 3GP video files for mp4 metadata may be worth a try (*see* **Image Processing and Analysis**).

Computer forensics is not the scope of this article. Further details may be found in dedicated books (*see* **Computers**).

Other Cell-phone-Related Forensics

Other Devices with GSM Capabilities[r]

Personal digital assistants (PDAs) with GSM capabilities are sometimes called *smartphones* and categorized in a different family from "plain" mobile phone handsets.

Some laptop computers embed a Global System for Mobile/General Packet Radio Service (GSM/GPRS) module (such as Siemens MC75) along with a SIM card slot.[s] With a bit of luck, this might be a way to identify and locate a suspect stealing a laptop and using his own SIM card instead of the victim's SIM card. Laptop computers may also connect to cellular networks using a GSM/GPRS PC Card.

Last but not least, computers may access the Internet through a cell phone used as a Bluetooth or IrDA modem.

Mobile Handset Hacking

Virtually any OS or any of its modules or installed applications may one day present vulnerability, so virtually any mobile handset may once be "hacked" (*see* **Analysis: Computer Network**).

This is especially true about mobile handsets with Bluetooth capabilities. Several viruses and worms for mobile phones, either "proof of concept" or "real and wild", surfaced in the past (e.g., Cabir, "the first virus for mobile phones", could spread from phone to phone *via* Bluetooth), so that the antivirus industry now boasts dozens of antivirus applications for mobile handsets. Similar malware spreading through IrDA file sharing were also announced (e.g., Liberty and Phage for PalmOS). As of Comwarrior, it was supposed to be the first mobile phone virus spreading through MMS service. Last but not least, Mosquitos virus was described as sending premium-rate SMS (see also section "Various Other Frauds").

Bluetooth hacking, using various attacks such as BlueSnarf, BlueBug, BlueSmack, BlueSpoof, etc., may allow either illegitimate access to user data, launching AT commands on attacked device, and sending calls or SMS[t], spoofing a Bluetooth handset identifier (see also section "Spoofing") in order to connect to other Bluetooth devices in the shoes of spoofed device, or provoking a Bluetooth deny of service on attacked device. Similarly, WiFi enabled mobile handsets may be subject to WiFi attacks; it is worth noticing that various firewall applications for mobile handsets are now commercially available.

Such attacks may soon bring the famous "Trojan horse defence/Virus made me do it defence" from the computer world to the mobile phone world.

Other types of mobile phone hacking have also been reported: they all intend at least to crash the phone remotely, at best to take full control over the phone remotely.

Historically, the first published attack may be the "SMS crash attack" by Job de Haas from ITSX

company;[u] since then, Job de Haas has conducted much work on the field of mobile phone security.[v]

Wilfried Hafner from SecurStar company claimed at the Systems 2006 IT Security Area show in Munich (Germany) that he could send a "Rexspy Trojan" to a GSM phone,[w] using both SIM Toolkit Application Programming Interface (API) and Over The Air (OTA) protocol; SIM Toolkit API allows sending commands to the GSM handset, while OTA protocol allows telecommunication operators to send "user-invisible" SMS updating either SIM card or handset firmware. The "Rexspy Trojan" was supposed to let the hacker eavesdrop any voice and SMS victim's communication, as well as downloading a copy of the victim's address book. Though this undocumented demonstration raised doubts and critics, it definitely opened perspectives in the GSM security field.

Strange as it appears, "spyphones" are officially designed and sold in order to spy on the user's "physical" audio environment, as a hidden microphone would do, or to eavesdrop his communications. Hardware solutions include handsets such as Siemens S55 Premium Spy, Siemens C55 FancySpy, and Siemens M50 EconomySpy, whereas software solutions (such as Call Magic, FlexiSpy,[x] or Wireflex Soft products[y]) require a specific application being (secretly) installed on the victim's handset. Legitimate use of such solutions may range from child monitoring to phone bill checking.

Spoofing

Spoofing is the act of using a fake identifier on a network (IP address, Media Access Control (MAC) address, telephone number, etc.) (*see* **Analysis: Computer Network**).

SMS spoofing is the act of sending an SMS with a fake sender telephone number (either existing or not). Many software solutions and websites offer such services, either paid or free. Privacy protection might be a legitimate use for SMS spoofing.

IMEI spoofing is the act of permanently changing IMEI on a (stolen) mobile phone. European GSM operators have set up the Central Equipment Identify Register (CEIR) database, registering all stolen mobile phones in order to ban them on the participating European GSM networks. Whereas GSM Association recommends that IMEI should not be modified in any way by any means (it should not be modified, overwritten or shunted to another IMEI), most of the mobile phones are still vulnerable to IMEI modification, especially through the use of "Flash-boxes" (see section "In/On Mobile Phone Handset").

Caller ID spoofing is possible at least through two methods: Bluetooth hacking (see section "Mobile Handset Hacking") and GSM gateways (also called *SIM Boxes*, *Mob boxes*, etc.). GSM gateways interface cellular networks and PSTN networks and can also take advantage of (Vo)IP networks, in order to reduce costs of international and/or fixed mobile voice calls; these gateways are also used as "anonymizing proxies" (as Internet anonymizing proxies do for computers IP address when connecting to a website), either for privacy protection or for marketing purposes. GSM gateways may be illegal in some jurisdictions.

Various Other Frauds

GSM voice mailbox access and settings may be PIN-protected, but default PIN may be easy to guess (e.g., 0000 or the last four telephone number digits). Hence GSM voice mailbox "hacking" may be made easier for fraudsters. Depending on the telecommunication operator security rules, using a victim's voice mailbox PIN may allow the "phreaker" to modify the welcoming voice mailbox, as well as calling any telephone number in the world at the victim's expense (when a voice message is left, some telecommunication operators allow the user to call back a telephone number of his choice, possibly different from the caller telephone number).

Premium-rate fraud remains as popular in the mobile phone world as it has always been in the fixed world. Most famous frauds consist in sending a "luring SMS" to the victim, leading him (e.g.,) to answer by SMS, or in having his phone ring only once, leading him to call back. Premium-rate fraud may also be based on some mobile phone virus (see section "Mobile Handset Hacking").

SMS and MMS services are not free from spam. Dedicated software can easily be found on the Internet to send thousands of SMS/MMS at low costs. Telecommunication operators' web gateways generally limit the number of SMS one can send through their website.

Geographical Positioning

Geographical positioning (*see* **Analysis: Computer Network**) may either be conducted on a cooperating

mode (target GSM user knows his geographical position is tracked) or on a noncooperating mode (e.g., police trying to locate a suspect). Geographical positioning may be tracked real time (e.g., when user wants to find a restaurant, when emergency services try to find a missing person, etc.) or afterward (e.g., investigators trying to locate the place where a mobile phone call was received in a murder case, based on the Cell ID obtained in detailed call logs from the telecommunication operator) (see section "In Cellular Network Core (telecommunication operator premises").

Real-time geographical positioning is either based on Cell ID (but this may lack precision), on distance triangulation (based on GSM signaling parameters, such as timing advance or power level), or on goniometry. IMSI catchers (also called *IMSI grabbers*) may be used to locate a subscriber independently from the telecommunication operator.[z]

Afterwards geographical positioning is generally used by investigators to determine whether the suspect was really where he pretends to be when he was having a phone call. It may be based on radio coverage maps provided by the telecommunication operator, but the latter are often not precise enough (they may be estimated with simulation software without any real field checking) (Figures 4 and 5). In such cases, cell site forensics with mobile test tools (such as Sagem OT490 or GSM receiver), GPS device, and cartographic software are required.

NICOLAS DUVINAGE

Guardianships of Adults

In the United States, all adults are considered legally capable of making and carrying out decisions regarding their personal and financial affairs unless a civil court of law, usually a Probate Court, determines otherwise. In those instances, after reviewing evidence, a judge appoints a person or agency to act as the decision maker for the person with diminished capacity. That person or agency is then termed a *guardian* or a *conservator* depending on the law of the state where the appointment is made. A guardianship or conservatorship can be terminated when the person regains capacity. In reality, however, for most people, the loss of capacity is permanent and the guardianship or conservatorship exists as long as the person lives.

Who are the People in Guardianship?

Some adults with diminished capacity, such as those with developmental disabilities never had the capacity to care for themselves. Other adults lose capacity during adulthood because of a catastrophic accident or illness, mental illness, war injuries, or substance abuse. Most people who are in guardianship or conservatorship are over the age of 65. This group of Americans particularly those over 75 years of age is the most likely group to lose the capacity to take care of themselves and to handle their affairs because of physical and/or mental impairments resulting from chronic conditions associated with aging [1].

Who are the Guardians?

A wide variety of agencies and individuals serve as guardians. Most guardians are family members and indeed, laws of most states reflect a clear preference for family members to be appointed as guardians [2]. When family members cannot serve as a result of incapacity or alleged abusive behavior or if there is no family available, other people such as neighbors, friends, and long-time professional associates such as accountants or attorneys may request the court for appointment as guardian. Or, an agency or private professional guardian may petition the court for appointment.

Private Professional Guardians

In the last three decades in the United States, individuals have emerged who are setting up private practices as guardians. They are termed *private professional guardians*. Most people starting private practice as guardians already have a professional identity that is related, such as social worker, nurse, trust officer, public guardian employee, accountant, or attorney. Others would have served as guardians for family members and found the work rewarding and now want to do it for a living. People entering guardianship practice usually have well-developed people skills or well-developed financial skills. It is the rare individual who has both. In large part, this new role is unregulated except for monitoring by the court, which may or may not be possible because of scant resources. Only a few states have licensing requirements, Florida, Arizona, California, and Washington being among them. In other states, practice is unregulated and anyone may petition the court to serve as a private professional guardian, regardless of skill, knowledge, or background.

Volunteer Guardians

Some states or jurisdictions seeking to provide more guardianship services, especially for people with low incomes and no one else to help them, are turning to volunteers. Typically, volunteers provide services connected with guardianships of persons. The volunteers may be individually appointed as guardians or the sponsoring agency may be appointed. Volunteer guardians cannot function without the support of a paid staff that is knowledgeable about working with volunteers [3]. Ideally, volunteers are treated as if they are staff members. This means there is an application process that includes reference checks and criminal background checks, job descriptions with clear expectations, training and supervision, and evaluations. There also must be a policy and protocol that permits the release or "firing" of volunteers who cannot do the work appropriately.

Agencies as Guardians

Agencies also serve as guardians. The agency may be public, for-profit, or nonprofit. Nonprofit agencies are usually motivated by religious ideals, charitable intent, or the social good. They often serve people who have few, if any assets. Their funding derives from United Way, public funds, foundations, endowments, grants, fees, fundraisers, Medicaid, or funds provided by the parent organization if there is one. For-profit organizations are competitive in the market place and therefore must pay taxes on their profit. They must consider cost effectiveness and financial bottom lines. Many accept only guardianships of estate and provide no personal services [4]. Others contract with professional case managers who then provide the personal care the person in guardianship needs.

Every state has a form of public guardianship. Public guardians serve when no one else will or can. They are often the first choice when family members are in conflict and cannot agree on anything or if the person with diminished capacity is physically dangerous to his or her family but not to anyone else [5]. Public guardian agencies are typically under funded

and frequently expected by county government to support themselves with fees from the estates of the people in guardianship, often a near impossibility.

History of Guardianships in the United States

Ancient Greek and Roman documents mention what could be considered the earliest form of guardianships. Mental disabilities or what we would now term *psychiatric disorders* were the focus. Concerns centered on the assets of the person and protecting them. Protection of the person was presumed to be the responsibility of the family [6]. A similar outlook prevailed in England until the fourteenth century when the statute, "De Praerogativa Regis" (the royal prerogative) was enacted. This law recognized the duty of the King to protect his subjects who could not protect themselves [7]. The doctrine *parens patriae* is based on this law. Implementation of the law resulted in formal proceedings for both "idiots" (those who never had capacity) and "lunatics" (those who had lost capacity) during which the Lord Chancellor held inquisitions to determine if a committee should be appointed for the protection of the person and property of the adult [6]. This process was available only to people who had assets because it was expensive. The main focus was on protecting property [7].

The doctrine of *parens patriae* prevailed in Colonial America and later, the United States. Protection of the person as well as the property began to emerge as a focus. Even so, protection of property remained the stronger focus. Gradually guardianship statutes and procedures were enacted in every state providing a variety of protections and due process provisions depending on the state. Very little attention was paid to individual rights although the courts, in keeping with state law, granted guardians sweeping powers over the person and estate of the individual. The concern was to protect the impaired person from harm, not to empower the person. This emphasis began changing in the 1960s, most likely because of the sweeping civil rights movements in the United States that focused on the rights of minorities, women, those with disabilities, and elders. There is now recognition that guardianship of the person is at least as important as guardianship of the estate. Various legal groups including the American Bar Association's Commission on Law and Aging have published scholarly articles and promulgated national conferences where like-minded reformers met and developed strategies. Newspapers still frequently run articles that expose abuses in guardianships. Gradually, state laws began focusing on due process rights of the person who is the subject of a guardianship as well as closer monitoring of guardianships by courts. In addition, the concept of global incompetency has lost currency. The awareness grew (and is growing) that people who have lost capacity in one area of functioning have other areas of functioning that are not impaired and those areas should be respected and promoted. The focus now is to recognize the still existing capabilities and tailor make the guardianship to fit the individual. For instance, many people in guardianship have the ability to make a will, marry, vote, or handle a small bank account. Implementation of the changes in state laws has been uneven for many reasons: lack of financial resources for courts, stereotypes about the disabled and elderly, and inertia.

Changing Demographics

The United States, like many other countries in the world, is experiencing an unprecedented growth in the number of people over age 65. There are greater number of older people than ever before and they are living longer as a result of medical advances and healthier life styles. In 2005, people over 65 represented 12.4% of the US population. That group had increased by 9.4% since 1995. By 2030, the number of people over 65 will account for roughly 20% of the US population. Of those over 65, the group over 85 is growing the fastest and will increase by 20% between 2000 and 2010 [8]; [9]. This is the group that anecdotally is most susceptible to guardianships because of one or more chronic illnesses that have worsened and have had an impact on cognition and the ability to carry out activities of daily living.

The acknowledgment and acceptance of the existence of elder abuse and neglect, beginning in the late 1970s is also having an impact on guardianships (*see* **Elder Abuse: Policy**; **Elder Abuse: Risk**). Many guardianships are sought as a way to address an abuse or neglect situation by removing the alleged abuser or neglector from decision making for the impaired adult and to substitute a responsible person or agency. According to the best available estimates,

between 1 and 2 million Americans, age 65 or older have been injured, exploited, or otherwise mistreated by someone, usually a family member, on whom they depend for care or protection. This figure does not include those who are victimized by strangers or those who self-neglect [10]. The number of cases of elder mistreatment will most likely grow as the elder population increases, which in turn will also result in more guardianships.

Alternatives to Guardianship

Guardianship can result in the removal of constitutional rights and can be complex, time consuming, and costly. It can also result in a loss of privacy because the guardianship court file may be public in part or whole. In reality, few people ever look at a guardianship file but the potential remains. For the above reasons and because the concept of the least restrictive alternative is now imbedded in guardianship law in most states, alternatives to guardianship are important to consider. Alternatives are "various legal tools, social services, and government programs that may delay or prevent the appointment of a guardian for a person who is not capable of making decisions on his or her own behalf" [11].

None of the alternatives is exactly equal to guardianship. Each alternative has a feature(s) of guardianship and, if tailored individually and appropriately to the individual, may delay guardianship or eliminate the need for it completely. Each has advantages and disadvantages just as guardianships do. One alternative may be appropriate at one stage of an illness and another more appropriate at a later time, especially with physical and cognitive impairments caused by progressively debilitating diseases. Appointment of a guardian does not necessarily represent a failure of the other alternatives. It may mean that the alternatives were not suitable or available or there was no one to serve as the surrogate decision maker [1].

The main alternatives for the health care of the individual are healthcare directives including durable powers of attorney for healthcare and living wills, healthcare or family consent laws, single court actions, and measures for alone elders. Alternatives for financial decision making include specific and general powers of attorney, durable powers of attorney for finances, trusts, and joint ownership of property, representative payee, and single court actions.

Alternatives for Healthcare

Healthcare Directives. These are alternatives that are planned by the person who has capacity in case he has decisional incapacity in the future. They consist of durable powers of attorney for healthcare and living wills. Some states combine the two concepts into one document called *Healthcare Advance Directives*. Either way, it is important to keep the document(s) current.

Living wills are documents that give directions to physicians that tell them what to do if the person who executed the document is in a terminal condition, or, in some states, a persistent vegetative state. Most states have enacted living wills but the provisions differ from state to state. The disadvantages of the living will are that often it cannot be located when and where it is needed. Moreover, it is simply a piece of paper unless someone actively advocates for the stated wishes of the person (Wood, E. (2004). Personal Communication).

A durable power of attorney for healthcare is a written, witnessed document between two people that authorizes one person to act or represent the other in healthcare decision making. The person who delegates the authority is termed the *principal* and the person accepting the authority is termed the *agent*. The person who grants the power must be fully capable of making decision in his or her own best interest at the time the document is signed or, it is invalid. A durable power of attorney usually takes effect once the person has lost decision-making capacity, which is usually determined by a medical doctor. The most important part of preparing this document is selecting the person who will be the decision maker. It should be someone familiar with the values of the person executing the document.

This alternative is inexpensive since the document can be found in stationary stores. Durable powers of attorney for healthcare can exist along with guardianships and in fact, provide guidance to the court as to what the now incapacitated person would want. Disadvantages include lack of supervision of the agent and the possible invalidity from one state to another. The document is frequently not available at the exact time and place when it is needed. Durable powers of attorney for healthcare do not cover giving consent

for living arrangements either, a common concern with the care of elders.

Healthcare or Family Consent Laws. Over 35 states and the District of Columbia have enacted statutory authorization for healthcare consent by family members (or others who know the patient) when there is no prior written document by the incapacitated person [12]. The decision maker acts in accordance with the statute. Most statutes provide for a hierarchy of decision makers, beginning with a guardian if there is one, and then family members in order of relationship. Friends are usually at the end of the list after family members. Physicians are not necessarily aware of these laws, however.

Single Court Transactions. Many state laws provide for single transactions that involve court action. An attorney for a healthcare facility, usually an acute care facility, brings the petition to the court. Depending on state law, another attorney is appointed to represent the patient. The judge then considers the evidence from both attorneys, including the statements of the person who may need the medical care. Single court transactions may also be allowed for moving a person from one setting to another.

Measures for Alone Elders. Medical decision making for older people who do not have capacity and have no one to make decisions for them has become a focus for policy makers [13]. The term *unbefriended elders* has been coined to describe these people, who may have been societal loners and who have left few traces of how they lived their lives or what their medical preferences might be. Some had close relationships and family but they would have died or become incapacitated themselves. Emergency situations and routine care are generally covered by common law and thus medical practitioners can carry them out without legal interventions. Usually the issue of decision-making for alone elders comes up in hospitals or nursing homes. The decisions to be made include end-of-life decisions, surgery, the administration of psychotropic medication, placement of feeding tubes and use of antibiotics, ventilator support, and transfers to acute facilities from nursing homes [13]. Existing measures to address the issue of decision making are scant and not uniform. Some states designate physicians, sometimes in combination with ethics committees, to make the decision. Three states have unique external committees of trained volunteers to make the decision. Some states have established public guardianship programs to serve this vulnerable population. In some instances, those professionals involved may decide to use the single court transaction option.

Existing institutional practices include ethics committees (which are usually advisory only and may not actually make the final decision) and other established procedures. Sometimes, by default, physicians serve as ad hoc guardians and do what they think is best within the ethical dictates of their profession [13].

Financial Decision-Making Alternatives

There are several alternatives to managing the financial affairs of someone who has lost decision-making capacity.

Powers of Attorney. A power of attorney is a written witnessed document between two people that authorizes one person to act for or represent the other. The person granting the power must be fully capable of making decisions in his or her own best interest at the time the document is executed. There are three types of powers of attorney for handling finances: limited or specific, general, and durable.

The "limited or specific" power of attorney is for one situation only. For instance, a person traveling to another country may delegate his or her real estate agent to sign refinancing documents while he or she is away. Or, a person with severe arthritis may delegate responsibility for handling a specific bank account to someone else so that routine bills can get paid.

A "general power" of attorney usually gives the agent the right to handle all the financial affairs of the person granting it. Both the specific power of attorney and the general power of attorney become invalid when the principal loses decisional capacity. In practice, however, many people, unaware that it is no longer legal, continue to use the power of attorney long after the principal begins manifesting diminished capacity [14].

"Durable" powers of attorney for finances designate someone to manage all assets and financial transactions in case of future decisional incapacity. It is an attempt to avoid guardianship.

Powers of attorney have the advantage of being private. They can be drawn up and signed without an attorney, which means they are cost efficient. Forms

are readily available in stationary stores. The powers to be delegated can be tailored to the individual's wishes. There are also disadvantages. Powers of attorney can be easily abused because the agent is not supervised by anyone. There is no bonding, which means that if the agent mishandles the assets or uses them for himself or herself, there is no "insurance" mechanism to reimburse the principal.

Trusts

Trusts are written legal agreements that provide for property management, which in some cases include provisions for distribution of assets after the person has died. State and federal laws govern trusts. The person who establishes a trust is termed the *trustor*, grantor, or settler. The person or institution that manages the trust is termed the *trustee*. The person who receives funds from the trust is termed the *beneficiary*. The trust document sets forth the exact nature of the trust, when it takes effect, its revocability, and its funding guidelines, as well as stating directions as to the care and disposal of the assets [15]. A guardianship may supplement the trust in order to manage properties that are not in the trust or to address the medical and other care decisions that may be needed.

There are three major types of trusts: testamentary, special needs and revocable living.

A "testamentary" trust takes effect on the death of the trustor. It is provided for in the will and dictates the distribution process. It is used when a testator does not want to make outright distribution to a beneficiary or beneficiaries after his or her death. They can be used to provide income to a spouse or partner with the remaining assets going to the rest of the family on the death of the spouse or partner. A testamentary trust is a tax savings plan.

"Special needs" trusts are irrevocable and are established for the sole benefit of a disabled adult, usually one under the age of 65. The usual special needs trust is pursuant to federal law created in 1993 which allows a disabled person to receive public benefits while at the same time trust assets are dispersed under strict definitions. Repayment to the state is required if there are assets left in the trust after death [16].

"Revocable Living" trusts are the most common types of trusts. This trust takes effect during a person's lifetime and may help avoid guardianship. Most people name themselves as the trustee initially and, at the same time, name another person or institution to serve as successor trustee should they lose decisional capacity. This type of trust has several advantages: it provides for financial and property management in the event of incapacity, it permits changes at any time by the trustor, it specifies the disposal of the trustor's assets should the incapacity be extended or permanent. The disadvantages include the lack of bonding and hence protection for the trustor when a successor trustee takes over, there is no reduction in taxes although "trust mill" purveyors the opposite, and no one monitors the actions of the successor trustee.

Joint Ownership. Real property and cash assets can be jointly owned. There are many types of joint bank accounts. Most states allow the type where the contents of the bank account(s) go to the person who survives the other regardless of whose money it was in the first place. Still others require both signatures on withdrawals. State laws and local bank practices dictate which options are available. Advantages of this alternative include ease of execution and assistance to those who cannot get to the bank. Disadvantages include loss of control of the assets or property, exposure to each other's creditor claims and tax consequences. Also, there is no bonding if one person takes all the money.

Representative Payee. Several federal agencies are authorized to appoint a person or institution such as a bank or a nursing home to receive federal benefits on behalf of the recipient. These agencies include the Social Security administration, Veteran's Administration, Railroad Retirement Board, Department of Defense, and the Office of Personnel Management. The person or institution receiving the check is termed a *representative payee*. Physician statements as well as those by relatives and friends are accepted as evidence. Anyone can serve as a representative payee [17]. Although annual accountings are required, enforcement is not rigorously enforced [1].

Single Court Transactions. Many states have laws that provide for single transactions pertaining to finances. One of the most dramatic is the one that allows courts to freeze bank accounts upon being provided sufficient evidence. This is particularly important when an abuser is draining a bank account. Some states allow or require that an attorney be

appointed to represent the person whose assets are to be frozen.

When is a Guardianship Appropriate?

It is obvious that many of the alternatives to guardianship can be very helpful. The next question is when should a guardianship petition be filed? The following basic criteria must all be met:

1. The guardianship state law is applicable.
2. The person in question has diminished capacity to make decisions.
3. Alternatives to guardianship have been carefully considered but found inadequate to the situation. Or, one of the alternatives has been used to abuse the person with diminished capacity.
4. There is objective evidence demonstrating the lack of adequate decision making on the part of the person with diminished capacity. This can include physician declarations, functional evaluations, and cognitive evaluations, perhaps by a neuropsychologist. In addition, there are several examples demonstrating that the person with diminished capacity cannot provide proper support for food, clothing shelter, medical care, and the handling of financial resources. Evidence may be nonpayment of rent and utility bills, failing to keep medical and dental appointments, marked confusion as to time and place, missing fund, or substance abuse causing medical problems.
5. There is risk of personal or financial injury or damage to the impaired adult that only a guardianship can prevent. A less restrictive alternative will not suffice.
6. Court authority is needed to stop abuse, protect the victim, and seek restitution, or to take some type of legal action, such as: settle a lawsuit, represent the person in an existing divorce proceeding, or file a civil lawsuit for personal injury, fraud, interference with an expected inheritance, false imprisonment, negligence, intentional or reckless infliction of emotional distress, institutional abuse, professional malpractice, or civil rights violations because of disability or age.
7. There is an appropriate person or agency willing to serve as guardian.
8. There are signs that undue influence is being exerted even though the person does not have obvious signs of mental impairment. Such signs include the following:
   (a) The elder signs documents and takes actions that run counter to his or her long-time values and beliefs.
   (b) Someone systematically isolates the elder from people who care about him or her.
   (c) The elder suddenly changes long-time providers such s physicians, dentist, or attorneys.
   (d) The elder suddenly moves into someone else's home under the guise of needing care, or someone suddenly moves into the elder's home.
   (e) The elder places unusual trust in newfound acquaintances when there is a history of mistrust in the family, especially with financial affairs.
   (f) The elder begins writing checks made out to "cash", always in round numbers, and frequently in large amounts.
   (g) Someone makes promises of lifelong care in exchange for the elder's property when he or she dies [14, 1].

Obviously, filing for guardianship is not to be taken lightly. Filing is only the first step in a guardianship. It is the start of the court process, which may or may not lead to the creation of a guardianship for an impaired person.

Court and Guardianships

Guardianships are considered to be matters for the civil justice system. The "guardianship court" may have a different name depending on the state. It could be Probate Court, County Court, District Court, Circuit Court, Court of Common Pleas (e.g., Pennsylvania, USA), Chancery Court, Surrogate Court, or Superior Court [18]. Some states handle guardianships of the estate in the Probate Division and guardianship of the person in the Family Court.

The process of guardianship in the court unfolds in a predictable fashion: petition filed, emergency guardianship (in some cases) court hearing re: the general guardianship, ongoing guardianship, and termination of the guardianship. Each stage of the guardianship process is or should be accompanied by due process protections. The Fourteenth Amendment to the United States Constitution requires that

due process protections be afforded to anyone who is threatened with the loss of liberty or property because of state action. While people in guardianship retain ownership of their assets, they lose control over them. They are not imprisoned but they lose control over where they will live and the freedom to choose the services that will be provided. There needs to be thoughtful procedures that are fundamentally fair, strictly defined and adhered to, and are taken step by step. There needs to be full disclosure of the steps to the person affected and opportunities for him or her to object and to give input with each step. This is called *due process* [19]. Implementation of due process is summarized as follows:

1. The person who is alleged to need a guardian is given written notice of the pending proceeding in a way that maximizes the change so that he or she will understand it.
2. There is sufficient time for the person to respond and prepare a defense, if desired.
3. The person is furnished with the evidence that supports the petition.
4. The person is informed of the right to attend the hearing, to object to the proceedings up to and including a trial by jury, to have someone else act as guardian, and to have an attorney.
5. An attorney is appointed to represent the person if he or she asks for it, if the court thinks it is in the best interests of the person, or if the state law requires it.

Unfortunately, in many jurisdictions, even when state law provides for due process protections, they do not take place evenly because of a lack of resources, because no one thinks they are really necessary as a result of ageism or biases against autonomy for people with diminished capacity, or because family and professionals think they know what is best for the person with diminished capacity [20, 21].

Court Stages of Guardianship

Petition Filed and Hearing. The first formal step in the guardianship process is the filing of the guardianship petition with the court. It is usually filed in the county where the person with diminished capacity lives or has real property. Most states have standard forms. The more complete the petition is, the better the judge can grasp the situation and the more carefully the guardian's powers can be tailored to meet the needs of the person with diminished capacity. At the time the petition is filed with the court, a date will be set for a hearing on the general guardianship. It is usually 6–8 weeks hence. After filing the petition for guardianship, the attorney of record must give notice of the filing including the time and place of the hearing, to a variety of people including the person affected and usually relatives within the first (children and parents) and second degree (grandchildren and siblings).

During the time before the hearing, a court appointed person may go out to interview the person alleged to need a guardianship and investigate the circumstances of the case. The person may or may not be a court employee. A written evaluation may be filed or perhaps an oral report. The labels of such professionals are guardian ad litem, court investigator, and court visitor. The judge takes the reports of these professionals quite seriously because they are neutral parties who do not stand to benefit whether the guardianship is granted or not.

Before the hearing, the judge reviews and considers the information that has been filed re: the proposed guardianship. The hearing is the time when the judge formally listens to comments from the person who is thought to need a guardianship and the proposed guardian. Their attorneys also speak. Anyone else can also speak about the case. Hearings are generally public matters and anyone can attend. Judges take care not to reveal the contents of any confidential documents that have been filed. Usually the judge will give his or her decision at the hearing in open court.

Temporary or Emergency Guardianships. It does happen that that there are situations where urgent action is needed and it would be a disservice to wait for the hearing on the general guardianship. There are two general situations where guardianship powers are needed urgently: the person with diminished capacity is in physical danger or assets are being actively dissipated or wasted. For example,

1. Someone is trying to move the person with diminished capacity to an undisclosed location.
2. Assets are actively being drained from the person's bank accounts and they need to be frozen until further investigation can be made.
3. The person's house has been put up for sale and escrow is closing.

4. The person has an urgent need for medical attention.
5. Court permission is needed to move the person, who is demented, wandering, and getting lost frequently to a secure facility.

When a temporary guardianship is granted, it is reviewed by the court appointees and the judge at the time of the hearing on the general guardianship.

Ongoing Guardianship. There are many activities during the "lifetime" of a guardianship. Official documents must be filed by the guardian including inventories and appraisement of all assets as well as accountings as required by state law if there is a guardianship of estate. Guardians of person must file General Plans in some jurisdictions, which detail what they expect to be doing during the guardianship. They may also be required to file Status Reports annually. While the reports that the guardian files are self-reporting and as such will not probably be incriminating, they are useful in the course of any investigations that are done and they serve to remind the guardian that the court is involved in what he or she does. Forward-looking courts make efforts to educate guardians with handbooks and videotapes. Most courts provide careful monitoring but many courts do not have the resources to do so. Close monitoring, to see that required documents are filed, that they comport with the state law, and that they are serving the person in guardianship, is important to detecting and preventing abuse and neglect.

Termination of Guardianships. Guardianships are terminated because the person in guardianship is restored to a state of full functioning, the person dies or moves to another state, or a trust is established and the guardianship is no longer needed. It does happen that people recover from difficult situations such as closed head injuries. An attorney also may seek to terminate a guardianship of estate if all the assets have been used.

Conclusion

Until recent years, guardianships and guardianship process have not been well understood in the United States. As more of our population ages and lives longer, guardianships will be more common. State laws have by and large been reformed but implementation is not uniform. The growing numbers of older adults and the emergence of elder abuse and neglect make it imperative that all those concerned about elders and disabled people view guardianships in their reality and work to make them effective and respectful for the people in guardianship.

Gunshot Residues ***see*** Firearm Discharge Residue: Analysis of

Gunshot Wounds

Introduction

Firearm injuries are regarded as a special form of blunt trauma. The damage to the organism is caused by the impact of a single projectile (or a multitude of pellets) propelled from a barrel by high-pressure combustion gases and striking the body at a high velocity. Gunshot wounds, in a broader sense, are also lesions caused by blank-cartridge weapons as well as injuries due to livestock stunners, stud guns used in the construction industry, and similar devices.

Weapons and Ammunition

Weapon Types

Firearms enable the user to hit a target from a distance. Depending on the weapon type (*see* **Firearms: Overview**), a distinction is made between handguns (short-barreled firearms for use with one hand: pistols, revolvers) and long arms (portable long-barreled firearms for use with both hands: rifles, submachine guns, machine guns, and shotguns).

Modern pistols carry a magazine in the handle; after firing a cartridge, its case is ejected as the bolt is sliding back. Revolvers have a rotating cylinder holding the cartridges; after firing the shot, the case remains in the chamber.

Weapons intended to be fired from the shoulder have either a rifled barrel (see below), e.g., hunting rifles (firing single projectiles) and military assault rifles, or they have a smooth barrel such as shotguns (firing lead pellets, shotgun slugs, or rubber/plastic pellets).

Rifled and Smooth Barrels

The inside surface of a rifled barrel has a spiral pattern of elevations (lands) and grooves in between. As the bullet passes through the barrel, the lands cut into the cylindrical part of the projectile, thus causing it to rotate around its longitudinal axis ("twist"). This gyroscopic spin stabilizes the bullet on its trajectory and improves the accuracy of the shot.

Shotguns have smooth-bore barrels without grooves and lands. They are designed for firing shells

containing mostly lead pellets or shotgun slugs. Shotgun shells loaded with rubber or plastic pellets are designed for self-defense or for police riot-control purposes [1]. The cylindrical barrel may be slightly tapered toward the muzzle end (choke bore) in order to keep the discharged shot in a tighter spread over a longer distance.

Caliber

On the one hand, the term *caliber* represents the diameter of the bore, and, on the other hand, the bullet diameter. For metric calibers, the caliber specifications are nominal values usually based on the diameter of the lands (maximum diametrical distance between the lands in the barrel). Most projectiles have a somewhat larger diameter. Example: The caliber 7.65 mm Browning has a land diameter of 7.63 mm, whereas the bullet diameter is 7.85 mm. The Anglo-American caliber specifications (in inches with 1 in. corresponding to 25.4 mm) are based rather on the bullet diameter.

In pistols, the predominant calibers are 6.35 mm, 7.65 mm, 9 mm, and .45 in, whereas in revolvers the main calibers are .32, .357, .38, and .44 in.

Cartridges for .22 caliber rimfire weapons can be fired not only from handguns but also from long rifles (LRs).

In cartridges designed for hunting rifles, it is usual to indicate not only the caliber but also the length of the case in millimeters (e.g., 7×64 mm, 8×57 mm). The same applies to the cartridges of military rifles (e.g., 5.56×45 mm, 7.62×51 mm).

The caliber of shotgun barrels is not identical with its internal diameter. It indicates the number of spherical lead balls collectively making up one English pound (1 lb = 453.6 g) in weight; the diameter of these lead balls corresponds to the internal diameter of the barrel (e.g., 18.2 mm for shot caliber 12 and 16.8 mm for shot caliber 16). An exception to this rule is the .410 shotgun, which is named after the barrel diameter in inches.

Cartridges

The cartridges of handguns and rifles consist of a case with a primer in its base, the propellant (gunpowder) above, and a bullet (projectile).

The case is usually made of brass. Cartridges for autoloading pistols have a groove just above the base so that the fired case can be extracted and ejected by the recoiling slide. Revolver cartridges have a base plate that is wider than the cartridge case.

The explosive compound is located in the base of the cartridge case. When the trigger is pulled, the firing pin strikes the base of the case, causing the primer compound to detonate and initiate the burn of the gunpowder.

The primer consists of an explosive compound sensitive to percussion. Initially, the primer was made of mercury fulminate, which was later replaced by a combination of chemical compounds typically containing the elements lead, barium, and antimony. Therefore, these elements play an important role in the detection of gunshot residues (GSR). On the other hand, nowadays, lead-free primers are also available (e.g., "Sintox" with the main elements zinc and titanium).

Above the primer, the case is filled with gunpowder (propellant**),** which does not detonate, but burns rapidly. "Black powder", which has been known for centuries and is a mixture of 75% potassium nitrate, 15% charcoal, and 10% sulfur, is rarely used as a propellant nowadays (for historical or reproduced muzzle loaders or some blank-cartridge weapons). Because of the high amount of solid combustion residues, a lot of dense smoke is produced [2, 3].

Currently, mostly smokeless powder is used as propellant because of its higher efficiency of combustion compared to that of black powder. It either consists of nitrocellulose (NC) alone ("single-base powder") or of NC dissolved in nitroglycerine ("double-base powder"). The powder grains are of pale green color or have a shiny silver-black appearance (if coated with graphite). The powder particles resemble thin platelets (flake or disk powder), small spheres (ball powder), cylinders, or short tubes (tubular powder). The individual powder particles have a diameter ranging from several tenths of a millimeter up to more than 1 mm. In Flobert cartridges (caliber 6 or 9 mm), the primer also serves as propellant.

The deflagration of the propellant produces an ample amount of gases (CO_2, CO, H_2, N_2, nitrous gases, water vapor), which are under high pressure and accelerate the projectile on its way through the barrel. The processes inside the weapon itself are called *interior ballistics* (*see* **Firearm Examination: Ballistics**).

In handguns and .22 caliber rimfire rifles, the muzzle velocity typically ranges from 250 to

400 ms^{-1}, whereas in hunting and military rifles it is considerably higher (approximately 700–1000 ms^{-1}).

Generally, ammunition designed for autoloading pistols and military rifles has full-jacketed bullets with a lead core and a jacket made of steel or a copper alloy covering the front and lateral parts of the projectile but not its base.

For hunting, most cartridges are equipped with a semijacketed bullet. As the jacket is open at the tip, the projectile with its soft-point or hollow-point lead core deforms more readily, thus transferring more energy to the animal body.

Standard .22 caliber rimfire ammunition usually has unjacketed lead bullets. Revolvers mostly fire lead bullets, but also semijacketed projectiles.

According to the bullet's head configuration, there are different shape categories: round nosed, flat nosed, pointed, cylindrical, and truncated cone.

Apart from the shape and the design of the projectile, its mass and velocity are also of importance for its potential effect. From the mass (m) and the velocity (v), the kinetic energy E_k can be calculated ($E_k = 1/2mv^2$); it is indicated in Joule (J). As examples, we may mention the mass of a .22 LR projectile (2.55 g) and a 9 mm Parabellum projectile (8.0 g); in the first instance (.22 LR), the bullet energy is about 140 J, and, in the second instance (9 mm Para), about 430 J. The bullet energy of military and hunting cartridges is many times higher. Note that the energy increases exponentially with the velocity of the projectile.

Shotgun Ammunition

Conventional shotgun shells are fired from smooth-bore shotgun barrels. Instead of a single projectile, they mostly contain numerous spherical pellets made from hard lead. The pellet diameter of birdshot varies between 2 and 4.5 mm, and the pellet velocity on leaving the barrel is about 300 ms^{-1}. The larger the pellet, the greater is its range, given the same velocity.

In addition to birdshot, cartridges with especially large pellets ("buckshot") are also available, with single shotgun slugs (e.g., Brenneke type, Foster, Smith & Wesson sabot) and with rubber/plastic pellets.

The cartridge cases are made of cardboard or plastic and the floor (mostly consisting of brass) contains the primer. The space above it is filled with a (smokeless) nitro powder, which is separated from the lead shot by intermediate layers (felt or plastic wad). Nowadays, the cardboard and felt wads have been largely replaced by plastic wads in connection with shot cups for the pellets.

Wound Ballistics

Exterior ballistics deals with the behavior of the projectile *after* leaving the barrel (trajectory, velocity etc.), whereas terminal ballistics covers the interaction between the projectile and the target (*see* **Firearm Examination: Ballistics**). If the target is a human or animal body, one speaks of wound ballistics.

Fundamentals of the Wounding Capacity

The wounding capacity of a projectile is partly due to the direct destruction of anatomical structures along the bullet track by crushing, punching, and tearing. Another type of lesion is caused by changes in pressure and displacement of tissue (with stretching and shearing) around the permanent wound channel. The extent of mechanical damage depends on the amount of kinetic energy (E_k) released in the tissue.

When a projectile penetrates the tissue, this is displaced laterally (radially) – i.e., at right angles to the bullet path – thus forming a temporary wound cavity, whose diameter can be considerably larger than the bullet. The radially displaced tissue then moves back in the opposite direction toward the geometric bullet path.

The process just described is especially marked with high-energy projectiles such as those fired from military and hunting rifles. In fluid-filled organs (heart, urinary bladder) or in the skull, the radial expansion may lead to a "hydrodynamic explosive effect" with bursting of the encasing structures. Cases in which the brain is completely flung out of the cranial cavity are referred to as *exenteration shots*. Even a shot with a smaller transfer of kinetic energy may cause indirect lesions away from the wound track, e.g., skull fractures, cerebral contusions, and stretch-mark-like tears of the facial skin.

The "permanent" wound channel represents the destructive passage of the bullet itself. The path is filled with blood and is surrounded by a more or less wide zone in which the tissue was temporarily stretched, thus suffering structural damage ("zone of extravasation").

By firing test shots at "simulants" such as gelatin or glycerin soap, the transfer of kinetic energy in biological soft tissue can be visualized, as the density of these materials is similar to that of muscle. In contrast to elastic gelatin, soap shows an almost plastic deformation. The bullet path and the volume of the cavitation remaining after firing the shot is proportionate to the energy transferred [4].

A stable bullet with a low deformation potential (full-jacketed projectile, as used in military ammunition) produces a "narrow channel" in the simulant at first, which then opens into the larger temporary cavity as the projectile moves in a sideways position (when tumbling) and imparts more energy to the surrounding tissue. An expanding deformation of the projectile also increases the effect of radial displacement and thus the volume of cavitation. In deformation projectiles (e.g., semijacketed hollow-point bullets as used in civilian hunting ammunition), the cavity starts forming immediately after penetration. A fragmentation of the projectile results in a multitude of wound tracks.

When projectiles of identical design, head configuration, and mass are fired, the transfer of energy in a dense medium and thus the extent of the temporary cavity essentially depend on the velocity of the bullet.

Wound Track

In gunshot injuries, the bullet may remain lodged in the body, or perforate it completely (through-and-through shot), or hit only the surface tangentially (graze wounds). In the first-mentioned type of gunshot wound, there is an entrance, but no exit wound. Rather often, projectiles traveling at a low velocity remain lodged under the tough and resilient skin on the side of the body opposite to the entrance wound, where their final position can be recognized by a hematoma and/or a palpable resistance (Figure 1). Radiological examination is advisable in any case to determine and document the localization of bullets and bullet fragments retained in the body.

For the determination of the angle of fire (in relation to the horizontal, sagittal, and frontal plane of the body), it is imperative that the length of the wound track and the localization of the entry and exit wound or, in shots with the projectile retained

Figure 1 Nonperforating gunshot injury to the chest (.22 caliber rimfire rifle, homicide). The spent lead bullet got stuck in the subcutaneous tissue of the back where a hematoma indicates its position (a). The projectile could be exposed by carefully incising the overlying skin (b)

inside the body, the final position of the bullet are exactly measured and recorded (height from the plantar plane and the lateral distance from the median plane). Statements as to the bullet's trajectory before entering the individual are possible only if additional facts (such as the position of the victim and/or the shooter) are known; in the presence of a through-and-through gunshot wound, it is essential to know any secondary sites of impact or penetration (on the floor or the walls, in the furniture etc.) to reconstruct the trajectory.

In most cases, the wound track in the body is linear. Full-jacketed rifle bullets, however, may produce a curved bullet path if its length in the body is longer than 20–30 cm. The deviation from the straight line begins when the projectile first moves into a lateral position, i.e., in the region of the first cavitation, as the pressure gradient along the projectile becomes asymmetrical, thus creating a force component lateral to the direction of the movement.

Nonlinear bullet paths are often caused by internal ricochet. Inside the cranial cavity, such ricochets are seen in 10–25% of the cases and occur if the projectile is deflected from the internal table of the skull with a low residual energy. Bullets either ricochet back into the brain at an acute angle or pass along the inner surface of the skull producing a curved wound track in the underlying brain.

The latter type of ricochet not only occurs on the concave side of the cranium but also on other inner surfaces (e.g., ribs) if a concave boundary surface continuously changes the direction of the bullet.

In a perforating shot, the projectile produces an exit wound as it leaves the body. Bullets with a low residual energy are sometimes no longer capable of perforating the clothing covering the exit wound. After having passed through one part of the body (e.g., the upper arm), the bullet may reenter in another part (e.g., the thorax).

Graze shots produce groovelike lesions on the body surface, occasionally accompanied by short tears along the wound edges. If a projectile strikes the body with low residual energy, but does not penetrate, the affected skin may show an excoriation and/or a hematoma.

Intermediate Targets, Deflection of the Projectile

For the interpretation of a gunshot wound, it may be essential to know if the projectile struck the human body primarily or if it interacted with an intermediate object before. For example, if the bullet passes through an intermediate target such as a door first, the typical "ring of dirt" on the site where it entered the clothing or body is missing, because the grayish-black depositions adhering to the bullet surface were already wiped off at the primary target.

When a bullet passes through the dense medium of an intermediate target, it loses its gyroscopic stability, resulting in a rotation around a lateral axis. If such a bullet then hits the body in an oblique or sideways position, the entrance wound is elongated and there is a higher loss of energy in the initial section of the wound track. Analogous effects may be seen when the bullet was already deformed at the primary target.

If a projectile is deflected by an intermediary target instead of penetrating it, one speaks of a ricochet. A change of direction may happen, for example, if the bullet strikes stone, concrete, or asphalt. In such cases, the bullet often shows a flattened, mirrorlike surface. The deformation and/or fragmentation of the ricochet bullet may cause an atypical entrance wound with no, or an incomplete ring of dirt. Owing to the loss of velocity and the instability of the ricochetting projectile, its depth of penetration is less than in primary hits after an undisturbed trajectory [5].

Lethal Gunshot Injuries

According to statistical investigations, about 20% of gunshot injuries are primarily lethal, i.e., the victims die before receiving medical care.

Generally, fatal consequences of a gunshot wound also have to be expected if weapons are used, which lay people would not consider very dangerous (e.g., air guns, blank-cartridge weapons, and .22 caliber rimfire rifles). For example, bullets fired from conventional air guns (with a common barrel diameter of .22 or .177 in, that is, 5.6 and 4.5 mm, respectively) may perforate the thin temporal squama or penetrate into the cranium via the orbital cavity (eye socket). The gas jet of blank-cartridge guns has repeatedly caused penetrating skin lesions, bone fractures, and lethal injuries of vessels or organs, when fired from a very short distance [6]. Of course, projectiles with a low energy fired from .22 caliber rimfire weapons may also produce fatal injuries if major organs or great vessels are hit along the bullet track.

In gunshot injuries with a fatal outcome, the direct lethal effect may be due to various causes. A special case is the gunshot-related "exenteration" of the brain from the skull [3]. When the shot strikes the nape of the neck or the occipital region, it may directly destroy vital centers of the brain stem. More often, it is not the cerebral lesion as such, but the subsequent increase in the intracranial pressure (due to intracerebral, subarachnoidal, and subdural bleeding, sometimes associated with cerebral edema) that is responsible for the lethal outcome.

Gunshot fractures of the bony skull base are often followed by a hemorrhage into the nasopharynx; if the victim is unconscious, fatal aspiration of blood will result. Gunshot-related lacerations of the venous sinuses may act as entrance sites for air bubbles, possibly leading to death from venous air embolism.

Injuries to the heart, great vessels, or parenchymatous organs cause massive internal bleeding with consecutive hemorrhagic shock. Gunshots to the lung with traumatic pneumothorax are an acute threat because of the impaired respiration – especially if both sides are involved. Inflammatory complications are potential causes of delayed death.

Ability to Act

It is often wrongly believed that a gunshot to the head or the trunk always incapacitates the victim immediately. This opinion is disproved by a multitude of well-documented cases in which gunshot victims performed surprisingly differentiated actions even after severe traumatization of vital organs [7].

If a victim becomes unable to act, this is usually due to functional impairment of the central nervous system caused either by tissue lesions directly or indirectly by insufficient oxygen supply. Immediate incapacitation is to be expected if the bullet destroyed parts of the brain essential for physical activity – with exenteration of the entire organ in extreme cases. Targets of immediate incapacitation are the upper cervical spinal cord, the brain stem, the cerebellum, the basal ganglia, the motor areas of the cerebral cortex, and the large motor nerve tracts [8]. The bullet need not necessarily pass through these cerebral regions directly, as the gunshot-related pressure and shearing forces can also damage nerve structures and impair functions away from the bullet path.

Cerebral hypoxia with consecutive unconsciousness following gunshots to the chest is mostly due to massive loss of blood. However, even if the bullet strikes the heart, the aorta, or other large arteries, blood circulation will hardly cease immediately and even then the oxygen reserves left in the brain may be sufficient for simple and short actions. Consequently, rapid but not immediate incapacitation is to be expected after gunshot injuries of the heart, the aorta, and the pulmonary artery. On the other hand, victims go down immediately if struck in the spinal cord.

The pathophysiological considerations just described have significant implications for the assessment of suicides in which several shots were fired. Continued ability to act after a cerebral gunshot injury is observed especially if low-energy ammunition was used and/or the bullet track did not involve the above-mentioned structures of immediate incapacitation (upper cerebral spinal cord, brain stem, motor cortex areas, and large motor pathways). In most suicides with more than one shot to the head, only the frontal lobe(s) or one of the temporal lobes of the brain is involved. Multiple gunshots to the cardiac region are seen more often than multiple suicidal shots to the cerebral cranium.

Stopping Power

The term *stopping power* is used to characterize the potential biological effect of a projectile, in particular, its capacity to prevent a person from moving or attacking [4]. Actually, the idea conveyed by movies and TV films that the impact of a bullet stops or even knocks down the affected person is not true in real situations. Bullets do not have the potential to throw people off their feet. Otherwise, the person who shoots the gun would be knocked over, as action and reaction are equal and opposite.

In fact, the effectiveness of the projectile depends on the amount of energy transferred to the body, leading to local displacement and destruction of tissue. In this context, the shape of the bullet is essential for its effectiveness: If the bullet head is blunt, deceleration and energy transfer are larger. However, in real cases, the effect of a bullet not only results from its effectiveness but also to a large extent from the point of impact, i.e., from the affected region and the relevant anatomical structures.

Embolism of Projectiles

The rarely seen transport of bullets or shot pellets within the vascular system is called *embolization*. Most of the embolized projectiles are of smaller caliber and low velocity, which is sufficient only to penetrate the artery or vein, but not to exit the vessel again, so that the foreign body, which is now localized inside the vessel, may be moved to a region of the body away from the bullet path where it can be easily visualized by radiography [9].

Bullet and pellet embolization is mostly seen in the arterial system (entry via the heart or the aorta and transport, e.g., to the leg arteries). In rare cases, a projectile may enter a vein and travel from there to the (right) ventricle or to the branches of the pulmonary artery [10, 11].

Delayed Effects

In survived gunshot injuries with retained bullets or pellets, the question arises, if this may cause chronic lead poisoning. Generally, the risk is assessed as being very low. Most cases reported in the literature refer to patients with projectiles lodged in the joints or bones. The latency period until an intoxication becomes manifest ranges from a few months to several decades.

Criminalistic Aspects

The purpose of clinical examination or autopsy of persons with gunshot injuries is to answer the following questions [3]:

- Do the findings confirm the assumption of a gunshot injury?
- Number of hits?
- Did a striking projectile pass through the body or is it lodged in the body or did it produce a graze wound?
- What was the direction and angle of fire (trajectory)?
- Are there any clues as to the type of weapon and ammunition used?
- From what distance was the shot fired (contact shot, close-range shot, distant shot)?
- Do the wound characteristics in connection with the traces at the scene suggest self-infliction or involvement of another party?
- Did the gunshot injury result in immediate incapacitation?

Entrance and Exit Wounds

In order to determine the direction of fire, it is imperative that entrance and exit wounds are interpreted correctly.

Characteristics of Entrance Wounds

Typical features of an entrance wound in the skin are

- punched-out hole (i.e., a central tissue substance defect that cannot be closed by approximation of its edges);
- marginal zone without epidermis (abrasion ring);
- grayish-black ring of dirt (provided the projectile did not pass through another target first).

When the shot was fired either with the muzzle in contact or at close/intermediate range, the respective signs can be regarded as further evidence of a bullet entry wound.

Entrance Hole

The central entrance defect is roundish (if the projectile strikes at a right angle) or oval (if it strikes at an oblique angle). The diameter is usually smaller than that of the bullet.

The discrepancy between the caliber of the projectile and the diameter of the permanent entrance hole can be explained by the elastic behavior of the skin: On impact of the bullet head, the edges of the defect temporarily move centrifugally due to radial forces causing a reversible widening of the bullet entrance hole [12]. When the deformation forces cease, the elastic skin resumes its former shape so that the permanent entrance defect may be much smaller than the diameter of the bullet (this discrepancy is particularly marked on the palms of the hands and soles of the feet [9, 13, 14]). The size of the skin wound therefore does not allow to draw accurate conclusions as to the caliber of the projectile.

The reason for the skin defect remaining at the entrance site is essentially that the projectile transports tissue particles into the depth of the wound track. Moreover, at the moment of impact, small skin

particles are flung back against the direction of fire [12, 15, 16].

Abrasion Collar (Abrasion Ring/Margin/Rim)

The central entrance hole is usually surrounded by a circumferential loss of epidermis (and its natural pigmentation [17]), forming a moist, reddish margin when fresh and later assuming a brownish color due to the drying of the unprotected corium (Figures 2, 5a and 5b).

With the help of high-speed photography, Sellier was able to prove already in 1967 that the epidermis-free margin of the entrance wound is not caused by any major indenting with consecutive overstretching and local friction [12, 18]. When the bullet head strikes the skin, backspatter of marginal tissue particles is induced by the pressure exerted on the entrance site. The former idea that the bullet head indents the skin before penetration, thus causing marginal abrasion, is not correct. It also neither results from the bullet being hot nor from its rotating movement.

In the peripheral parts of the abrasion collar, the epidermis is often torn and detached like wallpaper, so that parching can progress beyond the epidermis-free zone after prolonged exposure to air. When the bullet strikes at an oblique angle, the abrasion ring is elliptic and eccentric, being wider on the side from which the shot was fired. A unilateral widening of the abrasion collar thus gives an indication of the direction in which the bullet was traveling.

If the skin of the entrance region is under water, no abrasion ring is formed. The same is true for shots to palms and soles [9, 18]. Entrance wounds from high-velocity centerfire rifles may lack a typical abrasion collar, but show small splits radiating from the edges (so-called microtears).

Bullet Wipe-off ("Ring of Dirt", "Grease Ring")

The criminalistic importance of the bullet wipe is due to the fact that – at least on the primary target – this finding is a reliable sign of a bullet entrance.

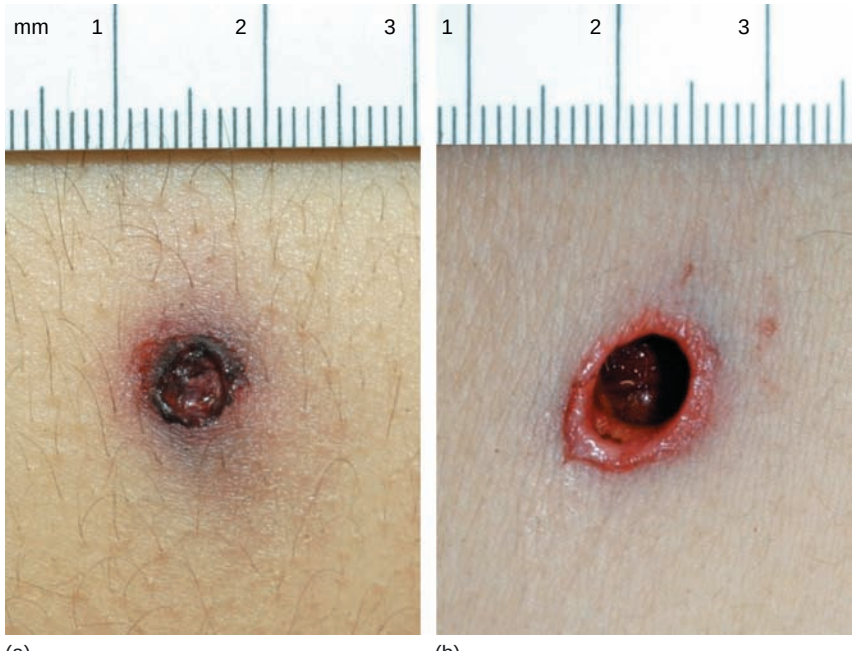

Figure 2 (a) Entrance wound (from a .22 LR projectile) in the epigastric region, which was covered only by a thin T-shirt. A vague grayish-black ring of dirt partly overlies the dried abrasion collar. (b) Entrance wound (from a 7.62 mm pistol bullet). The skin was covered by several layers of clothing. Therefore, the central defect is surrounded by a characteristic circumferential abrasion ring, but no bullet wipe-off

The term *bullet wipe* refers to the mechanism of formation: when the projectile hits a skin region not covered by clothing, sooty remnants and other residues deposited on the bullet's head are transferred to the wound margin, so that a grayish–blackish ring (partly) overlies the abrasion collar. More often, this "ring of dirt" is seen on the uppermost textile layer, but not (or only vaguely) on the margin of the entrance wound. In oblique gunshots, the bullet wipe is eccentrically enlarged on the side from which the shot was fired. The bullet wipe is *not* a sign of a close-range or a contact shot, as it also occurs in distant shots.

Exit Wounds

The exit wound presents as a slitlike or stellate severance of tissue (Figure 3a, b). In typical cases, there is – contrary to the entry wound – no real hole, i.e., no tissue defect. This means that the wound usually can be closed by bringing the edges into apposition. An exit wound produced by a bullet passing sideways through the skin may be slitlike and therefore mistaken for a stab wound.

Often, though not always, the size of the exit wound is larger than that of the entry wound. In practice, the uncritical application of this unreliable "rule" often leads to misinterpretations [5, 19]. Thus, contact shots fired to the head may show "stellate entrance wounds" with long radial tears; in such cases, the exit wound may be much smaller (Figure 4). In cases of splinter injuries (e.g., by fragments of explosive weapons), the entry wound is always larger than the corresponding exit. The differentiation between entrance and exit should never be made on the basis of simply comparing the wound dimensions.

The size of the exit wound mainly depends on the diameter of the temporary cavity at the site where the bullet leaves the body. In some cases, bone splinters carried along may also contribute to a larger exit hole. Many projectiles leave the body deformed and/or tumbling, which may also influence the shape of the exit wound.

It goes without saying that exit wounds cannot have a bullet wipe. Occasionally, the margins of the exit wound are abraded (shored) when a firm object (e.g., tight-fitting clothes, floor, wall or back of a chair) is pressed against the body at the site of the exiting projectile (Figures 3c and 5c). Under such circumstances, the skin around the exit is abraded by the supporting surface. In contrast to the "original" abrasion ring around the entry wound, in "shored" or "supported" exits the area of abrasion is not concentric, but irregular or lopsided and often disproportionately large [17].

Figure 3 (a) Slitlike bullet exit wound in the buccal region resembling a stab (.22 caliber revolver, homicide). (b) Stellate exit wound in the scalp, which was partly shaved before autopsy (7.65 caliber pistol, suicide). (c) Shored exit wound on the back. In the moment of discharge, a heavy backpack pressed against the bullet exit site (7 mm caliber hunting rifle, suicide)

(a) (b)

Figure 4 (a) Suicidal contact shot to the right temple with a revolver (caliber .357 magnum). The entrance wound shows a central defect with partially blackened edges (→) and radial lacerations of different length. Note the superficial stretch tear at the inner angle of the right eye, which is located several centimeters away from the wound channel (hyperextension of the facial skin by the expanding gases). (b) Irregularly shaped exit wound close to the left ear. The maximum diameter of the exit wound is much smaller than the large split at the entry site

(a) (b) (c)

Figure 5 (a) Five gunshot entrance wounds in the anterior thoracic region, which was originally covered by clothing. (b) Roundish entrance holes with circular abrasion rings (after removing the body hair). (c) Corresponding exit wounds on the back, which was in contact with the ground ("supported exits"). A 7.62 mm caliber pistol, homicide

Classification of Entrance Wounds in Relation to the Range from Muzzle to Target

To understand the different features of gunshot entry wounds, it is necessary to be familiar with the major processes occurring when a firearm is discharged. As the trigger is pulled, the firing pin is released and strikes the primer at the base of the cartridge case. The detonating primer ignites the propellant. The subsequent burning (deflagration) of the gunpowder generates a large amount of expanding gas, which is under high pressure and propels the projectile down the barrel. The gas is composed of carbon monoxide, carbon dioxide, oxides of nitrogen, and other compounds. A small percentage of the powder grains remains unburned or only partly burned.

Already, before the projectile leaves the barrel, a cloud of gunsmoke exits the muzzle. The term *gunsmoke* refers to the grayish-black combustion products of the powder that has not fully converted to gases. Essentially, gunsmoke consists of carbon in the form of soot.

Apart from the combustion gases and the finely dispersed soot, there are always unburned and partly burned powder grains expelled along with the projectile. The cloud of powder soot rapidly decelerates so that smoke soiling is to be expected only relatively close to the muzzle. The larger powder grains (having a diameter of at least several tenths of a millimeter) can also reach more distant targets.

The diameter of the spread and the density of soot and/or powder particles on a target are not only dependent on the range of fire but also on the cartridge type and the weapon (length of the barrel). Consequently, the range of discharge can only be evaluated by firing test shots with the respective weapon and ammunition [5].

In handguns, macroscopically visible traces of gunsmoke are to be expected up to a range of several centimeters. Depending on the weapon and ammunition, gunpowder grains may reach targets several decimeters away (in rifles even more than 1 m). The use of silencers strongly reduces the deposition of soot and powder particles, thus creating the false impression of a larger range of fire [20].

When a gun is discharged, two different light phenomena can be observed: first, the flame – a short, mostly dark red jet of fire caused by the not yet completely finished combustion of the powder particles; second, the muzzle flash – a glaring fire ball some distance away from the barrel end caused by the reaction of the incompletely oxidized combustion gases with the oxygen in the air.

With nitro powder, the extremely short impact of the muzzle flame is usually not sufficient to cause substantial burns on the clothing or skin. Sometimes, frizzing may be seen on the hair near the entry wound. Thermal damage is possible in shots with nitro ammunition fired from a very short distance (near contact) if textiles made of thermolabile synthetic fibers melt on the underlying skin [14, 15, 21]. If black powder ammunition is used, close-range shots may cause impressively large burns.

In forensic medicine, three ranges of fire are distinguished according to morphological criteria (*see* **Shooting Distance: Estimation of**):

- contact range
- short/close and medium/intermediate range
- long/distant range.

Contact Shots

The term *contact shot* means that the muzzle was held against the body surface at the time of discharge. In contact shots, soot-containing combustion gases are propelled into the depth of the entry wound. They expand beneath the skin and blacken the initial section of the wound track (pocketlike undermining, “powder cavity” containing soot and gunpowder particles). As the combustion gases have a high content of carbon monoxide (up to 50%), the surrounding tissue often assumes a bright cherry-red color. In tight (hard) contact shots, all the combustion products enter the wound, whereas in loose, angled, or incomplete contacts some soot may escape between the muzzle and skin so that the adjacent surface is blackened (Figure 6).

The entrance region is bloated by the inrushing powder gases and balloons backward against the muzzle end of the weapon, which is imprinted on the skin, causing a “muzzle abrasion” (“barrel marking”, “muzzle contusion”). Mechanically, the muzzle imprint is a patterned pressure abrasion with a tendency to parching after exposure to air [18]. Apart from the barrel end (or its contours), other constructional parts situated near the muzzle, such as the front sight and/or the recoil spring guide, may also be imprinted (Figure 7).

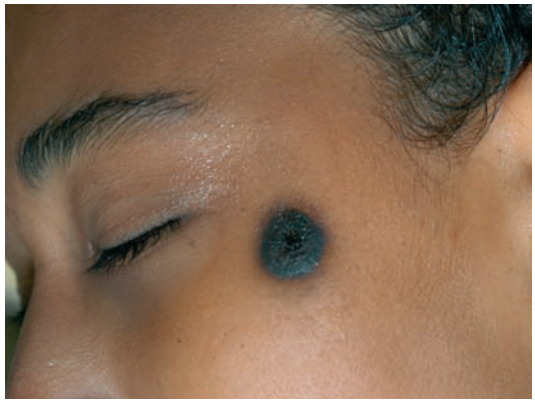

Figure 6 Near/loose-contact shot to the left zygomatic region (.22 caliber revolver, homicide). The entrance hole is surrounded by a wide zone of intense powder soot blackening

The muzzle contusion allows to draw significant conclusions:

- The weapon was in contact with the skin at the instant of discharge.
- The configuration of the imprint mark corresponds with the constructional elements being in line with the muzzle or just behind. Therefore, the imprint mark can characterize the type of weapon used (e.g., revolver or pistol) or even a specific make or model.
- The imprint configuration may provide information as to the way in which the weapon was held at the moment of discharge. For example, an imprint of the front sight below the bullet entrance means that the weapon had been held upside down (i.e., with the handle pointing upward).

If the entrance wound is above a bony support (e.g., in the frontal and temporal region), the subcutaneous expansion of the penetrating combustion gases may cause radial skin tears due to overstretching, resulting in a stellate wound of entrance. This additional sign of a contact shot is facultative: Shots fired with low-energy ammunition such as .22 LR do not necessarily cause stellate lacerations even at the sites having a bony support. Away from the entrance

(a) (b)

Figure 7 Hard-contact gunshot wounds to the right temple in two suicide cases with imprint marks mirroring the front end of the recoil spring guide and its position in relation to the muzzle. (a) "Normal" position (with the recoil spring guide being below the barrel and the grip pointing downward). The muzzle became blocked by soil when the pistol fell down after discharge. Brain substance protrudes through the bullet entrance wound. (b) The weapon is turned around the barrel's longitudinal axis so that the imprint is lateral to the bullet entrance hole

wound stretch-mark-like tears of the facial skin may occur, especially in shots to the forehead and the submental region (cf. Figure 4a, [22]).

Close and Intermediate-Range Shots

In close-/intermediate-range shots, GSR (soot and/or powder particles) are deposited around the entry wound. Usually a distinction is made between close-range shots and medium (intermediate)-range shots.

Close-range shots are defined by the presence of a zone of powder soot soiling surrounding the bullet entrance (often associated with additional powder tattooing). The grayish-black soot leads to skin or textile discoloration of a cloudy structure, whose intensity decreases with growing firing distance. Shots fired at an oblique angle result in an asymmetrical soot pattern with unilateral extension on the side of the shooter or away from it (depending on the angle at which the shot was fired and the range of fire). Interfering objects such as clothing or body parts (hand) may partially filter out the gunsmoke. Flash suppressors, which are often used in military rifles, have lateral smoke outlets, which may produce a flowerlike pattern of soot with several radial petals corresponding to the number of slits [9, 23]. In revolvers, there is a gap between the cylinder and the barrel, which allows the combustion gases to emerge sideward. The soot and the powder grains escaping from the gap may produce a characteristic linear or L-shaped mark if the skin or a fabric is in close proximity at the time of discharge [9, 24].

The term *medium-range shot* is used if no zone of powder soot blackening is discernible around the entry wound any more, but there are unburned or partially burned gunpowder grains deposited on, or forced into, the skin or clothing. The penetrating capacity of the powder grains depends on the propellant (flake or ball powder, grain size), the weapon, the range of fire, and the surface properties of the target. At short shooting distances, grains may be driven through thin textiles and cause stippling on the underlying skin [9, 17].

On the skin, the powder particles cause either superficial epidermal lesions (with subsequent drying) or – if deposited beneath the epithelium – petechial dermal hemorrhages (Figure 8). According

Figure 8 (a, b) Close-range shot to the left preauricular region (7.62 mm caliber pistol, homicide). The entrance wound (arrow) is surrounded by a dense dispersal pattern of unburned/partly burned powder grains associated with a small amount of soot around the bullet hole

to some authors, the term *tattooing* should be used to describe forceful in-driving, whereas the term *stippling* means the mere presence of impact markings.

The distribution pattern of powder tattooing/stippling varies according to the angle of fire: only perpendicular shots produce a radially symmetrical picture; in most other cases, the affected skin area is elliptic in shape. The entry wound may be localized outside the tattooing if the powder grains were partly filtered out by clothing or other primary targets (Figure 9, [17]). Pseudo tattoo marks can be due to fragments of an intermediate target such as the window of a car. In such cases, fragments of glass may produce irregular stippling lesions on the person seated behind the perforated window [9, 15, 21].

Distant-range Shots

In forensic usage, the term *distant shot* means that the weapon was discharged from such a distance that no soot and no powder grains could reach the body surface (skin or clothing in covered body regions). The minimum range for this type of gunshot wounds varies not only depending on the weapon and ammunition but also on the sensibility of the investigation method used.

The special methods of determining the range of fire cannot be discussed here. For securing and adequately preserving any GSR that may be present on the clothing or in the vicinity of entry wounds, close cooperation with the responsible experts is necessary (*see* **Firearm Discharge Residue: Analysis of**; **Shooting Distance: Estimation of**). In any case, the relevant findings should be documented by photographs and also by X rays, whenever possible.

Figure 9 Two intermediate-range shots to the sternal region. As the victim was clothed, the most of the unburned powder particles were filtered by the textile layers. Only some peripheral powder grains produced stippling of the uncovered neck. 7.62 mm caliber pistol, homicide [Reproduced from Ref. 17. © Hodder Arnold, 2000.]

Shotgun Injuries

Shotguns are hunting or sporting weapons intended to be fired from the shoulder (*see* **Firearms: Overview**). They are either single- or double-barreled, the latter ones being arranged either side by side or "up and under". A so-called pump gun has a pipe magazine under the barrel, which can take up several cartridges. Usual shotgun shells with birdshot or buckshot contain a multitude of pellets, which first travel together for a short distance and then separate more and more. The increasing dispersal of shot improves the hunter's chance of striking a moving target such as a hare or a flying duck. The criminal use of shotguns on humans is common, and improvisations, such as sawn-off barrels, facilitate the handling and hiding of the weapon [11, 14]. Shortening the barrel results in an increased spread of the pellets in midrange and distant-range shotgun discharges. Shot pellets are made from lead, which is easily deformed when striking dense tissue.

A shotgun contact wound is produced when the muzzle is placed tightly against the body surface. The entrance wound roughly corresponds to the gauge and is of circular shape in most body regions, but stellate over the bone (due to the expansion of the inrushing gases with consecutive backward ballooning of the skin). Sometimes, there is a clear imprint abrasion mark, e.g., from the front sight or – in double-barreled weapons – from the nonfiring muzzle. The wound edges may be blackened, but most of the soot enters the body and is deposited in the depth of the wound (Figure 10). The surrounding muscle is often colored cherry-red due to carbon monoxide. An intraoral discharge (Figures 11 and 12a) or a contact wound to the head (forehead, temple, under the jaw) leads to massive destruction of the skull ("bursting of the head", "shooting off the face") and is occasionally associated with evisceration of the brain [3, 9, 14].

Even in cases with extreme splitting of the face and the scalp, careful approximation of the wound edges helps in finding the entrance site

(a) (b)

Figure 10 Contact-range discharge to the left side of the neck (12 G shotgun, homicide). (a) Entrance wound with longitudinal splitting laceration toward the angle of jaw and soot staining in the depth. (b) Exit site on the right lateral neck

(Figure 12b). Loose-contact discharge allows the escape of sooty combustion gases, staining the skin around the entrance hole (Figure 13). Intermediate-range shots are characterized by the presence of stippling/tattooing from unburned propellant (up to 1 m, depending on the type of powder). In close-distance discharges, additional smoke soiling is seen.

The injury pattern of shot ammunition is mainly influenced by the distance between the muzzle and the target: As the range increases, the initially circular entrance hole shows scalloping of the wound edge ("nibbling", "crenation"); from a distance of approximately 2 m, peripheral pellets produce satellitelike holes outside the central entry defect. Ranges of several meters are characterized by a sievelike wound pattern [3, 5, 9, 14, 21, 24, 25]. If shots are fired from short distances, wads or plastic cups may either penetrate the body together with shot (cf. Figure 11) or cause excoriations of characteristic shape on the victim's skin ("wad abrasion") [3, 5, 9, 14, 24, 25].

Shotgun slugs are large, single lead projectiles destined for smooth-bore shotguns and also for those having a choke at the end of the barrel. The hitting accuracy of shotgun slugs is considerably lower than that of rifle projectiles; as a consequence, they should not be used for distances beyond 35–50 m in hunting. Some shotgun slugs are designed according to the arrow principle (heavy front part, light rear part).

Internal Findings

The gunshot lesions of the inner organs can only be briefly discussed here. Special mention should be made, however, of bullet holes in the flat bones of the skull. On the entrance side, the bone defect in the outer table is sharp edged and its minimum diameter roughly corresponds to the caliber of the projectile, whereas the inner table is beveled out in a conelike manner [1, 3, 5, 9, 14, 17, 21, 24]. This characteristic widening on the exit side allows to determine the direction of fire even in an isolated bone. For gunshot exit holes of the skull, the opposite is true: The outer table shows a craterlike defect ("outward beveling"). Projectiles striking at an acute angle produce keyhole-shaped entrance defects in flat bones with partial cratering of the outer table at the side away from the shooter. So the manner in which the bone breaks may

Figure 11 Intraoral discharge of a 12-gauge shotgun, resulting in facial disruption (suicide). The spent plastic piston and the lead pellets were recovered from the depth of the wound

indicate the inclination of the bullet path. Beveling is not restricted to the skullcap, as it is seen likewise in other flat bones such as the sternum, the pelvis, and the ribs.

In contact shots to the cerebral cranium (frontal, temporal, parietal, and occipital region), soot deposits are found not only under the skin but also around the bone defect and on the underside of the lifted-off periosteum (Figure 14), often even on the outer surface of the dura mater [14, 24, 26].

Frequently, radial fractures may extend from gunshot holes of the skull. According to Puppe's rule, a secondary fracture line ceases when it meets a pre-existing fracture line, which may help in determining the sequence of the shots.

In soft tissue, the wound track collapses and/or is filled with blood. Postmortem probing of the bullet path involves the risk of causing artifacts and should therefore be avoided. Parenchymatous organs such as the liver, the kidneys, and the spleen may show large stellate wounds at the sites of entry and exit.

Whole projectiles or bullet fragments removed from the body by surgical intervention or during autopsy must be preserved for further laboratory investigation, including ballistic comparison. A recovered projectile provides information regarding the caliber, twist direction, number and width of lands

Figure 12 (a) Intraoral shotgun wound with extreme facial splitting (suicidal discharge of a 12-gauge shotgun). (b) Reconstruction by reapproximating and sewing together the originally gaping lacerations. Note the superficial tears from overstretching along the nose. (c) Fragment of the skullcap (inner aspect) with shallow imprints (arrow) and one deformed pellet still adhering to the inner table of the bone. and grooves, as well as of individual characteristics imparted by the inner surface of the barrel (*see* **Firearms: Bullet and Cartridge Case Identification**).

Livestock Stunners ("Humane Killers", "Slaughterer's Guns"), Stud Guns, Blank-Cartridge Guns

Stunning devices are guns firing a cylindrical steel bolt about 10 cm deep into the brain of animals intended for slaughter, which usually results in immediate unconsciousness [27]. Humane killers are loaded with a blank cartridge. After the captive bolt has been fired, a recoil spring brings it back into its initial position.

In forensic practice, injuries from livestock stunners are seen primarily in suicide cases; homicides and accidents with a fatal outcome are very rare. Suicides are mostly committed by persons with a pertinent professional experience (farmers, slaughterhouse workers, butchers).

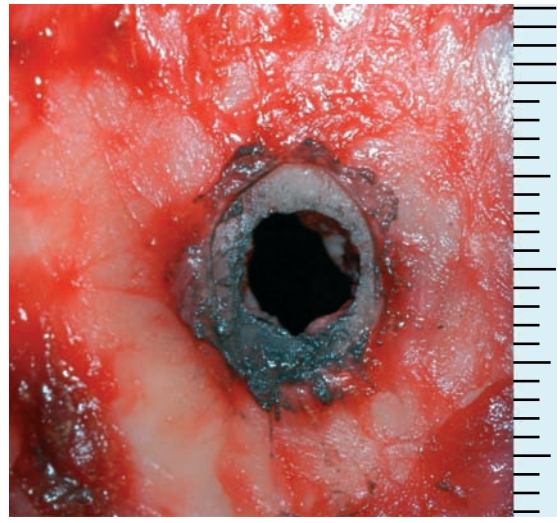

Figure 14 External surface of the skull (right temporal region) showing a roundish bone defect with soot deposited on the margin. The periosteum is detached and reflected. Suicidal contact shot, 6 mm caliber single-shot pistol

The steel bolt has a diameter of about 10–12 mm and a conically grooved distal end with a sharp edge and thus produces a punch injury (Figure 15a, b and c). As the bolt returns into the instrument, no projectile, but only punched-out material (skin, bone) is left in the depth of the wound track (Figure 15d). Because of the limited forward movement of the bolt, no exit wound is to be expected in shots to the head. Some types of livestock stunners have gas outlets in the muzzle plane. Corresponding to the openings of the smoke conduits, the entrance wound may be accompanied by two or, less often, four small zones of powder soot blackening located in pairs opposite each other (Figure 15a).

Cartridge-operated stud guns and nail guns are used to shoot fasteners into walls, wood, concrete etc. [3, 14]. In contrast to livestock stunners, the fasteners leave the device and may fly freely, thus causing an accident. For safety reasons, a shot can be fired only when the front plate of the instrument is pressed firmly to the object fired at.

Blank firing pistols and revolvers are detailed facsimiles of "real" handguns. The blank cartridges destined for these weapons contain gunpowder, but

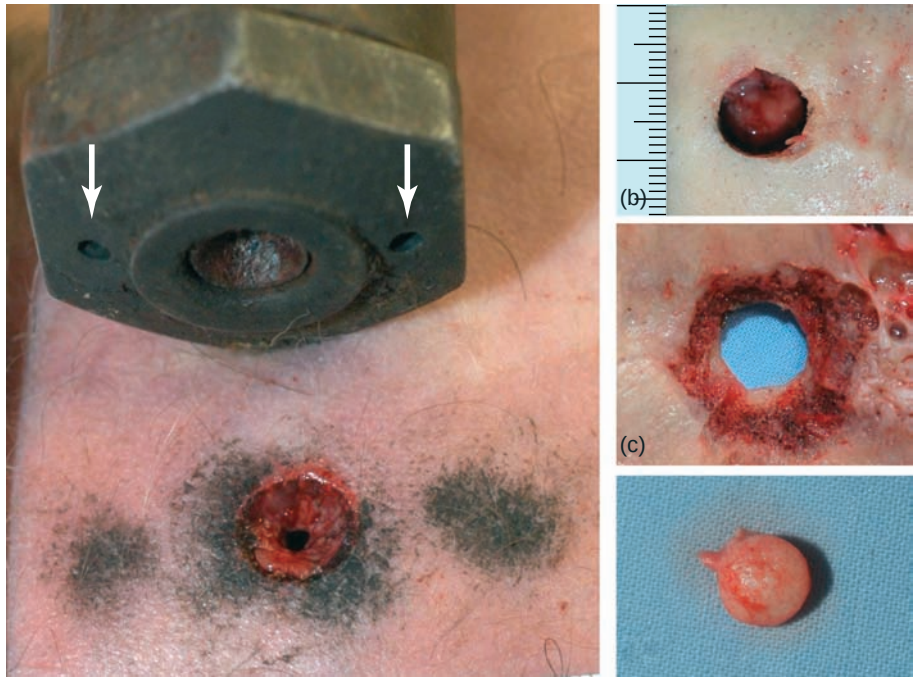

Figure 15 Suicidal captive-bolt injury to the parietal region from a livestock stunner (type Kerner). (a) Circular, sharply defined punch lesion of the skin. On both sides of the skin defect, roundish zones of powder soot blackening (corresponding to the opposite openings of the two smoke conduits in the muzzle end, arrows). (b) Circular entrance defect in the outer table of the skullcap, approximately corresponding to the diameter of the steel bolt. (c) Inner aspect of the skullcap with cone-shaped widening of the hole in the direction of the shot. (d) Punched-out bone fragment recovered from the depth of the wound channel

no projectile. If the muzzle is held in close proximity to the body surface or even in contact with it, the gas jet from the blank gun is capable of penetrating the skin and causing potentially fatal injuries [6, 28].

Forensic Examination and Documentation

In all firearm fatalities, careful documentation is of utmost importance [3, 5, 29]. This includes taking photographs and close-up views of each wound using a scale. The clothing must be preserved, as the uppermost layer may exhibit the bullet wipe around entrance holes and depositions of soot and/or powder particles in close- and medium-range shots, respectively.

Whenever possible, X rays should be taken before autopsy in two planes (anteroposterior as well as lateral views). They are not only a useful means of permanent and objective documentation but also help in exactly locating and characterizing all bullets and any metal fragments including separated jackets. Radiographs are also a valuable tool to find projectiles lodged in body regions, which are hardly accessible during autopsy (e.g., within the vertebral column). In addition, X rays provide evidence that a bullet might have been deflected or embolized [30].

All wounds have to be described exactly with regard to their location using fixed landmarks such as the base of the heels, the midline, the height above the buttocks, and the distance from the top of the head. The documentation should also mention the size and shape of each wound, the features of the wound margins and their surroundings, the presence or absence of GSR such as soot or stippling on the clothing and/or skin, the total length of the wound

tracks, and, of course, the injuries to the internal organs.

It is important to recover any bullets or major parts thereof from the body of the victim. Subsequent laboratory investigation may help in identifying the bullet type and to assign the fired bullet to a specific weapon (*see* **Firearms: Bullet and Cartridge Case Identification**).

Manner of Death

To classify a gunshot wound as suicidal, homicidal, or accidental, a synoptic evaluation of the scene and the circumstances of the case, the evidence obtained from the injuries, the victim's clothing, and the laboratory investigations concerning the weapon, ammunition, and range of fire has to be made [9, 30]. An easy access to weapons due to a permissive legislation is associated with increased rates of firearm homicide and suicide.

From the medicolegal point of view, the question has to be answered whether the entry wound is localized in a region typical for suicides [9, 31, 32]: temple (cf. Figures 4, 7 and 14), mouth (Figure 16; cf. Figures 11 and 12), cardiac region, forehead, and submental region (cf. Figure 13). In almost all cases of suicide, the muzzle is held against the body or inserted into the oral cavity. In shots to the chest, the skin is seldom bared before [33]. In more than 20% of the suicides committed with pistols or revolvers, the weapon is found clutched in the firing hand [9, 34].

The examination of hands to detect GSR, especially lead, antimony, and barium originating from the primer, can only be briefly mentioned here (*see* **Firearm Discharge Residue: Analysis of**). These residues mainly escape from the cylinder–barrel gap (in revolvers) or from the ejection port (in automatic pistols) and come to rest on the skin and/or clothing where they can be collected for subsequent chemical analysis. The presence of GSR is detected by flameless atomic absorption spectroscopy (FAAS) or by scanning electron microscope-energy dispersive X-ray spectrometry (SEM-EDX) [19, 35].

Sometimes, clues suggesting suicide are found on examination with the naked eye only (Figure 17), e.g., spray of blood or tissue deposits on the firing hand ("backspatter" from the entry wound [9, 36, 37]), traces of soot on thumb and index finger (if the muzzle end was held against the entrance site with one hand), or injuries from the edges of the recoiling slide. Direct and prolonged contact of the skin with steel parts of the weapon in a moist environment promotes the formation of brownish rust stains [9].

(a) (b)

Figure 16 Intraoral shot from a .22 caliber rimfire rifle (suicide). (a) Near contact entrance wound in the palate with eccentric soot deposition around the bullet hole. (b) Exit wound on the top of the head after reapproximation of the edges

(a) (b)

Figure 17 Suicidal shot to the right temple with a .38 caliber revolver. The left hand (a) was used to steady the barrel. Corresponding to the position of the cylinder–barrel gap, black soot is deposited on the palm (arrow). The trigger was operated with the right hand (b). The radial aspects and the back of both hands were spattered with a spray of blood

This phenomenon is found especially in suicides, although it is no proof that the shot was self-inflicted.

Injuries Caused by Explosives

In peacetime, injuries and fatalities due to the detonation of explosives are mostly seen in connection with politically motivated or terrorist attacks against persons (letter or parcel bombs), vehicles, and buildings (*see* **Explosions: Scene Investigation**; **Explosion Debris: Laboratory Analysis of**). Accidents are mostly due to natural gas ignitions, chemical explosions or improper handling of explosives, fireworks, etc. In countries without terrorist activities, suicides using explosives are rare and usually restricted to persons with a pertinent professional experience.

The injury pattern is often characterized by a complex combination of different lesions [1, 38, 39]. Mechanical tissue destruction up to traumatic amputation and evisceration is caused by blunt force (exploding device and other objects impacting the body, pressure wave), often associated with penetrating injuries from splinters, burning, and soot blackening of the skin. The internal examination may reveal organ and vascular damage, skeletal fractures, ruptured tympanic membranes, and acute pulmonary emphysema. Complete body X-ray examination should be performed whenever possible.

Hair: Animal

Introduction

The earliest publications acknowledging the significance and value of animal hairs in the forensic arena date back to the nineteenth century [1, 2]. In 1894, Alfred Swaine Taylor documented a case, which relied on establishing innocence by determining hairs on an alleged murder weapon to be animal, not human, in origin [3]. By the early 1900s, microscopical examination of hair was well established; in 1931 Professor John Glaister published his work on the study of mammalian hairs from the medicolegal aspect, which became a standard reference work [4].

Technological advances, in the late 1930s, for the textile industry prompted detailed hair structure studies by the Wool Industries Research Association (WIRA, England). Wildman published a booklet in 1940 on animal fibers of industrial importance and discussed their origin and identification. This work was subsequently enlarged upon, republished in 1954 [5], and became generally accepted as the definitive work on hair structure. However, Wildman's work concentrated on a detailed description of fibers of commercial importance and no attempt was made to produce a key or system of identification for unknown hairs. A further account of Wildman's work was subsequently given by Appleyard [6].

Descriptive keys to facilitate the identification of mammalian hairs were published by Mathiak [7], Mayer, [8] and Moore [9]. Brunner and Coman [10] acknowledged these works and their value but believed that a number of problems still existed in the identification of unknown animal hairs, which could not be addressed solely by a key based system. The authors attempted to address these issues and minimize the problems of inter and intraspecies variation and overlap by using a photographic reference system.

For almost a century, the compound and comparison microscopes remained the only reliable tools for the microscopical identification and characteristics found in animal hair. However, the advent of nuclear DNA (nDNA) and mitochondrial DNA (mtDNA) analyses in the forensic arena provided a degree of individualization of animal hair, which was not possible *via* microscopy alone [11–14].

Transfer and Persistence of Animal Hair

The forensic community generally accepts that whenever two objects or surfaces come into contact, a transfer of material occurs. Trace evidence material that is transferred may be used to associate objects, individuals, or locations. Once transferred, animal hairs may be recovered from evidentiary items using a variety of techniques that include removal with forceps or adhesive tape.

Until the mid-1990s, published material did not exist regarding the transfer and persistence of animal hair. Prior to this, forensic hair examiners relied on their experience and a plethora of published data detailing the transfer and persistence of textile

and natural fibers to determine if recovered animal hairs were transferred *via* primary or secondary transfer, i.e., animal sheds hairs onto a surface or object (primary transfer), which then become transferred onto a different surface or object (secondary transfer). As a result of these studies and based on the experience of the examiner, hair examiners based their conclusions on the tenet that the greater the number of hairs recovered from an item, the more likely that the transfer arose as a result of primary transfer rather than secondary transfer.

Robertson [15] addressed the issue of the transfer and persistence of hairs thus: "... there are elements common to fibers and hairs (after all, hairs are just natural fibers and the factors which affect their transfer and persistence appears similar).... Most of the work on transfer and persistence relates to studies with textile fibers. Hairs could be expected to behave like woolen textile fibers because both have scaled outer layers. Hence, many of the conclusions reached for fibers may also be applicable to hairs".

In 1998, D'Andrea *et al.* [16] published their findings from their preliminary studies on the transfer and persistence of animal hair during simulated burglaries and assaults. They concluded that the results "confirm the existence of an important transfer and persistence of this type of evidence". Furthermore, these authors determined that "the numbers presented ... are consistent with the kinetics of disappearance, well studied in the context of textile fibers". Their empirical data supported the premise on which hair examiners previously based their opinions regarding the transfer and persistence of animal hairs.

In 2008, Robertson *et al.* [17] investigated the transfer and persistence of cat and dog hairs in relation to wool and nonwoolen fabrics. The results indicate that these animal hairs exhibited an almost linear decay for hair loss from acrylic and woolen fabrics and a classic exponential loss with cotton and polyester fabrics.

Microscopical Examination of Animal Hairs

The morphology and composition of animal hair is comparable to human hairs in that there are essentially three components to the examination of animal hairs:

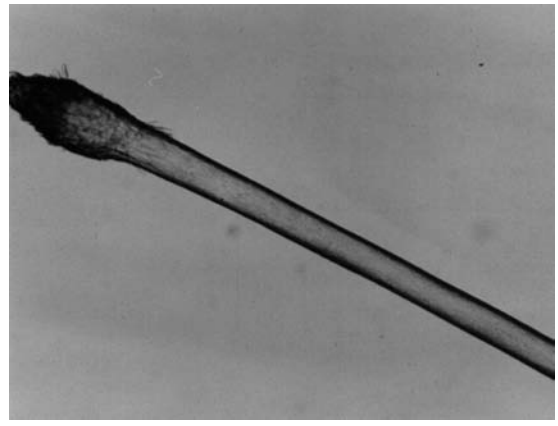

Figure 1 Human scalp hair that bears a club-shaped root

- The determination of the hair as animal versus human in origin.
- The identification of the animal hair as originating from a particular family or species.
- The use of the comparison microscope for the simultaneous examination of microscopic characteristics found in questioned and known animal hairs.

If the questioned animal hairs are sufficient in number and/or hair types, distinctive enough, and in good enough condition, the above goals may be readily achieved.

Animal Hair versus Human Hair

The identification of a hair as being animal versus human in origin is generally easy to accomplish and may be achieved at the macroscopic level. In general, human hair roots are club-shaped (bulbous appearance) or flattened (Figures 1 and 2). In contrast, animal hair roots may exhibit a variety of shapes and forms, which may be characteristic of the species as depicted in figures 3 and 4.

Human hair possesses a uniform flattened (imbricate) cuticular scale pattern (Figure 5) and, if present, an amorphous medulla, which constitutes less than a third of the shaft width (Figure 6).

In contrast, animal hairs exhibit an array of different scale patterns and medullae forms, which, in

Table 1 Characteristics that may be used to differentiate between human and animal hairs

Feature	Human hair	Animal hair
Color	Relatively consistent along hair shaft	Often showing naturally occurring abrupt, profound color changes known as *banding*
Medulla	Less than 1/3 of the hair shaft amorphous appearance, most discontinuous when present	Usually greater than 1/3 of the width of the hair shaft Continuous, often varying in appearance along the shaft, defined structure with a variety of configurations
Pigment distribution	Even, slightly more toward the cuticle	Central or denser toward the medulla
Cuticular scale	Imbricate, similar along the shaft from root (proximal end) to tip (distal end)	Variety of patterns often showing variation in structure from root to tip
Root	Usually bulbous (club-shaped) and indistinct	Variety of shapes and forms, usually distinct

Figure 2 Human scalp hair that bears a flattened (ribbon) root

general, occupy greater than a third of the shaft width. Figures 7–12

Table 1 details the major morphological characteristics of human and animal hairs that may be present and assist in distinguishing human hair from animal hair.

The most obvious characteristic feature exhibited by animal hairs is the naturally occurring

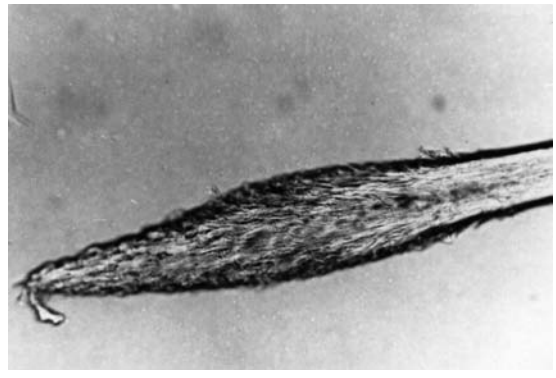

Figure 3 Photomicrograph depicting the spade-shaped root characteristic of dog hairs

phenomenon known as *banding*. Banding is an abrupt and profound color change in the same hair and can be seen with the naked eye. This naturally occurring phenomenon does not occur in human hairs.

Identification of Animal Hairs

Prior to attempting to identify an animal hair to a particular family or species, it is necessary to characterize the hair to a particular "type" to assess if characterization is possible. The hairs comprising the pelt of an animal may be identified on their gross morphological appearance.

Close examination of animal pelts reveals that some sparsely distributed hairs are distinctly longer than the remainder of the hairs. These longer hairs are called *overhairs*, for species identification purposes these hairs are not particularly useful as many

Figure 4 Photomicrograph depicting the wineglass-shaped root characteristic of deer hairs

of the characteristics required to determine species may not be present or visible if the hairs are heavily pigmented.

The guard hairs are coarser and larger than the remainder of the hairs forming the pelt. The largest of the guard hairs, the primary guard hairs, are of paramount importance in the identification of species as they exhibit the most diagnostic features. The secondary guard hairs bear characteristics, which are a hybrid of the coarse guard hairs and the finer underhairs, that is they are almost as coarse and of the same length as the primary guard hairs and wavy like the underhairs. These secondary hairs also bear diagnostic features and are just as important as the primary guard hairs for identification purposes.

The underhairs are shorter and much finer than the overhairs and guard hairs. These hairs are usually wavy and usually bear insufficient features upon which a reliable identification can be made.

The types of hairs that may be found on an animal pelt and examples of hair profiles that may be present are illustrated in Figures 13 and 14.

To further assist in the identification of animal hair to a particular species Brunner and Coman [10] introduced the reader to diagrammatic representations of some of the morphological features, which may be seen in animal hairs to assist in determining possible species of origin (Figures 15–17).

Cuticular Scale Patterns. Unlike human hairs, animal hairs bear a variety of cuticular scale patterns, which may change along the hair shaft. These patterns may be visualized by the use of a compound microscope (transmitted light) if the hair has prominent scale patterns or is not opaque. However, the use of a scanning electron microscope (SEM) greatly enhances the ability to view the cuticle. Another more routinely used method to view the scale patterns of

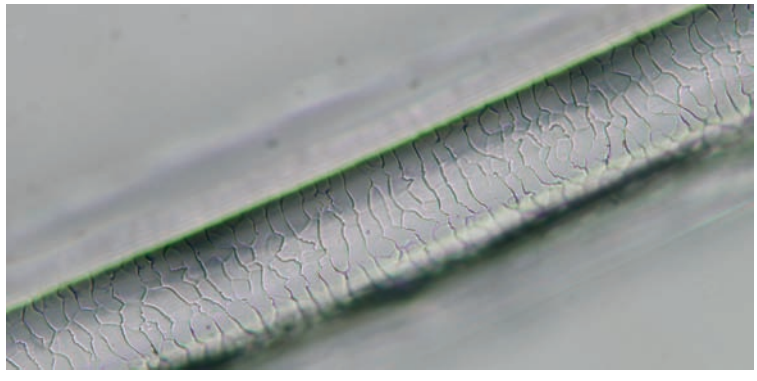

Figure 5 Imbricate scale pattern characteristic of human hairs

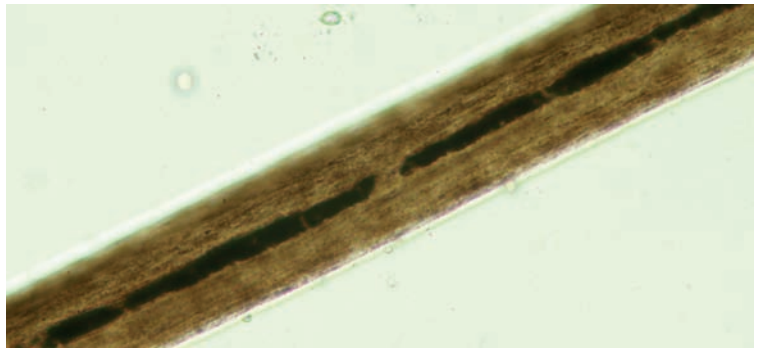

Figure 6 Amorphous medulla, which may be seen in human scalp hairs

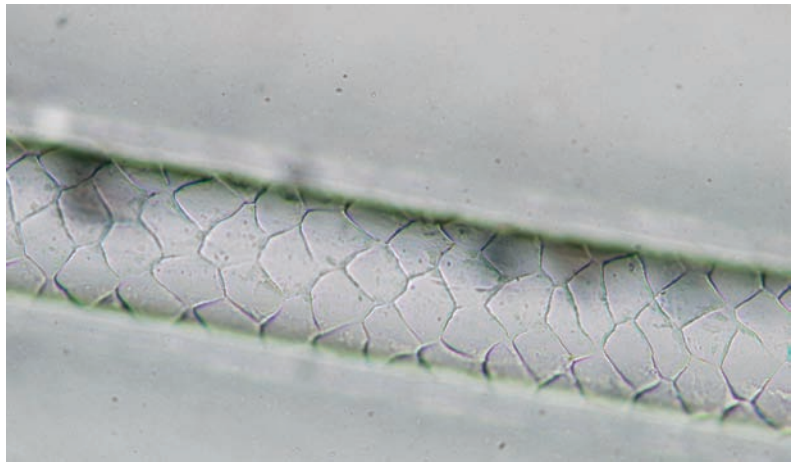

Figure 7 Example of scale pattern, which may be seen on cat hair

animal hair involves coating a glass microscope slide with a thin layer of clear adhesive or nail polish, placing the hair (with the tip slightly protruding from the slide to facilitate removal) in the adhesive, which is allowed to dry and upon removal of the hair the imprint of the scale (cast) pattern is revealed; this imprint may be visualized with the use of a compound microscope.

Figures 18 and 19 depict examples of cuticular scale patterns that may be seen in animal hairs. Rabbit hair shows a chevron scale pattern (Figure 18); whereas the dog shows a broader irregular mosaic scale pattern (Figure 19) as seen in scale cast patterns.

Medullae Patterns and Configurations. Hairs originating from members of the deer family characteristically exhibit a very broad honeycomb (wide lattice) medulla that virtually comprises the whole cortex (Figure 20), while the medulla of the dog hair is a much narrower simple medulla (Figure 21).

Root Shapes. Certain animal species bear roots of a certain morphology that is very characteristic of the species. For example, the forensic community widely accepts that dog hairs bear distinctive spade-shaped roots resembling a closed umbrella (Figure 3) and that deer hairs bear a wineglass-shaped root (Figure 4).

Cross Sections. Although the majority of family/species identification is based on cuticular scale

Figure 8 Example of the scale pattern, which may be seen on rat hair

patterns, root and medullae morphology, cross-sectional examination of animal hairs may be a useful tool in the preliminary grouping of mammal species for a rapid identification of hairs. However, cross-sectioning are not species specific and as this method is a destructive one, it is not recommended as a routine procedure.

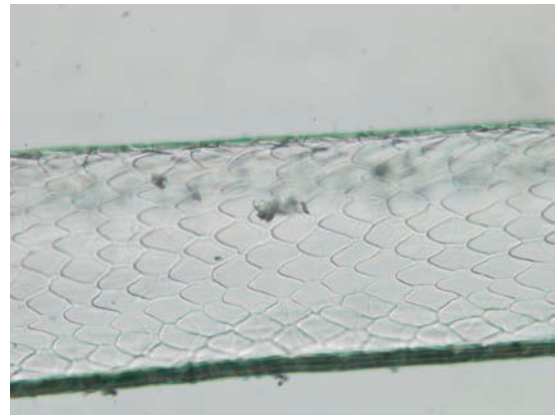

Figure 9 Example of the scale pattern, which may be seen on seal hair

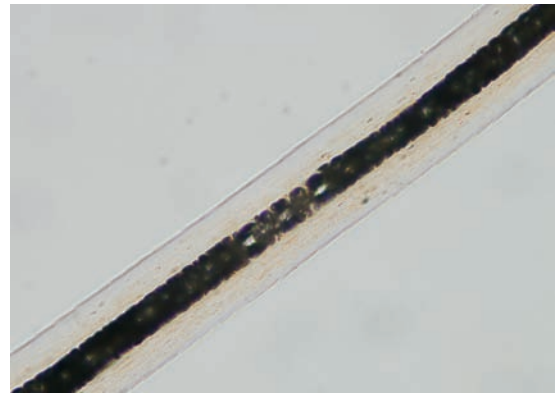

Figure 10 Example of the medulla exhibited by dog hair

Figure 11 Example of the medulla exhibited by rat hair

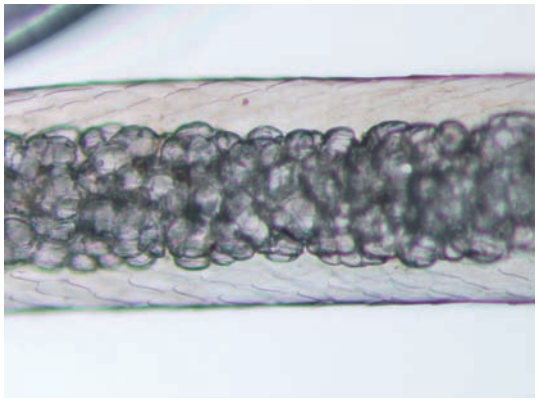

Figure 12 Example of the medulla exhibited by seal hair

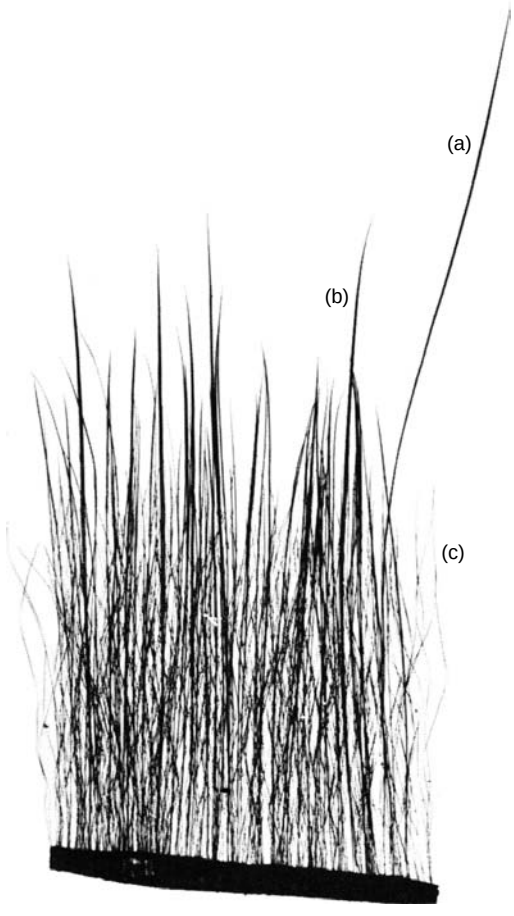

Figure 13 Examples of hair types, which may be found on the pelage of animals. A tuft of hair from the brown rat (*Rattus norvegicus)* showing an overhair (a), guard hairs (b), and underhairs (c)

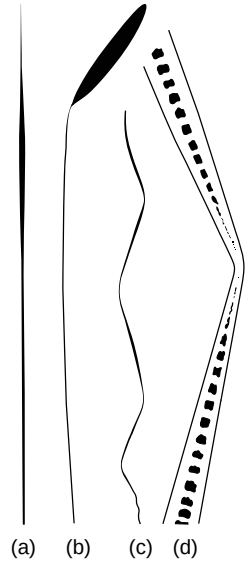

Figure 14 Examples of hair profiles: Guard hairs (a and b); underhair (c); magnified view of a constriction in an underhair (d)

The forensic analyst is often presented with only a few animal hairs to examine; family/species identification of animal hair is possible without having to resort to cross sectioning.

Thus, the use of keys [8, 9, 18] in conjunction with standard reference works [5, 6, 10] may assist the examiner to identify the family/species of origin of a particular animal hair.

Differentiation and Identification of Cat and Dog Hairs

Cat and dog hairs are probably the animal hairs most frequently encountered by forensic analysts, probably because of the popularity of these animals as domestic pets and the ease in which they shed their hairs on upholstery and clothing. Peabody *et al.* [19] described a method based upon a statistical difference between the medullary index (MI) of cat and dog hairs. The MI is the ratio of the width of the medulla in relation to the width of the hair shaft at a particular section of the hair. Peabody found that when the MIs are potted against shaft width, dog hairs predominantly lie below a line whereas cat hairs lie above it as illustrated in Figure 22.

The MI used in conjunction with other characteristics such as cuticular scale pattern and root shape may

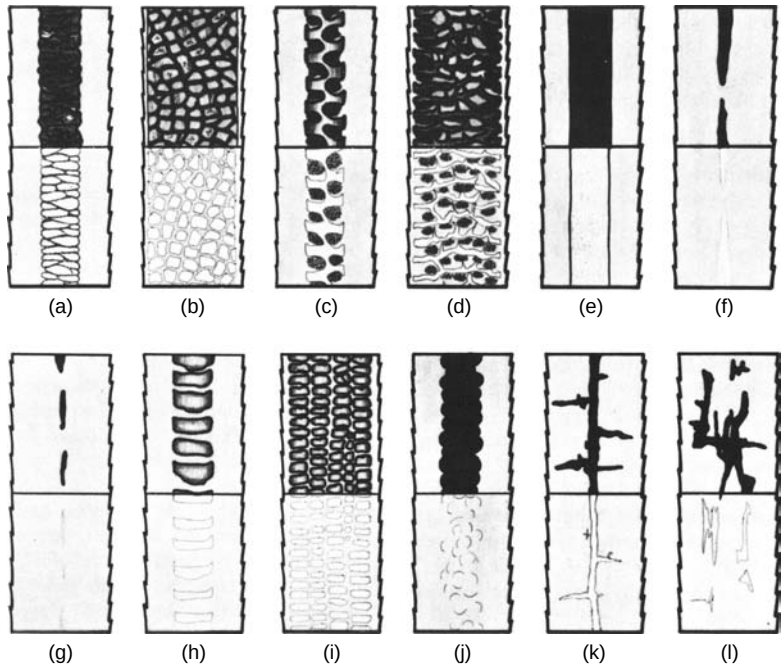

Figure 15 Medullae types exhibited by animal hairs as classified by Brunner and Coman. (a) Narrow medulla lattice; (b) wide medulla lattice; (c) narrow aeriform lattice; (d) wide aeriform lattice; (e) simple; (f) interrupted; (g) fragmental; (h) uniserial ladder; (i) multiserial ladder; (j) globular; (k) stellate; (l) intruding

further facilitate the identification and differentiation of cat and dog hairs.

The appearance of the root shape or form may assist in the identification of an unknown animal hair. Hicks [20] stated that cat hairs possess a fibrillar root (the appearance resembles a short bristled artist's brush) and dog hairs possess a spade-shaped root that resembles a closed umbrella, a tenet generally accepted by the forensic community. However, studies [21] revealed that cat hairs may also exhibit a spade-shaped root, which is shorter than those found on dog hair as illustrated in Figure 23.

The results of the study indicated that if the determination on whether a hair is of cat or dog in origin is based solely on the appearance of a spade-shaped root, an erroneous identification may be made.

Comparison Microscopy of Animal Hairs

The comparison microscope enables simultaneous examination of questioned and known hairs.

Although the comparison microscope is often used for the examination of human hairs, this is not the case for the comparison of animal hairs. Prior to 1988, no published literature existed regarding the significance of animal hair comparisons. Suzanski [22] conducted a number of comparisons of German Shepherd dog hairs to determine whether hairs from these animals possessed sufficient variation of microscopic characteristics to permit some degree of individualization. Suzanski performed the comparisons on the basis of the "unknown' dog hairs being selected, in his absence, from the known samples. The results indicated that with this particular breed of dog some degree of individualization was possible.

Suzanski [23] subsequently enlarged upon this work using the previously used known and" unknown" dog hair collection techniques by comparing hairs from a variety of purebred dogs and dogs of mixed breeds; the results supported his previous findings. In his 1988 publication, Suzanski noted that it is possible for two different dogs to have hair that is indistinguishable, only guard hairs and

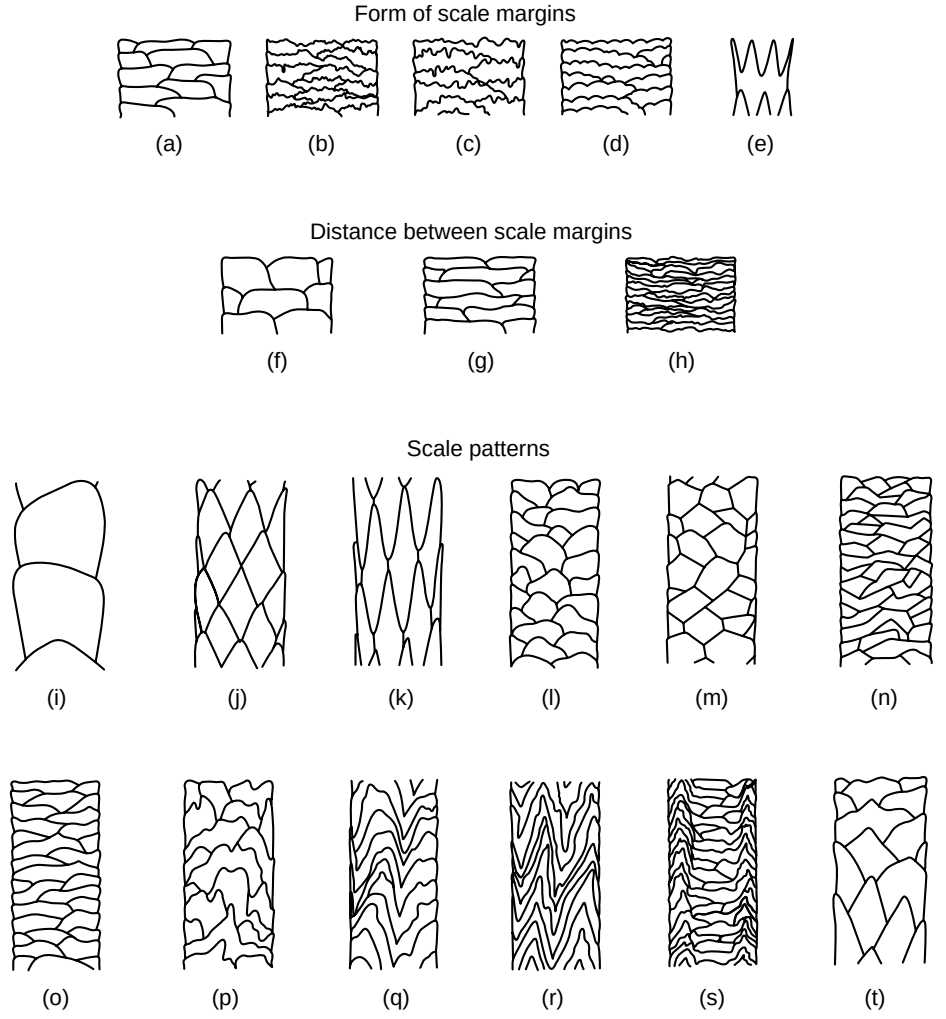

Figure 16 Cuticular scale patterns exhibited by animal hairs as classified by Brunner and Coman. (a) Smooth; (b) crenate; (c) rippled; (d) scalloped; (e) dentate (f) distant; (g) near; (h) close; (i) simple coronal; (j) diamond petal; (k) narrow diamond petal (l) broad petal; (m) regular mosaic; (n) flattened irregular mosaic; (o) regular wave; (p) irregular wave; (q) single chevron; (r) double chevron; (s) streaked; (t) transitional

intermediate hairs (secondary hairs) are suitable for comparison purposes and the principles of dog hair comparisons are generally the same as for human hair comparison although the relative weights placed on certain characteristics would be somewhat different.

DNA Analyses on Animal Hairs

Until the advent of DNA profiling, the hair examiner relied solely on microscopy to determine some level of individualization. DNA profiling of animal hairs has been able to place some statistical weight on the degree of individualization, which was erstwhile not possible. The following example illustrates this premise. In 1996 a North American forensic analyst presented testimony in which a suspect was linked to a homicide through cat hairs. A discarded jacket stained with the decedent's blood had several white cat hairs lodged in the lining; the suspect owned a white cat. The DNA profile obtained from one of

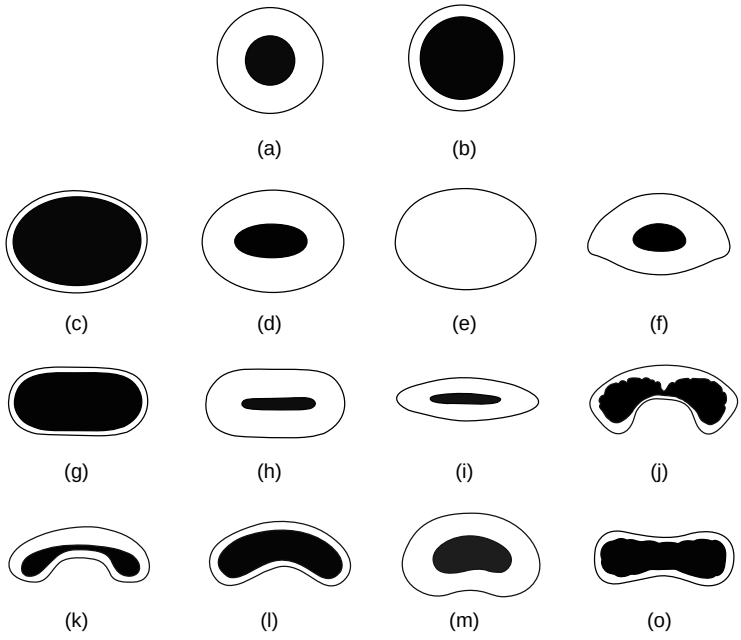

Figure 17 Cross-sectional shapes exhibited by animal hairs as classified by Brunner and Coman. (a) Circular medium size medulla; (b) circular large medulla; (c) oval large medulla; (d) oval medium size medulla; (e) oval medulla absent (f) eye-shaped; (g) oblong large medulla; (h) oblong medium size medulla; (i) cigar-shaped; (j) concavo-convex divided medulla; (k) concavo-convex bilobed medulla; (l) concavo-convex large medulla; (m) reniform; (n) dumb-bell shaped

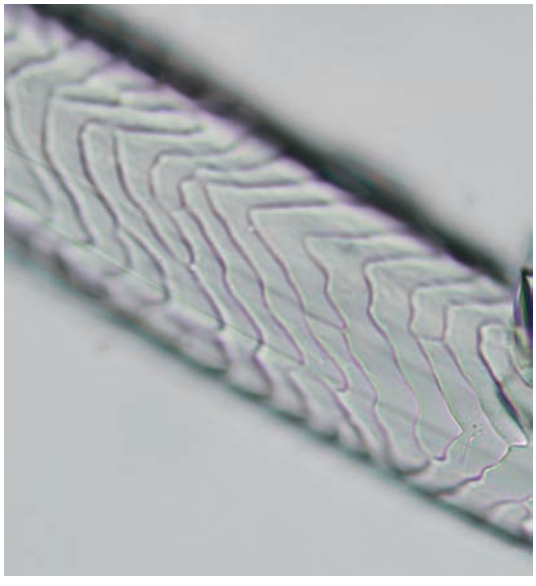

Figure 18 Chevron cuticular scale pattern as seen on rabbit hair

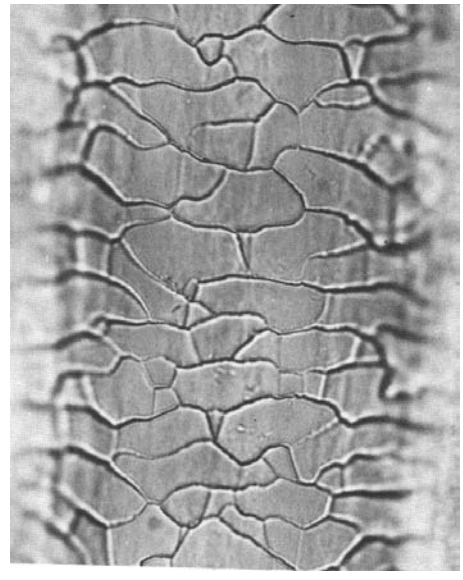

Figure 19 Irregular mosaic cuticular scale pattern as seen on dog hair

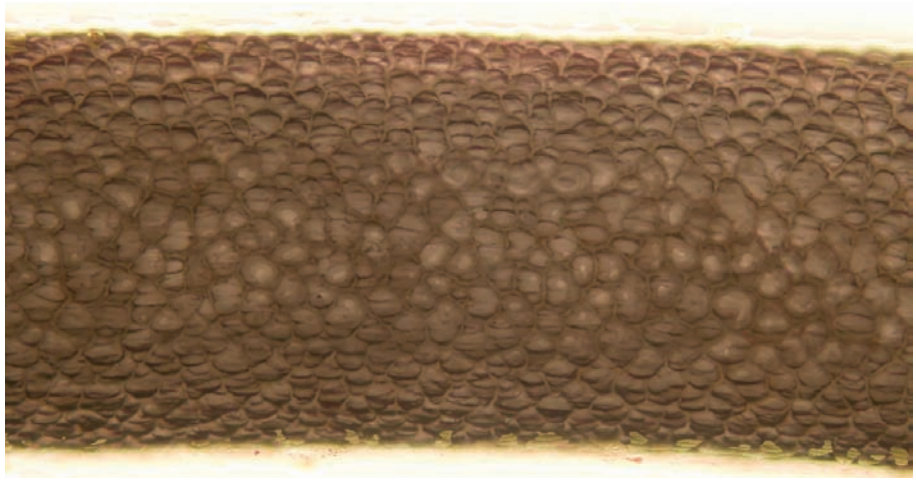

Figure 20 Example of a wide lattice (honeycomb) medulla as seen in deer hair

the roots of the recovered cat hairs was compared to the DNA profile obtained from the blood of the suspect's cat. The DNA profile from the recovered cat hair and the DNA profile from the suspect's cat matched. This evidence was presented at the trial and the jury subsequently found the suspect guilty of second-degree murder. This case represented legal precedence for the introduction of DNA profiling of pet animal hairs in forensic cases that associates the suspect in capital cases [11]. Thus, the advent of DNA profiling heralded a new era, not only for the forensic analysis of body fluids and human hairs, but also in the examination of animal hairs. As technology improves, the combination of microscopy and DNA analyses in the examination of animal hair is likely to become routine. However, until such times that the DNA profiling of animal hairs becomes routine, the only recourse available to the forensic analyst is the reliance on the "traditional" examination of animal hairs.

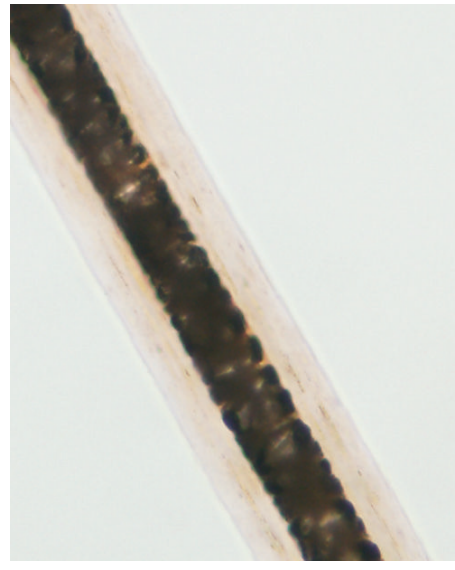

Figure 21 Example of a simple, narrow medulla as seen in dog hair

The Examination of Animal Hairs in Forensic Casework

The forensic examination of animal hairs is eclectic being conducted on, but not limited to, cases involving the illegal trafficking of animals, poaching, and killing of protected species, cruelty to animals, food contaminants, and in crimes against the person in which animal hairs may provide the nexus between offender and crime scene and/or victim.

Hair: Microscopic Analysis

Introduction

Hairs are a ubiquitous trace material in forensic investigation. Few trace materials give rise to such passionately held and differing views as to their value as evidence. Hair cannot be ignored as it is almost invariably present at a crime scene and there are (still) many laboratories conducting some level of hair examination. The aim of this short article is to describe the basics of hair examination, with what can, and what cannot, be safely concluded when examination of hairs is conducted according to appropriate standards, and finally to describe the role of DNA testing of hairs as part of that protocol.

Hair Biology and Physiology

The biology and physiology of hairs has been comprehensively studied by scientists from many areas of the biological and other sciences where most of our

knowledge of hair growth, basic structure, and genetic control comes from nonforensic-based research. As some hairs, notably wool from sheep, are used as textile fibers, there is a large body of literature dealing with sheep hair, from which much of our broader knowledge is derived.

Hair is only found in the tissue of mammals. The living part of hair is the hair follicle that develops as an invagination of the epidermis or skin. The development of the hair follicle has been extensively studied and reported on (see [1] and Figure 1). A basic understanding of this structure is necessary to

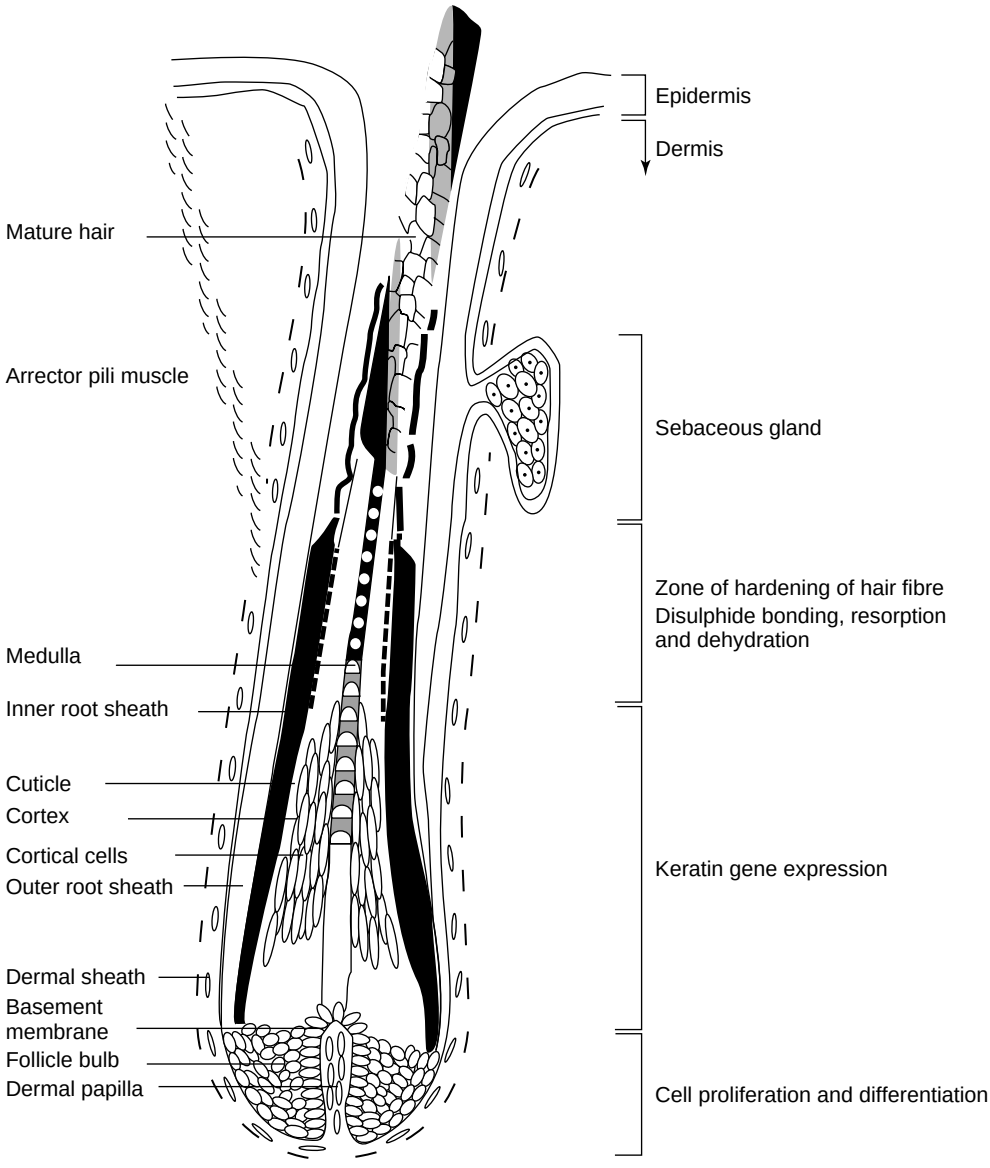

Figure 1 Schematic diagram of the pilosebaceous unit showing various main features and the regions where the main events of cell proliferation and keratinization take place. The cells in the bulb region move into different streams that give rise to the cortex, the cuticle, the medulla, and the inner root sheath [Reproduced with permission from Birkhauser Verlag Basel. © 1997.]

appreciate the various stages of hair growth and, from a particular forensic interest, hair "shedding". The basal part of the hair follicle, or bulb, can be considered to have two regions: a lower region of actively dividing cells and an upper region in which the cells differentiate and form the various cell types that comprise the mature hair shaft. The hair is quite firmly anchored in the dermis by two layers of sheath cells.

Hairs are composed of a protein called *keratin* and this soon hardens in the hair shaft through the formation of disulfide bonds. The hair shaft beyond the basal area is a dead structure and hair fibers are robust and resistant to degradation.

All five million hair follicles in a human are formed during fetal development. These follicles can produce different types of hair during the lifetime of a human. Before birth the follicles produce "lanugo" hairs. These are sometimes seen in a premature baby but are generally replaced at about the eighth month of pregnancy by short, fine "vellus" hairs. The main hairs of interest to forensic scientists are "terminal" hairs. These include primary and secondary hairs. The latter, sometimes called *sexual hairs*, develop during puberty and are subject to hormonal control.

The terminal hairs of humans are equivalent to the underhairs, fur, and wool of other mammals. Typically, a human will have in the order of 100,000 scalp follicles and about 2 million over the whole body area. These are all present at birth!

The Hair Cycle

The human hair cycle is a continuous process. Unlike with other mammals, where many hair follicles are at the same growth phase in a periodic fashion (hence, molting seen in domestic animals), human hair follicles are independent of each other. For convenience, the hair growth cycle is broken up into three phases, "anagen", "catagen", and "telogen" (Figure 2).

There is considerable variation in the reported duration of the anagen phase, but it is at least around 3 years and may be as long as 8 years for scalp hair. As scalp hair grows at about 1 cm per month, in theory a single growth cycle could result in hair of 1 m in length. As there are documented examples of hair being longer than this, hairs may go through more than one growth cycle.

The catagen phase occupies a relatively short period of time during which the follicle regresses. The telogen, or resting phase, can then last for 3–4 months. Telogen hairs lack the hair sheath cellular "anchor" of the anagen hair and are consequently easily removed during normal "growing" activities.

Although between 80 and 90% of scalp hairs at any point in time are anagen hairs and 10–20% telogen, "most" (95%) of hairs recovered in forensic work are telogen hairs because these are loosely held and more easily dislodged. Only 1–2% of hairs are catagen hairs as this is a short transition phase. The length of these growing phases,

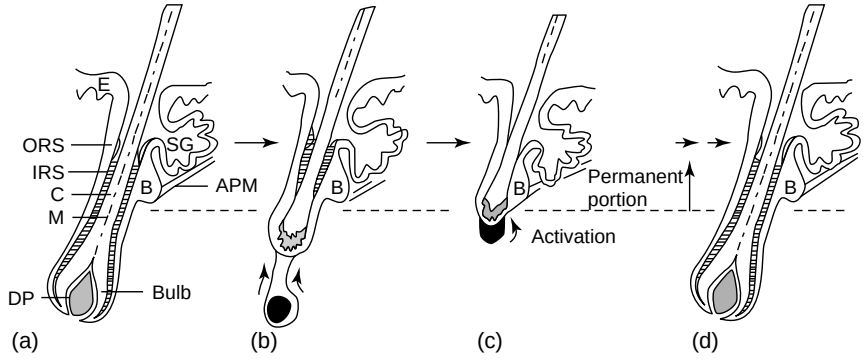

Figure 2 Diagrammatic representation of hair follicles at different stages of the growth cycle. Anagen is the active growth phase during which follicle development takes place and the hair fiber is produced. Catagen is the regression phase in which tissue changes occur as the follicle approaches telogen, the resting phase. The next anagen is thought to be initiated by an interaction between dermal papilla cells and pluripotent stem cells located in the bulge region. B, bulge; APM, arrector pili muscle; SG, sebaceous gland; C, hair cortex and cuticle; M, medulla; DP, dermal papilla [Reproduced with permission from Elsevier. © 1990.]

the percentage of hairs in each phase, and hair growth rates for other types of human hair are different [1].

Hair Transfer and Persistence

Hairs are not generally "shed" but are usually removed by normal everyday activities such as combing or brushing hair. This primary loss leaves hairs on clothing, bedding, car seats, and so on. Most recovered hairs are the result of a secondary transfer from the latter types of surfaces. Once transferred, hairs are not static and redistribute. Hence, great care needs to be taken in reading too much into the location of recovered hairs, although in some cases this is critical information.

Work on trace materials, especially fibers, has demonstrated a classic decay curve with a very high initial loss of trace material followed by a much slower loss over time. Until recently, hairs were thought to behave in a similar way. Work by Dachs *et al.* [2] and Boehme *et al.* [3] have shown that for both human and animal hairs, there is an initial loss but hairs are not lost as quickly as fibers, and the loss follows a more linear decay pattern. This is especially so with coarser or more open structured wool and acrylic recipient fabrics where the hairs appear to become physically "trapped".

Hair Morphology and Microscopic Structure

During the differentiation phase in the growth of a hair, three distinct cellular components are formed:

- the central "medulla" or core;
- the main body of the hair or "cortex"; and
- the outer "cuticle" comprising overlapping scales.

The development of these cell types in the follicle is described in Harding and Rogers [1]. Cortical cells are elongate or fusiform (spindle shaped) and have a complex chemistry based on filaments with different forms of keratin in macro- and microfibrils. In human hairs cortical cells are 80–100 μm long and 5–10 μm at their widest point. The total width of human scalp hair varies between 20 and 120 μm.

Hairs are visually and microscopically colored due to the presence of "melanin" pigment granules. There are two main types of melanin pigment, "eumelanin", which are dark brown to black in color, and "phaeomelanin", which are reddish yellow. All naturally colored hair contains various proportions of these two pigment types. Melanin synthesis takes place in melanosomes that are subcellular particles present in cells called *melanocytes*. These cells secrete the pigment granules into the cortical cells as they develop in the cells at the apex of the dermal papilla in the hair root. Pigment granules can be found in the medulla, but are not usually found in the cuticle.

The medulla comprises loosely packed cells with an open structure. In human hairs there are periods when the medulla is not produced in the follicle resulting in the medulla being absent from the hair shaft. The overall appearance of the medulla in human hair is amorphous or lacking a well-defined structure. When present it is often not continuous and it occupies less than one-third of the shaft diameter. By contrast, in nonhuman animal hairs, the medulla is most often continuous and broad, occupying more than one-third of the hair shaft. The width of the medulla over the width of the hair shaft is termed the *medullary index* (MI). In nonhuman hairs the medulla cellular structure usually has a well-defined structure that can be easily described and classified. Typical medulla types include multiserial ladder and wide aeriform lattice (Figure 3).

Finally, the cuticle forms the outer layer of the hair shaft. The cuticle is composed of flattened and overlapping (imbricate) scale cells. The scales slope outward with their edges pointing toward the tip of the hair. Although a single layer of cells in the follicle, they overlap such that, in human hairs, the effective thickness is about six cells. In nonhuman hairs the effective cell thickness can exceed 10 cell layers. The appearance of these overlapping scales, when viewed microscopically, can be described and used to differentiate animal hairs. All human scalp hairs have the same basic imbricate or flattened scale pattern and this feature cannot be used to differentiate between human hairs.

The Forensic Process

Hicks [4] describes the process of hair examination as a "procedural forensic taxonomy", based on the questions below:

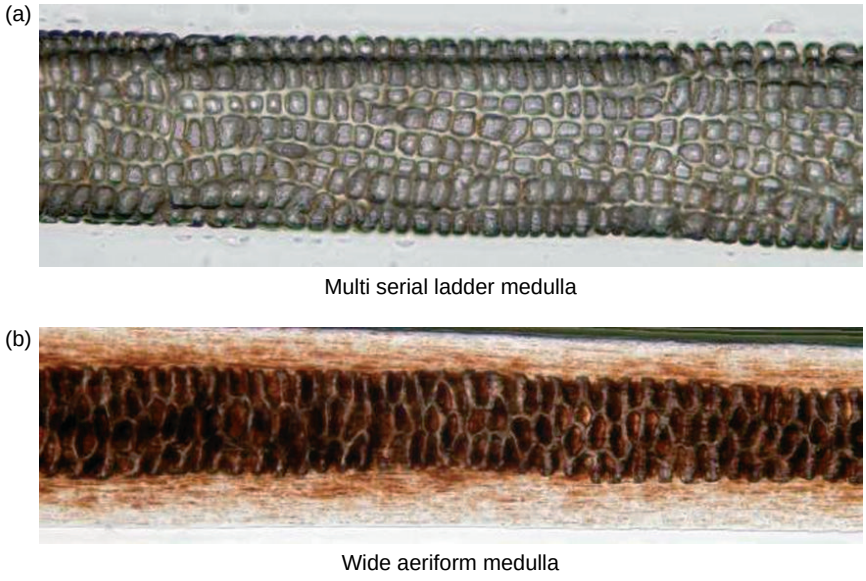

Figure 3 Examples of animal hair medulla: (a) multi serial ladder medulla and (b) wide aeriform lattice medulla

1. Is the object a hair?
2. If it is, is it human or animal?
3. If it is an animal hair, what kind of animal did it come from?
4. If it is a human hair, the hair is examined for the following information:
   (a) somatic area of origin (body area);
   (b) estimation of ancestry (race, ethnicity);
   (c) evaluation of root (phase of growth, presence of cellular material);
   (d) evaluation of the tip;
   (e) other damage, disease, or treatment; and
   (f) assessment of the hair's suitability for microscopic comparison.

To answer these questions, typically the forensic examiner has one or more (often many) hairs that have been "recovered" from a crime scene or following examination of clothing or other items. It is important, if the hair examiner has not personally recovered these hairs, that the examiner is fully aware of all information which may be relevant to assessing evidential significance. Hair examination is "not" merely an exercise in individualization.

These "recovered" hairs become the "questioned" hairs in the forensic process. The specific location of recovered hair(s) may be the critical factor. In some case situations, it may be sufficient to confirm that the recovered material are indeed hairs, and then whether or not they are human or nonhuman. In the absence of exemplar or "known" hair samples, it may be possible to individualize a recovered hair through DNA testing.

Routinely, the forensic hair examiner has samples of hair that have been collected from a deceased person, a victim of an alleged crime, from one or more suspects, or from other relevant persons for elimination purposes. For animal hairs, the known sample may come from an animal relevant to the alleged circumstances of the case.

It is essential that known samples meet appropriate standards in that there are sufficient numbers and the hairs are representative of any variation in the donor. Too often, known samples do not meet these basic requirements. For human scalp hair, the recommended number is in the order of 100 hairs. For human pubic hairs, which are less variable, in the order is 40–50 hairs. A mix of anagen and telogen hairs is preferable. For this reason, combing is the best technique as it yields more telogen hairs typical of what is seen in recovered hairs. Pubic areas of victims should first be combed to recover loose hairs which may be extraneous and of evidential value. Hairs should only be cut as a last resort and this must be at skin level. For animal hairs, where identity is

the issue, laboratories should have relevant reference sample collections.

A subset of the known hair sample is selected on the basis of visual examination, and, sometimes, after examination using a low magnification microscope with incident illumination.

At this level of examination it is usually possible to separate nonhuman and human hairs, but this needs to be confirmed by microscopic examination of mounted hairs. For nonhuman hairs, the microscopic scale features are very important in identifying an animal source. It is usual to take a caste or impression of the scale pattern before mounting animal hairs for microscopic examination. For human hairs, the subset of selected hairs (usually 10 hairs) are mounted by placing individual hairs onto glass microscope slides with a permanent mountant. There are several suitable mountants. The key factor is that the mountant should have a refractive index (RI) of 1.52–1.54, similar to the RI of the hair cortex at 1.55.

Table 1 lists the features of human *versus* nonhuman hair.

The subsequent examination of animal hairs involves systematically and thoroughly describing the microscopic detail at low magnification and higher magnification microscopy. Features assessed include hair shape or profile, cuticle and scale features, medulla appearance, and color. The most common animal hairs seen in forensic laboratories are domestic cat and dog hairs. These can be surprisingly difficult to differentiate. The easiest and surest method to distinguish cat from dog hair relies on measuring the MI and plotting this against hair width (see [5]).

For human hair, the forensic examination process starts with a detailed examination of mounted hairs using incident illumination and a low magnification ($\times 10$ to $\times 40$), stereomicroscope. At this magnification, features assessed include hair length, the shaft profile, the visual color, and the appearance of the root and tip. The literature contains numerous schemes to describe these features. The author's scheme for human hair features is included as Appendices 1 and 2. This classification of hair features is discussed by Robertson [5].

At the stereomicroscope level, the examiner is usually able to comment on somatic origin (body area) and may be able to estimate ancestry. Neither of these categories is as clear cut as one might expect as there are intermediate hair types and we live in a world of increasing mixed ancestry.

The most important element of the stereo examination of questioned hairs is to assess their suitability for "routine" nuclear (n)DNA testing. The critical requirement is to be able to accurately identify telogen hairs as these are "not" suitable for routine nDNA testing. Anagen hairs are suitable for nDNA testing and some success may be obtained with early stage catagen hairs. A common mistake made by inexperienced examiners is to select hairs on the basis of attached cellular material remaining from the hair follicle. Often telogen hairs have a small tag of cellular material but this does not contain DNA. Figure 4 shows hairs suitable and not suitable for nDNA testing. Recent work in any laboratory has shown that it may be possible to obtain in DNA from some telogen hair when a sufficient number of nuclei are present (Brooks, personal communication).

The appearance of the tip end may also yield important information including the individuals grooming habits and, sometimes, health condition.

Table 1 Human compared with nonhuman hair features

Feature	Human	Nonhuman
Color	Relatively consistent along shaft	Often showing profound color changes and banding
Cortex	Occupying most of the width of shaft – greater than medulla	Usually less than the width of medulla
Distribution of pigment	Even, slightly more toward cuticle	Central or denser toward medulla
Medulla	Less than 1/3 width of shaft amorphous, mostly not continuous when present	Greater than 1/3 width of shaft continuous, often varying in appearance along shaft, defined structure
Scales	Imbricate similar along shaft from root to tip	Often showing variation in structure along shaft from root to tip

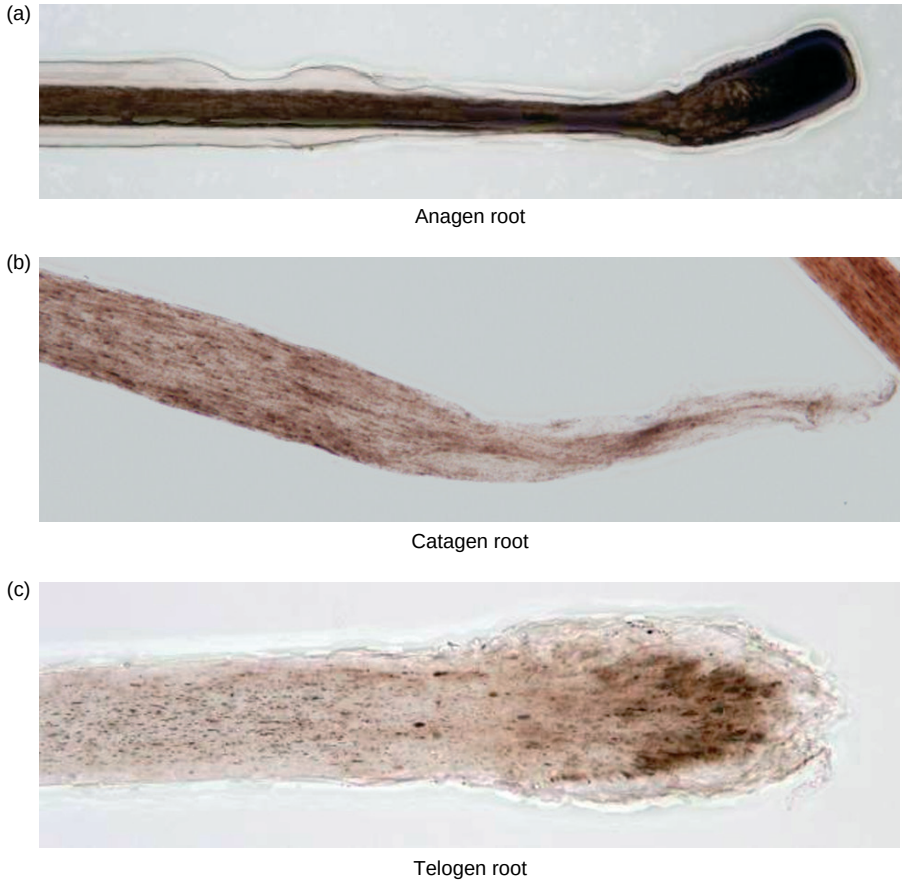

Figure 4 Hair root growth phases: (a) anagen root, (b) catagen root, and (c) telogen root

Color is an important feature initially assessed at stereo level. Here, an early indication of artificial coloring is often visible.

In the forensic process, examination may not be necessary beyond the stereo microscope level. It is critical to emphasize that hair cases require careful management focused on what are the aims of the examination process. The complexity of cases obviously varies but the fundamental aim is consistent, that is, to answer the question as to whether or not a questioned hair could have originated from a nominated individual. Provided a good quality known hair sample is available, the examiner can determine the variation present in that sample and the variation between samples. If a questioned sample is different from a known sample, then it can be eliminated. Simple as this sounds the reality is a little more complex. This is because no two hairs are identical in every respect and too often the known samples have limitations. Nonetheless the essential, and critical element, is that the examination focuses on meaningful differences and not on similarities. A similarity is a small difference!

If a questioned hair cannot be eliminated at the stereo level, the forensic process moves to the use of transmitted light microscopy with a normal total magnification range of $\times 100$ to $\times 400$. At this level it is possible to see the internal features of the hair including the medulla (when present), the cortex and in particular, the pigmentation and other features such as cortical fusi and ovoid bodies. Because hairs are essentially round (there is some racial variation in cross sectional shape), it has traditionally proved very difficult to produce photographic images that accurately convey what is seen by the examiner. The examiner constructs a mental three-dimensional

image of the hair by focusing through the hair. The recent use of automontage techniques, which allows the examiner to build up an image of an optical section of the hair, has enabled the examiner to now produce exceptional "in focus" images of hair features (Brooks, 2007). These images can be used for numerous purposes and hold the future promise that it may be possible to conduct numerical and objective assessment of the microscopically observable features.

At this time, hair examiners rely on personal judgment to "call" a particular feature. It is beyond the scope of this article to attempt to describe the subclassification of the detailed microscopically observable features (see [5]). Suffice to say that many of the features examined deal with pigmentation and how it is organized, or presents, to the examiner. Good practice must include the examiner making a detailed, systematic, and accurate record of the features seen. The use of data sheets as shown in Appendices 1 and 2 promotes this objective. However, it would be an inappropriate use of such a data sheet to expect that they could be "overlayed" to show a "match". A questioned and known hair "must" be compared side by side using a "comparison" microscope (see Figure 5). This allows the examiner to compare the overall pattern of the hairs and the precise detail at comparable points along the hair shaft. If there are no meaningful differences the examiner moves from the area of elimination to that

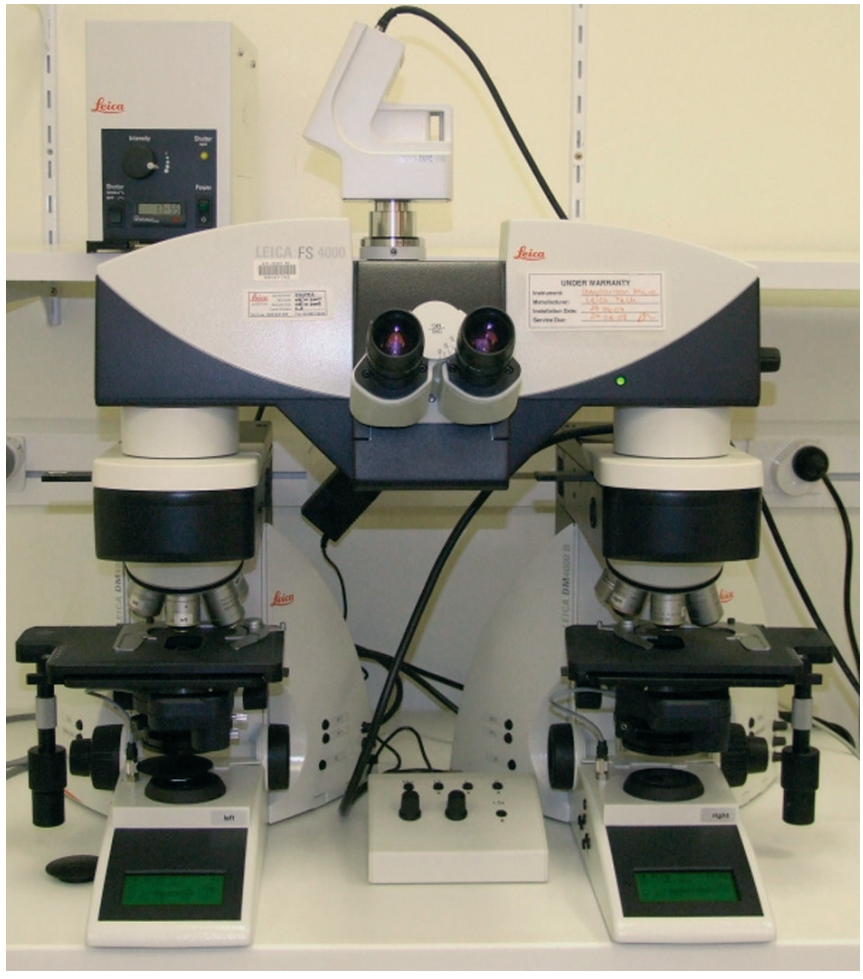

Figure 5 Comparison microscope

of inclusion. What does inclusion mean in forensic context and how far can a hair examiner go to individualize a hair?

Hair Individualization

As stated above, the primary focus of the hair examinations should be elimination. It is often possible to say that a questioned hair could not have come from a nominated individual(s). It is important to recognize that in many case situations, there are many recovered hairs and possibly many donors. It is often not possible to "assign" every recovered hair. By eliminating obviously different hairs the examiner can focus on the hairs that fall within the range of one or more known samples. Conceptionally hairs should be considered as "packages of information". A relatively colorless hair, or indeed an opaque black hair, have very low observable information. A hair with clear and well-defined pigmentation and other microscopically observable features would have a much higher information content. Many hairs are obviously different at the stereo microscope level, but a higher level of discrimination can be achieved with higher magnifications and transmitted light microscopy. If no meaningful differences are seen when two well-featured hairs are compared at high magnification this is a meaningful inclusion. However, it has to be accepted that the conclusions drawn by the examiner are subjective and result from judgment borne of experience. The word "experience" here fails to convey what is really meant. Someone could have 20 years experience and be a hopeless examiner for a whole spectrum of reasons. Experience, regrettably, is not always a key indicator of competence. Nonetheless, it is also inescapable that for the competent examiner it is the experience of simply dealing with numerous hair examinations, which assists in assessing the significance of a hair comparison.

Gaudette and colleagues have attempted to assist forensic examiners to place some numerical weight on their conclusions (Gaudette, 1999). Ignoring the possibility of an inconclusive result, Gaudette points out that there are two possible conclusions that can arise from a hair comparison:

(a) that the unknown or recovered hair could have come from the same person from whom a known hair sample was obtained or
(b) that the recovered hair could not have come from such origin.

(The author notes that he used "could have come from" and not "is consistent with" as used by Gaudette.)

Similarly there are two possible states of reality:

(1) the hair did originate from the same person as the known sample or
(2) the hair did not originate from the same person as the known sample.

If the true state of nature is (1) and conclusion (a) is reached, then the examiner is correct. If the true state of nature is (2) and conclusion (b) is reached, then the examiner is also correct. However, if the truth is (1) above but the examiner concludes (b), then an error is committed. The examiner has wrongly eliminated a person as being the source of the recovered hair. Gaudette refers to this as a "Type I error".

The final possible combination is that the truth is (2) above but the examiner concludes (a). This is a "Type II error" and has far more serious consequences because the examiner has wrongly included a person as the possible source of a hair.

Because the implications of a type II error are so serious, hair examiners have always tended toward a conservative approach to minimize this type of error, probably at the cost of an increase in type I errors.

When it is stated that a recovered hair could have come from a known source there are two possibilities: either the hair actually originated from that person "or" there was a coincidental match. It is well recognized in the scientific literature that it is possible for two different people to have hairs that are indistinguishable by present methods. Thus, coincidental matches occur. Gaudette aimed to quantify this possibility, but the interpretation of his figures is greatly debated. Many observers accept these studies do show that the chance of a coincidental match can be quite small. It is not possible to quantify this figure for general application because it depends on a number of factors. Paramount is the ability of the examiner to discriminate between hairs. For any examiner, the characteristics of the individual hair must be considered. Clearly, as previously stated, hairs with well-defined pigment and other features contain much more information potential than relatively colorless hairs.

Any reasonable hair examiner is willing to admit that hairs are not unique and no sensible examiner allows himself or herself to quote a statistical figure.

The advent of nDNA analysis means that in some instances it is possible to individualize and give a statistical estimate of the likelihood of a hair having come from a nominated individual. As previously stated "normal" mtDNA analysis is only possible with hairs in the anagen or early catagen growth phase.

Several studies have looked at extending nuclear DNA testing to telogen hairs [6] with some studies reporting limited success with telogen hairs using modified DNA analytical techniques. My own group are of the view that the DNA being detected is not inside (endogenous) the hair but is rather on the outer layer of the hair (exogenous) and that it may be better to view "hairs" as a surface on which trace DNA may be found. Regardless of the above debate, the current situation is that success rates with genuine telogen hairs are quite low and the profiles obtained are often incomplete and difficult to interpret.

It is also possible to analyze for mitochondrial (mt) DNA. There are only a small number of laboratories worldwide offering mtDNA testing which, for hairs, is time consuming and quite costly. The technique requires 1–2 cm of hair, preferably with the root present. Because of its cost and the fact it is a destructive technique, hairs should "always" be first subjected to microscopic examination from an elimination perspective. Even if a mtDNA result is obtained, it is not possible to separate brothers and sisters from their mother due to maternal inheritance of mtDNA. Statistical databases for mtDNA remain relatively small and some courts have only accepted mtDNA as having exclusionary value.

A recent study of microscopic hair comparisons and subsequent mtDNA analysis has confirmed the value of a dual approach of microscopy followed by mtDNA testing. Not all hairs are suitable for meaningful microscopic comparison and mtDNA testing is especially useful in these instances [7].

From time to time other nonmicroscopic approaches to hair examination have been proposed. Over the decades these have included elemental analysis using neutron activation analysis (NAA), protein analysis, ABO typing [5] and, most recently, it has been suggested that isotope ratio mass spectrometry (IRMS) may yield useful information. The scientific basis for the latter is that the hair is an environmental monitor and that isotopes reflect the geographic history of the donor.

None of these approaches has, or will, replace the core position of microscopic examination.

Admissibility and Evidential Value of Hair Comparisons

Rules of evidence and admissibility vary according to country and legal system. However, the Frye Test and subsequent Daubert Test in the United States have provided a useful framework to discuss whether or not hair examinations can meet relevant standards. Houck *et al.* [8] recently discussed these issues and concluded that hair comparisons can be reliable when such comparisons are conducted by a competent examiner working under an appropriate quality assurance framework. The Scientific Working Group for Hairs (SWGhair) continues to develop recommendations for such standards and for the training of hair examiners. Houck and Bisbing [9] have discussed what might constitute an appropriate training program. This must include the evaluation of testimony skills and comprehensive competency testing. The latter can be problematic given the lack of good quality and appropriate external proficiency tests for hair.

An area of concern to many forensic scientists is the apparent willingness of courts to accept scientists as qualified to give expert-opinion evidence "without" a rigorous examination of their qualification and relevant experience to offer an opinion. A difficult question in the area of hair examination is whether there is a relevant scientific community. Houck *et al.* [8] argue that there is a long history of scientific research in comparative biology and physical anthropology dating back to the eighteenth century. While this may be true, the difficulty faced by lawyers today may be in finding an expert who has experience and credibility.

Concluding Remarks

In many cases hairs are only one of a number of trace materials recovered. Often the condition of such hairs is important. For example, where a person has been assaulted by a particular type of implement or weapon. Sometimes

the number and location of hairs can be useful in attempting to reconstruct events. As demonstrated above, where hairs are not examined, this can leave unanswered questions that make it more difficult for juries to determine the circumstances and facts of a case.

The reality is that hairs are a very common, if not the most common, trace material encountered

in forensic work. To ignore them is facile and may jeopardize an investigation, and ultimately a "just" outcome.

There remains a need for a concerted research effort to provide a more solid basis for the interpretation of hair evidence. It is also time for laboratory systems and scientists that are either unable or unwilling to embrace hair examinations with the necessary investment in time and commitment to withdraw altogether from the field. Half-hearted commitment can only continue to do damage to the credibility of hair examination.

JAMES ROBERTSON

Hair: Toxicology

Introduction

Using hair as a medium to analyze drug exposure has been receiving increased attention during recent times because of the less embarrassing circumstances of collection, its long drug detection window, and because it does not decompose like other body tissues after death.

In 1979, Baumgartner *et al.* [1] published the pioneering report on using radioimmunoassay (RIA) to detect morphine in the hair of heroin abusers. This article was followed by a great number of studies, which mostly included RIA and/or gas chromatography–mass spectrometry (GC/MS). Today, chromatographic procedures, especially those coupled to MS or tandem MS, represent the gold standard for the identification and quantification of drugs in hair, owing to their separation ability and their low limits of detection.

Hair analysis is now routinely used as a tool for the detection of xenobiotics (drugs of abuse, pharmaceuticals, environmental contaminants, doping agents, etc.) in forensic science, traffic medicine, occupational medicine, and clinical toxicology.

Biology of Hair

Hair is a product of differentiated organs in the skin of mammals composed of protein (65–95%, keratin essentially), water (15–35%), lipids (1–9%), and minerals (<1%). The hair shaft consists of an outer cuticle that surrounds a cortex. In some types of hair, the cortex surrounds a central medulla. The hair shaft develops in a follicle closely associated with the sebaceous and apocrine glands. The growth of hair occurs in cycles, alternating between periods of growth (*anagen* phase) and periods of quiescence (*catagen* and *telogen* phases). About the one million hair follicles of the adult scalp, approximately 85% of the hair is in the growing phase and the remaining 15% is in a quiescent stage. Hair is produced during four to eight years for head hair (<6 months for nonhead hair) at a rate of approximately 0.22–0.52 mm per day or 0.6–1.42 cm per month [2] for head hair. The

growth rate depends on the type of hair, physiological factors, and anatomical location.

The exact mechanism by which chemicals are bound in hair is not known, but it is generally considered that xenobiotics can enter into hair by at least three mechanisms: from the blood during hair formation, from sweat and sebum, and from the external environment.

Collection procedures for hair analysis of drugs have not been standardized. In most published studies, the samples are obtained from random locations on the scalp, but hair is best collected from the area at the back of the head, called the *vertex posterior*. Compared with other areas of the head, this area has less variability in the hair growth rate, the number of hairs in the growing phase is more constant, and the hair is less subject to age- and sex-related influences. Pubic hair, arm hair, and axillary hair are possible alternative sources for drug detection when scalp hair is not available.

Hair Analysis

The most crucial issue facing hair analysis is the avoidance of false-positive results caused by passive exposure in the environment to the drug, causing it to be present on the surface of the hair rather than incorporated in it. In most laboratories, hair analysis starts with a wash step to remove external contamination.

Hair analysis involves at least five steps:

1. decontamination of the hair
2. preparation of the hair: pulverization, segmentation in short pieces
3. incubation: in methanol, acid, sodium hydroxide, buffer
4. extraction: liquid/liquid, solid phase, solid phase microextraction
5. analysis immunoassay screening (ELISA) and/or chromatography (gas, liquid) coupled to MS (tandem).

Cut-off concentrations from the Society of Hair Testing (SoHT) and expected concentrations in hair for drugs of abuse are presented Table 1.

These cut-offs were established to avoid false-positive results due to external contamination. They are used both for ELISA screening (enzyme linked immunosorbent assay q.v.) and chromatographic confirmations in workplace drug testing.

Table 1 SoHT cut-off concentrations (when tested by GC/MS) and expected concentrations for drugs of abuse in hair

Drug	GC-MS cut-off concentration	Expected concentrations
Heroin	0.2 ng mg^{-1} of 6-acetylmorphine, morphine	0.5–100 ng mg^{-1}, in most cases <15 ng mg^{-1}
Cocaine	0.5 ng mg^{-1} of cocaine and 0.05 ng mg^{-1} of benzoylecgonine and cocaethylene	0.5–100 ng mg^{-1}, in most cases <50 ng mg^{-1}, in crack abusers >300 ng mg^{-1} is possible
Amphetamine, MDMA	0.2 ng mg^{-1} for each drug	0.5–50.0 ng mg^{-1}
Cannabis	0.1 ng mg^{-1} for THC	THC: 0.05–10 ng mg^{-1}, in most cases <2 ng mg^{-1}
	0.2 pg mg^{-1} for THC-COOH	THC-COOH: 0.5–50 pg mg^{-1}, in most cases <5 pg mg^{-1}

MDMA, methylenedioxymethamphetamine; THC, tetrahydrocannabinol; THC-COOH, tetrahydrocannabinol-11-oic-acid

In most cases, they are not applied in forensic cases, where sometimes a single exposure has to be demonstrated.

Applications

Verification of Drug Use History

By providing information on exposure to drugs over time, hair analysis may be useful in verifying self-reported histories of drug use in any situation in which a history of past rather than recent drug use is desired. During control tests of hair, a drug user is not able to hide their drug abuse, as the window of detection is often very long, i.e., months. Urine or blood tests are not useful to detect drug use when drugs are consumed every few days even when the tests are repeated [3].

The advantages and disadvantages of drug detection in urine and hair are presented in Table 2.

Hair analysis can also provide a retrospective calendar of an individual's drug use. For this, multisectional analysis is required and involves taking a length of hair and cutting it into sections to measure drug use during shorter periods of time. The hair must be cut as close as possible to the scalp and particular care is also required to ensure that the individual hairs in the cut-off tuft retain the position they originally had beside one another.

The most extensive study on sectional analysis for drugs of abuse has involved patients in rehabilitation centers. Segmental hair analysis is used to verify both their previous drug history and their recent enforced abstinence. To verify abstinence, the lowest drug concentration is found in the segments nearest the root.

The differentiation of heroin users from individuals exposed to other sources of morphine alkaloids can be achieved by identifying directly heroin or 6-acetylmorphine [4].

Hair analysis is suitable for accurately monitoring relative changes in drug intake in the same individual. In several studies, it has been shown that a doubling of drug dose in the same individual results in a doubling of the drug content of the hair, which is not the case for blood and urine drug level. Patients who received constant methadone doses under close supervision showed considerable constancy in their methadone levels in hair.

Several studies have suggested that the hair color (or the melanin content) may be the major determinant of drug binding and, consequently, may result in color bias in hair testing. Researchers have demonstrated that different hair types incorporate differing amounts of drugs when exposed under identical conditions. The higher accumulation of alkaline substances (such as cocaine or heroin) in black hair as compared with blond hair will need to be addressed (or controlled) in order not to discriminate specific population due to their hair color, resulting in inequity during investigation [5].

Table 2 Main characteristics and performance of analyses in urine and hair

	Urine	Hair
Drugs of abuse and pharmaceuticals detected[(a)]	All	All
Main compounds	Metabolites	Parent drugs
Detection time window	2–3 days	Months, years
Analytical techniques	Immunoassays, followed by chromatography/mass spectrometry	Chromatography/mass spectrometry
Specificity	Family diagnosis, then specific confirmation	Specific identification
Analysis duration	+	+ + +
Type of measurement	Incremental	Cumulative
Sample collection	±invasive	Noninvasive
Adulteration	Possible	Impossible
Preservation	−20 °C	Ambient temperature

[(a)] only doping hormones erythropoietin(EPO), growth hormoneGH etc.) are not incorporated in hair

Alcohol Abuse

Considering the large dimension of alcohol-associated problems, the diagnosis of excessive alcohol consumption is an important task from medical point of view. Markers of ethanol consumption in hair are ethylglucuronide and fatty acid ethyl esters (FAEE). Detection of ethylglucuronide in hair is always associated with alcohol consumption, whereas a negative result does not unambiguously exclude the alcohol abuse [6]. Investigations on the FAEE have been proposed by Pragst *et al.* [7] to monitor alcohol consumption. FAEE are formed in presence of ethanol and free fatty acids, triglycerides, lipoproteins, or phospholipids by an FAEE synthase found not only in liver but also in hair roots. FAEE determination is of interest as they appear responsive to alcohol-induced organ damage. Four FAEE (ethyl myristate, ethyl palmitate, ethyl oleate, and ethyl stearate) are suitable markers for the detection of heavy alcohol consumption and show differential concentrations in hair of children, adult teetotalers, and social drinkers in comparison with FAEE concentrations found in hair of alcoholics.

Verification of Doping Practices

Athletes use both endogenous and exogenous anabolic steroids because it has been claimed that they increase lean body mass, strength, and aggressiveness and lead to a shorter recovery time between workouts.

The greatest use of hair in this context may be in identifying false-negatives results in negative test results on blood or urine due to recent abstinence of a drug a few days before the competition. Hair can also indicate the history and frequency of drug intake as repetitive use can be demonstrated by segmental analysis along the hair shaft.

Unlike testosterone in urine, the interpretation of concentration findings in hair can be difficult. The range between physiological concentrations of testosterone and those found in abusers seems to be rather small. Therefore, to complement testosterone determination, the identification of unique testosterone esters in hair enables an unambiguous determination of doping because the esters are exogenous substances and therefore could not come from endogenous testosterone [8].

Another advantage of hair analysis is the possible discrimination between nandrolone and abuse of other 19-norsteroids (norandrostenedione and norandrostenediol), which lead to the same urinary metabolites (norandrosterone and noretiocholanolone). This is obviously not possible in urine, where hair can identify the exact identity of the parent compounds [9].

In the case of longitudinal surveys of athletes, hair analysis appears as the solution of choice to document doping practices.

β-Adrenoceptor agonists are banned in competition sports because of their sympathomimetic properties (stimulant effects) and their activity as anabolic agents at higher dosages. However, salbutamol is permitted only by inhalers and must be declared prior to the competition. As the drug is permitted for specific therapeutic purposes, together with a medical prescription, it is relatively easy to evade a positive urine test. Again, segmental hair analysis would document unambiguously doping by the athletes, when the drug (such as a corticoid or an anabolic compound) is found in several consecutive hair sections. This can also be controlled in the case of long-term abuse of corticoids.

Regranting of Driving Licenses

The major practical advantage of hair testing compared with urine and blood testing for drugs is its larger detection window, which is weeks to months, depending on the length of the analyzed hair shaft, against a few days for urine. There is a reasonable agreement that the qualitative results obtained from hair analysis are valid and that hair can provide long-term histories of drug use. In some countries, persons whose driving license has been refused, revoked, or suspended for addiction to psychoactive drugs or for driving “under the influence” can obtain a license after a medical committee has confirmed the actual and complete abstinence from illicit drugs by the use of hair testing and has excluded any additional risk of future relapse of drug abuse. To provide objective evidence of abstinence from drugs with an acceptable chronological window in order to support the clinical decision of this medical committee, hair analysis has been included in a panel of clinical and laboratory tests, aimed at investigating retrospectively any drug-associated behaviors of subjects. Comparison between hair analysis and urinalysis shows a much higher diagnostic sensitivity for hair tests [10].

Drug-Facilitated Crimes

The use of a drug to modify a person's behavior for criminal gain is not a recent phenomenon. However, the recent increase in reports of drug-facilitated crimes (sexual assault, robbery, incapacity, etc.) has caused alarm in the general public. Drugs involved can be pharmaceuticals, such as benzodiazepines (flunitrazepam, lorazepam, etc.), hypnotics (zopiclone, zolpidem), sedatives (neuroleptics, some antihistamines), or anesthetics (γ-hydroxybutyrate (GHB), ketamine), drugs of abuse, such as cannabis, ecstasy, or LSD, or more often ethanol. Owing to their low dosage, excepted for GHB, a surreptitious administration into beverages such as coffee, soft drinks, or alcoholic cocktails is relatively simple.

Most of these substances possess amnesic properties and therefore the victims are able to less accurately recall the circumstances under which the sexual offence occurred. As they are generally short acting and short lived, they impair an individual rapidly and are then excreted or metabolized quickly. In these situations, blood or even urine can be of little assistance in demonstrating the use of drugs. Hair was suggested as a valuable specimen in situations where, as a result of a delay in reporting the crime, natural processes may have eliminated the drug from typical biological specimens. The introduction of the use of liquid chromatography (LC)-MS/MS allows the detection of a single dose of most sedatives [11].

The discrimination between a single exposure and long-term use can be documented by multisectional analysis. In the absence of migration of the drug or its metabolite along the hair shaft, a single spot of exposure must be present in the segment corresponding to the period of the alleged event, using a growth rate for hair of 1 cm per month. As this growth rate can vary from 0.7 to 1.4 cm per month, the length of the hair section must be calculated accordingly and this variability accounted within the estimates of time of use. A delay of three to five weeks between the offense and hair collection for sectional analysis (2-cm segments) is recommended so as to analyze the hair shaft at the point of exposure. The hair must be cut as close as possible to the scalp. Particular care should also be taken to ensure that the individual's hair in the strand retains the position it originally had beside every other strand.

Conclusion

It appears that the value of hair analysis for the identification of drug users is gaining recognition. This can be seen from its growing use in preemployment screening, in forensic sciences, and in clinical applications. Hair analysis may be useful adjunct to conventional (urine and blood) drug testing in toxicology. Specimens can be more easily obtained with less embarrassment, and hair can provide a more accurate history of drug use.

Although there are still controversies on how to interpret the results, particularly concerning external contamination, cosmetic treatments, ethnic bias, or drug incorporation, pure analytical work in hair analysis has reached a sort of plateau, having solved almost all the analytical problems. Although GC and LC-MS are the methods of choice in practice, GC and LC-MS/MS are today used in several laboratories, even for routine cases, particularly to target low-dosage compounds.

Hallucinations

Introduction

Hallucinations are sensory perceptions experienced while awake with a compelling sense of reality in the absence of external stimuli. Hallucinations can involve one or more of the five primary sensory senses of hearing (auditory), vision (visual or optical), smell (olfactory), taste (gustatory), and touch (tactile). Auditory hallucinations consist of sound, usually voices, although noises and music are not uncommon. Visual hallucinations may consist of complex images such as living creatures as well as simple images such as flashes of light. Olfactory and gustatory hallucinations involve usually unpleasant false perceptions of smell and taste, respectively. Tactile hallucinations involve the sense of touch, such as in formication (the sensation of insects crawling under the skin).

Hallucinations differ from illusions, which are misperceptions or misinterpretations of objective sensory stimuli. Insight as to whether the hallucination represents a false sensory experience may or may not be present. A hallucination is a symptom or a manifestation of a mental or medical condition resulting from a variety of etiologies. Hallucinations often co-occur with delusions (*see* **Delusions**).

The Origin of Hallucinations

Research has shown that during the experience of hallucinations, the part of the brain responsible for the actual sensory perception is active. For example, when experiencing auditory hallucinations, the auditory cortex of the brain is active as if actually hearing an external sound [1].

Hallucinations have been associated with various biological causes. Pathology of the central nervous system (CNS), i.e., the brain and related structures, has been associated with the development of hallucinations. Traumatic brain injury, cerebrovascular accidents (strokes), infectious or inflammatory CNS illnesses, tumors or other space-occupying lesions, and seizure disorders have been associated with hallucinations.

With advancing age, the likelihood of developing dementia increases. Although the central feature of dementia involves cognitive impairment, visual and auditory hallucinations frequently appear in individuals suffering from the commonly seen dementias arising from Alzheimer's disease, Parkinson's disease, and dementia with Lewy bodies [2–5].

Medical illnesses that lead to metabolic disturbances, such as endocrine, vitamin deficiency, hepatic, or renal disorders that have CNS effects, can also lead to the development of hallucinations. Recreational drugs (e.g., methamphetamine, cocaine, cannabis (marijuana), mescaline, lysergic acid diethylamide (LSD), phencyclidine, psilocybin (hallucinogenic mushrooms), and 3,4-methylenedioxymethamphetamine (MDMA or Ecstasy) frequently give rise to hallucinations with their use. Alcohol has been associated with hallucinations, though the most common manifestation has been visual hallucinations associated with alcohol withdrawal syndrome. Several prescribed medications have also been implicated in the development of hallucinations, including medications prescribed to treat mental disorders [6–8].

Hallucinations can also arise in association with intense stress, sleep deprivation, and sensory deprivation. In acute grief reactions, the recently deceased

loved one may be perceived by the survivor as having communicated via auditory or optical means. Extreme psychosocial stressors, such as experiencing events involving actual or threatened death or serious injury, can lead to the development of posttraumatic stress disorder (PTSD). A principal feature of PTSD involves recurrent and intrusive flashbacks of the traumatic event that involves one or more of the primary senses.

The most common manifestation of hallucinations occurs in the context of psychosis, particularly schizophrenia and related psychoses, mood disorders with psychotic features, and substance-induced psychotic disorders [9]. Nonetheless, despite various scientific explorations regarding the biological origin of hallucinations, our knowledge at this level remains in the embryonic stages [10, 11].

Treatment of Hallucinations

When there is an identified biologic causation to the hallucinations, such as a vitamin deficiency giving rise to beriberi, the treatment consists of treating the medical condition with the vitamin thiamine. Similarly, when treating a substance-induced psychotic disorder with hallucinations, abstinence from the offending drug should, but not always, quell the hallucinations and other psychotic symptoms. Treatment of hallucinations associated with dementia, even with a known illness such as Alzheimer's disease, Parkinson's disease, or dementia with Lewy bodies, has a lower success rate in view of the limitations of the therapeutic interventions for these medical illnesses.

In treating auditory hallucinations in the cases of schizophrenia, mood disorders with psychotic features, or other psychoses, use of antipsychotic medications has resulted in reduction of auditory hallucinations, delusions, and/or other manifestations of psychosis. Nonetheless, the proportion of individuals whose hallucinations or other psychotic symptoms fail to respond to clinical intervention is not insignificant.

Command Hallucinations

When the content of hallucinations involve a command or order for the individual to act, such hallucinations have come to be known as *command* hallucinations. Command hallucinations may be the most commonly known form of hallucinations by the general public whether in the venue of a high profile criminal trial, or when family members, neighbors, or strangers are thought to be experiencing them in the community. Command hallucinations can take one of two forms, auditory or visual. Visual hallucinations involving text (known as *orthographic* hallucinations) generally are comprised of individual letters, words, or nonsense letter strings. Orthographic hallucinations generally appear in the context of medical or neurologic disease. Only one case of command visual (orthographic) hallucinations has been reported in the literature in the past quarter of a century [12].

Command auditory hallucinations alert the psychiatrist or other mental health professional of a potential for harmful or destructive acts. Individuals have been known to castrate or enucleate themselves in the presence of command auditory hallucinations [13–15]. Delusions generally accompany the command auditory hallucinations that result in such self-mutilation. Command auditory hallucinations have also been associated with homicidal violence toward others such as the case of a man with a command auditory hallucination and delusions who killed his infant daughter [16]. Nine percent of a sample of "White House cases", i.e., individuals who had been psychotically preoccupied with prominent political figures who had come to the attention of the Secret Service, experienced command auditory hallucinations [17]. Clinical research into command auditory hallucinations using sample populations and not just single case reports or a small case series dates back only about two decades to a study based on data collected from a general psychiatric inpatient service at an urban academic medical center [18]. Subsequently, samples of individuals with command auditory hallucinations from a variety of settings, inpatient and outpatient, clinical and forensic, and public and private settings, in a variety of countries (United States, United Kingdom, Australia, Germany, New Zealand, and Singapore) have since been reported in the anglophonic literature [19–30].

The limited literature on command auditory hallucinations does not find this type of hallucinations to be more prevalent in forensic than in nonforensic samples [31]. The various studies find a large range (7–70%) for the prevalence of command auditory hallucinations containing harmful content with a

median prevalence of about 40% [31]. Harmless commands are not of clinical or forensic concern, even if obeyed. Besides the harmfulness of the content of the command auditory hallucination, the extent of the individual's compliance with the command also assumes clinical and/or forensic significance. The presence of delusions and the individual's affective (emotional) state play a substantial role in whether an individual complies with a harmful command. Some recent statistical studies on command auditory hallucinations [30, 32] do not give much guidance as to who complies and only suggests that command auditory hallucinations with harmful content signal a need for careful clinical assessment.

Malingering of Hallucinations

The central feature of malingering involves the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives [[9], pp. 739–740]. The frequency of feigned psychosis is unknown [33]. Research has not yet arrived at a foolproof method to determine the presence of genuine verses manufactured psychosis.

From reviewing the literature and his clinical experience, forensic psychiatrist Philip Resnick has listed six areas of inquiry regarding the genuineness of reported auditory hallucinations. These six areas include vocal characteristics, source of the hallucination, characteristics of the hallucination, relationship to the hallucination, belief/response to hallucinations, and associated characteristics [33]. However, on closer inspection of Resnick's inquiry, Resnick's method involves comparing the individual's description of the auditory hallucinations with characteristics of auditory hallucinations described by actual patients. Although the survey of the literature on the presentation and content of auditory hallucinations shows likely characteristics as to what constitutes a genuine hallucination, the clinical research has shown considerable variability across studies. Of course, during the course of ordinary and routine clinical practice of inpatient psychiatry, individuals may misrepresent the presence or extent of hallucinations to resist or gain admission, remain in the hospital, or seek release from the hospital. Resnick uses a similar strategy to assess the genuineness of visual hallucinations, though in the case of visual hallucinations the frequent association with specific biologic causes such as medical illness and (recreational or prescribed) drugs may complicate the task of assessing reported visual hallucinations.

At this point, keeping abreast of the clinical and research psychiatric literature may be the best strategy for psychiatrists and other clinicians to know the characteristics of a typical hallucination. For example, in a recent study of individuals with visual hallucinations in the context of mental disorders, the subjects described the hallucinations as generally humanoid in content, with only a minority consisting of animals or objects. The visions almost invariably arose without warning. Most reported feeling overwhelmed and frightened, though the visions lasted only seconds or minutes [34].

The determination of the genuineness versus the manufacture of a reported hallucination often does not present as a simple dichotomous choice. Individuals who have had previously experienced hallucinations, whether from a mental disorder, medical illness, and/or recreational or prescribed drug use, have first hand knowledge of the characteristics of a hallucination, thereby complicating the task.

Probably the most frequent occurrence of manufacture or exaggeration of hallucinations involves requests for admission to psychiatric facilities, whether by individuals with no history of mental illness or by individuals who have previously experienced actual hallucinations. Also the most frequent manifestation of denial of actual hallucinations takes place when individuals seek to avoid psychiatric hospitalization, or if already hospitalized, to obtain release.

Hallucinations in Forensic Settings

Outside the civil commitment setting, hallucinations arise in a variety of legal contexts. In a nutshell, forensic evaluators attempt to determine the presence of hallucinations with regard to the legal issue involved and if present, the effect(s) of hallucinations on the legal matter at issue. Outside of the treatment-related civil commitment realm, the three most common forensic evaluations in which hallucinations may be especially germane involve disability, competency to stand trial, and the mental state at the time of the offense.

Functional Capability versus Disability

Hallucinations can be a significant factor in determining a person's work ability or degree of compensable disability. Command auditory hallucinations may order the person to stay away from others and prevent the person from working in a job that requires interpersonal interaction. The distraction caused by hallucinations could interfere with a person's concentration or attention and so job tasks cannot be accomplished.

Competence to Stand Trial

A pretrial defendant who experiences hallucinations may have significant impairment in the capacities to communicate with defense counsel to prepare a defense or to participate in the courtroom proceedings. Such impairment could jeopardize the defendant's competence to stand trial. The presence of auditory hallucinations does not automatically confer incompetence as some individuals can proceed with the case if the defendant can ignore the hallucinations. Nonetheless, exaggeration, manufacture, or denial of hallucinations can arise depending on the defendant's goal.

Mental State at the Time of the Offense

Hallucinations may form part of the basis for a clinical-legal opinion supporting the insanity defense or diminished capacity. Hallucinations may also be viewed as a potential mitigating factor for the trier of fact to consider during the sentencing phase of a criminal trial. With regard to the insanity defense, command auditory hallucinations commonly play a crucial role. An adjudication of not guilty by reason of insanity can be made if the trier of fact finds that the command hallucinations negated the defendant's cognitive or volitional capacities as outlined by the jurisdictional insanity statute. A forensic evaluation would involve arriving at a hypothesis regarding the genuineness of the hallucination with regard to the alleged crime and the extent of the defendant's compliance with the hallucinated command.

Handwriting and Signatures, Comparison of

Introduction

The forensic examination of handwriting is considered by some to be the oldest of the forensic sciences [1]. The discipline appeared to develop into a formalized study aided by the publication of Albert S. Osborn's "Questioned Documents" textbook in 1910. A second edition of this text appeared in 1929 and the work is still considered by many to be the pivotal doctrine [2]. Since then, other texts have appeared that provide detail of the principles and processes of forensic handwriting text and signature examinations [3–7].

In contemporary legal arenas, forensic handwriting examiners (FHEs) are regularly called upon to provide their opinions regarding the authorship of writings that are either in question or in dispute. As a subdiscipline of forensic document examination, forensic handwriting and signature examination is one of the most commonly accepted lines of behavioral identification evidence in existence today. Despite this, handwriting examination has in recent times attracted a healthy variety of academic criticism [8–10]. The first of these articles criticized the poor scientific character of the handwriting identification discipline [8]. This position was confirmed in

a subsequent court ruling [9]. Since the mid 1990s, the debate has continued to develop, both in the literature [10–16] and the courts (see review of relevant court rulings in [1]). It is clear that the basis and probative power of the opinions that FHEs regularly table will remain the subject of scrutiny in future. For the overview presented here, we must set aside this controversy to some extent. In practice, handwriting evidence continues to be led in courts of law internationally and, in the vast majority of instances, is accepted into evidence. This article explores, in general terms, the basis, the structure, and the characteristics of forensic handwriting and signature investigations.

Handwriting of individuals can find its way into a variety of criminal and civil investigations. Theoretically, it is convenient to think of questioned handwriting as either comprising a population of text characters that are designed to be read, or a signature. Signatures are developed and executed by individuals as their "mark", which may or may not exhibit textual elements. Essentially, the FHE applies their expertise to the task of comparing the population of features associated with the questioned writing, to a comparable population of features associated with the exemplar (known) writing of a particular individual or person suspected of writing the entries. Propositions that may account for similarities or dissimilarities between the exemplar and questioned writings are then considered by the FHE. On the basis of their detailed knowledge of handwriting features, simulation (copying) processes, and disguise strategies, the FHE, where they deem the evidence to be sufficient, may express an opinion as to whether or not there is support for the proposition that the exemplar writer wrote the questioned entries.

It is not difficult to imagine that for any particular case, the populations of characters and writing features, and the quality and quantity of comparable features will differ with respect to previous cases that FHEs have had exposure to. Herein rests one of the key elements of the handwriting identification paradigm. The instrument performing the comparison task is the FHEs cognitive machinery and, although a variety of techniques may be used to assist the examination process (for example, magnification and image-enhancement techniques), the approach remains essentially internalized and contains an element of subjectivity. Objective or FHE assisted computer comparison approaches have been reported and are mainly used to search large databases of writers [17–20]. Examples of other algorithmic-based objective comparison techniques that have been used to research aspects of writing dynamic or static characteristics can be found [21–27]. Despite a relatively rich interest in computer comparisons, objective techniques are not routinely applied to casework tasks.

The subjective element in handwriting and signature examination should not necessarily alarm client groups and the courts. It is a fact that all studies comparing FHEs with lay persons opinions, although limited in their number and scope, have shown that FHEs are significantly more skilled than their lay counterparts in handwriting and signature examination tasks [28–32]. Sadly, however, only a fraction of practicing FHEs has participated in such studies. The studies published to date have been limited in terms of their number and extent to which they can address the wide range of writing behaviors thought to exist in the population.

What is Handwriting?

Handwriting is a complex overlearnt motor behavior that is carried out, at least to some extent, by most members of the population. A major occupation of primary school children is the development of their writing skills. Children are generally taught a copybook system of writing. These systems provide the repertoire of characters and instructions as to the appropriate process by which each character is to be formed. Years of guided, informal, and sustained practice is then invested by individuals in order to fluently capture the concatenation of strokes that form the elements of each character. Particular energy is focused on each formation in terms of its construction, its internal proportions, and its connections. This is carried out in order for the individual to satisfactorily perform the myriad of coordinated muscle contractions that will participate in forming characters and words. It is these patterns of movements that drive the writing implement that will ultimately lay down the richness of spoken language in the visual domain.

There are many copybook systems taught worldwide. At least 76 different systems are taught in North America alone [7]. Signatures, a common identifier of individuals, develop later as a visual mark. These marks may be stylized to the extent that the final form may have little relationship to their handwritten text characteristics.

Basis of Identification

FHEs embrace that handwriting behavior, at least in the skilled adult population, possesses two key qualities, which makes it a potentially useful form of identification evidence in the forensic sciences. Although the behavior (like nearly all learned pattern movements) does vary from one performance to another (referred to as "natural" or "intrawriter variation"), it is found to be relatively stable within the adult individual. This relative feature invariance within an individual's writing results from the complex process by which handwriting commands are laid down, retrieved, and played out from our long term motor memories [33, 34]. Such is the robustness of the behavior in the skilled writer that it may remain relatively unchanged over the best part of adult life. It is also found that the richness of features associated with an individual's handwriting (whether these be character constructions, proportions, the relationship between characters, the placement of words, the quality of the line, or the relative pressure that is exerted to form the line trace) markedly varies from one person to another. This is evident even when individuals are initially taught an identical copybook model. This phenomenon is referred to as *interwriter variation.* These two key qualities of handwriting behavior are used to mount identification and exclusionary lines of evidence by FHEs. The practical examination of handwriting does become considerably more complex when unnatural writing behaviors (such as disguise and mimicking (simulation behaviors) as well as environmental and/or circumstantial factors (illness, age, etc.,)) are taken into account; however, we shall deal with these specific types of activity later in the article.

In the very simplest of forms, the process of handwriting comparison and identification can be described as follows [35]. FHEs are provided with a handwriting sample (whether text based or signatures) whose author is considered unknown or disputed. This sample is termed "*questioned*". The questioned writing is compared with another sample of writing (a "comparison sample"). This comparison sample could be writing submitted as having been written by a particular person (an "exemplar") or it could be another sample of questioned handwriting (an approach termed a "*common authorship*" examination). Exemplar writings are the most frequently encountered form of comparison sample. These may be either "requested", where the content of the handwriting is dictated to the individual, or "collected", where an investigator locates samples of an individual in day-to-day writing. The comparison sample is examined and the pictorial, structural, and line quality features that the FHE believes to characterize the handwriting are assessed and documented. These features are compared to the features associated with the questioned sample. If it is found that the questioned features are similar to the specimen features, then propositions are advanced that could account for the similarities. Should the examiner be of the opinion that there is evidence to support the proposition that the similarities result from both the questioned and specimen images having been produced by the one writer then the handwriting is said, with some level of confidence, to be "identified". Alternatively, if the features are found to be dissimilar to the questioned images, explanations are proposed that could account for the dissimilarities, and in some instances the examiner will form the opinion that there is evidence to support the proposition that the handwriting was not written by the specimen writer.

Handwriting is a behavioral artifact. It is what is left behind in the physical, visual domain after our bodies have cognitively processed and executed the commands required to perform a specific sequence of ordered muscle contractions. As a behavior, the evidence is characterized by a number of potentially limiting factors. It is the case that there is not "an amount" of handwriting that can fully characterize the extent of the variation in the behavior or provide sufficient information to describe definitively the characteristics of the movement system responsible for the storage, retrieval, and control of the movement instructions that form the characters as they finally appear in physical form. Databases are still not commonly used to estimate objectively the relative frequency of any particular handwriting feature in the population and as such "chance-match" probabilities, the very numbers that bestow upon DNA sciences its "gold status" in the identification sciences, remain subjectively assessed by the FHE. Elements of the behavior may change over time. The fluency of handwriting movements may alter over the course of different writing events, and the features of writing may change naturally over time or in response to more significant events (for example, a purposeful intervention by the writer, in response to altered writing conditions or demands [36, 37], or in response to

other factors including illness or drug-induced states [38–42]). Complicating the dynamics of the writing behavior itself is that the forensic identification technique is based on learnt human (the FHEs) perceptual and cognitive strategies. There is the potential for normal human variation to play a part in any opinions that are ultimately formed. Handwriting "identification" is better referred to as "*opinion identification evidence*" whereby opinion refers to the FHEs belief in the extent to which the evidence supports that the writer of the comparison sample did or did not write the questioned writing. Although this may be at odds with the beliefs of some practitioners in the field, this approach will fit more comfortably with the behavioral scientists practicing within the discipline.

Many concepts, of varying practical importance, are not addressed here. For example, the extraction of writer demographic features such as age and gender. Although there has been some controlled research conducted for the determination of such characteristics [43, 44], the results either do not support that the techniques employed are sufficiently reliable for their routine usage, or that the techniques themselves can not be applied to casework samples due to the limitations associated with the format of commonly encountered written documents.

Exemplars for Comparison

The sample of handwriting that is in question is not within the control of the investigator or the FHE. What is potentially within the realm of control of at least the investigator is the extent to which the writing behavior of any suspect, or subject, might be sampled. The most critical aspect of any forensic handwriting investigation is sourcing suitable known examples of an individual's normal writing for comparison. Exemplar material is also referred to as "*known*", "*standard*" or "*specimen*" writing by different FHEs internationally. The success of any case involving disputed or questioned handwriting will be heavily dependent on both the quality and quantity of the specimen (known) handwriting, submitted for comparison, in conjunction with the quality and quantity of the questioned writings. The terms "*quality*" and "*quantity*" with respect to any particular case and any particular FHE may vary and these factors remain hidden within the subjective processing of the evidence by FHEs. Although there are exceptions, FHEs are generally not responsible for sourcing exemplars or validating that the exemplar material submitted is the known writing of a particular individual. The onus of proof regarding the source of exemplars usually remains with the submitting investigator. The history and development of the US rules compelling suspects to provide handwriting samples has been reported [45].

Exemplar handwriting can either be "requested" or "collected". As a guide, the process by which these two populations of writing may be sourced is described.

Requested Exemplars. These samples are written by an individual at the request of another and are specifically performed for the purpose of providing a set of known writings for forensic comparison. The following approach is generally used to generate material of this type:

1. The subject is allowed to sit comfortably and is provided with all material required to produce the exemplars (writing instruments and writing medium).
2. The subject is not permitted to view the questioned writing prior to taking of the exemplars (in order to avoid any allegation that the individual in any way copied either the form of the characters or the formatting of the questioned writings).
3. Multiple documents, similar in format to the document on which the questioned writing appears, are prepared and held by the investigator. For example, if the questioned writing is text on a lined foolscap page, similar lined foolscap pages would preferentially be used.
4. A writing instrument similar to that used to form the questioned handwriting is provided. Most exemplars are generated using ball point pens. Should the questioned writing be generated using a less common writing implement (such as pencil or crayon), then the subject may be requested to repeat the writings using these devices.
5. The subject is provided with the first prepared document. All writing instructions are provided verbally. The content of the exemplar to be dictated will depend on the form and format of the questioned writing. If the questioned writing is a signature, then the subject will be asked to sign their name (one to a page). If the questioned writing is uppercase handwritten text, then the subject will be asked to write in uppercase and the content will be dictated to them. As the

subject completes each exemplar, the investigator signs and dates the document, and it is removed from the subjects view. This process is repeated for the remaining exemplar document repetitions that have been prepared.

In some cases, *pro forma* exemplar documents either take the place of case-specific prepared documents, as described above, or are added to the prepared documents to be provided to the subject. *Pro forma* documents provide the subject with written prompts as to what to write and in what format the entries are to be written. Documents of this type are generally designed to capture as many of the subjects handwriting characters and their combinations as is practical. This approach provides a broad sample of the subjects writing behavior to the FHE for any comparison purposes that might be required. Occasionally this approach is used in preference to case-specific exemplars as the investigator may not wish for the subject to know the content of the questioned document.

Requested exemplars offer the advantage that the writing behavior will be directly comparable to the questioned material (that is, the exemplars will exhibit the same format of document, and the same letters, letter combinations, word forms, and sentence structures). The disadvantages associated with requested exemplars is that they are unlikely to exhibit the full extent of the subjects range of natural writing variation (since they were executed at a single point in time), they may be disturbed due to the inordinate attention placed on the writing act, and they do offer the subject the opportunity to disguise their normal writing habits. For this reason, requested exemplars are normally supplemented with "collected" exemplars.

Collected Exemplars. Collected exemplars are writings that are made by an individual during the course of their day-to-day activities. These exemplars are considered by many FHEs to be the most desirable for forensic comparisons. The collected writings are unlikely to be the product of disguise (particularly those collected prior to the time that a questioned sample of handwriting was written) and are likely to show the range of normal variation in an individuals' writing behavior.

When collected exemplars are sourced, particular attention is paid to the format of the writings. In general terms, signatures can only be compared with signatures (unless an individual has signed using their normal handwritten text forms), uppercase can only be compared to uppercase writing, cursive can only be compared to cursive, and printed can only be compared to printed writing. As such, when an investigator collects a subject's handwriting, the format of the questioned text needs to be represented in the final body of collected exemplar material.

Timing of the Exemplar Handwriting. One of the most important elements of the exemplar collection process is the relationship of the date(s) associated with the questioned writing with the date(s) associated with the exemplar writings (this is particularly true when dissimilarities are detected between the questioned and exemplar writings). The preference of FHEs is for the exemplar material to "time bracket" the questioned writing. Ideally, the exemplars should be drawn from normal writing activity both before and after the date(s) associated with the questioned writings. Repetitions of exemplar writings should also attempt to be sourced as close in time to any date associated with the questioned writings as possible. In practice, this is often a challenge.

Sources of Collected Exemplar Writing. Exemplar handwriting can be sourced from a wide variety of document types [7]. Commonly submitted "collected" handwritten text and signature exemplars are documents associated with charge accounts, change of address forms, affidavits, business agreements, credit and insurance applications, membership applications, passport applications, work and school assignments, attendance records, banking documents, general business correspondence, recipes, credit card documents, declarations, grocery lists, guest registers, hospital records, identification cards, leases, mortgages, personnel records, greeting cards, postcards, tax returns, time sheets, and wills.

Although it is not the task of the FHE to validate the source of exemplars, it is the case that examiners do inspect the body of writings submitted as exemplars for any potential contamination by another writer. Generally, any spurious entries in minority are excluded prior to any detailed examination being carried out. Should there exist uncharacteristic variation between different exemplar documents the investigator may be quizzed as to the reliability of the sample and further exemplars may be called for.

Handwriting Examination Theory and Practice

The extent to which the FHE supports an identification or exclusionary conclusion is referenced by their use of opinion level scales. A variety of these scales are in use internationally and the wording differs from place to place. A common form is the verbal probability scale and makes use of nine levels (four opinion strength levels either side of an inconclusive opinion) [46]. Included here is a five-level scale that is used for international validation and proficiency testing and shows how both verbal probability (probability of a proposition – prior odds) and Bayesian reporting language (likelihood ratio assisting the expert to quantify his or her support for a proposition against an alternative proposition) is used.

Level 1 – Identification

The writer of the specimens wrote the questioned writing. This is an opinion that can be thought of as a "moral" certainty (rather than a scientific certainty) and is a categorical opinion that the writer of the specimen handwriting wrote the questioned handwriting [47]. Some examiners also define this opinion as "very strong support for the proposition that the writer of the exemplars wrote the questioned writing."

Level 2 – Qualified identification

There are indications that the writer of the specimens wrote the questioned writing.

This opinion level is used when there is an identifiable limitation on the comparison process (e.g., a limited amount of questioned and/or exemplar writing/nonoriginal questioned and or exemplar writings). This opinion has also been defined as "moderate-to-strong" support for the proposition that the writer of the exemplars wrote the questioned writing.

Level 3 – Inconclusive

Owing to limitations to the structure or content of the case, the FHE is not able to form an opinion as to whether or not the writer of the exemplars wrote the questioned handwriting.

Level 4 – Qualified exclusion

There are indications that the writer of the specimens did not write the questioned writing. This opinion level is used when there is an identifiable limitation on the comparison process (e.g., a limited amount of questioned and/or exemplar writing/nonoriginal questioned and/or exemplar writings). This opinion has also been defined as "moderate-to-strong" support for the proposition that the writer of the exemplars did not write the questioned writing.

Level 5 – Exclusion

The writer of the specimens did not write the questioned writing. This is an opinion described as a "moral" certainty and is a categorical opinion that the writer of the specimen handwriting did not write the questioned handwriting. Some examiners also define this opinion as "very strong support for the proposition that the writer of the exemplars did not write the questioned writing."

Handwriting Characteristics

Clearly, it is the character of the visual artifacts that FHEs rely upon to perform their comparisons. Underlying any opinion formed by the FHE regarding the concept of individualization must be a detailed understanding as to the extent of intra and interwriter variation and how these might interact with each other. Intrawriter variation might be considered as a major source of "noise" in the identification paradigm. But this is an overly simplistic view. The way that an individual's handwriting varies can provide the FHE with features that might be considered to assist in discriminating between writers (that is added to a body of features that can be used to discriminate between writers). FHEs' understanding of intrawriter variation is likely to be finely tuned through their constant exposure to the phenomenon due to their detailed examinations of enormous amounts of exemplar documents. This exposure provides an environment where their cognitive systems learn what features may change naturally within a writer, and what dissimilarities between questioned and exemplar writings should evoke particular suspicion.

For FHEs to form any opinion at all, there must be a firm belief that there is a wide range of interwriter variation present in any particular population of writers. Evidence for the extent of interwriter variation can be drawn from a variety of sources. At the most basic-level interwriter variation is what allows individuals to easily recognize both their own handwriting and the writing of others to which they have

had prolonged exposure. Further empirical evidence comes from the study of closely related individuals. It may be expected that genetically close individuals, or those with similar family backgrounds may exhibit handwriting features that have the potential to be indistinguishable. This is not found to be the case [48]. Large-scale handwriting investigations have been reported where the correct writers were ultimately identified from surveys of multitudes of individuals' exemplars [49, 50]. A qualitative approach was used by Huber (2000) on nearly 1000 samples of writing. This author found that for all bar two of the samples, the balance of the authors could be discriminated [51]. Database searching systems would be unable to function with any measure of success without there being a marked degree of interwriter variation. More recently, Srihari and his colleagues (2002), using computer algorithms, were able to validate handwriting individuality in a sample population of 1500 individuals with a 96% confidence [24]. Further lines of empirical support for the large degree of interwriter variation have been reported [52–55].

Ultimately, it is all the elements that form handwriting images that FHEs' cognitive machinery compares between the exemplar and questioned line traces. These are described in various, but essentially similar ways within the major texts in the field. As a summary, a holistic approach to the issues of what constitutes handwriting features is described here and is based on feature descriptors that have been described [7]. It is the case that, due to a combination of the intrawriter variation phenomenon coupled with the continuous signal that handwriting presents to us, FHEs do not "count" features. There are no objectively based minimum thresholds to define when an FHE will form an opinion that the evidence supports a particular level of identification or exclusion. This characteristic of the evidence can result in variations in the strength that different FHEs will form opinions, even given the same material to examine. This can also result in FHEs supporting propositions at odds with each other. The extent that this occurs remains essentially unreported.

Huber and Headrick (1999) find it helpful to classify handwriting features into four general types [7].

Type 1 – Elements of style

This includes the relative placement of text, the uniformity of the margins, the interline spacing, the parallelism of the lines of writing, the character, position and frequency of interlineations, the depth of any indentations (for example, when the writer commences new paragraphs), the paragraphing format, the use of numerals and symbols in monetary amounts, the location of handwriting relative to any printing on the document, the class of character (whether cursive, printed, manuscript (disconnected), or composites of these styles), the connections (between both characters and words), the characters design and construction, the proportion of features both within and between characters, writing size, the slant of writing, and intra/interword spacing habits.

Type 2 – Elements of execution

These features include the use of abbreviations, the orientation of the handwriting relative to real or imaginary baselines, the length, direction, path and taper of commencing and terminating strokes, the presence, style and location of diacritics and punctuation, the presence of embellishments, the legibility of the writing, the presence of pen stops and pen lifts, the quality of the line, and pen control characteristics (as evidenced by pen pressure differentials in the line trace).

Type 3 – Consistency or natural variation

This comprises an assessment of the extent of imprecision with which the writer executes the movements, which results in variations in the handwriting features on repeated occasions.

Type 4 – Lateral expansion and word proportions

These factors contribute to the pictorial character of the writing and refer to a combination of the horizontal dimensions of a group of successive letters and words, the relative horizontal to vertical character of the writing and the size and spacing of the writing components.

As FHEs assess these types of writing components, and compare the features between the exemplars and questioned entries, their cognitive machinery is likely to be interpreting the weight of the similarities and dissimilarities that they observe in terms of the extent to which they might support either an identification or exclusionary conclusion. Only limited studies have been reported, which attempt to explore how FHEs might cognitively approach the

task and so the rationalization of how this hidden process may be achieved remains anecdotal [56].

For some FHEs, the theoretical basis on which identification opinions are mounted is centered on what is generally described in the accepted texts as "*Class and Individual Characteristics Theory*". Stated simplistically, it is accepted that handwriting is comprised of features that are shared by populations of writers and are of little or no value to identification processes (in many cases, these are remnants of the copybook system that the writer was originally taught). Although not useful for identification, these characteristics may be very useful in terms of writer exclusion. When inexplicable repeated dissimilarities in characteristics (including class elements) are observed between a population of naturally written exemplar and questioned writings, this would support the proposition that the population of writings were written by different individuals. Identification opinions are mounted on the basis of individual characteristics. On the basis of their experience, FHEs who support this theory claim that they can detect features in handwriting that are individual to a particular person. Other FHEs, while embracing the belief that handwriting is composed of class characteristics and characteristics that vary from "class", do not claim to be able to detect characteristics that are unique to a particular writer. "Complexity Theory" is an example of such an approach [57]. This theory embraces the notion that there is a wide range of interwriter variation in the population. It proposes that there are two basic relationships that exist, which underpin all handwriting identifications. The first is that, as the amount of writing available for analysis and comparison increases, the more likely that writing is to contain features that are deviant when compared with other individuals' handwriting (that is, the probability of a chance match with respect to all features decreases). For example, at the simplest level, if we were to collect random samples of handwriting exhibiting identical text and compare them letter by letter, we should find increasing sample to sample deviations as the comparison proceeds. The second relationship in this theory is that as the amount of writing increases, the more difficult it will be for another individual to simulate (copy or mimic) it successfully. Although relevant to handwriting text evaluations, simulation behaviors will be dealt with in more detail in the signature section of the article.

There are at least anecdotal accounts of varying interpretations and strength of belief in these theories. Ultimately, to differing extents, both theories suffer due to the subjectivity associated with the interpretive processes coupled with the lack of detailed empirical investigations into their veracity. FHEs have varying personal views as to the basic theoretical process. The more pressing issue is, however, to provide validating information regarding the probative value of their opinions. This is for many being addressed. This occurs through the medium of small externally set proficiency testing (for example, those provided through Collaborative Testing Services (USA)), through between laboratory collaborative trials or resulting from participation in large-scale blind tests that have been reported [58–63].

When FHEs perform their comparisons, detailed notes are made. The form that the documentation of observations takes can vary quite markedly. In many instances, for the exemplar material, each character, character combination and any word formations shared between the exemplar and questioned material are carefully drawn out. In some cases, the FHE will extract each of these elements digitally so as to avoid the inaccuracies of the drawing process. The same process may be undertaken for the questioned material. In this way, an ordered set of the features of characters and their variations are documented, a detailed knowledge of the characteristics of the writings are laid down in the mind of the FHE and the comparison process is facilitated. Other methods are also used. A FHE may mark on reproductions of the handwriting the features that are similar or dissimilar between the populations of exemplar and questioned writings. What remains is for the FHE, on the basis of all their observations of the feature similarities and/or dissimilarities, to address the ultimate set of propositions; whether the evidence supports the proposition that the exemplar writer did or did not write the questioned material. Documented methods that articulate the key elements of the process are likely to be able to be secured from most laboratories offering handwriting evidence. One such treatment of method has been reported [35].

The identification and exclusion approach summarized here is extremely effective when FHEs are provided with naturally written skilled handwriting. Practically, in their deliberations, FHEs are confronted with the casework reality that, even given

suitable naturally written exemplar writings, the questioned writing may not be naturally written. Questioned writing may be the product of disguise (either by the exemplar writer or by an individual other than the exemplar writer) or may be the product of simulation behavior (written by a writer copying the handwriting characteristics of the exemplar writer for the purpose of implicating them in the preparation of a document). In both cases, when the significance of the features in terms of authorship is being addressed, these unnatural writing behaviors are taken into consideration.

Disguised and Simulated Handwriting

Much has been written on the subject of disguised writing behaviors [64–70]. In essence, the writer is attempting to purposefully change elements of their normal handwriting output while simultaneously suppressing their natural handwriting feature habits. This is typically done to avoid being identified through the medium of any handwriting comparison process. Disguised writing behavior is most commonly observed on threatening correspondence. The approach and effectiveness of the disguised strategy adopted does vary markedly from person to person. Some individuals feel that simply altering the construction of one character will be sufficient. Others adopt more complex approaches that may include simplifying their writing style to modify characters into a series of straight line constructions. Still others will use their nondominant hand to which may alter the pictorial character of the writing as well as bestowing on the writing the character of reduced skill.

Testing of FHEs on blind trials has discovered that, in general, disguise strategies adopted by individuals are effective in cloaking their identity. FHEs, when considered as a group, exhibit high rates of inconclusive opinions on disguised writings and disproportionately high errors when compared to the natural writings of individuals [62]. There are examples of individual FHEs that do appear to have more advanced skills in determining the authorship or nonauthorship of disguised writing; however, only a fraction of practicing FHEs expose themselves to large-scale testing and the number of these tests to date do not provide any firm foundations to state convincing claims as to expertise for questioned writings of this type.

Simulated text writings are found to result in slower movement velocities and a greater number of movement disfluencies [71]. Simulated writings have also proven to be problematic for FHEs. Although the frequency of occurrence of these writing types in the casework population is likely to be low, it does not alter the fact that the probative value of any identification opinions is dependent on the skill of the FDE at not incorrectly opining that a sample of simulated writing was written by the writer of the exemplars. A similar pattern of inconclusive and error scores are found for the simulated writing group as for the disguised writings. The most current research strongly suggests that when FHEs, particularly those from a nonblind testing culture, are confronted with questioned writings exhibiting a mixture of similar and dissimilar features to the exemplar writings, then the appropriate opinion to reach is no opinion at all [62].

Signature Examinations

One of the major fields of study of the FHE is signature behavior. Signatures appear as personal identifying marks on all manner of documents. Although the control mechanism underlying their performance is similar to that associated with handwritten text, their role is not necessarily to be a readable representation of the name of the signer. As a consequence, signatures do vary from a readable text-based representation of an individual's name all the way through to a stylized pattern where no indication may be present as to the identity of the component characters.

The purpose of a signature clearly is for the signer to acknowledge the content of the document on which it appears. For skilled signatures at least, the complexity of the underlying movement control system guiding their production bestows, upon any act of copying such a movement, some considerable difficulty. The process of copying a signature is described by FHEs as "simulation behavior". The more common, but inaccurate, term used in the lay environment is "forgery". A considerable amount of information and research is available on simulations in both book form [2–7] and research literature [72–77].

Simulations form part of a wider family of signing behaviors encountered in forensic casework. The following provides a brief summary of the types of questioned signatures that FHEs encounter.

Genuine Signatures

FHEs, subsequent to an analysis and comparison between the features associated with the exemplar and questioned signature, may find support for the proposition that a signature is genuine. In these instances, the questioned signature is usually naturally and fluently written and exhibits no significant dissimilarities with respect to its constituent features when compared to the exemplar group.

Spurious Signatures

Questioned signatures of this type may appear to have no relationship to features of the genuine form other than those that could exist by chance. The writer of the spurious signature either did not have access to, or did not choose to directly simulate the genuine form. These signatures may be stylized (which excludes any opportunity to compare its features with exemplar text of any suspect) or may be text based. Text-based spurious signatures may be able to be compared directly to the collected or requested handwriting exemplars of an individual.

Disguised Signatures

These signatures are written by the exemplar writer; however, an attempt is made to alter the characteristics of their normal signature for the purposes of potential denial of the signing act at a later point in time. It has been reported that typically obvious characters are altered (for example, the initial letter in any component forms) [78–81]. The reality is that the strategy that the exemplar writer may use is limited only by their imagination, their motor abilities, and the extent to which the signature might need to pass initial inspection when the documentation on which it appears is first passed.

Freehand Simulated Signatures

The simulator, having access to a genuine model signature, attempts to replicate the form either by directly referring to a model or by referring to their memory of its appearance. The simulator may embark on a detailed study of the genuine signature in order to practice its component parts. Alternately, a simple drawing of the form may be the only strategy that the simulator attempts. Typically, simulated signatures show a range of defects when compared to the exemplar signature. Tremor in the line, a reduction in shading patterns (which in natural writings are caused by smooth changes in pen speed and pen pressure) and blunt initial and terminal strokes may be evident. Uncharacteristic pauses or pen lifts may be detected. These are thought to be associated with the simulator either assessing the progress of their copy or indeed halting the movement in order to refer back to the genuine model signature. Touching-up, adding strokes, or "patching" of the signature may be evident where the simulator, unsatisfied with the overall reproduction, attempts to improve the form through the application of additional pen strokes. Dissimilarities with respect to overall size of the signature, the relative proportion of constituent features, and the slope of the form may also be detected. Alternatively, the simulator may wish to capture the fluency characteristics of the genuine signature. The speed-accuracy trade-off will, in many instances, result in a simulation that displays inaccuracies in fine movement detail, construction, and relative proportions of features.

Traced Simulated Signatures

One of the ways that a simulation can be produced (either of handwritten text or a signature) is to use a model of a genuine form as a physical guide [82, 83]. Traced signatures are related to the freehand simulated signatures with respect to all but the defects associated with size and relative proportions. Owing to the additional demands of following a guide, these signatures tend to show greater deficiencies than do freehand simulations. Examples of tracing methods are as follows:

- A document bearing a genuine signature is placed against a light source (for example, a window). The document on which the simulator wishes to trace the signature is placed over the genuine document and aligned according to where the tracing is to appear. Depending on the paper, sufficient gross information may be seen through the medium for the simulator to follow the line of the genuine formation. This technique is relatively effective at reproducing the gross pictorial characteristics but as one might imagine any fine detail in the genuine signature features may be missed, the sequence of pen strokes may be incorrectly executed and the line quality is generally found to be poor due to the very

slow speeds that the simulator might execute the movements in order to faithfully follow the trajectory of the line.

- The document on which the simulation is to be made is placed under a document where the genuine model signature appears. The simulator, using a writing implement such as a ballpoint pen, firmly follows the line of the genuine signature. The pressure that this creates causes an indentation line on the underlying document in the shape of the genuine signature. The uppermost document is removed and the simulator then uses a writing implement to follow the indentation line. This technique will still result in the defects associated with the tracing process described previously. Additional evidence will be left in the form of the indentation line which, due to the inaccuracies typically associated with the simulators movements, will not be overwritten in its entirety by the inking medium. Indentation lines in close proximity to the questioned signature, however not always parallel to the trajectory of the written trace, will typically be in evidence. There are a number of variations on this technique. The simulator may use carbon paper between the two documents. The simulator then is only required to exert minimal pressure to create a weak visual outline of the genuine signature that appearing on the top document onto the document below it. This outline can then be overwritten with any given writing implement in an attempt to obscure it. Alternately, a graphite (pencil) layer can be placed on the rear of the document directly over the back of a genuine signature. This document is placed over the document where the simulation is to appear. Pressure is applied over the genuine signature in the same way as described previously. This transfers some of the graphite from the rear of the uppermost document onto the front surface of the document below it. Again, the simulator can then follow this outline using a writing implement of their choice. Any fragments of the graphite line can then be removed using an eraser. What is often observed, with this technique of tracing, is not only partial lines of indentation caused by the pressure of the transfer process but also fragments of graphite resulting from incomplete erasure. Smudging and paper fiber disturbance caused by the physical trauma to the writing medium itself may also be in evidence.

Traced simulations are more likely to deposit additional evidence for the FHE to base their opinions on. On occasions, the model used for the tracing can been found. The traced simulation can be found to be sufficiently superimposable on the submitted model such that the FHE opines that it is unlikely that the tracing shares such close association by chance. Alternatively, additional ink lines, indentation lines (caused by drawing over the genuine signature with a noninking pen) or graphite on the rear of the document may be detected in close association with the genuine signature. Traced simulation behavior can also assist in the forensic investigation of cases involving multiple questioned signatures. One model may have been used by the simulator for their repeat tracings. This will result in questioned signatures not only bearing the typical deficiencies of the simulation process but also exhibiting such a close correspondence in their features that FHEs will opine that they were traced from the same model.

Machine-Generated Signatures

The quality, accessibility and ease of use of contemporary photocopiers, printers and digital image capture, and manipulation techniques provide yet another means for a simulator to reproduce handwriting, and in particular signatures. The older “cut and paste” approach to signature reproduction simply comprised cutting out a genuine signature (or a reproduction of it) from a document, placing it on a photocopier platen and feeding the document on which it is to appear either through the manual feed mechanism or placing it in an existing paper tray cartridge. Typically, some attempts are made such that the reproduced signature appears in the desired position. Alternately, the cutout signature may be stuck to a fabricated document and photocopied directly. Evidence of this process is detectable by the FHE. Microscopic examination will reveal that the line of the signature is not comprised of ink, but rather photocopier toner particles. The toner usually appears on top of the paper fibers as differential pressure is not applied in its production (we observe pressure fluctuations in the performance of genuine signatures). Often, there might also exist a toner shadow where

the edge of the paper cut, associated with the questioned signature, meets the surface of the document onto which it has been stuck.

More advanced approaches involve the utilization of a scanner, a computer with some image-enhancement/manipulation software and a printer (for example, color laser or high-resolution inkjet). Genuine signatures can be scanned into appropriate software, manipulated if required (for example, the slant may be changed, the internal features stretched proportionately or disproportionately, the internal constructions can be altered, etc.,) and either digitally cut and pasted or imported into a document for printing. Excluding the use of robotic arms as an output medium [84, 85], the FHE still has the means to determine that the final product is not the result of human movement using typical writing implements but rather a machine-generated process.

Other Signatures

There are yet other signatures behaviors that are less well understood and which have attracted few reported empirical studies (with respect to the FHEs claims to validity) than those described above. These include signing behaviors associated with various forms of ill health and degenerative neural conditions, those affected by both legal and illegal drugs affecting fine manipulative movements, and the effect of unusual signing positions and backing surfaces. Fortunately, these types of signing behaviors are less commonly encountered in routine casework and, in many instances, the robustness of the approach may compensate for any of these internal or external conditions having an effect on the overall reliability of the opinion. The potential for alterations to normal motor output resulting from factors associated with these behaviors is generally considered by the FHE, particularly with respect to securing appropriate exemplars for comparison.

Few large-scale signature validation studies have been reported [31, 32]. In general, these studies show that the expertise claimed by FHEs in discriminating between genuine and simulated signatures is real. However, little is known regarding the potential error rate associated with the application of the technique across wider casework problems. The most recent report suggests that, in a similar way as has been shown for handwriting text, questioned signatures displaying combinations of similar and dissimilar features remain the most problematic in terms of FHEs attribution of authorship [86]. These are the disguised and simulated signatures (only freehand simulations have been used in studies, to date). The identification of genuine signatures attracts only small numbers of erroneous opinions and FHEs used in the reported study call these signatures confidently (with only small inconclusive scores being recorded). Disguised and simulated signatures attract large inconclusive scores and, at least for disguised signatures, significantly high errors. FHEs opinions, at least with respect to freehand simulated signatures, are still useful if we take into account their first stage observations. Some FHEs provide opinions that questioned signatures are “nongenuine”. Nongenuine questioned signatures refer to formations that are either the product of a simulation or disguise process. These FHEs, recognizing the problematic nature of exclusionary opinions on questioned signatures, offer this opinion without proffering any opinion as to whether or not the exemplar writer wrote the formation. Limited empirical studies, to date, show that, in order to avoid serious error, this is the most desirable position for the majority of FHEs to take. It leaves the court with the ultimate decision as to the likelihood of disguise behavior (which, in many instances, due to the courts access to the full circumstances of the case, they will be far better placed to make a ruling on).

In some instances, there is general agreement that it is appropriate for an FHE to support an exclusionary opinion. These are cases where the exemplar material is ideal, where it time-brackets the alleged date of signing of the questioned signature, and where the skill of the exemplar writer is far lower than the skill at which the questioned signature was written. These cases are, however, relatively rare.

Who are FHEs?

FHEs emerge from a wide variety of backgrounds. Some are police or investigators that have undergone advanced training or apprenticeships in the forensic handwriting discipline. Still others are individuals with science qualifications exhibiting a variety of academic specialties (reflecting the requirements of the wider document examination field within which handwriting examination is often placed). These individuals are also required to undergo training in the discipline. A variety of individuals, from all walks of life, do claim expertise in the

field based on a variety of mentored training programs. Their mentored relationship is usually coupled with forensic document examination society affiliations. All practitioners tend to gravitate toward the same set of dedicated textbooks [2–7], and there are a variety of scientific journals reporting research in the forensic handwriting field (many of these are listed in the reference section of this article).

Forensic handwriting examination is essentially a deregulated discipline. Many individuals may support their claim to expertise based on their affiliations to particular organizations or groups. Examples of such organizations are The American Academy of Forensic Sciences, The American Society of Questioned Document Examination, The Southwestern Association of Forensic Document Examiners (USA), The Southeastern Association of Forensic Document Examiners (USA), The Forensic Science Society (UK), The European Network of Forensic Handwriting Experts, The Gesellschaft fur Forensische Schriftuntersuchung (Germany), the National Association of Documents Examiners (USA), and The Association of Forensic Document Examiners (USA). Some organizations offer the FHE the opportunity for certification (usually in the broader discipline of Forensic Document Examination). As an example, The American Board of Forensic Document Examination offers certification to applicants with a combination of appropriate character and professional standing, with at least a bachelors degree (or equivalent), who have completed at least a two year full-time training program in a laboratory recognized by the Board, and who can demonstrate a profile of professional activities deemed appropriate. More information about training and certification in criminalistics can be found in **Training and Certification (in Criminalistics)**.

Besides their membership to groups or associations, FHEs may further support their claims to expertise through their years of experience in the field. Unfortunately, studies to date have not shown that there is any relationship between years of experience once FHEs are trained and their performance on blind trials [1]. There are still no reported studies comparing the relative abilities of different group memberships or even comparisons of FHEs opinions where their training process is uncommon. That forensic handwriting examination is a human skill that does exist is not essentially in dispute. The difficulty for the courts, in the absence of a strong scientific culture focused on testing of both underlying belief and practitioner skill, is the assessment of the suitability of any particular specialist to have their opinions heard. There is no doubt that professional memberships, certification, proficiency test records and rules of evidence admissibility (such as the Daubert checklist [87]) do go some way to address this dilemma; however, the environment within which FHEs practice still can be argued to rally its strength from historical acceptance rather than from scientifically based empirical studies [10]. This, at least in the very short term, is unlikely to change. Inevitably the so called Paradigm Shift [16] in the identification sciences will begin to impact appropriately on this discipline. The shift is likely to be accelerated through the ever increasing number of scientist entering the field. Their knowledge of scientific culture and, hopefully, their enthusiasm to question underlying theory and apply appropriate research skills, including advance statistics, will result, in so far as behavioral identification will allow, in many of the shortfalls of this science being addressed.

BRYAN FOUND

Handwriting and Signatures, Interpretation of Comparison Results

Introduction

The comparison of handwriting is one of the oldest forms of identification evidence. Since ancient times the signature has been recognized as a reliable way of ensuring that the correct authority has been given by the correct person and history is littered with examples of handwriting being used to identify an individual, from wills and wedding certificates to the Royal Ascent and the Magna Carta. There are a number of books describing the application of handwriting to forensic problems [1–3]. However, with the advent of DNA and the use of electronic devices, handwriting has started to take a back seat in both forensic identification and personal identification and people have begun to take a more critical look at the science behind handwriting comparison. Used carefully, and in the right hands, handwriting comparison still has a lot to offer the investigator but its interpretation must be updated to cope with the challenges of the modern world.

A Note on Graphology

Before discussing the interpretation of handwriting comparison, the reader should be aware of the other branch of handwriting examination known as *Graphology*. Graphology is the process of determining character traits from handwriting – whether a person is extrovert, introvert, a good communicator, shy, a leader, etc. While graphology has its place in society, it is not forensic handwriting comparison and should not be confused with the process of trying to determine who wrote a specific document. There are practitioners who claim to be able to do both forensic handwriting comparison and graphology, but proficiency at one skill does not imply proficiency in the other. This article relates only to forensic handwriting comparison.

Why Handwriting Can Be Used to Identify an Individual

Handwriting comparison is based on the premise that no two people write exactly the same.[a] This cannot be proved but, as with fingerprints, the theory has never been disproved and therefore stands. A person's handwriting is the result of their physiological makeup, their motor control (their ability to control intricate motions) and their experience in writing. Basic forms of writing are taught in schools, providing the underlying style of the writing, but a person very quickly moves away from the taught style to suit their own personal circumstances. By the age of 18 a person's writing style is a habitual form, which they can use fluently without thinking and which is very difficult for them to alter without sacrificing speed. The habitual writing form for most people is so complex and there are so many variables that the assumption that "no two people's writing is ever exactly the same is reasonable and in accord with long experience.

Overlying the physiological and experiential influences on a person's handwriting, which are in-built, are the immediate physical influences such as the health of the individual, the influence of drink and drugs, writing surface, writing implement, the ambient temperature, clothing, external movement, and so forth, all of which may influence the appearance of the written work on the page.

Handwriting is a very complex image to analyze and the writing of one person contains a degree of natural variation that must be assessed and taken into account when making a handwriting comparison. Handwriting has often been described as simply pattern recognition, and likened to fingerprint comparison or footwear comparison. However, it is more complex than that, because it can be deliberately varied and deliberately simulated. These factors are difficult to build into an interpretative model and are what makes the comparison a highly skilled process that should not be underestimated in its difficulty. Nevertheless the application of an appropriate interpretation framework (on the basis of the concept of likelihood ratio) to the interpretation of handwriting comparison helps to mitigate most of the major errors. Moreover, it makes the interpretative process more transparent. In a series of papers by Evett *et al.* [4], three general principles emerge. They are as follows:

1. To evaluate evidence it is necessary to consider at least two propositions.
2. Evidence is evaluated in the light of the other (relevant) information in the case.
3. It is necessary to consider questions like "what is the probability of the evidence"?

A Short History of Handwriting

Handwriting comparison has been instrumental in many high profile prosecutions; the prosecution of Jeffery Archer for perjury, the detection of the Harold Shipman murders through the identification of a forged will, the conviction of the Brighton bomber, and so forth. However, the reliability of handwriting as a forensic tool is increasingly being called into question on both sides of the Atlantic more by perception than by reality [5, 6]. To understand the difficulties in the interpretation of handwriting and the need for a more modern approach, we must first look at the history behind handwriting comparison. There are many literary examples of the use of handwriting to identify an individual. Some are successful, such as that carried out by Sherlock Holmes in *The Sign of Four*, but many revolve around the false identification of an individual. In William Shakespeare's Twelfth Night, Malvolio discovers a letter and states:

> By my life, this is my lady's hand! These be her very C's, her U's and her T's; and thus makes she her great P's. It is, in contempt of question, her hand

The letter is in fact a careful simulation of Olivia's writing, but his erroneous conclusion results in his humiliation, spending the rest of the play grinning and wearing cross-gartered stockings. In the Winslow Boy by Terrence Rattigan the court case hangs on the testament of the handwriting expert, who is subsequently discredited, thus causing the case against the Winslow boy to collapse. There are also real-life examples of errors of interpretation resulting in miscarriages of justice and humiliation of the individuals concerned (the case against Alfred Dreyfus for example [7]). Perhaps the most famous of recent years is the Hitler Diaries, which were announced as genuine by several eminent historians and scientists. Unfortunately they proved to be forgeries, the mistake being made because some of the specimen writing was in fact not the writing of Hitler but of the forger. These examples show where the inherent weaknesses of handwriting comparison lie. Firstly,

handwriting examiners are too ready to "transpose the conditional" and infer that matching handwriting implies that the individual is the author, and secondly that the ability of someone to simulate another's writing is very difficult to estimate in scientific terms.

Recent Criticism of the Interpretation of Handwriting

Two factors have emerged in the last 20 years and this has meant that handwriting examiners have had to re-evaluate the way they interpret their findings: the Starzepyzel judgment in the United States and the emergence of DNA as an identification science.

In 1993 there was a trial in the United States in which the right of the handwriting examiner to give evidence was questioned. The gist of the argument was that handwriting comparison was not a science and therefore the identification evidence gained through handwriting comparison was inadmissible; consequently the examiner should not have expert status. The judge held a "Daubert" hearing to determine *inter alia* whether handwriting comparison was a scientific endeavor. The trial judge's conclusion was that it was not, but that handwriting comparison was more practical in character. He likened handwriting examiners to harbor pilots, guiding ships into dock. They were much more familiar with the rocks and shallows of the harbor than the captain of the ship and therefore they had an expertise that was very useful, but only in certain circumstances: put them in another harbor, and their knowledge is useless. He allowed forensic document examiners to testify to their examinations and comparisons, but prohibited them from testifying to the ultimate conclusion they had reached [8]. While the opinion of the *Starzecpyzel* judge is not followed by the majority of other courts, it is nevertheless legitimate to argue in the United States that handwriting is not appropriate in certain circumstances. This judgment led to some more fundamental criticism of handwriting comparison in the United States by a group of eminent lawyers. Faigman summarized it all in 1999 when he criticized handwriting examiners as not moving with the times [9] and Risinger, Denbeaux, and Saks [5] have written a number of articles exploring the weaknesses of handwriting comparison, the most famous of which is equating handwriting comparison to witchcraft [5, 6]. The main criticisms can be summarized as the lack of reproducibility, the lack of consistent and universal standards, and the lack of formal qualifications to practice. Some of these issues have subsequently been addressed. To answer reproducibility, Kam and others in the United States [10, 11] have published a series of papers looking at the performance of handwriting examiners and Bryan Found of the University of La Trobe has developed a testing regime for State examiners in Australia so that the skills of examiners can be assessed against known results. This has led to written standards and formal qualifications [12, 13]. In Europe, the European Network of Forensic Institutes (ENFSI) working group for handwriting has also been working on a set of written standards and in the United States there are formal qualifications to be gained from the American Society of Questioned Document Examiners (ASQDE) and the American Board of Document Examiners (ABFDE), and again written standards are to follow. In the United Kingdom all state examiners are expected to gain admittance to the Council for the Registration of Forensic Practitioners (CRFP), which ensures that their work is regularly reviewed by other practitioners. However, the fundamental question of whether the examiner has interpreted the results in the correct way still remains, because the traditional regime relied on a holistic assessment based on the examiner's training and experience.

Handwriting and DNA Interpretation

Handwriting examiners have always interpreted their findings in terms of authorship, reaching such conclusions as "Mr X was the writer of the check" or "Mrs Y probably wrote the mortgage application". The emergence of DNA as an interpretive framework in the 1990s led to questions about the way scientific evidence generally was interpreted. In the UK court of appeal (R. v. Doheny and Adams 1 Cr App Rep 369, 375) the court ruled that it was the function of the scientist to inform the court of the likelihood of the evidence (i.e. the similarity in the DNA of the questioned and specimen samples) if the DNA came from a suspect or, alternatively, if the DNA came from someone other than the suspect (the *random occurrence ratio* as named by the court). However. the scientist had no right to tell the court that the DNA came from the suspect (*which would be transposing the conditional*). Fundamentally it is the court's role to interpret the scientific evidence in

the light of all the evidence in front of it, not the scientist's. The implications for handwriting comparison are that, however good the match, the scientist's interpretation can only be probabilistic and therefore only support the view of authorship.

Handwriting Comparison – the Basics

Handwriting comparison for forensic purposes is the comparison of the letterforms in one piece of writing with that in another. It is done in three stages: investigation, comparison, and evaluation. We deal with each stage in turn, although in reality an experienced examiner often performs all three stages at the same time.

Investigation

A handwriting examiner often states that the handwriting comparison is not dependent on outside influences and in this sense is a pure comparison. However, this may not be true. Peirce [14] gives many examples of the ways in which a forensic scientist may reason at the scene of a crime. At this stage, there may be no suspect and part of the role of the scientist is in advising the investigator about how the incident took place. Many hypotheses may be informally generated by the scientist and most are discarded as they become incompatible with subsequent observation and reasoning: others survive and may become refined by the particular circumstances of the case. The process of hypothesis generation and refinement characterizes the scientist as *investigator*.

Later in the same case, we find the scientist at the laboratory supervising the examination of materials from the scene and, perhaps, carrying out comparisons with other materials taken from a suspect for the crime. Here the process of hypothesis refinement may continue, culminating wherever possible in a pair of propositions that might represent prosecution and defense positions at court. This stage clearly represents the scientist as *evaluator*.

It is possible to see these two roles emerging as a document examiner first approaches a handwriting comparison.

Consider a case that consists of a passage of questioned handwriting and request specimens from a person, Mr X. The request is, did Mr X write the note? When an examiner first examines the questioned and the specimen material, they have in their mind the two possible alternative propositions, which are either of the following two:

- The documents were written by the same person.
- The documents were written by different people.

The likelihood ratio will be given by the probability of the evidence given the first statement is true divided by the probability of the evidence given that the second statement is true, or

$$\mathrm{LR} = \frac{\begin{array}{c}\text{The probability of the evidence}\\ \text{given Mr X wrote the note}\end{array}}{\begin{array}{c}\text{The probability of the evidence}\\ \text{given that someone other than}\\ \text{Mr X wrote the note}\end{array}} \quad (1)$$

At this stage, what the "evidence" comprises is yet to be determined. Before the examiner can address these alternative propositions, they must first address the joint issues of disguise and simulation, and to do this they must refine the propositions.

Refining Propositions

If we translate this back into a body fluids case, the likelihood ratio is as follows:

$$\mathrm{LR} = \frac{\begin{array}{c}\text{The probability of the DNA evidence}\\ \text{given Mr X was the source}\end{array}}{\begin{array}{c}\text{The probability of the DNA evidence}\\ \text{given that someone other than}\\ \text{Mr X was the source}\end{array}} \quad (2)$$

where the source of the DNA is a recovered blood stain. In this case the DNA expert can simply determine the DNA profile of the stain, assign probabilities in the two propositions and establish the likelihood ratio. With handwriting comparison, the process is not so simple. For example, if we asked the examiner, before they looked at the handwriting, "do you expect to find many similarities and a few differences between the two sets of handwriting, if the prosecution proposition is true" then they would rightly say that the number of similarities and differences depends on many factors about which she has no knowledge. If the two pieces of writing are naturally written and both are extensive then the examiner would expect to find many similarities and a few significant differences. However, if the specimen writing is disguised the examiner would expect to find many differences, but also a few significant similarities. Similarly, if the questioned writing is simulated, another set of expectations would arise. The examiner, therefore, has to act as an investigator to refine the propositions before they can move on

to the comparison and evaluation stages. We could think of a range of ways in which the prosecution proposition could be refined to make the question easier to answer; one such method is to break the main propositions into component parts (a concept known as *nested* propositions):

Mr X wrote the questioned handwriting

H_{p1}: in his normal natural hand;
H_{p2}: in a disguised hand;
H_{p3}: while suffering from a temporary debilitating illness;
H_{p4}: while under the influence of drinks or drugs;
H_{p5}: while under the influence of some environmental factor (e.g., while in a moving vehicle; in an awkward position; against an unsuitable surface);
H_{p6}: with his unaccustomed hand.

Likewise, the examiner's expectations would be easier to assess if the defense examination were also broken down. Possible alternatives include the following:

Someone other than Mr X wrote the questioned handwriting:

H_{d1}: in their normal style;
H_{d2}: as a simulation of Mr X's handwriting;
H_{d3}: in a disguised hand.

To ease the assessment of a relevant likelihood ratio, the examiner must refine the propositions. She can do this in a variety of ways. The simplest procedure would be to have a quick look at the documents *before* speaking to the customer. She may look for evidence of disguise or simulation (such as a lack of fluency or amended or inconsistent letterforms) and she would check to ensure that both the specimen writings and the questioned writing are consistent with being the work of one person. During this investigative phase, she may speak to the investigator to gather information about the way the samples were taken or the location where the note was found (e.g., if it was found in the back of a car, then movement could account for inconsistencies; if it was written in front of a bank clerk, then movement is very unlikely to be the cause).

By conducting this investigative phase, some possibilities can be eliminated. Assume that, as a result of this first examination, the examiner observes that both the questioned and specimen writings are fluent and that both are written in a very distinctive hand. As a consequence the evidence allows refinement of the propositions and they now become as follows:

Mr X wrote the questioned handwriting:

H_{p1}: in his normal natural hand.

Someone other than Mr X wrote the questioned handwriting:

H_{d1}: in their normal style;
H_{d2}: as a simulation of Mr X's handwriting.

A full and detailed comparison of the writing can now be conducted, which should reveal whether any differences present between the writings are the result of natural variation, different writers, or simulation. In most cases, this is straightforward and leads the layman into believing that handwriting comparison is simply a matter of looking for similarities (e.g., Malvolio); they do not look for the differences.

If the investigative phase reveals that the questioned writing is very hesitant while the specimen writing is very fluently written and there are many obvious differences between the writings, then the expectations of the examiner will alter, and the propositions are refined in a different way. They become as follows:

Mr X wrote the questioned handwriting:

H_{p2}: in a disguised hand;
H_{p3}: while suffering from a temporary debilitating illness;
H_{p4}: while under the influence of drink or drugs;
H_{p5}: while under the influence of some environmental factor (e.g., while in a moving vehicle; in an awkward position; against an unsuitable surface);
H_{p6}: with his unaccustomed hand.

Someone other than Mr X wrote the questioned handwriting:

H_{d1}: in their normal style;
H_{d3}: in a disguised hand.

The most important factor to note here is that the examiner would not now look for lots of similarities (as they know that they do not exist) but would assess the nature of the differences and whether they would be expected to occur if any of the subsets of the main proposition is true. Sometimes they are much more likely to occur if one particular nested proposition is true, and this can shift the likelihood ratio in one direction or the other, but on other occasions (particularly simple signatures) no one proposition

stands out, and the likelihood ratio may remain near to one.

Two important points emerge from this reasoning: first, it is very difficult to place actual numbers of the probabilities we are considering here, and therefore a likelihood is always qualitative and is based on the experience of the examiner. While some studies have been conducted into the occurrence data for individual letterforms, which would give values that could be put into a likelihood ratio, this would only be applicable if the alternatives to be considered were as follows:

Mr X wrote the questioned handwriting

H_{p1}: in his normal natural hand.

Someone other than Mr X wrote the questioned handwriting:

H_{d1}: in their normal style.

This is rarely the case, but again is often assumed to be the case by the layman. It is much more difficult to estimate the probability of the evidence given that the writing is disguised or simulated, although qualified examiners will be able to make an estimate of this on the basis of their experience.

The second is that the investigative exercise does not eliminate any nested propositions but only informs which ones are going to be most influential on the likelihood ratio. Therefore it is difficult to justify the definite opinion on this argument.

Comparison

The next part of the examination is to look at the writing in detail and assess how similar the questioned and specimen writing is, in the light of the investigative findings. This is generally done by the systematic comparison of each character in turn, comparing its structure (the way the pen moves in constructing the character) its shape, its variation (some people have two different forms of letter or vary the letter according to its position in the word) and the characters' proportions with respect to adjacent characters (e.g., some people always write a "P" much bigger than a "O"). Even a small piece of handwriting contains a wealth of information and it is therefore not surprising that the degree of match between the questioned and known characters is often a point of debate between two handwriting examiners. However, the disagreements are usually about magnitude and range of variation rather than fundamental differences of opinion and are influenced by the experience of the examiner. Once this assessment has been done for all the characters and other features present in both, the questioned and specimen writing, then the examiner will have a list of the similarities and the differences between the writings. They then assess the significance of the match or mismatch in the light of the previously conducted investigative phase.

Interpretation

As has been previously described, there are some inherent problems to be overcome in the interpretation of evidence gained from a handwriting comparison. It is not sufficient to simply say "these writings are similar" or "these writings are different" because both observations can occur whether or not the writings are by the same person. In terms of the harbor pilot, making observations, without deciding upon a likely course, leaves the ship still at sea.

The first challenge the handwriting examiner is faced with is inherent variability of one person's writing. If they see a difference between one piece of writing, does this mean that the writing is by a different person, or simply that the writer has a wider range of variation than is demonstrated by the specimen writing? This assessment often comes down to a matter of experience and this is why comparisons in scripts which are not intimately known by the examiner, should be treated with caution. The judge in the Starzecpyzel case said that the handwriting examiner was more like a harbor pilot guiding a ship into port than a scientific expert. By implication, they are more likely to be reliable when they are in waters they are familiar with, but that is not to say that they cannot be of some use in other arenas, as they will be able to interpret the signs better than a layman.

The second challenge is deliberate disguise; if the two pieces of writing appear very different, then disguise of one or both pieces of writing must be considered as a possible explanation for the differences. In larger amounts of writing disguise is often difficult to maintain but in smaller amounts it has to be considered as a real possibility and the results of these examinations are often inconclusive.

Signatures

The treatment described earlier, while being focused on handwriting, can equally be applied to signatures. However, in this case the examiner is now dealing with a small amount of writing, often written in a very personalized way. The effect of this is to alter the importance and influence of some of the subpropositions described earlier. For instance, assume we have a signature that is so personalized that one is unable to distinguish individual letters. Consider the nested prosecution and defense propositions described earlier:

Mr X wrote the questioned signature:

H_{p1}: in his normal natural style;
H_{p2}: in a disguised hand;
H_{p3}: while suffering from a temporary debilitating illness;
H_{p4}: while under the influence of drink or drugs;
H_{p5}: while under the influence of some environmental factor (e.g., while in a moving vehicle; in an awkward position; against an unsuitable surface);
H_{p6}: with his unaccustomed hand.

Someone other than Mr X wrote the questioned signature:

H_{d1}: in their normal style;
H_{d2}: as a simulation of Mr X's handwriting;
H_{d3}: in a disguised hand.

The examiner quickly undertakes the investigative stage of the examination, and finds that the questioned and specimen signatures look the same in general appearance. The possibility of this occurring is much higher for some of the subpropositions than the others, and the propositions, for practical purposes, can be reduced to the following:

Mr X wrote the questioned signature:

H_{p1}: in his normal natural style.

Someone other than Mr X wrote the questioned signature:

H_{d2}: as a simulation of Mr X's handwriting.

The chance of a coincidental match is so small as to be eliminated, and the crux of the examination becomes whether or not someone would have the skill to be able to simulate the signature in question. To answer this, the examiner then has to draw on their experience as to the complexity of the signature and the ability of people to simulate this complexity of signature this well. It can be seen that signature comparison draws more heavily on the skill and experience of an examiner than handwriting comparison, but the principles for comparison and evaluation are the same.

Summary

In summary, the concept of a likelihood ratio can be applied to handwriting comparison in much the same way as to other branches of forensic science. However, because the examiner has an investigative role to play in making a handwriting comparison there is an added complexity to the examination. This can be addressed by using the concept of "nested" or subpropositions.

End Notes

[a.] The same here refers to a holistic view of the writing, rather than the exact reproduction of each written line. In fact, even one person never writes "exactly the same" on two different occasions. The premise is that "within person variation is smaller than between person variation".

Handwriting Comparison *see* Handwriting and Signatures, Comparison of

Hardy-Weinberg Equilibrium

The Hardy–Weinberg equilibrium is a state in which the allelic frequencies do not change. Its forensic significance is that in the process of calculating the expected frequencies of genotypes in the population, this equilibrium, or steady state, is assumed as a starting basis.

Given that any person will normally have two alleles at each locus (although both may be the same), the allelic frequencies can be used to calculate genotype frequencies (paired combinations of alleles) by multiplication.

In a simple example, if there are only two alleles (A or B) possible at a locus then there are only three types of individuals: AA, BB, and AB. If the frequency of allele A is p, and the frequency of allele B is q, it is possible to calculate the frequency of each type of person in the population *assuming the Hardy–Weinberg rules*. One of these is "random mating". The alleles exist in pairs within men and women, but the pairs separate in the formation of sperm and egg so, in effect, the next population is a sample of drawing two alleles together, one from the male and one from the female. For p As and q Bs, it is quite simple algebra to calculate the result of one round of mating where a child will receive (A or B) and (A or B):

$$(p + q) \times (p + q) = (p + q)^2 = p^2 + 2pq + q^2 \quad (1)$$

This gives the frequency of AA people as p^2, AB people as 2pq, and BB people as q^2.

Thus, an allelic frequency database can be used to calculate a random match probability (RMP) to an individual: the probability that one could pick a person who would have the same genotype (profile) at random from a population of unrelated individuals. In forensic applications, the loci chosen will have many more than just two alleles, i.e., A, B, C, D, etc. with frequencies p, q, r, s, etc. The principle for the calculation of genotype frequencies is the same as above, just involving a larger equation (1) for the whole population. Then, if you want to know the RMP for a person who has the genotype of BD, the algebra dictates that it would be calculated as 2qs, the RMP for a person who is CC would be r^2, and so on. This is the value for one locus. For a group of loci as used in a profiling multiplex, the RMP is derived by calculating the combined genotype frequencies using the product rule such that the genotype frequency for each locus is multiplied together.

The full set of "rules" of the Hardy–Weinberg Equilibrium for a population are that it must be large, there must be random mating of individuals, no mutations, no migration out of or into the population, and no selection acting on any of the individuals. If these rules are not met, the population is not in equilibrium and the allele frequencies will be changing.

For the purposes of forensic DNA profiling, the most important consideration when doing the RMP calculation using the equations above, is the effect of selective interbreeding of small populations in the real world, whether geographically or culturally isolated to some degree. This nonrandom mating will alter the frequency with which some alleles will be

seen compared with the frequencies of a wider population from which a sample database may have been collected. There is some debate on how to accommodate this, and other possibilities, into calculating the statistics of the random match probability for a profile (*see* **Short Tandem Repeats: Interpretation**; **Mixture Interpretation: DNA**). Most commonly a correction factor is incorporated into the calculation for genotype frequencies to allow for population substructures [1–2].

Hare Psychopathy Checklists *see* Psychopathy Checklists

HCR-20 *see* Risk Assessment: Patient and Detainee

Head Injury: Neuropsychological Assessment

Traumatic brain injury (TBI) is defined by the International Neuropsychological Society (INS) Dictionary of Neuropsychology as injury to the brain resulting from "an external force such as a blow to the head, concussive forces, acceleration–deceleration forces, or projectile missile (e.g., bullet)" ([1], p. 160). Most incidents of TBI are caused by falls, with motor vehicle crashes and violent assaults also causing significant percentages of TBI as well. The National Center for Injury Prevention and Control estimates that approximately 1.4 million Americans sustain a TBI every year resulting in nearly 50 000 deaths, a quarter of a million hospital stays, and over a million treat and release cases handled by emergency departments throughout the country. These statistics are very likely to be a significant underestimation of TBI's prevalence, as many persons who experience a head injury never seek medical care for their ailments [2]. The Center for Disease Control and Prevention (CDC) estimates that nearly 2% of the country's population, over 5 million citizens have long-term deficits resulting from TBI [3]. The cost to the country's economy resulting from TBI is staggering with estimates as high as 50+ billion dollars yearly [4]. Of course, this does not take into consideration the personal toll that TBI takes on those afflicted and their loved ones and dependents.

After sustaining a TBI, regardless of its cause, first responders and medical professionals typically assess the severity of the injury with behavioral rating scales such as the Glascow Coma Scale (GCS). This rating scale has three individual components on which the patient's ability to respond is rated across three different areas: eye opening response; verbal response; and motor response. The sum of the three scales ranges from a minimum score of 3 to a maximum score of 15 [5]. GCS ratings are taken upon initial contact with the TBI patient, and often ratings will be taken at various points in time after initial evaluation. For example, ongoing assessment of consciousness may be needed to gauge changes arising from the neurological insult (e.g., a subacute, subdural hematoma), or other elements not directly related

to the injury itself such as states of intoxication at the time of the injury that will affect the patient's level of consciousness as time passes and sobriety sets in. It is generally accepted that an individual has sustained a "severe" TBI when their GCS score is in the 3–8 range, a "moderate" TBI with scores in the 9–12 range, and a "mild" TBI with a score in the 13–15 range. In emergent contexts, assessment with the GCS often dictates the next course of assessment and treatment taken by medical professionals. For example, severe TBI patients, as measured by GCS, may require a critical care physician to address issues relevant to appropriate airway management and to assist with resuscitation. A request for neuroimaging (e.g., computed tomography (CT)) may be the first assessment procedure required for persons with GCS ratings in the moderate to mild range. Moreover, scales such as the GCS may be relevant to predicting outcome [6]. However, one must always consider the circumstances surrounding the time period in and around the TBI, the specific nature of the physical injuries sustained at the time of the TBI, and any other treatment issues relevant to the case (e.g., if the person had to be sedated because of agitation) before drawing conclusions about GCS scores as relevant predictors of adjustment to the TBI.

The CDC estimates that nearly three-quarters of TBI in a given year are due to concussions or other mild forms of TBI resulting in changes across the neurocognitive spectrum, in particular, attention and memory. The Diagnostic and Statistical Manual of Mental Disorders Fourth Edition Text Revision (DSM-IV-TR) [7] addresses the sequelae of mild TBI by proposing a new diagnostic category for this phenomenon, postconcussional disorder. Concussion typically involves an incident resulting in loss of consciousness for a brief period of time (e.g., 5 min), loss of memory after the traumatic event, and possibly posttraumatic seizures within 6 months of the injury. However, loss of consciousness may not be a necessary condition for postconcussive symptoms to emerge [8, 9]. Symptoms associated with postconcussional disorder may include becoming fatigued more easily, sleep disturbance, headaches, bouts of dizziness, irritability, changes in mood such as depression, disinhibition, and reduced motivation. The changes in cognition may be observed after the traumatic incident, typically a closed head injury, and for many persons may resolve overtime. Of course, more serious TBI cases effect change in various aspects of thinking (attention, memory, and reasoning), sensation (touch, smell, and taste), language (expression and reception), and emotion (anxiety, mood, personality functioning, and social skills). All of these functional areas can be formally assessed and compared with premorbid abilities.

The Context of TBI Forensic Evaluation

There are many reasons for which a formal forensic assessment of the TBI patient may be requested (*see also* **Neuropsychological Assessment**). In civil law cases, psychologists, psychiatrists, neurologists as well as rehabilitation medicine specialists with specific training in TBI are often needed to inform the trier of fact. Certainly, expert testimony in tort cases for both plaintiff and defendant is often called for to help understand the impact of TBI upon the alleged victim, and its likely course overtime. Forensic evaluators give expert opinion on both sides of the adversarial process in courts, often explaining the severity of injury, its specific manifestations, and amenability to treatment. Some cases may not involve tort issues *per se*, but custodial matters and/or civil liberties. For example, a person's capacity to be a responsible parent may be called into question after a TBI, or one's ability to live independently, control one's finances, or engage in contracts (including making a will) may be the relevant issue of inquiry.

In the criminal jurisprudence arena, there are a number of areas in which a TBI defendant's neurocognitive capacities are questioned and may be relevant. This includes a defendant's ability to comprehend verbal information such as Miranda warnings, to rationally engage with his or her defense counsel, and to understand the criminal charges and possible implications (competency to stand trail). In severe cases of TBI, there may be an issue of whether the defendant can ever be restored to competency to stand trial, pursuant to *Jackson v. Indiana*. There may be issues of criminal culpability that surface and as such, a formal assessment of the defendant's mental state at the time of the alleged criminal incident will be investigated. These criminal responsibility (i.e., insanity) evaluations may play a pivotal role in how the court decides a case, that is, whether or not the defendant will be held criminally responsible for his or her actions. Neuropsychological impairment could certainly impact the defendant's *mens rea*, or capacity to form the specific intent for the crime charged, and

how the perpetrator of the criminal event thought about his or her actions at the time. Such information is also relevant to the sentencing phase of a criminal trial, that is, what may happen to the defendant after the guilt phase is completed (e.g., incarceration vs. hospitalization). Forensic assessment of TBI may determine in what type of correctional setting a guilty defendant will be placed, or even whether TBI symptoms are considered aggravating or mitigating factors that the trier of fact (a jury and/or a judge or panel of judges) considers before deciding to sentence a defendant to death in capital cases [10].

Elements of the TBI Forensic Evaluation

Before one can begin to understand how TBI has impacted the allegedly brain injured patient's life (if at all), it is necessary to collect information from collateral sources to gain a functional understanding of how the patient was getting along prior to the critical incident. The forensic evaluator must get a thorough family history, educational background, occupational history, medical history, mental health history, substance abuse history, and history of contacts with the criminal justice system (juvenile and adult). It is preferable to obtain written records to substantiate any reported information. The evaluator should also contact and interview persons who are familiar with the TBI patient and his or her life history. This may include family, friends, previous employers (e.g., supervisors), teachers, etc. Some indication of the TBI patient's premorbid neurocognitive status is also needed if the evaluator is to reliably assess for the presence of deficits. Forensic neuropsychological assessment mostly involves intraindividual comparison of abilities such that premorbid functioning and current performance on tests are compared, and differences between these ability levels are determined and analyzed. Neuropsychological testing must also be compared to appropriate normative samples. If direct measures of premorbid abilities (e.g., achievement tests, intelligence tests, school grades) are not available, one may have to estimate a person's premorbid abilities. This usually includes testing an individuals reading ability (or test of verbal capacities), and combining the obtained scores with demographic information (e.g., age, sex, race, education, and occupation). Reading test scores are noted to be relatively unaffected by TBI and are referred to as *hold scores*. This, of course, is not true if a person has sustained a TBI affecting those areas of the brain specifically utilized in language ability (for a full discussion of different methods for estimating premorbid abilities, please read the article entitled "The Rationale of Deficit Measurement" [10]).

There are far too many neuropsychological assessment tools to mention in this brief overview. For a comprehensive presentation of this field of study, the reader is referred to updated texts such as Lezak, Howieson, & Loring's *Neuropsychological Assessment* [11], and Mitrushina, Boone, Razani, and D'Elia's *Handbook of Normative Data for Neuropsychological Assessment* [12]. The following areas should be thoroughly assessed: the patient's level of consciousness at the time of the assessment(s); orientation to person, place, time, and circumstance; attention and concentration; memory for both verbal and nonverbal material across short and long time spans; receptive and expressive language skills; constructional abilities; executive functions; judgment and insight; affect and mood. Each of these areas is briefly described below.

Orientation

A good neuropsychological assessment must first account for the how alert the patient is at the time of the assessment procedures. There are times when patients arrive for an assessment after taking prescribed narcotic analgesics for pain they report experiencing subsequent to an injury. Patients have arrived intoxicated on alcohol or seemingly hung over, yet they report that they are prepared to proceed with the evaluation. In serious cases of documented TBI, it is not unusual to observe patients who fatigue rapidly while working on challenging neuropsychological tasks. These observations are critical for the assessment. However, under such circumstances it is nearly impossible to determine if deficits produced on testing are a product of the altered state of consciousness which may be a reversible condition, or some underlying deficit sustained as a result of the TBI.

One's orientation to self refers to not only knowing who the person is (e.g., one's name), but other pertinent biographical information as well (e.g., date of birth, place of birth, names of siblings, children, etc.). Orientation to place accounts for present knowledge of the patient's whereabouts, where the patient presently resides. Time orientation is typically assessed by asking the patient the date, day of the

week, season, and time of the day. Finally a patient should be asked how he or she understands the reason for his or her being with you, the evaluator. This is an excellent time to correct any misunderstanding the patient may have of the role of the evaluator, and to inform the patient that there may be limitations to confidentiality entailed in the assessment. For example, the evaluation may be court ordered, or requested by the opposing side in a tort case.

Attention and Concentration

Assessment of attention is certainly critical to understanding how well an individual responds to demands in his or her environment. Assessment involves "tuning in" what is important, while "tuning out" extraneous information not specifically relevant to the completion of some demanded task. Patients may be requested to repeat strings of numbers, varying in length, both forwards and backwards. Concentration typically involves more sustained effort across a specific time span. For example, the patient may be asked to cross out a specific letter on a page filled with letters and numbers and to work as quickly as one can. Looking at how accurately one can do such a task as well as how quickly it can be completed tells the evaluator much information about an individual's concentration skills and efficiency of thinking.

Memory

Memory tasks are critically important because they tap one's ability to learn new information, thereby indicating how well one can adapt to new challenges. Verbal learning tests often look at an individual's ability to learn a list of words read aloud multiple times, or a story (a complex prose paragraph). Typically, these tests require the information to be verbally reported immediately after the information is presented, and then after a time delay, usually at least 20 min or more. There are nonverbal learning tasks as well that involve committing to memory drawn figures or pictures depicted on a page and displayed to the examinee for a specific period of time. After a free recall component following a time lapse, many tests will require the examinee to recognize and discriminate what he or she was asked to commit to memory. For example, the examinee may be told to choose the words he or she learned previously from a longer list of words, some that were previously presented and others that were not (distractors). It is not uncommon to find TBI patients who do poorly when attempting to freely recall information, but they can recognize what they had been asked to learn with very fine discrimination (called a *retrieval deficit*). Memory tasks are designed to assess types of amnesia that may afflict persons with TBI.

Language

An individual's ability to communicate can be adversely impacted by TBI. The entire spectrum of speech from production (e.g., motor skills, word knowledge, syntax, vocal inflection, and facial expressions) to receptive abilities (e.g., carrying out verbal and/or written commands) should be assessed. Reading ability should be tapped as well. Particular attention should focus on the person's capacity to think abstractly.

Constructional Ability

Constructional tests usually require that the examinee reproduces pictures (drawing) or puts together designs of varying complexity with different color blocks. Careful attention to the examinee's approach to the task often reveals how one perceives the test's challenge, plans to complete the tasks, and then carries out the plan with efficiency and speed. These tasks are usually referred to as *visual-motor*.

Executive Functioning

Executive functions have been described as the "most complex of behaviors", which are "intrinsic to the ability to respond in an adaptive manner to novel situations" having four components: volition (being aware of the goal of the act); planning (identifying and organizing the steps to attain the goal); purposive action (carrying out the plan and if need be, adjusting the plan to changing circumstances and contingencies); and effective performance (self-monitoring and self-correcting) [11, pp. 611–638].

Judgment

Many neuropsychologists utilize tests that tap into social judgment. Questions may be posed that require the examinee to generate socially acceptable solutions to a problem (e.g., "What should one do if he or she discovers a fire in a crowded building?"). The

ability to generate appropriate solutions to interpersonal problems can be negatively impacted by brain injury, especially injuries affecting the frontal lobes. In addition, it has long been known that TBI patients will sometimes get extremely frustrated in stressful encounters with others. As a consequence, they may exhibit exceptionally poor responses to stress including acting out with episodes of verbal aggression or even violence [13]. Arrest rates for criminal acts in the TBI population are well above the arrest rate in the population at large [14], and the percentage of inmates in prisons who have reported sustaining a TBI is well above the prevalence rate of TBI in the nonincarcerated population [15].

Insight

It is also important to assess how the brain injured examinee views his or her functional capacities since the TBI itself. The ability to recognize that one has sustained deficits in functioning is a critical step in the rehabilitation of the individual. Yet, there are some persons who are incapable upon reflecting and evaluating their own abilities, showing poor insight into their condition since the TBI. If one is unable to recognize under what conditions one is incapable of completing a specific task, he or she will be unable to implement newly learned skills or utilize mental prosthetic devices so often an integral part of the rehabilitation plans.

Mood and Affect

Some indication of a person's level of anxiety and mood at the time of the examination process is necessary. An examinee may be highly anxious at the time of the assessment for various reasons. The adversarial nature of court proceedings and the reasons for the testing could produce great anxiety in some examinees. The tasks themselves are often challenging and may produce stress that the examinee feels ill-equipped to cope with. Highly anxious examinees may perform poorly or the anxiety levels may negatively impact test performance [15]. Depressed TBI patients, especially those with vegetative signs of depression, often exhibit a variety of cognitive deficits that may be reversible if the depression remits after treatment; this is particularly true of older patients [16].

Effort and Malingering

Finally, it is known that a considerable number of individuals being assessed in a forensic context will either fabricate or exaggerate symptoms. One must assess the individual's level of effort, and rule-out the possibility of malingering during these evaluations. Malingering is defined as "the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives" ([7]; p. 739). Incentives may include the avoidance of criminal prosecution, financial gain from a tort case, or receiving disability benefits. Measuring the effort one gives during the neuropsychological examination is considered by clinicians to be core of the assessment [17]. There are a number of valid and reliable measures to assess level of effort and/or malingering of neurocognitive impairment, with good sensitivity and specificity. It is well accepted that assessment for malingering is a necessary component of the TBI evaluation. The National Academy of Neuropsychology issued a position paper on this topic in which they wrote: "... the assessment of symptom validity is an essential part of a neuropsychological evaluation. The clinician should be prepared to justify a decision not to assess symptom validity as part of a neuropsychological evaluation (p. 421)" [18].

Interpretation of the TBI Forensic Evaluation

The neuropsychological evaluation results are assessed together with results from a thorough physical examination, usually performed by a neurologist, including an analysis of the alleged TBI patient's gait and posture, cranial nerves, motor skills, tendon reflexes, coordination, sensory functioning, and autonomic system. Neuroimaging studies, such as CT or magnetic resonance imaging (MRI) scans may also be included. The examiner must make rational connections between test results and purported deficit states that exist and are attributable to the TBI. Moreover, the ecological validity of the findings must be discussed in full. Ecological validity is defined as "the functional and predictive relationship between the patient's performance on a set of neuropsychological tests and the patient's behavior in a variety of real-world settings (e.g., at home, work, school, community)" [19]. At this stage of

the evaluation, there is another important issue that must be considered. The fact that a TBI patient did poorly on a small number of neuropsychological tests (assuming adequate effort was given) might not necessarily mean that the TBI patient had significant deficits in the area tapped by the test in which he or she did poorly. If you give a large number of neuropsychological tests to someone, whether he or she has brain impairment or not, there will be a few tests in which poor performance is expected to occur by chance alone. This issue must be addressed in the interpretation section of the assessment report [19, 20].

Future Trends in TBI Evaluation

As emergency procedures become increasingly more sophisticated at stabilizing patients, and new generation medications are discovered that quickly decrease swelling in the brain, more persons who have sustained TBI will survive, where just a few years ago many such injuries would likely have resulted in death. New assessment procedures with sophisticated computerized methods of interpretation and more refined images will emerge. Measures of hemodynamic response of neural activity (functional MRI) observed while a person performs a specific task will allow stronger inferences to be drawn between TBI and functional deficits. More subtle abnormalities often associated with closed head injury can now be studied with diffusion tensor imaging [21]. The usual array of TBIs including closed head injuries and penetrating head injuries will challenge examiners. Blast-related injuries from improvised explosive devices (IEDs) used in warfare and terrorism are resulting in a sizeable number of veterans and other victims who suffer concussion and contusion from sudden increases and decreases in air pressure near the blast. These symptoms can be combined with posttraumatic stress disorder making it very difficult to tease apart what is causing the blast victim's reported deficits [22]. For example, a recent study of veterans returning from combat duty in the Iraq war found that those who suffered mild TBI (approximately 5% of the large sample surveyed) caused by loss of consciousness as a result of exposure to an explosive device, also had symptoms of posttraumatic stress disorder and depression. When these psychological injuries were controlled in the statistical analysis, symptoms usually associated with TBI such as concentration difficulties and memory impairment were no longer significantly associated with the TBI. Only the symptom of headaches remained as a significant correlate with TBI [23]. Simply stated, there is evidence to support that the psychological injury may be far more debilitating than the actual neuropsychological impairment. A more refined approach studying this phenomenon is certainly needed [24].

SCOTT A. BRESLER AND DANIEL A. MARTELL

Hearsay Evidence

Hearsay Evidence Banned . . . Sometimes

There are a number of requirements that must be fulfilled before the hearsay exclusionary rule will bar the use of oral testimony or documentary evidence. First of all, the statement or writing must have been made at a time prior to its attempted use in a legal proceeding. The maker of the statement or the author of the writing, often referred to as the *declarant*, is usually not present at the proceeding when it is sought to be introduced as evidence. The content of the statement or writing is sought to be introduced as evidence by a person who, earlier, overheard the declarant uttering the words or executing the writing. Finally, the out-of-court communication is offered as proof of the truth of what it contains.[a]

If a statement or writing satisfies these requirements, the basic principle of the rule against hearsay evidence in a jurisdiction that follows the common law prohibits its use as evidence.[b]

The rule against hearsay evidence has no equivalent in civil law countries, where all evidence is admitted and considered by the tribunal.

Reasons for the Rule's Existence

The fact finder in a trial typically must be satisfied that any witness or evidence presented is reliable. In a jury trial, the jury is the finder of the disputed facts. The very basic proposition is that all persons who are expected to present evidence must be competent witnesses. When a litigant objects to the competency of a witness offered by the opposing side, or if the court has reservations about that competence, there may be a need to determine whether the person had the ability to perceive, remember, and communicate the events about which he offers to testify. All witnesses must possess a minimum of competence, perception, memory, and communication.[c]

Reliability of witness testimony may be particularly difficult to ascertain if the declarant of the out-of-court statement is not in court, and its content is sought to be conveyed by the testimony of someone who merely overheard the statement when it was being made or seeks to use a document prepared

out of court. There is a potential risk of untrustworthiness if the declarant is absent and cannot be cross-examined.

Where a litigant objects to evidence on hearsay grounds, he is arguing in essence that the statement ought not to be received in evidence, because to admit it would deprive the litigant of the opportunity to explore the circumstances under which the statement was allegedly made, and indeed to challenge whether it had been made at all. If the declarant is not present, and cannot be cross-examined, evidence of unknown validity may well mislead or distract the jurors.

The right to confront and cross-examine witnesses who give evidence against a litigant is one of the bedrocks of the adversary criminal justice system.

Rule Does Not Apply to All Out-of-Court Statements

It must be noted that the rule against the evidentiary use of hearsay does not apply to all out-of-court statements or documents, but only to those that are sought to be used as proof of the truth of their content. Thus, if the reason for introducing an out-of-court statement is not to prove its truth, but to prove that the statement – whether true or false – was made at all, the rule against hearsay does not apply. If the statement or document is probative of the issue on whether it was uttered, then it is not considered hearsay and will be admissible.

In addition to exempting all out-of-court statements from the rule against hearsay that are offered to prove some fact independent of the truthfulness of its content, the rule of exclusion also does not apply to a series of statements where, despite its purpose seeking to use it as proof of its truth, the system of justice nevertheless believes that, for policy considerations, exclusion ought not to occur.

Thus, FRE 801, which defines hearsay, specifically exempts a series of out-of-court statements that would, in the absence of the exemption from the hearsay rule, be considered "hearsay". Therefore, FRE 801 simply, and somewhat illogically, calls such statements "nonhearsay". FRE 801(d)(1) states that, in some cases, prior out-of-court statements by witnesses who are currently testifying and subject to cross-examination will not be considered hearsay statements.[d]

The same FRE 801, in its subsection (d)(2), also exempts from the prohibition against admitting hearsay evidence any admission of a party opponent or his employees and agents.[e]

It can be observed that this rule eliminates from the hearsay exclusionary concept's applicability a great number of out-of-court statements.

There are Many Exceptions to the Rule against Hearsay

Even statements that clearly fit the definition of "hearsay" may be admissible, because, in addition to assertions that are not considered hearsay at all, common law courts have, over the years, created a long list of exceptions to the rule against hearsay. These court-made hearsay exceptions are, today, also codified in codes of evidence such as the Federal Rules of Evidence (FRE) and other similar compilations of evidentiary principles.

Thus, a true hearsay statement, which is sought to be used as evidence of the truth of its content, may be admitted in evidence if it fits one of the many recognized hearsay exceptions.

Some legal commentators suggest that the prohibition against the use of hearsay evidence might just as well not exist anymore, because the exceptions have swallowed the rule. Despite this assertion, the rule continues to exist, perhaps with greater force in US courts than in other common law countries.

In the United States, the exceptions to the prohibition against hearsay are codified in FRE 803 and 804.

In FRE 803, an impressive list of 23 exemptions allows the admission of certain types of hearsay evidence. These exceptions apply whether or not the declarant of the out-of-court statements is available for testimony. In FRE 804, an additional five exceptions to the rule are noted, but, in these cases, the hearsay statement will be admissible only if the declarant of the statement is unavailable for testimony or cannot be found.

Exceptions to the rule against use of hearsay are fairly technical. There are many court decisions that describe, in great detail, the circumstances under which they will be applicable. Litigators are familiar with these court rulings. In many cases, these technicalities are unimportant to forensic experts, but at least six of these categories of hearsay exceptions do involve forensic experts with some regularity. They are discussed hereafter.

Important to forensic practitioners are these statements excepted from the rule against hearsay:

1. statements made for purposes of medical diagnoses or treatment to doctors or medical personnel[f];
2. records of regularly conducted activity (which would include laboratory or QA (Quality Assurance) entries and an expert's bench notes)[g];
3. the exception for public records and reports of public offices or agencies[h];
4. records of vital statistics[i];
5. statements contained in ancient document in existence 20 years or more[j]; and, perhaps most importantly for forensic experts
6. statements contained in learned treatises and professional publications.[k]

End Notes

[a.] In the United States, the FRE regulate the conduct of civil and criminal proceedings and the evidence which it is appropriate for a court to consider. These rules apply in all federal courts. The FRE also have their equivalent in the evidence codes in most of the US states, many of which have incorporated the FRE in whole or in part in their own state laws.

FRE 801(a) defines a hearsay statement as "(1) an oral or written assertion or (2) nonverbal conduct of a person, if it is intended by the person as an assertion". In FRE 801 (c) the definition further limits the concept's applicability to only those statements "offered in evidence to prove the truth of the matter asserted".

[b.] FRE 802 provides: "Hearsay is not admissible except as provided by these rules or by other rules prescribed by the [United States] Supreme Court pursuant to statutory authority or by Act of Congress". All states have an equivalent rule of evidence.

[c.] An additional historical requirement for testimonial capacity requires a commitment to be truthful. This commitment is sought to be safeguarded by requiring a witness take the "oath" to speak truthfully or, if a witness's religion prohibits oath-taking, by his affirmation of the commitment to tell the truth.

[d.] FRE 801(d)(1) provides that an out-of-court statement is not hearsay if the maker of the statement, referred to in the Rule also as *the declarant*, "testifies at the trial or hearing and is subject to cross-examination concerning the statement, and the statement is (A) inconsistent with the declarant's testimony, and was given under oath subject to the penalty of perjury at a trial, hearing, or other proceeding, or in a deposition, or (B) consistent with the declarant's testimony and is offered to rebut an express or implied charge against the declarant of recent fabrication or improper influence or motive, or (C) one of identification of a person after perceiving the person."

[e.] FRE 801(d)(2) states that the hearsay exclusionary rule also does not apply where "The statement is offered against a party and is (A) the party's own statement in either an individual or representative capacity or (B) a statement of which the party has manifested an adoption or belief in its truth, or (C) a statement authorized by the party to make a statement concerning the subject, or (D) a statement by the party's agent or servant within the scope of the agency or employment, made during the existence of the relationship, or (E) a statement by a coconspirator of a party during the course and in furtherance of the conspiracy. . . . "

[f.] FRE 803(4).

[g.] FRE 803(6). This used to be called the *Business Records* exception, but it is, today, much broader than it once was and applies also to not-for-profit institutions, professions, occupations, or callings of any kind.

[h.] FRE 803(8).

[i.] FRE 803(9).

[j.] FRE 803(16).

[k.] FRE 803(18). The "learned treatise" exception is much broader than its designation intimates. It permits the use as evidence of "published treatises, periodicals, pamphlets, on a subject of history, medicine, or other science or art, established as a reliable authority by the testimony or admission of the witness or by other expert testimony or by judicial notice". If a statement contained in such a source is admitted, the text may be read into evidence, but the publication or document itself may not be received as an exhibit.

Histology

Short Historical Introduction into Microscopy and Histopathology

Although some medicolegal practices, e.g., the investigation into causes of sudden unexpected and violent deaths by barber-surgeons, were established early in medieval Europe, the idea of forensic histology became theoretically possible first with the improvement of light microscope and histological methods, and secondly after the cell theory by Schleiden, Schwann, and Purkinje in the first half of the 19th century and the concepts of pathogenesis of diseases by Carl von Rokitansky (1804–1878) and lastly cellular pathology by Rudolf Virchow (1821–1902) in 1858 [1, 2].

It took over 200 years from the invention of the first microscope in the early 1600s in the Netherlands until its use started to strike root as a scientific instrument useful for the study of pathology. Many obstacles hampered the beginning of microscopic pathology and in addition to poor optics, several other reasons have been mentioned as an explanation; e.g., secrecy of the art, high cost of the apparatus, technical difficulty, lack of ideas, and late acceptance by Universities [3, 4].

Interestingly, Marie-François Xavier Bichat (1771–1802), the first to introduce the concept of tissues as distinct entities and often called the *father of modern histopathology*, did not use microscopy. Likewise, René Théophile Hyacinthe Laennec (1781–1826), another famous French physician of the era, was against the use of microscope [4].

Through accumulation of knowledge of pathological processes and their histological features, histological examination of major organs became gradually an integral part of every academic autopsy, although daily routine practices may still vary considerably according to resources and cultural setting. It is noteworthy that already the Prussian decree on the procedure of a medicolegal autopsy (1875) recommended (§ 5) that the forensic doctor should have a microscope with two objectives and the minimum of 400-fold magnification. Also, Virchow pointed out in his book about dissection technique, with particular consideration for medicolegal practice, that certain pathological changes cannot be recognized by the naked eye, but only with the help of a microscope or a magnifying glass [5].

Indication for Forensic Histological Investigation

The procedure of the cause of death investigation in a medicolegal setting depends largely on jurisdiction, as in some countries, it is limited to clearly suspicious, crime-related deaths, whereas in others, the forensic pathologist deals, in addition to the previous ones, also with the whole spectrum of other types of deaths including sudden unexpected deaths due to presumed natural causes, accidents, suicides, occupational diseases, and iatrogenic causes i.e., deaths due to medical diagnostic or therapeutic procedures.

Medicolegal autopsy often differs from hospital autopsy by the lack of any preliminary knowledge of

the deceased, neither of possible illnesses nor circumstances of death and who may be unidentified and just found dead. Therefore the forensic pathologist ought to be prepared for every eventuality as presumed natural death may turn out to be a homicide.

In the vast majority of cases forensic histology deals with tissue samples retained for cause of death investigation purposes during autopsy. Additional questions that need to be dealt with include vitality, timing, and causes of injuries and their differentiation from postmortem changes.

In the broadest sense, if one includes methods other than just classical histology, forensic aspects of tissue investigation may concern other situations. In mass disasters, bodies may be fragmented and the human origin of isolated tissue fragments as well as the personal identity of the victims has to be established usually applying molecular biological methods. A question about the origin or identity of samples may also arise as a result of mix-up during tissue processing or other similar situations where the chain of evidence may have been broken. Occasionally the question of paternity first arises postmortem when the alleged father dies before the paternity issue has been investigated. In cases where there has been an autopsy and tissues have been retained for histology, the formalin fixed and paraffin-embedded tissue blocks can be used as material for DNA extraction. The extracted DNA can then be compared with the DNA of the child and the mother. Once we investigated paraffin-embedded tissue from a curettage, in which the patient had been diagnosed with endometrial cancer but the histological examination of the uterus that had been operatively removed did not show any signs of malignancy. The question arose whether the original cancer diagnosis had been incorrect and whether the patient should be given postoperative chemotherapy in case the diagnosis had been false, for example, owing to a sample mix-up. Extraction of DNA from the paraffin-embedded tissue from the scraping and comparison with the DNA sample from the patient was able to confirm that the original diagnosis had been correct.

Guidelines

Many autopsy guidelines express a view as to autopsy histology. As a rule, complete histological examination of all major organs is considered an essential part of every postmortem and this principle has been adopted by many guidelines:

A recommendation of the Council of Europe: Rec (99) 3 of the Committee of Ministers to Member States on the harmonization of medicolegal autopsy rules; Adopted by the Committee of Ministers on 2 February 1999, states in section 6. Sampling:

> . . ., the following minimum rules should be applied:
> a. in all autopsies, the basic sampling scheme includes specimens from the main organs for histology. [6].

The Royal College of Pathologists (United Kingdom) Guidelines on autopsy practice, September 2002, takes a similar position in section 9 Autopsy histology:

> 9.2 As best practice, sampling of all major organs for histology in all autopsies is recommended.

The importance of histology to the cause of death investigation is further emphasized.

> 9.6.2 . . .. If in advance of the autopsy, discussions with a Coroner indicates to the pathologist that retention of material that may be relevant to the investigation will not be permitted, the pathologist should decline the request to perform the autopsy [7].

The Code of practice and performance standards for forensic pathologists by the Home Office Policy Advisory Board for Forensic Pathology and The Royal College of Pathologists, November 2004 and Code of Practice and Performance Standards for Forensic Pathologists dealing with Suspicious Deaths in Scotland by Scottish Government, Crown Office Procurator Fiscal Service (COPFS) and The Royal College of Pathologists, November 2007, have the same standpoint to postmortem histology:

> A histological examination should be made, by the pathologists themselves, of the major organs (assuming that they are not heavily decomposed) in all suspicious deaths. Histology is of value in confirming, evaluating and sometimes revising the course of natural disease processes that may have contributed to the cause of the death. Other samples should be taken for histological examination depending on the circumstances of the case, e.g., for the purposes of aging injuries. The reasons behind any decision not to undertake a histological examination must be adequately recorded, in order that the pathologist may be in a position to defend this decision if required [8].

Methods

General Remarks. The choice and use of correct methods is paramount for reliable results. This starts with sampling of tissues, in which several aspects have to be considered. Samples should be taken from suspected pathological findings, or when no such findings are visible to the naked eye, representative samples should be taken from the main organs bearing in mind that special sampling procedures and protocols may apply, e.g., for neuropathology, the cardiac conduction system or pediatric cases.

Samples have to be cut using sharp instruments to minimize mechanical damage to the tissues that may cause artifactual changes and hamper the interpretation of the findings. Sites, where the samples have been taken from, have to be recorded and numbered in the autopsy protocol to enable topographical correlation and comparison with macroscopic findings and possible later review and quality assurance measures.

For routine histopathology most tissues are fixed using buffered formaldehyde to stop the autolytic processes and degradation by bacteria and to stabilize the proteins. The size and the thickness of the sample must be in compliance with the choice of the fixation method and appropriate fixation time to avoid fixation artifacts and to allow the use of special methods such as immunohistochemistry, as too long fixation may destroy the antigenic properties of the tissue and produce false negative results. Special procedures are often necessary for enzyme- or immunohistochemical methods or to demonstrate substances that are easily inactivated, destroyed, or removed during routine fixation or tissue processing procedures. In these cases frozen fresh tissue can be used that is cut using a cryostat. At every stage of tissue handling, the specimens have to be properly labeled to preserve the chain of evidence. After fixation the tissue samples are processed either manually or using automated tissue processors to impregnate them with solid medium, usually with paraffin wax, to enable sectioning with microtome. In transmission electron microscopy samples are usually embedded in epoxy resin and cut with ultramicrotome into semithin or ultrathin sections that are stained using heavy metals such as lead, uranium, or tungsten.

The choice of embedding material, optimal thickness of the sections when cutting, and the staining methods are all important factors contributing to the final result. One has to be aware that each of these individual steps is a potential source of artifacts that may hamper the correct interpretation of the findings [9].

Staining. Paraffin sections are usually stained to visualize the various tissue components and structures. The affinity to a given stain depends on complex physico-chemical interactions between the solvent, dye, and tissue. Many of the classical staining methods, such as hematoxylin-eosin, Mallory Phosphotungstic acid-hematoxylin (PTAH), or Van Gieson stain, among others, were introduced in the nineteenth century and quite a few of them are still in use today. Depending on their chemical composition and the characteristics of the staining solutions, they show characteristic affinity to different tissue components that help to recognize morphological features of normal tissue and to differentiate them from pathological changes. In addition to the capability to visualize tissue structures some staining methods show a shift in color when tissue becomes injured, e.g., the well-known phenomenon of increased cytoplasmic eosinophilia resulting from increased binding of eosin by cytoplasmic proteins with hematoxylin-eosin stain in myocardial injury or ischemic nerve cell injury. The conventional histological staining methods are mainly used to visualize morphological changes in the cells and tissues [9].

Special Techniques. In histochemistry, staining methods are used to demonstrate specific components in cells or tissues such as iron. In Perls Prussian or Berlin blue reaction the section, is treated with dilute hydrochloric acid to release ferric ions from binding proteins. These ions react with potassium ferrocyanide to produce an insoluble blue compound. Fat or lipids have to be stained using frozen sections as fixation and tissue processing usually removes them (Oil-red-O or Sudan stain).

Microorganisms can be demonstrated using special stains, e.g., bacteria using Gram-stain and Mycobacterium tuberculosis using Ziehl-Neelsen-stain. Periodic acid-Schiff or PAS-stain can be used to stain fungi. It also stains glycogen, mucin, mucoprotein, and glycoprotein. Viral antigens can be detected using immunohistochemistry by specific, typically monoclonal, antibodies against viral protein generated in laboratory animals. The sensitivity and specificity varies according to the type of the virus. In situ

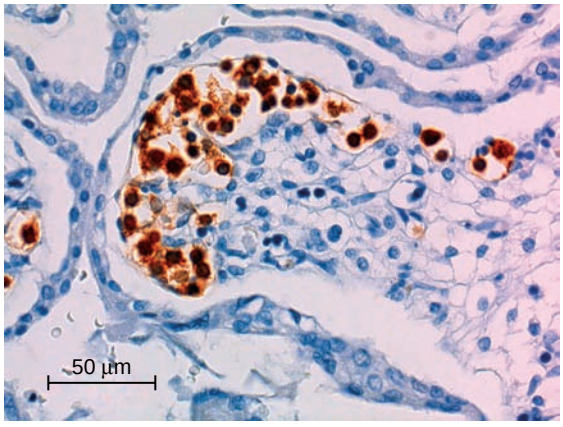

Figure 1 Localization of parvovirus B19 DNA in chorionic villi of placenta determined by *in situ* hybridization assay (dark brown cells). (Courtesy of Dr. Tytti Vuorinen, Department of Virology, University of Turku)

hybridization is a method that uses a labeled viral DNA or RNA probe to localize a specific DNA or RNA sequence of the virus within a tissue section (Figure 1).

Special histological techniques are applied in timing of injuries particularly in context with skin wounds and cerebral trauma. A prerequisite for using these is that both the pathologist and the laboratory have solid expertise with methodology preferably based on experimental research and proven in practical casework.

Enzyme histochemical methods are rarely applied to autopsy material for diagnostic purposes. When applied, fresh frozen cryostat sections have to be used as routine fixation and subsequent tissue processing usually destroys or diminishes the enzyme histochemical reactivity of most enzymes. It would be misleading to speak about enzyme activity in this context as, although the enzyme histochemical methods have been named after the individual enzymes, the enzyme histochemical reactivity need not necessarily correlate at all with the actual biochemical activity of the enzyme in question, suggesting that other factors, such as the presence of auxiliary enzyme systems or other cofactors of the histochemical reaction, may be rate-limiting [10].

This generates an analogous problem as with conventional histological methods in which a shift in color, e.g., when using Acid Fuchsin (AF) or Haematoxylin-Basic Fuchsin-Picric acid (HBFP) stain was claimed to demonstrate early myocardial ischemia but was proven to be unreliable; unless the scientific basis and limitations of any histological method is thoroughly understood, it is hazardous to use it for medicolegal purposes [11].

After the great advances of immunohistochemistry in basic research, clinical pathology and the availability of a huge number of new antibodies, the use of immunohistochemical methods was soon applied to medicolegal problems both in animal experiments and autopsy material to elicit new insight into questions of vitality, aging of wounds, and head injury and to find new markers of early myocardial injury. So far, the results have not always been unambiguous and their practicability and reliability has been difficult to assess because of diverging results and sometimes also because of shortcomings in experimental design and control material. It is obvious that in experienced hands with well-established methods, immunohistochemistry can be of advantage over conventional histochemistry [12].

Histological Findings as Forensic Evidence. In the administration of justice, a high degree of reliability is expected also from forensic histological evidence. Janssen [13, 14] contemplates the value and significance of histological data from the following aspects: “first, according to the evidential value of the tissue data itself; second, according to its position within the framework of evaluation, which results from the facts of the case that have come to light in combination with other findings”. He further grades the evidential value of forensic histology results in three groups (slightly modified from [14]):

Group 1: Comprises histological findings in which identification of their cause, character, and chronological pathogenesis is definite permitting conclusion about the etiology and causality independent of any further data. As examples serve, certain stages of tuberculosis and foreign body granulomas (Figure 2).

Group 2: Comprises findings that have forensically verifiable significance in association with further premises. The presence of additional facts is, therefore, prerequisite for the conclusiveness of such evidence.

Janssen describes, as an example, suspected homicide by means of an assault to the neck, where isolated fresh hemorrhages in the deep soft parts of

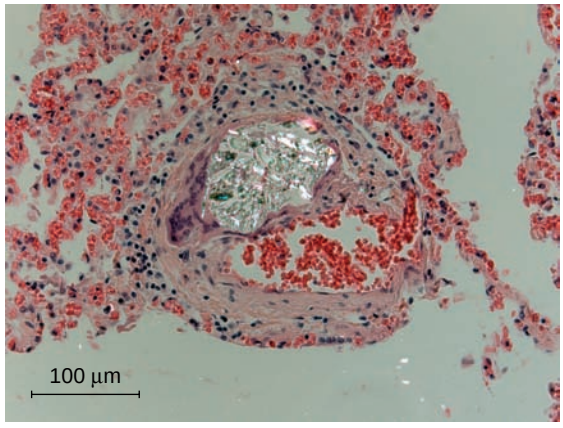

Figure 2 Microscopic view of a foreign body giant cell in polarized light showing birefringent material (probably talcum powder) from the use of adulterated drugs within pulmonary vessel wall of an intravenous drug addict

the victim's neck can be considered as evidence of strangulation only in combination with corresponding injuries of the overlying skin and larynx and further indications of asphyxiation and vascular congestion. As such, the hemorrhages alone are not unequivocal and not of conclusive significance.

Group 3: Comprises findings, which neither singly nor in combination with other facts, represent evidence that excludes all other possibilities of casual explanation. Examples are given as acute vascular congestion, pulmonary emphysema, petechial serous hemorrhages, cerebral edema, and the majority of all parenchymal necroses. Janssen considers these findings either inappropriate or only of limited use as forensic histological proof.

Problem Areas. Postmortem diagnosis of sudden cardiac death (SCD) can be taken as an example that illustrates the problems related to the way of thinking that is common in this context in scientific literature. Ischemic heart disease is the most common cause of sudden unexpected deaths in Western countries and in those jurisdictions where these belong to the domain of forensic pathology; they form, by far, the largest proportion of medicolegal autopsies. In the pathology of sudden cardiac death, sclerosis and stenosis of coronary arteries is not sufficient to diagnose SCD and obvious infarcts are the exception. As early morphological changes seen in light microscopy are unspecific, many pathologists have been actively searching for more sensitive methods to demonstrate early myocardial injury. This is logical as such, but leads to another problem, because, as a rule, the more sensitive the method, the more easily it detects agonal ischemia and along the autolytic changes these may be very difficult to differentiate from changes during life. Research on early myocardial injury may give us a better insight into the pathophysiology of cardiac injury but purely from the cause of death viewpoint it is nonsensical, as strictly speaking, even a fresh myocardial infarction visible to the naked eye does not prove that the person died of infarction unless other causes of death have been excluded. This was well demonstrated by the following case. A middle-aged man was found dead in his room in a mental hospital and the autopsy showed a large fresh myocardial infarction visible to the naked eye and comprising approximately 70% of the left ventricle muscle mass. If the pathologist had not been aware of the circumstances, the diagnosis might have been different, as the man did not die from natural causes he had hanged himself [12].

A recent survey of myocarditis deaths showed a high error rate as histopathologic reanalysis of samples taken during autopsy showed that only 32% of the 142 subjects met the Dallas criteria for myocarditis. The most evident cause of death in the Dallas-negative subjects was ischemic heart disease ($n = 78$, 55% of all cases), suggesting that myocarditis is overdiagnosed in routine autopsies, particularly in patients who have died suddenly or are found dead [15] (Figure 3).

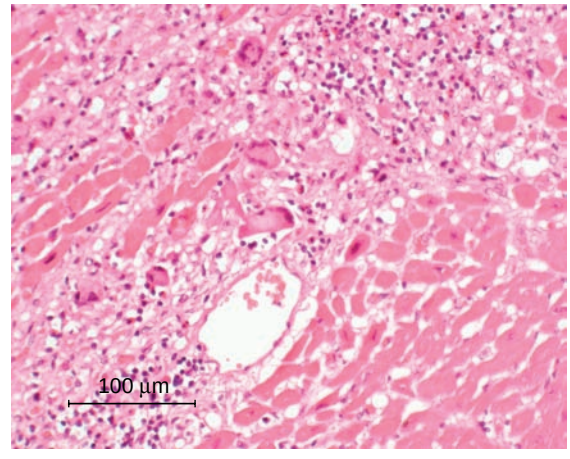

Figure 3 Giant cell myocarditis (Haematoxylin-Eosin)

Other problematic areas where special expertise and methodology is often necessary are, e.g., head injury, sudden death in epilepsy, and pediatric forensic pathology, in which forensic neuropathologist or forensic pediatric pathologist should be consulted and involved at an early stage of investigation. Unfortunately, such an expertise is rarely available worldwide.

Medicolegal autopsy with its ancillary investigations resembles the scene of crime investigation in so far, that if, e.g., histology samples have not been taken, the neglect can seldom be corrected afterwards. Considering the high requirement for reliability of forensic evidence and the widely accepted principles in many autopsy guidelines that histological examination is an integral part of every autopsy, it seems inconceivable that this is not consistently practiced. One reason for this may be the common miscomprehension about the degree of certainty as to the cause of death that can be achieved even after an autopsy. With the exception of disease processes causing major bleedings by rupture of an artery, such as the aorta, or even minor vessels in vital centers like the brain, or rupture of the heart wall because of infarction, or obstructing vessels which stopping a vital part of the blood circulation, as in pulmonary embolism, the cause of death can rarely be established with absolute certainty. Even in traumatic deaths, where the gross injuries are most obviously incompatible with life, they need not have anything to do with the cause of death as they may have been caused postmortem owing to a secondary accident triggered by a disease, for example, sudden cardiac death while driving a vehicle.

Even in cases where everything appears to be "clear" at first sight, new questions may arise later, which may remain unanswered if histology samples have not been taken. It is further not wise and unacceptable, though it happens in many jurisdictions, that a layperson should have the say whether or not histology should be taken. It is ignorance or self-deception to believe that, for instance, the cost of histology is the issue, as a single miscarriage of justice can cost the authorities more both in terms of money as well as in loss of credibility. An autopsy is not complete without histology and both sampling and microscopy should preferably be in the same hands and carried out by the same pathologist who performed the autopsy.

Homicide *see* Aggression; Homicide: Multiple (Behavior)

Homicide: Multiple (Behavior)

Murder is the common law offense of homicide; unlawful killing of another human being with malice aforethought. While definitions vary by jurisdiction, there are generally distinctions in legal definition such as between premeditated or without deliberation and premeditation; murder in the course of commission of a felony; and various degrees of manslaughter or homicide without malice aforethought. Murder is a serious crime and its investigation, and the dynamics of the incident and the perpetrator, vary from case to case and are the subject of an extensive literature [1, 2].

This discussion focuses upon relatively rare subsets of murder involving the death of multiple victims. Some of these multiple death situations are discussed in depth elsewhere and for these the reader is referred to **Serial Homicide**; **Suicide (Behavior)**; **Stalking**; **Battered Spouse Syndrome** for specialty discussions on specific topics such as elder abuse *see* **Elder Abuse: Policy**; **Elder Abuse: Risk**.

Serial killers may murder large numbers of victims, but the individual killings are separated by often-extended periods of time during which emotions cool and the perpetrator focuses upon other thoughts and activities. This discussion will deal specifically with instances in which the killer acts in continuous heat of passion. These are usually referred to as *mass murders* in which multiple victims are killed at the same time, and spree killings in which multiple victims are killed at two or more locations as the perpetrator moves from place to place. There are variations in each of these scenarios, and at times the distinctions can become blurred, but each is discussed separately.

Mass Murder

The US Department of Justice's Bureau of Justice Statistics [3] defines a mass murder as the murder of four or more victims at one location, within one event. Some researchers [4] have expanded this definition to include incidents where the perpetrator had a clear intention of killing a large number of persons, for example, carrying or firing a hundred or more rounds of ammunition, but nevertheless failed to kill four victims. On the other hand, some domestic killings may result in four or more deaths, but still possess the characteristics of a domestic homicide or murder/suicide (*see* **Suicide (Behavior)**). Although guns, knives, and blunt instruments are the most common weapons, mass murder can also be accomplished with bombs, collisions, fires, drugs or poisons, and through other destructive means.

Mass murders have been documented throughout history [5]. The Bible cites several examples including Samson's slaying of the Philistines (Judges 16 : 27–30) and King Herod's order for the murder of all male children age two years or less in the region of Bethlehem while trying to kill Jesus (Matt. 2 : 16). On August 10, 1810, at Ywahoo Falls, Kentucky, racist whites murdered over 100 Cherokee women and children. In 1993, close to 1 million Rwandans were slaughtered over a period of 100 days by an extremist faction of the Rwandan armed forces. Terrorist attacks on the World Trade Center in New York City and the Pentagon in Washington, DC, killed thousands of civilians on September 11, 2001. While mass murderers are often civilians; genocide, unprovoked killings during such activities are taking back

prisons and other facilities commandeered unlawfully [6], and violations of the rules of war by the military are also mass murder.

The Westroads Mall shooting on December 5, 2007, is representative of civilian mass murders. Nineteen-year-old Robert A. Hawkins killed nine people (including himself) and wounded four, two of them critically, when he entered the Von Maur department store in the Westroads Mall in Omaha, Nebraska, and opened fire with a stolen AK-47 rifle and two 30-round clips of ammunition. The entire incident took just 6 min. Hawkins had a history of mental difficulties, was estranged from his parents, had just lost his job at a fast food outlet for allegedly stealing $17, and had recently broken up with his girlfriend. He left a will and a long note including "I just want to take a few pieces of shit with me . . . just think tho [sic], I'm gonna be fuckin [sic] famous".

On the morning of April 19, 1995, Timothy McVeigh drove up to the front of the Alfred P. Murrah Federal Building in Oklahoma City in a rented Ryder truck in which he and Terry Nichols had assembled a 5000-pound bomb of ammonium nitrate fertilizer and nitromethane motor-racing fuel. McVeigh ignited a 2-min fuse and ran. When the bomb detonated at 9:02 am, it lifted McVeigh 2 in. off the ground. The explosion killed 168 people, and 450 were injured. Nineteen of the victims were small children in the day care center on the ground floor of the building. More than 300 buildings were damaged and 12 000 volunteers and rescue workers supported operations following the bombing.

McVeigh was an Army veteran and loner who planned the attack for the second anniversary of the Waco, Texas, siege of a religious compound as revenge for what he considered to be a tyrannical federal government. The deadliest act of terrorism within the United States prior to the attacks of September 11, 2001, this represents another form of mass murder and one which has escalated worldwide with increases in terrorist car bombings and suicide bombers.

Spree Murder

One of the best-known spree killers is the team of Charles Raymond Starkweather and his girlfriend Caril Ann Fugate. Starkweather was aged 17 in 1957, and Caril Ann 14, when Charles committed his first murder by killing a store clerk with a shotgun. Two months later, the pair killed 10 additional victims in a Nebraska and Wyoming road trip crime spree that has inspired at least six movies and influenced popular literature and music. [7]

Many of the crimes that we think of as mass murders are technically spree crimes. Charles Whitman's 1966 "Texas Tower" shooting rampage from the observation deck of the University of Texas, where he was a student, killed 14 people and wounded 31 others. However, this actually occurred after he had murdered his wife and mother at two separate locations, later, the day before. Similarly, the Virginia Tech massacre on April 16, 2007, which resulted in 32 deaths, the deadliest shooting incident by a single gunman in U S history, consisted of two separate attacks approximately 2 hours apart.

Causes and Circumstances

There has been considerable speculation, in both academic and popular literature, about what "causes" multiple murders. The topic itself, however, is so emotionally charged that interpretations are often shaped by personal fears and preconceptions. In reality, there are almost as many possible explanations as there have been perpetrators.

Physical illness is occasionally implicated. For example, Texas Tower shooter Charles Whitman was troubled by severe headaches for which he took extensive over-the-counter medication. The day before his death he requested that an autopsy be conducted on him, and asked that a part of his estate be donated to mental health research in an effort to prevent further tragedies of the type he knew that he was about to commit. His autopsy did disclose a highly cancerous glioblastoma that probably would have taken his life within a year. This condition, however, unlike Whitman's deadly rampage, is not unusual. Other than the fact that he was clearly uncomfortable, there is no reason to believe that the glioblastoma created a mental condition that set Whitman on an inevitable path to murder. In fact, there are few, if any, cases in which mass homicide can be traced to a physical determinate.

Mental illness is also frequently advanced as a cause. Whitman, however, is typical of most mass murders. He was rational, systematic, and his actions were clearly premeditated. He was not under the influence of a mind-altering drug, and even the notes that he wrote about his killings of his wife and

mother reflect love, compassion, and a belief that he was acting to spare them pain and grief. The systematic and carefully planned nature of virtually all multiple murderers precludes an insanity defense (*see* **Insanity: Defense**). We are limited by the fact that such a large percentage of mass murderers die in the commission of their crimes and, therefore, have not provided a sizable research population; but those who survive to be taken into custody seldom even attempt a mental illness or even diminished capacity defense (*see* **Behavioral Science Evidence**). Moreover, even if grounds could be found for such a defense, juries are unlikely to view a mass murder perpetrator as a candidate for rehabilitation or even mercy.

So what does drive the multiple murderers? Several studies have addressed this question, and the literature provides a range of diverse alternative explanation [8–10]. Many cite deficiencies in moral development [11, 12], but this often conflicts with the firm, if perverse, moral beliefs seen particularly among former military perpetrators including Whitman and McVeigh. Most perpetrators do exhibit some level of psychopathy (*see* **Psychopathy**). Often, young perpetrators such as Robert Hawkins have had experiences with substance abuse (*see* **Alcohol: Behavioral and Medical Effects**; **Substance Abuse**), although this exposure in itself may not have been satisfying, and few incidents are carried out while under the influence. Perpetrators may also have histories of personality disorders such as attention deficit, mood disorders, oppositional defiant disorders, and other conditions associated with authority figure conflicts.

Psychosis has been advanced in a small minority of mass murderers, but most of these cases fall short of legal insanity. Occasionally, psychotic mothers have killed their dependent children, but these crimes only meet the definition of mass murder because there happened to have been four or more children. Other diminished responsibility diagnoses have been reported, such as posttraumatic stress disorder (*see* **Posttraumatic Stress Disorder**), depression, masochism, and various levels of paranoia; but these personality disorders rarely come close to explaining the level of premeditated violence.

Thrill killing is perhaps most associated with the 1924 Chicago case of intelligent upper-class college students Nathan Leopold and Richard Loeb [13], who were convicted of murdering 14-year-old Bobby Franks for the experience of committing the act. A more recent similar case was the killing of a university couple in New Hampshire by Vermont teenagers Robert Tulloch and James Parker in 2001 [14]. While rare, documented cases of mass murder exist for which no other explanations can be offered.

Sexual homicide can be linked to at least two different types of motives. The first relates to power. The perpetrator is not driven by sexual gratification but by the power to terrify his victim. As the victim wears into numb exhaustion and fails to express a terrified response, she is killed, and a new victim sought [15]. While actually a form of serial homicide (*see* **Serial Homicide**), serial sexual homicide can also resemble spree killings.

Unlike with serial homicide, however, direct sexual motivation is rare in mass murderers. The leading exception is the Austrian Sylvestre Matuschka who apparently derived sexual pleasure from blowing up trains with dynamite, thus killing the passenger. His lethal sexual fetish claimed 22 lives before he was apprehended in 1932.

Ideological/disciple and the related *Political/hatred* murders are among the most pervasive and virulent. Reflected in the Nazi holocaust and radical Islamic genocide, as well as the Ywahoo Falls murders and the many instances of "racial cleansing" seen in Eastern Europe, Africa, and elsewhere, related dynamics are seen in individual acts such as suicide bombings, ideologically propelled murder rampages, and violent sprees by religious and political disciples. A noted variation was seen in the 1978 Jonestown incident that ended the lives of 918 Americans involved with the "Peoples Temple Agricultural Project" cult in Guyana [16, 17]. Jonestown is significant not only in that it provides one of our most recent demonstrations of ideological power and the lengths that disciples go to please their leader but also in that it involved people killing their own family and friends.

Perverted love is frequently seen in murder/suicide, and Charles Whitman appears to be a good example. Here, family members and loved ones are seen as an extension of the perpetrator. When the perpetrator sees no hope for survival, this belief is broadened to include loved ones who are killed in the belief that death will spare them future suffering. The perpetrator's extended sense of self prevents him from viewing others as having a life separate from his own.

In other instances, particularly when murder is not followed by suicide, the motivation is often more rooted in anger and loss. Ronald Gene Simmons, the father of his daughter's son, killed 14 members of his family on Christmas in 1987 when his wife threatened to divorce him. Julio Gonzalez became jealous of his girlfriend in 1990 and torched the Bronx's Happy Land Social Club, killing nearly all 97 persons inside. In still other instances, mass murder has been committed to protect a family member or members. During the Allen-Edwards feud in Hillsville, Virginia, on March 13, 1912, feudists entered a courtroom where a family member was being tried and killed the judge, sheriff, commonwealth attorney, a juror, and an innocent bystander.

Revenge/execution killings often involve "getting even" with persons who are seen as having inflicted harm or humiliation. Sometimes this is simply part of a criminal pattern, as with the Saint Valentine's Day "massacre" shootings of seven people in a garage as part of a 1929 Chicago gang war. Occasionally, multiple murders take place during crimes simply because the opportunity presents itself.

Other instances involve disgruntled employees, classmates, and even patients who rationalized their responsibility and transfer the blame to others (*see* **Threat Assessment: Workplace**; **Threat Assessment: School**; **Violence Risk Assessment for Mental Health Professionals**). Examples include David Burke, a fired airline employee, who followed his boss onto a plane on December 7, 1987, shot him, and caused the plane to crash killing 43 people. Mark Barton, a day trader, became angry after losing a great deal of money and on July 29, 1999, killed his family and entered two brokerage firms, slaying 9 and wounding 12. Dylan Klebold and Eric Harris committed suicide after their mass murder at Columbine High School in Littleton, Colorado, on April 20, 1999.

Other factors can also be cited for mass murders. A great many theories of mass murder have been advanced and will be discussed further. A frequent classification however, is "unexplained" that is used to characterize cases that do not fit obvious patterns. Some classification systems focus upon method of operation; some upon victim characteristics, and others upon perpetrator characteristics. In this last grouping, a few patterns do emerge. Perpetrators are often found to have been bullied as children. Many are characterized as "loners", often with violent fantasies, who feel socially excluded [18]. This sense of being cut off from others can lead to reduced empathy and emotional numbing and can mark a fairly abrupt change associated, for example, with a relocation or a change of environment [19].

Perpetrators are frequently from vulnerable age groups: adolescents and older workers who see their lives as offering few options and fear the loss of something seemingly minor but very important to them. Thomas Hamilton, after losing his volunteer position as a scoutmaster in Dunblane, Scotland, entered a primary school and killed 17 children. Mass murderers often have no significant criminal record, and others perceive him or her to be reasonable or at least harmless. Typically, many years of frustration have occurred before the fatal event.

Overall, retrospective analysis (*see* **Psychological Autopsy**) often discloses feelings of hopelessness and possibly despair or depression, in people who otherwise live quiet and even solitary lives, which have not attracted attention, but who decide to go out in a blaze of glory taking others with them. When they have a particular target in mind that is seen as responsible for their fate, they focus systematically upon that target, taking out bystanders if they simply wander into the way. If there is no specific target, victims are taken randomly.

Another recurrent finding is a critical mortality event. Charles Starkweather apparently had no intention of killing the store clerk that was his first victim. The clerk, however, attempted to snatch Starkweather's shotgun. There was a tussle, and when it was over Charles shot and killed the clerk. This was a transformative event for Starkweather – he had made the transition from ordinary citizen to murderer, but otherwise the world had not changed. Timothy McVeigh described his military experience as a similar transformation, removing the constraints that prevent most people from taking human life. This pattern is also seen in civilian massacres by the military, as well as in other situations where people became ideological or mission-driven executioners. For these individuals, once they have taken a life, the second and the third and all the rest that follow seem almost inconsequential.

These transformative events seem to have different impacts upon different people. Most confront the realities of life's fragility as just another insight. A rare few progress to mass murder. Others, including some military veterans and police officers, appear to

have been so impacted by the loss of the clear line between their commitment to the sanctity of life and the sudden ease with which they can end life that, perhaps protectively, they have killed themselves.

Social Influence

Human activity takes place within a social context. Even the solitary gunman is interacting with society. Therefore, it is impossible to look at violence outside of social contexts. With mass murder, these social factors are multiple and intricate.

First, mass murder is often carried out by pairs or groups of perpetrators. Terrorists, totalitarian hit men, and criminal mobs all are generally part of a social network. Charles Starkweather and Caril Ann Fugate were a pair, and Starkweather was reportedly astonished by Caril Ann's unleashed viciousness. Dylan Klebold and Eric Harris worked together to carry out the Columbine murders. John Allen Muhammad and Lee Boyd Malvo worked together as the Beltway Snipers to kill 10 people in the Washington, DC area in 2002. Catherine Wood and Gwen Graham worked together at a nursing home when they discovered that murdering patients together enhanced their lesbian sexual pleasures [20]. Shared secrets strengthen intimacies and reinforce fantasies. This powerful dynamic is seen repeatedly in case histories and no less so, in all of its combinations and permutations, in mass murder. In many instances, it is unlikely that involved individuals would have participated in crimes had it not been for their social reinforcements.

Social influence in the form of media coverage and general social fascination can also play a role in precipitating any deviant behavior [21]. Copycat behavior can be of two forms: it can inspire tactics to hide one crime against the backdrop of another, and it can ignite a social contagion that may increase the incidence of a publicized form of deviant behavior. It is widely speculated that John Allen Muhammad was motivated in part in his random shootings by plans to shoot his estranged wife and make it look as though it were part of someone else's unrelated crime spree. There are numerous instances in which people have taken advantage of a publicized series of crimes to carry out a killing in a similar manner to divert attention from the actual perpetrator – the person with the obvious motive to commit what would otherwise have been an isolated act of murder.

Greater attention has been devoted to the belief that publicity inspires others to commit atrocities. Certainly public recognition can spread bad ideas as well as good, but one of the strengths of open societies is their marketplace of ideas. This marketplace may often seem to be saturated by tasteless and absurd examples of impropriety. However, even when faced by irresponsible media, society constantly measures its own conduct against all other examples of human behavior and generally comes to an appropriate balance. The impressionable and those already leaning in a deviant direction can view bad examples as support for their predilections [22], but to conclude that the public forum "causes" mass murder is no more correct than the reality that social forces play a role in all behavior.

Occurrence and Demographics

Most research data describe mass murderers as having been more than 90% male, and about 70% white. This is consistent with the facts discussed earlier, but by no means establishes that other groups are not at risk [23]. Many believed that only whites were serial killers, until Wayne Bertram Williams was convicted in the 1984 serial murders of 29 black Atlanta youths. One of the lessons from the Muhammad/Malvo Beltway Sniper case is that police missed several opportunities to capture the shooters because they were relying on a "profile" of the shooter as a white male (*see* **Profiles: Psychological and Behavioral**). Similarly, Countess Bathori of Transylvania, who killed 650 girls between 1604 and 1611, probably holds the all-time record as serial killer, providing one good example of the error in assuming that violence is the sole province of males [24–26] (*see* **Aggression: Gender Differences in**).

The popular media would suggest that certain setting and certain types of mass killings are now occurring with disproportionate frequency. The American slang phrase for turning into a rampaging killer, "going postal", grew out of a few post office mass shootings, while the facts show clearly that post offices are still among the safer working environments [27]. Similarly, school shootings are often portrayed in the media as on the rise, while they have actually been decreasing.

Even academics have contributed to the belief that mass murder is a recent American phenomenon, and a growing threat [28]. A careful analysis of the facts

does not support this conclusion [29]. Lists of multiple murders disclose that such crimes occur even in the most peaceful countries, although different cultures have different names for and cultural interpretations of the phenomenon such as the concept of "running amok" in the Malay/Indonesian/Filipino culture [30].

Mass violence is a problem that predates recorded history. While the largest number of deaths occur during times of war and under totalitarian rule regardless of political leanings, individual civilian incidents are rare, fairly evenly distributed over time and geography, and are associated not only with a broad diversity of contributing factors; but furthermore arise out of common human emotions and traits that influence social interactions as a whole.

As human beings, we tend to feel that our current lives are at the center of events. We also seek to solve problems and take responsibility for preventing needless suffering. Unfortunately, this perspective can also cause us to lose sight of a larger picture, and to be convinced that current events or circumstances are the cause of all calamities. In the process, simple fundamental awareness such as never assuming that anyone is "harmless" and that all people should be approached with respect and consideration can too easily fade from view.

Conclusions

Mass murders do occur, but they are very rare. Nevertheless, their catastrophic and unpredictable nature, combined with a universal fascination with inner potentials for violence, lead to many distortions in its perception. Mass killers seldom meet the criteria for insanity or even diminished responsibility defenses. Most plan their crimes systematically and with premeditation.

Mass violence can take place anywhere in the world, increase during war and under totalitarian regimes, is seem in many forms, does not fit a single pattern, and has been traced to diverse causes and circumstances. Mass murderers often lead quiet lives and do not have criminal records. While techniques have improved for the assessment of threats made by those who display prior warning signs, prevention is difficult without infringing upon important human and civil rights. There is no proof that mass murder is a recent phenomena, or that it is increasing because of current social conditions. The dynamic of mass violence parallel the dynamics of human behavior in general, and as a problem, is best addressed not as a harbinger or alien concept but as an unfortunate aspect of human existence.

Homosexual Panic

Background and Definition

In its most general definition, "Homosexual Panic" (also referred to as *Gay Panic*) has been described as an adverse reaction, whether affective, behaviraol, or autonomic, to a perceived homosexual advance. Homosexual panic was first described by Edward J. Kempf in 1920 as "acute homosexual panic" and has alternately been referred to as *Kempf's Disease* [1]. Kempf defined acute homosexual panic as "panic due to the pressure of uncontrollable perverse sexual cravings" (p. 477) that present with physiological indicators of arousal (e.g., increased blood pressure), an overly defensive state against possible homosexual encounters, and sensory disturbance (e.g., visions, voices, and complaining of feeling "dopy") ([2], p. 514).

Kempf's conceptualization of acute homosexual panic was strongly influenced by Sigmund Freud's psychoanalytic theory. Acute homosexual panic was seen as the ego's response to the id's "lurking (homosexual) libidinous urges, over which the (individual) has no control" ([3], p. 296). Homosexual panic was similarly described by Glick [4] as an "acute episodic schizophrenic reaction" due to the individual's "unconscious wish to present himself as a homosexual object with the expectation of dire consequences" (p. 20).

As the definition of homosexual panic has evolved, it is now used less to describe an internal psychological condition and more as an acute reaction when one's heterosexuality is externally "threatened" by perceived homosexual advances. Indeed, some psychologists (e.g., [5]) continue to describe homosexual panic as an adverse psychological reaction that is singly rooted in internal causes; specifically, repressed homosexual desires and insecurity. However, the majority of current definitions describe homosexual panic as the occurrence of rage or violence due to an external stimulus (i.e., a perceived homosexual advance) combined with an individual's ambivalence toward homosexuality. Additionally, current descriptions of homosexual panic typically omit the occurrence of a psychosis.

Legal and Psychological Use

Homosexual panic has never been recognized as a disorder by the Diagnostic and Statistical Manual (DSM) of the American Psychiatric Association [6]. Legally, however, homosexual panic has been used in defense of acute violence both successfully and unsuccessfully. While the homosexual panic defense has resulted in sporadic cases of jury nullification (i.e., acquittals), it is most frequently used to justify charging defendants with a crime less serious than the potential maximum charge (e.g., charging aggravated assault instead of attempted murder) and in mitigating sentences.

In the highly publicized "Matthew Sheppard case" [7], a homosexual panic defense was raised. The defense alleged that the defendant, Aaron McKinney, went into a violent rage subsequent to being sexually propositioned by Matthew Sheppard. The Judge rejected the defense, stating that it amounted to a temporary insanity or diminished capacity defense, both of which were disallowed by Wyoming law. In the case of *West Virginia v. Bee* [8], a homosexual panic defense was successfully raised. In this bizarre case, Dean Ludwig Bee stabbed Dent Pickman to death after Bee accepting a ride home with Pickman from a bar. In his trial, Bee stated that he woke up at Pickman's house to find his body covered in various condiments and Pickman licking them off. Bee asserted that he "went crazy", leading to Pickman's death. Bee was acquitted of murder by a West Virginia jury.

While the *Sheppard* and *Bee* cases show that the homosexual panic defense has been both rejected and accepted by American courts, the most common result of such a defense is a "compromise verdict" (i.e., convicting a defendant of a less serious offense or passing a minimum rather than maximum sentence). One of the most well-known examples of homosexual panic and a compromise verdict is the 1995 "Jenny Jones case". In 1995, Scott Amedure went on *The Jenny Jones Show* (a then-popular talk show) to express his sexual attraction toward his friend Jonathan Schmitz. Soon after the taping of the show, Schmitz killed Amedure. In *Michigan v. Schmitz* [9], Schmitz admitted to the killing but claimed that he was humiliated by Amedure's sexual advances, exacerbated by the fact that the show aired on national television. Although Schmitz was charged with first-degree murder, he was ultimately convicted of a lesser crime of second-degree murder.

Homosexual Panic and *Daubert*

Currently, most conservative standards regarding the admissibility of scientific evidence in all federal and most state courts are set forth in the U S Supreme Court decision in *Daubert et al. versus Merrell Dow Pharmaceuticals, Inc*. [10]. This decision requires that, to be admissible in court, scientific evidence must: (i) be amenable and have been submitted to scientifically testing, (ii) have been peer reviewed, (iii) include a known error rate, (iv) have limits regarding its definition, and (v) have widespread acceptance within the relevant scientific community.

While some of the *Daubert* language is imprecise (e.g., widespread) and has been debated in relation to various scientific methods and concepts, its relation to the homosexual panic defense is clear. Readers of the clinical literature related to homosexual panic

will note its heavy psychoanalytic underpinnings, a theoretical perspective that is plagued by an inability to directly observe, thus validate, its central concepts. Moreover, homosexual panic has been characterized in many ways. In some literature it is defined by internal distress or anxiety. Others have described it as an acute panic to an external stimulus, leading to rage and violence.

With this lack of diagnostic specificity, homosexual panic does not meet the standard of having been or being amenable to scientific testing. Owing to this lack of rigorous study, there exists no known prevalence data, prognosis, or error rate for homosexual panic. Moreover, homosexual panic is clearly deficient in the area of "widespread acceptance", in that literature regarding the phenomenon is lacking and clinicians have varying opinions as to its validity. It must thus be concluded that homosexual panic does not meet the standards put forth by *Daubert*.

In a definitive legal review, Wall [1] examines the use of homosexual panic in evaluating criminal responsibility and diminished capacity. Wall concludes that, "... there is little empirical evidence to justify excusing or mitigating criminal behavior on the basis of anxiety stemming from a nonviolent homosexual advance" (p. 458). His recommendation that "... forensic evaluators should be wary of advocating for the potential relevance of homosexual panic because there is poor evidence to support its existence" is supported by this review, as is his statement, "... the poorly understood relationship between being the recipient of a homosexual advance and the carrying out of criminal behavior should not be elevated to the status of a syndrome or excuse by forensic evaluators" (p. 459).

Summary

Homosexual panic is currently described as a rage reaction to a perceived homosexual advance. As a defense to an acute violent episode, it is indeed problematic. Homosexual panic fails to meet standards set forth by *Daubert* in several ways. Homosexual panic lacks diagnostic specificity and widespread acceptance by clinicians. It has not been rigorously tested and lacks ability to be evaluated scientifically. As such, the incidence of homosexual panic has no known prevalence, prognosis, or associated error rates. It is thus a concept that lacks exculpatory value, although it continues to be used to explain extreme reactions to perceived homosexual advances.

Human Factors: Industrial Incidents

Introduction

This is a review of the basic issues commonly encountered in product liability cases, with an emphasis on human factors (HFs). HFs (ergonomics) is the study of the capabilities and limits of the human, which must be considered in the design of a safe product. HF topics can be summarized by how we perceive, (vision, hearing, touch, taste, and smell), how we process information (cognitive functions, memory, learning, errors, motor, and control processes), and how we move in a physical world (physiology, anthropometry, and biomechanics).

Product liability litigation is based on the concept that an injured party (plaintiff) can seek to recover damages for personal injuries or loss from the manufacturer (defendant) and others in the chain of commerce, because the plaintiff believes that the damages were caused by an unreasonably dangerous and therefore defective product. Industrial incidents tend to take on two flavors; a dramatic accident with chemical releases, collapses, and explosions or smaller scale failures related to equipment failures, misuse, or design failures. Both flavors invariably have significant elements of HFs that directly or indirectly contributed to the event.

The courts are challenged to maintain a balance between the benefits of the products produced by the manufacturers and the risk to users of these products, namely the consumers, or end users in commerce. In effect, the court balances the responsibility (duty) of the manufacturer to provide a safe product and imposes on the ordinary consumer a similar responsibility to use the product in a responsible manner. This balance is played out in product litigation cases, and ultimately the jury decides the issues, with varying consistency. At the heart of the argument is always the reasonable and foreseeable use of the product, and the foreseeable misuse of the product, and in the case of a failure of a product, the manner in which it fails.

Human Users of Human-Designed Products

Many of the challenges confronting today's human senses did not exist a mere 200 years ago. The tasks of driving a complex vehicle, sitting and typing at a computer, using a cell phone, or following written instructions are all new environments for the human. Further, our abilities as individuals vary significantly, by stature, gender (yes, they are different), and age, not to mention individual variability in the summary elements just mentioned.

Because HF principles are so fundamental to the design and utility of all products, there are many instances of product liability actions (as well as many accident reconstruction cases) that involve a HF expert on behalf of the plaintiff or defendant. Almost always there are questions as to the adequacy of warnings and instructions. Operating controls, warning lights, and their location and functionality, visibility, and field of view are other common areas of interest. The further one investigates a near miss, material loss, injury accident, or fatality, the more insight one gains from considering the HF aspects at each stage. Eventually, we confront the fact that we live in an imperfect world and that errors can creep in at many levels. Therein lays the true challenge, to design in a manner that mitigates potential errors, by both the manufacturer and the user.

Product Liability

The primary purpose of designing and manufacturing consumer products is to put them to use by other humans, while recovering costs and making a profit. This simple fact applies to every object produced by the creative genius of mankind ranging from housing, transportation, and the myriad of tools and appliances we use in our lives. The degree to which these products are successfully used is directly linked to the skill of the designer, particularly in understanding the user population abilities and limitations.

One of the recurring themes in the forensic field is the finding that the designer (if one can be identified) rarely has any training in the application

of safety or Human Factors Engineering (HFE) or related fields. The result is that all too often known design principles are ignored, violated, or misapplied. For example, a common consumer reaction is "who designed this?" or "how is this thing supposed to work?" or "how am I supposed to get my finger in here?". One need look no further than the common appliances (TV/VCR/DVD controls and cell phones) we find in ordinary life. When consumer products exhibit injury or fatality failure modes linked to a lack of design foresight, the question is no longer one of inconvenience or frustration, but injuries or fatalities, and becomes the focus of investigations and litigation.

Hence there is the necessity for the designer and manufacturer to seriously address the needs and limitations of the consumer, whether in the private or industrial sector. The product must be physically robust to meet the conditions of use and functionally suited to be used safely by the consumer. Finally, the product must be produced free of defects, or if they are present, must fail in a safe mode. If any of these considerations fail, an injury can result.

Few product engineers or designers receive sufficient engineering training, and fewer yet complement their basic technical knowledge with study in the areas of HFs or safety engineering. All too often, the deliberate (often ignorant) choice is made to use warnings in order to mitigate a known design or manufacturing hazard (Be Careful of Sharp Edges). *Uloth v. Cititak Corp* (1970) established the duty of the designer or manufacturer to the consumer. A warning is not sufficient to avoid responsibility for negligence, when a design change could have mitigated or eliminated the hazard.

In other instances, a marketing directive supercedes or undercuts the engineering criteria. Marketing or business decisions may dictate an unsafe design feature, safety compromises, derating or reduction of appropriate safety factors, merely to compete with another equally unsafe design. Standards, which are often consensus standards, can become mired in committee politics that are by definition dominated by members with an interest to be on the committee, and all too often a vested interest.

To balance this duty of care or responsibility placed on the designer and manufacturer, the consumer's responsibility is to be informed of the instructions and warnings, to use the product in the intended manner, and to protect themselves and others from hazards that may be reasonably encountered in the intended use of the product. In the end, the benefit and utility of the product to the consumer must outweigh the risk of harm.

Contributing Sciences

HFs draw from a wide spectrum of technologies that have evolved as disparate fields of study. The study of humans and work (ergonomics) evolved in Central Europe with the coming of the industrial age. Its more technical offspring HFE originated in the developmental work during World War II aimed at improving the performance and survivability of complex weapons systems. Building on this foundation, space exploration and even nuclear ballistic missile technologies all added to our understanding of human performance limits.

In a dated but nevertheless illustrative diagram, F. Dukes-Dubos represented the roots and interrelationships of HFs (ergonomics) as the mathematical, physical, and biological sciences, including also social and behavioral Sciences. (ASSE Journal, Oct. 1972) In essence, all sciences are represented.

In HFs work, it is easy to recognize the contributions of statistics, fluid dynamics, physical anthropology or psychology or biomechanics. All these fields and their many related areas are combined to further our understanding of what works best for human use. The end product is seen in specialty fields, from sports medicine to bioenvironmental engineering or HFE.

Interaction of Human Factors, Ergonomics, Safety, and Safety Engineering

In product liability forensic practice, and for that matter in many industrial investigations, the key issues are always the same. What were the physical and human aspects of the situation that contributed to the event sequence, and what role did the human-designed product have in the outcome? These questions are not new. Over thousands of years of recorded history, the methods of answering these questions have evolved from simple direct retribution or thoughtful judgments by elders to today's expensive and all too often ineffective legal proceedings.

One can argue that the origin of law itself is rooted in the formalized retribution for perceived wrongs going back to the Code of Hammurabi. In

recent times, based on English common law, we have adopted statutory and regulatory law as a means to safeguard ourselves as well as important property. We invoke laws that are intended to make us safe, provide for a safe workplace, and safely transport us from place to place. We base these laws on our understanding of the cause and effect relationships between unsafe acts, behaviors, products, and injuries or deaths.

HFs provides the foundation for human safety by defining the boundaries or limits of human perception and performance, considering the five senses, and modifiers such as age effects or cultural stereotypes. HF answers questions such as how well can we see under specific light conditions, what is the human response to vibration, how do we respond to perceptual cues in the visual field, how to we perceive dangers and react in a timely manner, how do we respond to complex cognitive (decision) situations, how do we interpret warnings, amongst many. The practice of HFs has grown to include every aspect of human activity from cognitive modeling, to aging, aerospace systems, communications, ergonomics, computer systems, vision, medical and transportation systems, and so on.

Ergonomics, as practiced in the United States (as opposed to the more workplace-oriented practice in the European Union (strike EU)), provides guidelines for human performance optimization for routine interactions with our man-made environment. Ergonomics answers questions such as how can we design our products to minimize human fatigue or discomfort, how much can we carry without undue strain, and how long can we work under severe heat or cold conditions?

Safety programs evaluate this information, and with other sources, such as industrial hygiene (which studies the human in the atmospheric and chemical work environment) structure human behavior in the workplace, and transfers this experience to the consumer forum. Today's consumer safety consciousness is rooted in the development of safety programs in industry.

Safety engineering evolved from the realization that very complex systems such as modern weapons systems or combined human/machine/computer systems cannot be effectively safeguarded by conventional preventive safety programs. The development of system safety analysis techniques such as fault tree analysis (FTA), failure modes and effects analysis (FMEA) and preliminary hazard analysis (PHA), and their derivatives permitted the study of these complex systems in both quantitative and qualitative ways that minimized the mission risk. These safety engineering methods have now been used in the chemical, aerospace, and automotive industries. These methods are now applicable to the design and manufacturing of consumer products, and include HF issues, such as human error and foreseeable use and misuse. By extension, these same techniques can be used in the investigative process.

The emphasis on safety was institutionalized with the advent of the US Occupational Safety and Health Act (OSHA) of 1970. OSHA incorporates many lessons from safety engineering principles that apply not only to consumer goods but also to the industrial workplace.

HFs, HFE, ergonomics, safety, safety engineering, combined, summarize our knowledge of what constitutes human safety. All have a role in the forensic analysis of consumer product issues. They are complimentary elements of the study of the human, the human environment, and the interactions.

Product Lifetime

A consumer product typically follows the classic product development curve, with some notable exceptions. Products are characterized by discrete time frames such as product conception, research and development, design, prototyping, test marketing, manufacturing, distribution, useful lifetime, extended lifetime, salvage, or disposal. It is during the distribution and initial useful lifetime that many use and safety issues arise. Also, toward the end of a product's useful lifetime, more instances of product failure occur, which may raise the frequency of safety issues. In many cases, as a product reaches maturity in its cycle, another product or variant is introduced. Changes are often made for cost reduction, functionality, technology change, market needs, price points, market coverage, or just to give a product a new look. All these elements can adversely influence consumer products. HFs forensic issues often include questions of why changes were or were not made, what testing was performed, what usability, instruction, or warning aspects were affected, and when.

Product Need

Why is a product deemed necessary in the first place? Products are introduced to assist with work

or perform work not practical otherwise, to provide entertainment or recreation, to provide transportation, health care, and so on. Inevitably, the profit motive can be found in the mix of answers. Either the demand exists, and the manufacturer hopes to profit from selling into the demand, or a demand can be created through novelty, fad or astute marketing.

In either case, the product need has been identified and evaluated by someone, either empirically or through planned research or deliberate planning. Many products are introduced as enhancements or reincarnations of similar past products. Even in developed markets, similar competing products are introduced. Ultimately, the market judges the need for a product. Successful products are rarely associated with chronic safety problems in the consumer product arena. Similarly in the industrial environment, products, devices, or systems are vetted by their historical success, or discarded or redesigned after associations with lost time accidents, or OSHA fines. Successful products excel in areas of sound design, high-quality manufacturing, and appropriate instructions, warnings and warranty programs.

Products that convert, consume, produce, or transmit energy, in any form (electrical, mechanical, chemical, thermal, radiation, potential, or kinetic) are particularly susceptible to consumer product liability actions. Products that involve chemical reactions, fuels, and combustible gases must be justified from a utility standpoint, with safety as a prime consideration. HF issues can extend to the ability to smell a dangerous substance, adequacy of complex instructions regarding consumer assembly of products, fit of body parts in nip points, and length of hair in entanglement cases among others.

Legal Context of Products

Government Role: Consumer Product Safety Commission

Two serious safety problems stand out as historical motivators for US government action. With the advent of the steam boiler, (in factories and on ships) there came explosions and massive carnage. This new situation generated action in the form of the first industrial standards. The American Society of Mechanical Engineers (ASMEs) formulated boiler design standards, which were eventually adopted in1846 as Federal Government mandatory standards. Similarly, in the late 1800s and in the early 1900s, equally serious accidents caused by industrial and railroad mishaps led to the adoption of workmen's compensation programs (Theodore Roosevelt's Federal Employer's Liability Acts) and initiated the structured development of safety standards and regulations, laws that are with us to this day.

In 1970s, the OSHA was promulgated as the next major government push for industrial safety. Not long afterward, this trend came to consumer goods when Congress, in 1972, passed the Consumer Product Safety Act and created the Consumer Product Safety Commission. (CPSC).

This was the first significant safety legislation on behalf of the consumer, specifically in the area of product hazards and defects. CPSC maintains records of consumer reports of near miss or actual injuries, and on the basis of its investigations it can force the recall of consumer products. The CPSC database is augmented by the National Electronic Injury Surveillance System (NEISS), a nationwide injury reporting system from hospital emergency room reports.

Every year, the CPSC receives and investigates thousands of reports, issues product recalls, and can compel action against a manufacturer, or even preemptively ban a product deemed an imminent hazard. At any given time, the CPSC (www.cpsc.gov) lists hundreds of products (into the millions of units) that have been recalled in the areas of child products, toys, household products, outdoor products, sports and recreation products, and specialty products (but excludes automobiles, trucks, and motorcycles, which are under National Highway Traffic Safety Administration (NHTSA)/Department of Transportation (DOT)). There is no such specific oversight of industrial products; OSHA administers this issue with the overall requirement that the employer is responsible for all safety issues inside the plant or workplace boundary.

Another complimentary element of the government's presence in consumer product and industrial safety is the emergence of standard setting organizations (American Society for Testing and Materials (ASTM), American National Standards Institute (ANSI)) and industrial and product test laboratories such as Underwriters Laboratories Inc. (UL). Over the last 50 years, these organizations have developed the testing procedures, product, and performance consensus standards that have often been adopted by the

government regulators. As minimum consensus standards, there is always room to improve them, and they are not a guarantee of an adequate defense. On the other hand, failure to meet these minimum standards almost always assures that the plaintiff prevails.

Legal Theories

Strict Liability

Strict liability is one theory that the plaintiff can use to present his case. The plaintiff must prove that the product had a defective condition, the defective condition existed when the product left the control of the manufacturer, the condition made the product unreasonably dangerous, and the defect was the cause of the injury.

The defense will try to show that the defect was the result of some action or event after the product left the defendant's control, or that the plaintiff had knowledge of the existence of the hazard, and voluntarily assumed the risk.

In a HF context, again warnings and instructions are the primary issues. Those are the relatively soft targets. Secondary issues arise in the manner of use of the product, the perception of risk by the user, and the physical attributes that permit use or misuse.

Negligence

Another theory the plaintiff can use is that the defendant was negligent, and must prove that the product had a defective condition when it left the manufacturer's control, the defective condition caused the injury, and the harm was foreseeable to the manufacturer, who did not exercise due care to guard against the harm.

The defense will try to show contributory negligence on the part of the plaintiff or a failure to act as a "reasonable man under like circumstances". A variation includes comparative fault and similar fault apportioning schemes. In the modified comparative fault, the plaintiff will not recover at all if the percentage of fault is over 50% (varies by state).

This theory appears to favor the defense, in as much as any reduction of plaintiff's damages is considered a win. In a more cynical mode, the more doubt (real, smoke, or spin) that can be attributed to the plaintiff's circumstances or their actions, or in the case of minor children, their parent's actions or inactions, and even a finding of fault on the part of the defendant can totally negate any actual damage awards.

Types of Product Defects

Product Defects

Product liability issues would not exist without product defects. The basis of litigation is the identification of a defect, consisting of a design, manufacturing or warranty defect, or a combination thereof. Oftentimes, for a HF practitioner the primary focus is the analysis of warnings. However, design and manufacturing defects can contribute to the manner of use of the product, or failure mode, and so must not be ignored. Although this is the predominant arena of product liability, a fair number of industrial environment accidents result in third party lawsuits based on the premise that the product involved was defective. Otherwise, workmen's compensation insurance precludes a lawsuit against the employer.

Design Defect

A design defect exists in a consumer product if the potentially harmful aspects of the product are present as a part of the intended design of the product. A product can be unreasonably dangerous to an ordinary user by virtue of a design element, for example an unprotected gear sprocket on a go-cart. This feature, when combined with loose clothing or long hair, a reasonably foreseeable element of the user population, can result in scalping or fatal neck injuries. This is an example of a fundamental guarding design defect combined with an expected anthropometric population distribution and behavior that caused harm to the user.

A design defect can further be parsed into subcategories. These can be configurational (proper size, orientation, hazardous surfaces, and product instability), constitutional, (contains unnecessary toxic or flammable substances, inappropriate strength or flexibility or durability), functional (did not perform as intended, fostered inappropriate use, and did not perform as well as it should have), and prophylactic (lacked guards against abuse or misuse, lacked protection against injury enhancement, and lacked backup protection against failure).

Manufacturing Defect

A manufacturing defect exists in a consumer product if the potentially harmful aspects are present due to mistakes or omissions in the manufacturing process, and can include material defects, process-induced defects, and assembly errors. An unfortunately common occurrence is the omission of critical parts or bolts, which leads to the overstressing of other parts, resulting in eventual failure. Similarly, inclusions or other metal defects can lead to premature failures of springs or similar elements. The challenge to the HFs practitioner is to link the failure mode to the human error (missing assembly step) event, or inspection error, or quality control procedure. If a product does fail, is there a fail-safe modality that was included in the design, or was the manufacturing defect and its consequences not properly anticipated? The HF engineering expert must be able to dig into engineering documentation, and understand the design, testing, design change, manufacturing, and quality control processes. A comparative analysis of competing products from other manufacturers often helps to point out critical differences (e.g., steam iron, insulated wires, and terminations versus open connections in a water environment, or sealant application procedures that differ over model changes). This analysis combined with an understanding of how a product is actually used (yes, people really do test touch irons with a wet finger) can sort out seemingly unrelated events.

Marketing Defect

A marketing defect exists in a consumer product if the information accompanying the product contains potentially harmful aspects, including omissions, or errors that present an unreasonable risk to ordinary users of the product. Warnings are covered in detail elsewhere in this publication. Marketing issues include both warnings and instructions, as well as other communications that affect the usability or fitness for use of a product.

The cornerstone of warnings is the ability of the warning to elicit from the reader the safe behavior desired. Under no circumstance is a warning sufficient if the hazard could have been eliminated, or a design change could have eliminated or mitigated a hazard. Similarly, a warning is not an adequate substitute for an effective guard. Only when design and guarding (or safety device) issues have been thoroughly exhausted is a warning feasible (hierarchy of protection). For maximum effectiveness, the warning must take a specific form, and comport with HFs standards for warnings, or on a second tier, other applicable statutory standards.

Consumer Use, Foreseeable, and Unforeseeable

Foreseeability

A fundamental concept in product liability is the reasonably foreseeable use of a product, which should have and could have been anticipated by the manufacturer, and it is opposite, the unreasonable use of a product by the consumer, in the sense that such use was unintended and unforeseeable by the manufacturer. The courts do limit the definition or interpretation of “foreseeable”, to both protect the consumer and also prevent unreasonable claims against the manufacturer.

On the one hand, the manufacturer is tasked with the anticipation of all the reasonably foreseeable uses and misuses of a product, and providing a product that if it fails, does so in a passive or fail-safe manner, and that inherent (cannot be removed by design) hazards are clearly communicated to the user by appropriate means, such as warnings, instructions, or training.

The consumer is tasked with being sufficiently knowledgeable (through written instructions and warnings) about the product to avoid uses that would expose the user to obvious hazards, or situations where the user is exposed to hazards through deliberate neglect, lack of maintenance, care in use, or ignoring warnings or instructions.

Another complicating factor is the presence of children in the user environment. Assumptions made of adult users and foreseeability do not apply to children. The key differential between adults and children is experience and the knowledge that comes from it in evaluating potential hazards. Children simply have not developed the risk perception attributes of adults. Even teenagers, seemingly mature in many ways, are not adults, and are treated as such under the law.

This is an important aspect of HF forensic practice. Products from swimming pools, to playgrounds, to appliances in the garage, home or school are in the child environment. Children are creatures that taste, touch, feel, and explore their new world by

turning things upside down and inside out. They are not privy to those things that we as adults know as *hazards*, or the finality of injuries and death. There are good reasons that the dumb stunts we commonly see on television are almost exclusively the domain of adolescents. They are indeed stupid in the literal sense, and can be exploited by their peers for "fun" and others (adults) for profit. The message to other consumers from these stunts or for that matter similar product advertising stunts is that this seemingly irrational behavior is acceptable. Have you ever seen a snowmobile or go-cart or car or similar commercial where the vehicle is not speeding along? But then read the warnings on these same products, all will of course advise against speed. This aspect is a goldmine for the plaintiff, and a minefield for the defendant.

The often mentioned notion of "common sense" is predicated upon the false assumption that we humans in fact have a common understanding of safety. One need only travel to see regional, societal, and cultural differences in the notion of human safety, or the very value of human life. The manufacturer must anticipate not only the reasonably foreseeable actions of adults and children but also, in this global marketplace, the actions of all people in the international consumer market. Literacy affects the consumer's ability to understand basic technical concepts necessary to safely operate many modern products that use energy, chemicals, high pressures, or energy sources. A manufacturer must contend with this disparate user population, if they wish to tap into the potential profits of an extended marketplace.

The analysis of accidents has the benefit of hindsight. The task for the plaintiff's HF expert is usually to investigate the circumstances of use, and to determine (as a basis of their opinion) whether the consumer use in question was reasonably foreseeable and whether the manufacturer knew or should have known that significant hazards existed.

Safety is the result of a deliberate effort to analyze the need for the product, develop a complete and tested design, and provide the necessary quality control program to assure a defect-free product. The plaintiff expert's responsibility is to consider all the available information and testimony that deals with the use of the product, and develop the product performance and use characteristics with a particular emphasis on underlying causes of the injury or death. Although the accident occurred with certainty, it is important to try to be objective in the analysis of foreseeability. If the expert's conclusion is that the use was indeed foreseeable, especially based on prior cases or near misses, and that the consumer used reasonable precautions, the burden to prove otherwise falls on the defendant.

Any record of prior or repeated negative instances of circumstances that the manufacturer knew or should have known about strengthens the plaintiff's case. The plaintiff's expert must not overstate the case, or presume to know how the actual consumer plaintiff thought or perceived the conditions at the time of injury. The opinion basis, particularly in HF cases, when possible, should be derived from studies of a wide range of subjects, in similar circumstances.

As an example, forklift trucks (FLTs) are involved in thousands of injury or fatal accidents every year, almost exclusively in the industrial environment. Although they are very sophisticated machines, they are fundamentally overloaded as a matter of course, with minimal stability due to their three-point suspension and marginal counterweights. From the manufacturer's perspective, this is done to maximize mobility and to minimize transportation and operating costs, and thereby maximize sales. Although patents and literature regarding overloads go back 50 years, most FLTs are capable of lifting well in excess of their safe loads, and very few convey this fact to the operator through even rudimentary alarms. Although their counterparts, cranes, by law must indicate lifted weights to the operator, this is not the case with FLTs. The result is that detailed instructions exist in manuals, decals and warnings appear on the machines, rated capacity is printed on a plaque, but actually lifting the load amounts to guesswork by the operator. From a HF perspective, the key element, timely notice of a hazard not obvious to the operator, is missing, and can be provided at little or no cost without compromising the fundamental utility of the machine.

The defense expert will seek to find flaws in the plaintiff expert's understanding or representation of the case, or question whether the consumer's actions were foreseeable by the manufacturer. The key opportunity for the defense expert is to determine if indeed the event occurred as described. If a significantly different fact set or theory can be proved to be indeed true, the plaintiff's case may well evaporate. However, merely floating trial balloons of alternate unsubstantiated theories, or creating "smoke" is neither helpful to the court or to the case.

A faulty HF technique (plaintiff or defense) that occurs from time to time is to gather response data from seemingly random pools of subjects by the use of "loaded questionnaires". These are statistically false results that appear to support or refute the reasonableness of a consumer's behavior in the use of a product. HF experts must be particularly careful about such techniques. Working with questionnaires requires specific research experience, and going down to the local mall to do random interviews of the population does not necessarily qualify as a valid representation of how a plaintiff actions were reasonably foreseeable or not. One of the paramount difficulties with HF research is that dealing with subjects (participants) in rigorous studies is time consuming, expensive, statistically tenuous, and limited in the transferability of results to other seemingly similar situations. Many studies also suffer from the use of college age (mature?) subjects that may or may not be appropriate for the question at hand. For example, they may be appropriate for perception reaction visibility studies of drivers at night, but must be balanced with subjects of different age groups to better represent the actual user population.

Consumer Misuse

The defense can often prevail if consumer misuse can be clearly demonstrated. The plaintiff's knowledge of the existence and character of a dangerous condition and the voluntary assumption of the attendant risk can be a defense. In HFs issues, for example, given that well-written warnings and clear instructions are provided, and an obvious hazard (such as a power cutting tool) is present, misuse or misapplication by a consumer plaintiff will not make for a strong case. If, however, the hazard is not as clearly recognized, the outcome may be different. Consider a high-pressure water jet, where even playful misuse by a consumer can result in lethal injuries. The danger is not as clear as that of a cutting saw, and a consumer (adult or child) may not necessarily relate water flow to an extreme hazard, even if the warnings are adequate. Hence there may not be as clear an assumption of risk as in the preceding case. In this case, the presence of warnings is necessary to alert the user of the hazard.

If the consumer knowingly tolerates an unsafe condition, (a guard is removed) and continues to use the product, this can be construed as misuse. If however, the guard is of such poor design as to fall off on its own, or interferes with reasonable use of the device, or can be removed with little or no effort, the tables may be turned. Similarly, placing a washing machine interlock switch under the lid in plain view invites the user to place a finger on the switch, to keep the machine running, easily defeating the purpose of the switch.

Error

When humans operate complex machines or equipment, there is a significant probability of human error, particularly when unusual or unexpected conditions arise. For this reason, HFs engineering techniques must be used in the research, development, testing, and implementation of industrial or consumer products. Error or fault tolerance is important in a complex product, particularly in the area of controls. A control that can be actuated with a single motion, (shift lever, for example) is more prone to faults than the same control with an L-shaped path, requiring a deliberate sequence of two or more specific but different actions. Similarly, a fault-tolerant system must permit an easy return (undo) to the initial state. For example, a control lever on a motorized vehicle (in this case a vibrating compactor) combined directional control with vehicle acceleration and roller vibration, but did not have a detent or clearly defined neutral position, resulting in a loss of control fatality.

Another common source of errors is the rental equipment environment. As a very industrialized society, we have available to us a huge variety of capital intensive equipment for rent or lease. Things that most people would never dream or owning can be rented for industrial use, transportation, home use, or recreation. However, little or no training is provided. The written instructions may be furnished and the renter may listen to a short explanation and demonstration, and sign the fine print. But is that enough? The manufacturer and renter have a higher duty of care when knowingly providing equipment to a potentially naïve or ill-trained client. Errors will occur as the user becomes familiar with the safe operation of the equipment, and this must be reflected in the speed, response, and other characteristics of the machine. From a HF error perspective, the fact that the renter signed the rental contract with all the attendant disclaimers is not a particularly compelling defense when the renter is known not to be fully trained in the use of that particular device.

Emerging Situations

The advent of the "big box warehouse" stores has pushed products that were formerly industrial products into the home. From industrial cleaners to automotive repair equipment to massive barbeques, many such items can now be found in the home environment. Machine tools and construction equipment are no longer the domain of the farm or industrial shop. High-pressure (4500 psi) water washers, which can easily maim or amputate limbs, are used to clean driveways, and 20 horsepower chippers hog away at branches in the backyard. These types of powerful industrial appliances were not prevalent until the last decade or so. Many of these situations will involve HF experts, in the usual issues.

Another issue is the global distribution of goods. More and more pictographs are used to try to communicate important messages. Alternately, abbreviated brochures printed (in very small print) in up to 30 languages can be seen attached to products. How well this accomplishes the need to communicate effectively remains to be seen. At some point the cost savings of using universal pictographs is offset by the failure to effectively communicate important information. The safest, most direct method is to clearly identify controls and their functions in native language(s).

As the global economy continues, the Asian economy is producing more and more goods that flow to other markets. Of particular concern is the flood of cheap tools and machine parts from China and other sources. Private or industrial consumers are not necessarily aware that the original products when produced in the United States several decades ago were more conservatively rated (for example, hydraulic bottle jacks). In order to maximize profit, and compete on advertised ratings, the products themselves may have been weakened over time. Although warnings are provided, there is no attempt to convey to the user the critical information that the safety margins that existed at one time have been lowered. This is just one example of the generic problem of cheapening a product to the point where the fundamental risk–benefit balance is compromised. The beneficial aspects and, to some extent, high costs of United States and EU product safety programs have yet to reach around the globe.

Another interesting development is the emergence of a class of products that are not strictly consumer products but rather mission-specific law enforcement electronic control devices. These devices are used in a highly controlled environment by police agencies as less than lethal weapons, although lethal backup is recommended. These electronic immobilization devices are better analyzed from a system safety engineering perspective modeled after MIL STD 882 where the mission requirements are defined, and the risks/benefits are starkly different from the classic consumer product perspective. The users are highly trained, the devices are controlled, and the persons affected are usually being apprehended or arrested after other means of simple persuasion have failed. HF expert issues are somewhat different, as the usual relationship between a consumer product and an end user are masked by an employer/employee situation, which usually falls under OSHA or workplace constraints. The warnings issues are also somewhat more complicated as the training of instructors and classes of officers overrides the usual product labels and simple instructions.

These and similar issues will occupy HF experts in the years to come.

The Expert and the Court. The HF expert is presented as an individual who by training, education, and experience can offer specialized knowledge that will truthfully add to the understanding of the case circumstances by the court. The court includes the judges, lawyers, and the jury. The expert must present opinions based on the known facts of the case, deposition testimony, and the specific analysis performed by either the plaintiff or defense expert. Unfortunately, this noble goal is all too often subverted through overzealous representation, pressure from attorneys, or simple greed.

One of the problems with HF studies is that it is often not practical or affordable to replicate or even attempt full studies with a large subject pool. If it is not possible or feasible to conduct studies, then the HF expert must rely on similar topics from the literature, or a basic analysis that considers both contributing and mitigating factors in the case. For example, an analysis of a scene where visibility is an issue should list, compare, and contrast individual factors that facilitate or minimize an individual's ability to see a scene. On the basis of this analysis, founded on basic HF and HFE knowledge, the expert can present the court with an unbiased opinion.

HF is not as neat and clean as some other disciplines. For example, a metal fracture can be classified

as a brittle or fatigue failure. There are distinct characteristics that can be tested and absolutely agreed upon by opposing experts. HF and HFE disciplines are on similar firm grounds on the basics of human endurance parameters, some vision issues, and some standard warning issues. But the very nature of testing human subjects has to deal with within-subject, between-subject errors, and other errors in arriving at statistically significant conclusions in almost all fields of HF study. That is why warnings and their effectiveness are such a soft science compared to the earlier example of metal fracture. These aspects of HF research must be explained to the court to properly convey both the strengths and the limitations. One of the key elements to convey is that the HF expert can only present data that applies in a general sense for a specific population that has been studied. A HF expert should not and cannot present testimony that purports to characterize the specific response of an individual in a given situation. For example, only the actual driver of a vehicle knows what they saw in the instant before they hit the train. The HF expert can only testify to the field of view, to the ambient or luminaire lighting, to general perception reaction times, to the conspicuity of the scene, and so on. In other words, was the train visible to an average representative subject? The HF expert cannot testify as to what the driver actually saw or what they were looking at or when they saw it! It is the purpose of the court to determine the outcome of the litigation issue. The adversarial system can be used effectively to show distinctions between experts. All too often it is far from perfect.

There are things that the HF expert can do to improve their effectiveness. One is to be proficient in several complementary disciplines and the other is not to rely only on their individual experience, but rather to rely on the documented response of a large subject pool. A very important attribute is to have more than just academic experience. Working in the field and in real-world situations places theory in a far more practical perspective. Where possible, a report can be a very effective tool to sharpen one's focus on the case.

The HF experts, as all persons offering forensic testimony, are bound by their own technical abilities, knowledge of the field, and personal responsibility to offer only opinions they can truthfully swear to, which aid the court in determining the final outcome of the case.

Examples

These three cases are presented to illustrate home appliance, recreation vehicle, and construction equipment accidents, with HF elements, including risk perception, foreseeable behavior, and induced human error through defective design.

Home Washer/Arm Avulsion

A girl aged 14 was washing the family clothes. A 22-month-old child was in her care. In order to amuse the young child she decided to show him the wonderful colors as fabrics were spinning in the machine during the spin cycle. She lifted the washer lid and placed a dime into a slot in the frame next to the open washer (which she often did to keep the cycle going when adding bleach) that housed the interlock switch. The protruding plastic button was then held down by the dime, as if the lid were still closed. She then picked up the child so he could see into the spinning machine. Before she knew what happened, the child reached into the machine to touch the spinning fabric, and his arm was avulsed at the elbow as it tangled in the fabric.

Comment: There had been multiple prior instances of injuries or avulsions, even to adults, in similar circumstances. The switch was in an open and easily defeated location, negating its utility. The behavior of the girl was no different than that observed at the county fair, where small children are held up so they can see the colors on spinning paint platters mounted in drums. The case was settled on behalf of the plaintiff. HF issues included child-risk perception, reasonably foreseeable behavior to defeat the switch, and a record of past incidents. Identical washers furnished to commercial laundries had for some years been fitted with a recessed and hence protected switch, to prevent users from doing multiple loads on one paid cycle.

Go-Cart/Neck Fracture, Fatality

A young girl aged 13 asked to use her brother's new go-cart in a large enclosed corral. She was instructed about the use of the cart, and fitted with her father's helmet. She even tucked her long braided hair into

her T shirt, and put on the seatbelt. She proceeded to drive the go-cart in 33 meter (100 ft) diameter circles at a moderate rate. Her younger brother was in the area, but her parents had to leave on an emergency call. After a few minutes, the brother noted that the cart was stopped, and investigated. The hair that had been tucked away had apparently been jostled out of her shirt, and slipped behind the seat. In an instant, it wrapped around an improperly guarded shaft and drive sprocket, fracturing C2.

Comment: Because state law is a modified comparative negligence statute, the defense claimed that the parents and the decedent were negligent. Defense experts claimed the helmet size was too big, and that the parents and the girl were negligent in not sufficiently heeding the long hair warning. This latter claim was based on a questionnaire presented to adults in a mall, and teens in a classroom, wherein photos of the cart and instructions were presented and opinions were solicited as to the safety of the actions of the girl and her parents. The defense HF expert refused to answer questions related to the guard.

Plaintiff's expert testified that the product was defective, that testing (dangling a scarf behind the seat) was inadequate, that the warning was inadequate when a simple guard would have eliminated the hazard, that the helmet was irrelevant given the rapidity of the snap (fractions of a second), and that even if the parents were there the outcome would be the same. Plaintiff's expert further testified that the guard was easy and inexpensive to implement, and that the questionnaire data was not inappropriate. Anthropometric data was presented with respect to stature based on recent photos, and data was obtained documenting the prevalence of long hair in the general population.

A reconstruction of the accident identified the resting position of the decedent, which was masked in the coroner's photos by a sheet. Exemplar wigs worn on persons of varying stature in the go-cart demonstrated that the hair would readily get into the sprocket. Furthermore, evidence of eight or more similar past cases was presented, which involved young children and teens that suffered complete scalpings, or fatal neck fractures. The go-cart industry knew of these incidents, but resisted adopting a standard.

The jury found for the plaintiffs, the parents, and found the go cart product to be defective, but due to jury instructions attributed 50% comparative negligence (10% decedent, 20% each parent) to the plaintiffs. This jury finding under Idaho law precluded any monetary award. The case was appealed to the Idaho State Supreme Court, which affirmed the decision.

The CPSC however, on August 15, 2000, issued a recall for all 91 000 affected Manco Go-Carts, in *Woodburn v. Manco* (Idaho). Industry standards now call for a complete molded guard behind the driver's seat. Ironically, in 1996, the same firm had had to recall carts because of exposed rotating rear axles.

Compactor Rollover/Fatality

An experienced construction worker, who had previously used a rented vibrating compactor machine of a similar make and model, was operating on a pad being built adjoining a slope. The operator and machine went off the edge of the pad unseen, and overturned, crushing the driver.

Comment: The defense claimed that the operator was unsafe, and drove the machine off the pad through inattention, although there were no eyewitnesses. The plaintiff's expert testified that the machine-directional control switches were in fact changed after the incident and before the machine was rented again some months later. The control lever operated a cable control line that operated a cam, which actuated a pair of opposed switches that operated the drum vibrators and a neutral position switch on the dash. The cable also actuated the hydrostatic transmission in forward, reverse, and speed. Exemplar machines demonstrated that the switches were commonly defective, difficult to adjust, and unreliable. In effect, the control of the machine was easily compromised, giving the operator little feedback, and only gross control over the speed and direction. Furthermore, defective adjustment permitted the vibrators to continue to vibrate when the machine was supposedly stopped. Marks in the pad indicated that the machine was reversing close to the edge of the pad and that the machine had vibrated off the edge. The reconstruction of the event indicated to the plaintiff's expert that the operator likely tried to stop the machine, but the continued vibration walked the unit off the edge. This effect was observed in exemplar machines. The expert concluded that the design was defective, depriving the operator of sufficient feedback to prevent a possible fatal control error.

The case was settled in favor of the plaintiff.

Table 1 Forensic Engineering Case Expert Considerations

Primary factor	Considerations
Defects, design	Present as part of the intended design
	Can induce operator errors
	Not obvious to ordinary consumer
	Fails in hazardous mode
	Dangerous beyond consumer's ordinary expectation
	Risk of harm > benefits of design
Defects, manufacturing	Mistakes in manufacturing
	Human errors, omissions, reversals, substitutions
	Quality control deficiencies
Defects, warranty	Hidden hazard w/o warning
	Inadequate warning, high residual risk
	Warning instead of design remedy
	Not warning to protect marketability
Product not defective, design	Meets consumer expectations
	Risk reduced by safety features
Product not defective, warranty	Adequate warning of risk
	Safe use if warning is heeded
	Conspicuous, immediate reaction
	Choice made to accept risk
	Not feasible to further reduce risk
	Benefits > risks, cannot be obtained otherwise
Foreseeable use	Meets ordinary consumer's expectations
	Used within capability of product
	Children have lower or no risk perception
Foreseeable misuse	Can be reasonably expected in the environment of use
	Product lends itself to such use, even if unintended
	Caused by human error
Government databases	CPSC: Consumer Product Safety Commission
	NEISS: National Electronic Injury Surveillance System
	NHTSA: National Highway Traffic Safety Administration
	DOT: Department of Transportation
Standards	ANSI: American National Standards Institute
	ASTM: American Society for Testing and Materials
	Compliance with standards not adequate defense
Errors	
Product design	Engineering documents, change orders
	Hazard analyses or FMEA or FTA documents
	Communications regarding failure analysis, incident reports
Product testing	UL: Underwriter's Laboratories communications
	Manufacturer test records

Checklist

Main Factors to Consider, In Addition to Basic HF Issues

A checklist is presented in Table 1, Forensic Engineering Case Expert Considerations, which can be helpful in the formulation of investigative and analytic issues. The reader should bear in mind that additional checklists can be used in a matrix that considers individual contributions of case or scene elements, such as perception reaction time, conspicuity, age, glare, and other HF concepts. These can then be evaluated as positive, neutral, or

negative contributions to the case element being evaluated.

Definition of Relevant Terms

Consumer Expectation Test. Beyond the scope of this review, but important to note, is the definition of relevant terms. It is important to be aware that Forensic Engineering HF investigations often deal with terms that have specific definitions, some in law, some from related fields, such as Safety Engineering. For example, the definition of a defective product. Also known as the Consumer Expectation Test, a product is defective if it is "dangerous to an extent beyond that which would be contemplated by the ordinary consumer who purchases it, with the ordinary knowledge common to the community as to its characteristics". These definitions help focus the expert on the particular aspects of the case that need development.

Human Remains and Identity

The scene of crime is a well-known forensic scenario. And when human remains are in fact the issue, anthropological and archaeological techniques are indispensable. Anthropologists are progressively and frequently involved in the retrieval of or, to a lesser extent, the search for human remains [1–4].

Physical anthropologists are key personnel in the case of skeletonized or partly skeletonized remains, badly charred bodies, and buried bodies. In the case of quasi-skeletal, skeletal, or charred remains found on the "surface", the person appointed to observe, register, recover, and generally "take care" of the remains must have experience in osteology. Lack of such experience may lead to serious errors such as nonretrieval of skeletonized remains scattered across the surface by fauna. In order to recover the entire skeleton, it is necessary to be able to quickly perform an inventory of all human bones and know how to identify them. In particular, when dealing with nonadult skeletal remains, very small bone pieces can be misidentified or simply not recognized at all. This implies loss of information. Similar or even more difficult problems are encountered in the case of charred bodies, where the specialist has to retrieve all fragments of burnt bone and distinguish them from other debris (Figures 1 and 2).

Sometimes, particularly in urban contexts, commingled remains are found. Once again, the presence of an anthropologist may be fundamental for immediately verifying whether they are human or not, or if fragments of several individuals are present. This is necessary in order to simplify procedure on-site. Discovery of animal bones or of the ancient origin

Figure 1 The inside of a burnt car, where debris can still be seen on the floor

Figure 2 Debris from which fragments of burnt human bones (prevalently cranium and long bones) were recovered after a meticulous collection and study of all material visible in Figure 1

Figure 3 Example of commingled human remains found in an urban context during gas works. In such cases, the presence of the anthropologist on-site will be useful for verifying the type of remains. In fact if remains are commingled, it is necessary to verify whether several individuals are present. The presence of numerous individuals, in an urban context, may help exclude forensic interest

Figure 4 A quick assessment of the minimum number of individuals (done by counting the number of the most frequently found bone) may help indicate whether one is considering the burial of a single individual or of several subjects. In this figure the presence of two right temporal bones (to the right), a part of an adult humerus (top left), and a child's humerus (lower left) indicate the presence of at least three individuals

of bones may exclude a forensic interest (Figures 3 and 4).

In the case of buried remains, these must be exhumed and collected with stratigraphical and archaeological strategies. Retrieval and registration of remains without archaeological methodology will entail loss of body parts, loss of stratigraphical information useful for determining the postmortem interval, and damage to bones, which will lead to difficulties in interpreting bone trauma.

Sometimes, however, the task is different: the remains still have to be found. This usually is the case of criminals who performed or witnessed a killing and burial and who, maybe after years decide to tell investigating authorities where the body was buried. A search must be performed in order to do this. Forensic archaeology is necessary in these cases. Forensic archaeology is the discipline of archaeology applied

to legal matters. It is the adaptation to the forensic scene of archaeological sciences, intended not only as the study of postdepositional events, but also as the application of archaeological methodology to excavate and recover human remains. Application of forensic archaeology is therefore crucial in reconstructing perimortal and postmortal events – and in particular when the site of burial has to be found [5–11].

It may in fact happen that a person has gone missing and that authorities suspect he or she has been killed and buried. Search for burial sites of human remains may be performed with different methods. Aerial photography is one method of detecting anomalous ground peculiarities which may indicate a burial site. Aerial photography allows one to have a large perspective of a suspected area and detect anomalies in geomorphology or vegetation which may suggest the presence of a burial site. All soil variations in fact influence the vegetation above. When a body is buried, soil and vegetation are drastically affected. Thus long-lasting alterations may be found. Aerial photography is however a costly means of search and frequently obstructed by the presence of trees in woody areas and buildings. Other more commonly used methods can be field walking, geophysical techniques, and cadaver dogs.

Field walking involves detailed observation of open areas performed by rows of experts walking in a line next to one another so that there may be a 20–30% superimposition of each participant's field of vision with his or her neighbor. Some researchers recommend using a T-bar which may test the consistency of soil. At times it may be convenient to test the area with a metal detector, particularly if the body is known to have been buried with metal artifacts. Geophysical methods are based on the use of specific traits of the soil, such as conductivity and resistivity. They indicate alterations in the underlying soil which may point to a burial site. Cadaver dogs may also be used. They are dogs that have been trained to detect decomposing remains. It is not well known if they can be species-specific, but, particularly in cases where postmortem interval is not too long, they may be useful in detecting the bodies [12–23]. All the above-mentioned methods, however, entail the risk of false positives (which, at the most, will oblige one to excavate an area that does not contain human remains) and false negative results. This is more risky. If these methods do not give a positive result, this does not mean that there are no human remains buried in that area. The only way to exclude a suspected area is to perform an archaeological excavation. This consists in excavating the area according to archaeological methods so that significant soil characteristics come to the surface. The archaeologist will therefore proceed to excavate carefully and in depth the entire area until he or she either finds the remains or can conclude, having excavated the area thoroughly, that a specific area has not been used as a burial site. All this has to be performed following archaeological methods and with appropriate tools. Archaeological excavation is carried out by the removal of individual layers and by the investigation of the contents of respective layers. Excavation by the archaeological method has the following main goals: to delineate stratification of the site; to preserve the context and identify the remains *in situ*; to avoid producing lesions on the human remains which may hinder interpretation of trauma; and to establish relationships between the different objects found. Frequently, human remains are excavated with inadequate methods – picks and shovels (Figures 5 and 6). This inevitably leads to loss of information and destruction of forensic evidence. Fundamental questions that magistrates may ask and need to be answered could be the following: the original depth and position of burial (in mafia cases for example it is important to verify the witnesses' reliability); cause and manner of death; identification; and time since

Figure 5 Improper excavation of human remains, with a shovel and pick, which has led to destruction of the skeleton and loss of information

Figure 6 Proper excavation of a skeleton, where the position of every bone has been preserved and no damage has been done to the skeleton

Figure 7 In 2001 a young man confessed to having killed and buried a male and female teenager six years prior to his confession. The woody area visible in the picture was the general site indicated

Figure 8 After removal of the initial layer of soil, an oval outline appeared in the soil, which was lighter in color than the surrounding area and of approximately 2 m × 1.5 m

Figure 9 The fill was fully excavated with archaeological methods

Figure 10 Human remains appeared at the bottom of the pit, at a depth of approximately 2 m

death. All these questions may remain unanswered if recovery is not performed appropriately.

The "tomb" must be excavated delicately layer by layer, with horizontal movements of a trowel. Once all the remains are exposed, a grid is then performed and correct positioning of every bone and object is performed (Figures 7–10). Newer technology, such as laser scanners, applied on typical scenes of crime, allow the operator to immortalize the original position of the skeleton.

Hypnosis and Memory

The legal admissibility of hypnotically recovered memories has stirred contentious debate (*see also* **Eyewitness: Suggestibility of**; **Memory: Repressed**). Court rulings regarding hypnosis have varied widely from rejecting hypnotically elicited recall to treating it as more reliable than actual physical evidence [1, 2]. Laws regarding the admissibility of hypnotic recollections diverge, with 27 states ruling hypnotically elicited recall *per se* inadmissible,[a] 4 states with precedents of *per se* admissibility,[b] and 13 states examining admissibility on a case-by-case basis.[c] In this article, we will assess the status of forensic hypnosis and evidence that pertains to disparate legal decisions.

In one of the first court cases involving hypnosis, *People v. Ebanks*, 117 Cal. 652, 665, 49 p. 1049, 1053 (1897), it was ruled that "The law of United States does not recognize hypnotism" (p. 1053). This decision was justified because at that time hypnosis was not recognized as a legitimate scientific tool by any professional organization. Because of this situation, much expert testimony about hypnotically elicited testimony was excluded by *Frye v. U.S.*, 293 F. 1013 (D.C. Cir, 1923), which held that scientific information must be "sufficiently established to have gained general acceptance in the particular field to which it belongs" (p. 1014).

However, opinions about hypnosis evolved as scientists increasingly accepted the idea that memory provides a comprehensive, accurate, permanent, and potentially accessible [1, 3] record of historical events. This "video recorder model" of memory supported the use of special recall enhancement techniques, including hypnosis, to access purportedly repressed, dissociated, or otherwise unavailable memories [3].

By 1968, hypnosis had gained enough acceptances that in *Harding v. State*, it was ruled that hypnotically elicited testimony was admissible because the hypnotist was a well-trained professional, and the procedures were neither leading nor suggestive. This ruling set the precedent for *per se* admissibility of hypnotic testimony, and began the heyday of forensic hypnosis, which lasted until it became apparent that many "recovered" memories were wildly inaccurate.

For example, in *State v. Mack*, 292 N.W.2nd 764 (Minn., 1980), a hypnotized person recalled eating pizza in a restaurant that did not serve pizza, seeing tattoos on someone who did not have tattoos, and being stabbed with scissors or a knife where there was no physical evidence that a weapon had been used. Such inaccuracies prompted researchers and triers of fact to reexamine their earlier conclusions. In *People v. Shirley*, 723 P. 2nd 1354 (Cal., 1982), the California Supreme Court adopted a *per se* inadmissible rule, and set into motion a tidal change of judicial opinion against *per se* admissibility [1]. Professional organizations such as the American Psychological Association [4, 5] and the American Medical Association [6] followed suit with statements that discouraged the use of hypnosis for memory recovery.

Nevertheless, at the present time, judicial opinions about hypnosis are mixed, and some individuals [7] have strongly defended the value of hypnosis in the forensic arena. Below we review the relevant empirical evidence for each of the three main stances that courts have taken regarding hypnotically elicited testimony: *per se* inadmissible, *per se* admissible, and admissibility determined on a case-by-case basis.

Per se Inadmissible

The majority of states that have ruled on the issue of the admissibility of hypnotically elicited testimony have applied the guidelines set forth in *Frye v. U.S.*, 293 F. 1013 (D.C. Cir, 1923) or *Daubert v. Merrell Dow Pharmaceuticals*, 509 U.S. 579 (1993), and have adopted a *per se* inadmissible rule.[a] Some courts have gone as far as to equate hypnosis with tampering with or manufacturing evidence, and others have excluded all testimony from previously hypnotized people, even testimony regarding memories recalled before being hypnotized [8, 9].

Research provides support for *per se* inadmissibility. Many studies indicate that memory, in general, is reconstructive, incomplete, and imperfect. Numerous reviews [10–15] converge in the opinion that

hypnosis does not offer recall advantages beyond waking conditions, and can result in an increase in accurate memories that is often more than negated by an increase in inaccurate memories. Steblay and Bothwell [11], for example, reported that relative to waking conditions, hypnosis produces more recall errors, more intrusions of uncued errors, and higher levels of memories for false information relative to nonhypnotic methods.

False memories are associated with hypnotic responsiveness, such that highly suggestible subjects (15–20% of the population) tend to report more false memories than low hypnotizable persons, and highly suggestible individuals are particularly prone to memory errors in response to misleading information [11, 16]. However, even relatively nonsuggestible participants (lowest 15–20% of the population), report false memories [17]. Accordingly, the vast majority of people are vulnerable, to some extent, to hypnotically elicited false memories.

The confidence expressed by a witness is the single most important factor in persuading jurors that a witness correctly identified the criminal [18]. Therefore, judiciary parties have been very concerned about claims that hypnosis can increase confidence in inaccurate memories and have the potential to distort testimony. Significantly, more than two-third of the studies that have examined confidence in recollections have shown inflated confidence rates for memories as a product of hypnosis [19]. More specifically, 23 studies have shown that hypnosis either increases confidence relative to a nonhypnotic group, or participants confidently report hypnotic pseudomemories of events that they earlier denied occurred when they were not hypnotized. Nine published studies have found no difference in confidence expressed in hypnotic versus nonhypnotic situations. However, in five of these studies, hypnosis produced more errors or less-accurate information on some or all measures, and in all of the remaining studies, with one exception, there were no differences in memory accuracy across hypnotic and nonhypnotic conditions. The single study in which differences emerged had design flaws that likely accounted for the discrepant findings [19].

Only two studies have assessed confidence in recollections in terms of the breakdown of testimony among hypnotized *versus* nonhypnotized participants in a cross-examination situation. Spanos, Gwynn, Comer, Baltruweit, and deGroh [20] determined that hypnotizable individuals who viewed a videotape of a crime misattributed a substantial number of suggested characteristics to the offender and frequently misidentified a mug shot of the offender. Hypnotic and nonhypnotic interrogations with leading questions produced equivalent effects across the two conditions. During later cross-examination, the hypnotized and nonhypnotized participants were equally likely to "breakdown" during questioning, and disavow their earlier misattributions and misidentifications. However, of the eight participants who selected a mug shot during interrogation, a total of 50% maintained their selection during cross-examination. In contrast, only one of the control participants (no hypnosis, imagery, and no leading questions) selected the mug shot during interrogation, and that individual did not maintain the selection during cross-examination. Spanos did not report an analysis from this comparison, but it appears as if the rates of misidentification differed between hypnotic and control participants. The general finding that hypnotized participants did not differ from participants who received guided imagery and leading questions is not at all surprising in that both guided imagery and leading questions have been shown to produce false memories.

In a second study, Spanos, Quigley, Gwynn, Glatt, and Perlini [21] reported that hypnosis inflated participant confidence in mug shot identifications. Moreover, participants who underwent a hypnosis interrogation, and were then prepared for cross-examination (i.e., told to tell the truth but to be polite but firm and not let the prosecutor plant doubts in their mind), expressed higher certainty in their mug shot identifications than participants who were not prepared. In contrast, preparation did not influence nonhypnotized participants' certainty of identifications: prepared and nonprepared individuals responded equivalently.

All participants were subjected to cross-examinations of their earlier testimony. Hypnotized participants were neither more nor less likely to break down under cross-examination than nonhypnotized participants. However, across conditions, 37 out of the 78 participants evaluated (47%) did not break down in the face of both direct examination and cross-examination. In fact, a total of 73% of people who were prepared for cross-examination did not break down under cross-examination. In contrast, 86% of individuals who were not prepared by lawyers

to withstand cross-examination did break down, and reversed their earlier testimony.

In short, the combination of hypnosis and routine trial preparation to withstand cross-examination resulted in a high rate of certainty and resistance to changing mug shot identifications while testifying. Combined, research on confidence and memory accuracy provides substantial justification for *per se* inadmissibility rulings.

Per se Admissible

Despite research showing that there are perils associated with admitting hypnotically elicited recall, there are still four states that allow all hypnotically elicited testimony to be admitted.[b] Courts in these states view the issue of such testimony as one of credibility rather than admissibility. Instead of determining admissibility based on rules and case law concerning expert testimony and the admissibility of scientific evidence, they invoke evidentiary rules concerning witness competence and relevance [8]. For example, in *State v. Brown* 337 N.W. 2d 138, 151 (N.D. 1983), the court noted that if they were to rule out any testimony in which there were concerns about suggestibility or difficulty due to confidence at cross-examination, "we would not allow a lawyer to talk to his witness before trial, we would exclude most identification testimony, and relatives and friends of a party could be excluded as witnesses." The research reviewed above suggests that hypnosis increases the risk of inaccurate remembrances; however, the psychological principles that account for the cognitive errors that occur during hypnosis are universal.

Courts that have supported *per se* admissible rulings generally believe that an attack on credibility is the proper method of determining the value of hypnotically induced testimony. Given the available evidence, an expert witness should be able to establish doubts about the reliability of hypnotically elicited testimony; however, this might not always be the case because of the continued belief of the public in hypnotically elicited testimony and differences in expert opinions before the courts.

Case-by-Case Basis

Federal courts and the minority of states[c] determine the admissibility of hypnotically elicited recall on a case-by-case basis because courts in these jurisdictions have ruled that hypnotically enhanced testimony is reliable under certain conditions, or hypnosis is not unduly biasing [7, 8]. Experts who support this position can cite research showing the following:

1. Hypnosis increases the sheer volume of recall, and hypnotic recollections are not necessarily inaccurate. Accordingly, it can be argued that hypnosis has a place in criminal investigations, especially in situations where few leads are available, and when accurate recall can be potentially corroborated.
2. Hypnosis should not be "scapegoated". Many procedures, including leading questions, carry the risk of false memories that equals or surpasses that of hypnosis, and are not excluded from the bar [22, 23].
3. Limited research suggests that hypnosis does not necessarily preclude cross-examination. Moreover, the effects of hypnosis on confidence are variable.
4. Many false memory studies are conducted under sterile laboratory conditions, and hypnosis is reasonably reliable for enhancing memories that have been blocked due to emotional trauma [7].

However, experts whose opinions support *per se* inadmissibility can counter with the following claims:

1. The risk of false memories is a trade-off for any increase in memory accuracy. In many criminal investigations, hypnotically elicited inaccuracies in recollections are sufficiently biasing so as to outweigh advantages in securing "leads" that can be better obtained using nonhypnotic recall enhancement procedures. Although hypnosis has assisted investigations in a number of instances, it is unclear whether repeated recall attempts were responsible independent of hypnosis [24], or whether other recall techniques would have been equally, if not more, effective.
2. Many procedures are suggestive (e.g., misleading questions and guided imagery). Nevertheless, this fact provides no warrant for the use of hypnosis in criminal investigations, or for the admissibility of hypnotically elicited testimony.
3. The consilience of evidence indicates that hypnosis can inflate recall confidence in inaccurate memories, and that many individuals who are hypnotized do not reverse their testimony following cross-examination [25].

4. At least eight studies (see [19]) have compared hypnotic *versus* nonhypnotic memory in the face of relatively emotionally arousing stimuli (e.g., depictions of fatal stabbings, recollections of the death of Princess Diana, shop accidents and mutilations, and sexual intercourse). All studies have failed to confirm the hypothesis that hypnosis is especially effective in enhancing memory in emotionally arousing situations. An applied study with the Los Angeles Police Department concluded that hypnosis did not augment recognition memory for victims of violent crimes such as rapes and shootings [26].

Advocates of admitting hypnosis on a case-by-case basis are likely to contend that hypnosis, when conducted appropriately, without leading questions, and when other procedural safeguards are followed is no more biasing than routine interrogation.

The seminal case, *State v. Hurd*, 86 N.J. 525, 432 A.2d 86 (1981), delineated a set of "procedural safeguards" that must be followed in order for hypnotically elicited testimony to be admissible in New Jersey. Other states either require compliance with the Hurd rules or have developed their own set of guidelines [e.g., South Carolina in *State v. Chesseboro*, 552 S.E. 2d 300, 308 (2001)]. The Federal Bureau of Investigation (FBI) and the American Society of Clinical Hypnosis (ASCH) have also developed procedural guidelines, which range from making videotapes or other recordings of the procedures to evaluate suggestive influences, to discussing the imperfections of memory "in and out of hypnosis".

Unfortunately, no set of applied guidelines has been systematically evaluated. Previous guidelines probably do not go far enough in that they do not recommend assessing participants' confidence in their initial and posthypnotic recall. Without this information, it is impossible to fully evaluate the potentially biasing effect of hypnosis and hypnotic testimony on the witness. However, limited evidence regarding prehypnotic "warnings" about the imperfections of hypnotically elicited recall do not inspire confidence in their protective effect. In one study [27], warnings mitigated some of the memory distortions associated with hypnosis but did not improve recall above and beyond a nonhypnotic condition; in another study, warnings minimized memory distortions during but not after hypnosis [25]; and in a third study [28], repeated warnings that hypnotic and nonhypnotic memories are not necessarily accurate did not improve recall relative to a nonhypnotic condition. In short, the value of procedural guidelines has not been adequately investigated or well established.

Critics of guidelines argue that hypnotically elicited testimony is so unreliable that no array of procedural measures can outweigh the inherently biasing effect of hypnosis. As stated in *People v. Gonzales* [108 Mich. App. 145, 310 N.W. 2d 306 (1981), aff'd, 415 Mich. 615, 329 N.W. 2d 743 (1982)], the Hurd guidelines have the potential to confer an unwarranted "aura of reliability" on hypnotic testimony, thereby raising the specter of a miscarriage of justice. The Supreme Court of New Jersey found this and other arguments compelling, and recently reversed their earlier decision regarding the Hurd Guidelines. However, research on the biasing effects of hypnosis alone, absent suggestive questions, is mixed [22, 23].

Finally, advocates of a case-by-case position can argue that it is unduly restrictive to prohibit a person from testifying even about "nonhypnotic" recollections. This point may be valid. However, previous research has not examined the extent to which a previously hypnotized person's nonhypnotically refreshed memories are tainted, so the court can expect little evidence-based guidance on this issue.

Conclusion

Courts must contend with difficult issues that stretch the ability of triers of fact to fully comprehend. Accordingly, it is not surprising that many jurisdictions have opted for *per se* exclusion to avoid proverbial battles of experts, reduce costs and time associated with dealing with complex issues and discourages the use of a technique that can be misapplied or is unreliable. Indeed, a strong case can be made for *per se* inadmissibility of hypnotically augmented testimony. Nevertheless, it is also true that certain nonhypnotic recall enhancement and suggestive procedures may be equally or more prejudicial. Given that the majority of courts adopt a *per se* exclusion rule regarding hypnosis, it is appropriate to take steps to ensure that a variety of potentially biasing procedures are better understood and more carefully scrutinized in the judicial process.

Hypothetical Question

In adversary system jurisdictions, when a forensic expert testifies to facts that are within his personal knowledge, it is relatively simple to lay an evidentiary foundation. He acts just like an ordinary fact witness in stating the circumstances under which he became aware of facts and the observations he made. When an expert has done a laboratory examination of evidence and has arrived at an opinion, the witness will also be permitted to state that opinion if he has been qualified, preliminarily, to give opinion evidence as an expert.[a]

However, if the expert has no personal knowledge of the facts of the case, and has made no investigation of them, it is still possible to draw upon his scientific skill and expertise when called to court. He can be asked to assume certain facts disclosed to the court by other witnesses, and offer his opinion based upon the assumed facts. This has been a time-honored manner of eliciting expert testimony in common law jurisdictions.[b] The questioning process is referred to as eliciting *hypothetical question* opinion evidence. It is a method often used as a way of drawing upon prominent authorities in forensic fields involving science or medicine when these authorities lack personal knowledge of the case-specific facts.

The hypothetical question may be asked of expert witnesses during direct examination. On cross-examination the expert may thereafter be asked to assume supplemental facts and base his opinion taking into account these additional facts. Another hypothetical question approach on cross-examination simply supply the witness with a different hypothesis of the facts based on the cross-examiner's theory of the case.

It should be evident that there is a significant weakness in this artificial process of eliciting opinion evidence. In practice, while the witness must be familiarized, in the hypothetical question, with the undisputed relevant facts, these facts rarely portray the whole panorama of investigative evidence. Despite these misgivings, hypothetical question evidence has achieved a time-honored place in common law jurisdictions as a means of questioning an expert witness.

End Notes

[a.] This is the traditional way, in common law jurisdictions, in which expert opinion has been elicited.

[b.] In addition to common law principles, Federal Rule of Evidence 703, in the United States, also specifically permits an expert to offer opinions on facts of which the expert may not have had personal knowledge, but of which the expert was apprised either before trial or at the hearing or trial. The rule provides that if the facts of which the witness was apprised are "of a type reasonably relied upon by experts in the particular field in forming opinions or inferences upon the subject, the facts or data need not be admissible in evidence in order for the opinion or inference to be admitted. . . ." In that fashion, medical doctors are permitted to answer questions based on reports of X-ray technicians, nurses, other medical personnel, and hospital records.

Identification and Individualization

Identity, Identification, and Individualization

Prof Paul Kirk [1] introduced these terms as they relate to forensic science in a very elegant manner:

> *Identity* is defined by all philosophical authorities as uniqueness. A thing can be identical to only with itself, never with any other object, since all objects in the universe are unique. [...] Bowing to general scientific usage, we must however accept the term *identification* in a broader context, referring only to placing the object in a restricted class. [...] The real aim of all forensic science is to establish individuality, or to approach it as closely as the present state of science allows. *Criminalistics is the science of individualisation*.

An individualization can be viewed as a special case of identification, where the restricted class is populated by one object only.

Definitions of individualization in the forensic literature (e.g., fingerprint, footwear marks, or toolmarks) systematically refer to the capability of pointing to the right source *to the exclusion of all others* (objects or persons). Hence, by default, the size of the population of relevant sources considered at the outset of the examination is systematically set to its maximum, regardless of the specific circumstances of the case. We call this the *Earth population* paradigm. In that paradigm, the individualization conclusion cannot be reached in a deductive manner, but is *de facto* probabilistic in nature [2–4]. This is well spelled out by Tuthill and George [5]:

> The individualisation of an impression is established by finding agreement of corresponding individual characteristics of such number and significance as to preclude the possibility (or probability) of their having occurred by mere coincidence, and establishing that there are no differences that cannot be accounted for.

At the end of the examination process, the quantity of features observed in agreement between two objects (without discrepancies) is such that the examiner is prepared to rule out the possibility of a coincidental match, whatever the initial population of sources involved. That has been described by Stoney as a "leap of faith" [6].

If we ask ourselves the order of magnitude of the probability of adventitious matches in the mind of an examiner at the moment of its decision, we can derive it simply using the odds form of the Bayes theorem (*see* **Evidence Interpretation: a Logical Approach**, another formal analysis can also be found elsewhere [7]):

$$\frac{\Pr(H_p|E,I)}{\Pr(H_d|E,I)} = \mathrm{LR} \times \frac{\Pr(H_p|I)}{\Pr(H_d|I)} \qquad (1)$$

where E stands for the evidence, e.g., a correspondence between a mark and a print, H_p stands for the proposition that the mark has been left by the same source as the print, H_d stands for the proposition that the mark has been left by another source (here $H_d = \overline{H_p}$), and I stands for the background information; here, the adoption of the Earth population paradigm dominates all other information.

If the prior probability of H_p is set as the inverse of the size of the Earth population of sources (e.g., 1 in 7 billion), then the likelihood ratio (LR) required to achieve a posterior probability for H_p that is close

to 1 (e.g., 0.9999) can be derived from the following:

$$\frac{0.9999}{1-0.9999} = \mathrm{LR} \times \frac{1/(7\times 10^9)}{1-1/(7\times 10^9)} \qquad (2)$$

This can be re-arranged to give:

$$\mathrm{LR} = \frac{0.9999}{1-0.9999} \times \frac{1-1/(7\times 10^9)}{1/(7\times 10^9)} \qquad (3)$$

For a posterior probability of 0.9999, the LR should at least be above 7×10^{13} or a match probability (MP) (if we assume for the sake of argument that $\mathrm{LR} = 1/MP$) below 1.43×10^{-14}.

Leaving aside the consideration that the assignment of a given posterior probability is outside the duty of the scientist, we face, in the Earth population paradigm, the prospect of having to articulate probabilities out of reach of the current systematic research. Taking fingerprints as an example, the recent published statistical research [8] would allow us to quote MPs on the order of one in a billion confidently. Articulating any smaller number (down to the probability of zero) is nothing more than an unsupported leap of faith. In the above context, we agree with Saks and Koehler [9] that: "The concept of 'individualisation', which lies at the core of numerous forensic science subfields, exists only in a metaphysical or rhetorical sense."

DNA Evidence and Individualization

Current DNA short tandem repeat (STR) profiling techniques are typically based on 10–15 loci, so that the MPs for individuals unrelated to the defendant are extremely small, often less than one in a billion (*see* **Short Tandem Repeats: Interpretation**). This is enough for some commentators to suggest that the profile can be considered as unique "with reasonable scientific certainty" [10]. Apart from the technical issues for computing such posterior probabilities [11, 12], there are four arguments that call for a more humble approach here: (i) the threshold (e.g., above 99% as proposed by the FBI in [10]) amounts to quantifying the concept of reasonable doubt and is outside the realm of the scientist; (ii) invoking a very large population (such as 260 million for the FBI policy) or the population of the Earth is hardly meaningful in a forensic context; (iii) the levels of relatedness within this population with regards to the defendant are generally not available; and, (iv) more importantly, Foreman & Evett [13] argue that an order of magnitude of 1 in a billion is a fair and reasonable approach, given the current state of knowledge of dependence effects. Hence, we should discourage anyone from believing that a matching DNA profile amounts to definitive attribution of sources – committing the *uniqueness* fallacy according to Balding [14] – but to encourage the interpretation of DNA evidence within the specific context of the case. The fact that absolute certainty is not achievable does not prevent the findings from being useful in court.

Uniqueness

Considerable confusion exists among laymen, indeed amongst forensic scientists about the use of a word such as *unique* also. The phrase "all portions of friction ridge skin are unique" is no more than a statement of the obvious – every entity is unique and identical to itself only.

What matters is how two objects left in forensic contexts (as an inked print and as a latent mark for example) can be distinguished from each other; either in the case where they have come from the same source or in the case where they have come from different sources. This distinguishability or variability of prints/marks not only depends crucially on the examination method but also on the intrinsic qualities of the prints/marks to display selective features (extensiveness, clarity, etc.). One striking feature in most forensic identification fields is the constant confusion between the between-*persons/objects variability* (which may be infinite) with the *variability* that is expressed in *marks* left by these persons or objects. The loss of information from a complete three-dimensional organ or object to a two-dimensional mark detected on a surface needs to be investigated specifically. The crux of the matter is not really the uniqueness of the sources involved, but the ability of an examiner to distinguish reliably marks and prints left by these sources.

Hence, invoking statements such as "Nature never repeats itself" [15] while referring to the uniqueness of the organs under examination and by consequences to the strength of the conclusion that can be derived from their examination is not legitimate. Cole named this tendency the *fingerprint examiner's fallacy* [16].

Reporting Identification Evidence in Court

The above analysis suggests that scientists should refrain from reporting categorical opinions of individualization, but should report the strength of the findings and leave the integration of that element into the overall context of the case to the jury.

For fingerprint evidence, a systematic analysis of the standards for conclusions (either in terms of criteria for sufficiency or in terms of a range of authorized conclusions by the profession) shows how the evaluation phase has been dominated by policy and pragmatic decisions instead of the application of a scientific approach [17]. The practice of reporting only individualizations and exclusions, leaving all other corroborative evidence under the heading of "inconclusive", cannot be justified on scientific grounds.

Other identification fields have suggested the use of scales of conclusion that are focused on posterior probabilities by either following the Earth population paradigm [18–22] or by applying the Bayes theorem incorporating a highly debatable 0.5 prior probability [23, 24]. All these proposals fall short of providing a logical framework for the reporting task. For a discussion on the scales of conclusions, the reader can refer to the following papers [25–27].

All identification evidence types (DNA included) should be governed by the same principles when it comes to their interpretation.

There is an urgent need to find a common, coherent, and harmonized framework to report such evidence in court. The one proposed here is not new and is already embraced in other forensic fields. Broadly speaking, in all forensic areas seeking to help address issues of identity of sources, there are three inter-related factors that determine the nature of the inference that may be made: the quantity and quality of relevant detail, within-source variation, and between-source variation. These three factors impact on the LR defined as follows:

$$\mathrm{LR} = \frac{\Pr(E|H_p, I)}{\Pr(E|H_d, I)} \qquad (4)$$

The weight of forensic findings is essentially a relative and conditional measure that helps move a case in one direction or the other, depending on the magnitude of the LR. The numerator of the LR considers the within-source variability of the features defined by E and the denominator of the LR deals with their between-sources variability.

Reporting identification evidence in court could be viewed as simply assigning and reporting an LR without the need to claim individualization and set any operational threshold to reach it. All items of evidence for which the LR differs from one then becomes relevant [28].

It is a matter of principle that the scientist may not express an opinion with regard to the hypotheses themselves – that is a matter for the jury. That principle no doubt influenced the English Court of Appeal in the judgment in *R.v. Doheny. G. Adams* [29] which states "The scientist should not be asked his opinion on the likelihood that it was the Defendant who left the crime stain [. . .]."

Conclusions that use terms such as *very likely* or *almost certain* in relation to a proposition are only logically possible when the nonscientific evidence is taken into account (*see* **Evidence Interpretation: a Logical Approach**). Then, the statement follows from the combined effect of the scientific observation and an assessment of the prior probability that encapsulates all the evidence available to the court. The inferential process used here goes far beyond forensic science. Moreover, most of the time, the forensic scientist is not aware of the other pieces of evidence available in a case, and clearly does not have the information at hand to make inferences such as these. Forensic scientists should not make any assessment of the prior information because that ought to remain a matter for the court. To avoid such situations, we need to adopt a reporting convention that allows the scientific statement to remain consistent within a given framework irrespective of other evidence at hand. The LR provides the means for achieving this objective.

CHRISTOPHE CHAMPOD

Identification of Human Remains

The previous articles have focused on the most important steps in achieving a biological profile from the skeleton, i.e., aging, sexing, determining stature, and ancestry, recording every single detail of the remains that may provide a thorough “identikit” of the person. This procedure can be completed with facial reconstruction from the cranium in cases of badly decomposed remains. In this way, such a complete identikit can be given to the investigating authorities and the media (newspapers and television) in order to achieve a suspicion of identity, in case somebody “recognizes” the biological profile. In the better organized countries, this kind of information

can be inserted into a postmortem database and will then be cross-matched with an "antemortem" database containing data from missing persons [1–4], in order to reach a suspicion of identity or at least possible matches for those specific human remains. At times, circumstantial evidence can help, in the sense that when the remains arrive the pathologist already has knowledge of a suspected identity (e.g., a burnt body in a car whose owner is known).

Whatever the case may be, the forensic anthropologist or pathologist is faced with the need to compare antemortem with postmortem data, in order to finalize the identification process. The most popular disciplines for positive identification are genetics and odontology. However, sometimes it is not possible to perform DNA or dental matching because of the lack of antemortem data (or relatives, in the case of DNA) or because of the bad state of preservation (e.g., dry bone, charred bone, and missing teeth). In these cases, bone morphology may be useful.

Generally speaking, morphological methods (forensic anthropology and odontology techniques), which simply compare shape, size, and/or peculiar anomalies of bone and teeth, are valid methods. They are advantageous because they are quicker to perform and much cheaper when compared with the costs of genetic reagents; however, they may suffer, in the view of some experts and judges, because of the qualitative (and not quantitative) responses they give. Genetic and fingerprinting methods give a quantitative result, because the specific traits are analyzed and compared and their relative frequencies among the population quantified using statistical methods. This allows one to answer in a quantitative manner on the question of probability of two individuals having similar characteristics. In the case of "morphological" methods (such as the odontological and anthropological ones), a final judgment can be given in terms of exclusion, certainty (very few times), or in less-defined terms of probability, possibility, consistency, etc. In other words, it is impossible to quantify the chances of two individuals sharing the exact same dental or osseous asset. Furthermore, a unanimous and clear agreement on the quality and quantity of the characters needed to achieve personal identification does not exist.

The recurrence of discordant characters settles the case, by excluding the identity; some or many concordant characters, particularly if not uncommon within the population, can permit one to express a judgment of compatibility or possibility; few characters or a combination of characters, rare among the population, will allow one to express a judgment of high probability or certainty [5]. Though it may at times seem a semantic matter, the importance of how the expert anthropologist may express him or herself in a report or in court is crucial. In certain parts of the anthropologist's work (such as sexing, aging, and estimation of stature.), a standard error, a confidence interval, or any instrument for expressing the error of a method may be given. As far as "personal identification", i.e., the significance of shared osseous traits, is concerned this is not the case for the reasons stated above. And the difficulties met (along with the limits one should admit) have recently been dealt with by forensic anthropologists which have started paying attention to the effects of court rulings (e.g., Daubert and Kumho) on the significance of anthropological testimony [5, 6].

It is therefore reasonable to admit that the aim of morphological techniques is more frequently that of excluding, reducing the candidates among a population to one (hence the use of the term individualization), more rarely, in the case of anthropology, establishing identity with certainty. The aim of this article is therefore to illustrate how anthropology may help identify (forensic genetics and odontology are treated in separate articles) the rationale behind this assumption, being that each bone of every single individual has its own peculiar shape and dimension. In order to identify a person, it is therefore possible to compare the shape of the bones retrieved with those on an antemortem X ray of a missing person, just as though each bone were a fingerprint [7–47].

Before speaking of bones, however, a brief comment should be made concerning fingerprints. One should keep in mind that the anthropologist may have to deal with remains with some soft tissue still present (Figure 1) and should know that the fingerprints can and must be preserved.

Qualified personnel exists for fingerprint analysis, however, pathologists and anthropologists frequently deal with very decomposed human remains and need to be aware of the fact that within an apparently useless piece of soft tissue lying over the phalanges of a skeleton there may still be a partial print. It is therefore useful for the anthropologist to give priority to such potential prints and aid in the recovery. Once fingerprints are taken, if the person has a criminal record, the automated fingerprint

Figure 1 Right hand of an almost completely skeletonized body with conservation of soft tissue on fingers and palms. It was still possible to "extract" fingerprints from these tissues

identification system (AFIS) system will find the appropriate identity. In some countries, it is in fact the pathologist or anthropologist who tries to enhance fingerprints on the cadaver, or at least guide the investigating authorities in doing so. Thus, the following lines provide very general indications for the treatment of decomposed fingers and the recovery of prints [5–7].

Bodies that have reached the stage of quasi-skeletonization because of putrefaction processes or postmortem factors (such as fire) may still show fingertip and hand soft tissue residues. Depending on the case, the papillary crests can present deformations consisting of folds of the epidermal or dermal layer (as in mummification); they can be flattened/thinned because of erosive effects of environmental phenomena, or dehydrated, and therefore retracted and fragile, as in the case of exposure to high temperatures and flames. In these cases specific methods should be used in order to enhance the papillary design. Different techniques have been developed for this purpose: chemical techniques (methanol solutions, sodium hydroxide, and ethylene diammine tetracetic acid (EDTA)) can be applied for the purpose of softening and rehydrating the skin. Once the finger is softened, subcutaneous injections of glycerin or saline solution can be performed to reinflate the finger. Chemical techniques are, however, potentially destructive, complex, and require constant monitoring. The choice of which technique to use depends mainly in the kind of degradation process the fingertips have been through. For example, if the body has been soaked in water for a long time or is in the wet stages of decomposition, this leads to peeling off of the skin with a consequent progressive loss of the papillary design and the first step should be to block the putrefactive process by hardening the skin via immersion in ethanol for a time ranging from a few minutes to 1–2 h. Dehydration due to the immersion in alcohol, though necessary, introduces serious problems, such as the thinning of the papillary crests, which are already compromised. At this point, however, it should be sufficient, once the epidermal glove, i.e., the peeled off skin, has been worn by the examiner, to ink the fingertip and transfer the fingerprint on paper.

Mummification and carbonization, on the other hand, provide a very dry substrate. The fingertips show more or less pronounced folding and hardening, which prevents the application of the normal techniques of fingerprinting. A technique frequently used in these cases consists in softening and reinflating the finger. This is obtained by carrying out alternated incubation in 90% methylalcohol and 5% sodium hydroxide solutions. However, the sodium hydroxide treatment is destructive for the skin and it is not advisable to repeat it. Once the fingertip is softened, it is possible to "reinflate" it by means of saline injections. When the folds have flattened and the papillary design becomes sufficiently readable, it is important to try to "ink" it or, if this is impossible, to take a photograph with tangential lighting. However, both for mummified fingers and burnt bodies a new versatile technique can be used. This involves applying a thin film latex (after cleaning the tip with ether) on the finger and obtaining an enduring negative copy of the print, which can then be inked and photographed [6]. The fingerprint obtained from the latex film will have to be inverted in place and color before fingerprint comparative analysis.

Regardless of the case, the anthropologist should always be in touch with the fingerprint expert who carries out the individualization, for the purpose of explaining what he or she is looking at.

Going back to bones, it is clear that the comparison, as always, must be carried out between antemortem and postmortem radiographs of different skeletal districts. Consequently, if radiographs of the various osseous regions (e.g., head, thorax, limbs, and abdomen.) are available, it will be possible to compare the morphology of the skeletal elements visible

in the radiograph with the same osseous elements belonging to the human remains (both working on the actual osseous elements, and on their radiographs) [8–49].

Exceptional morphological peculiarities (osteophytes, bone calluses, prosthetic or surgical devices, etc.) will make identification relatively simple; however, most of the time one has to deal with general bone morphology, for example, the observation of a transverse process, which may be particularly rounded, a clavicle with an unusual foramen, or a humeral head with a specific shape: given that an antemortem and a postmortem comparison yield similar characteristics, how many morphological elements are sufficient for individualization? There is no answer to this specific question; in other words, a minimum number of points does not exist – as it exists instead for fingerprints – in order to carry out an individualization. Some authors claim that one to four "significant" characters, without evident discrepancies, are considered sufficient for an individualization. The problem is that there is no clear description of what exactly is meant by a significant character: they must be visible in the same orientation as in the antemortem X ray, for example, and must be scarcely modifiable in time. However, the peculiarity of the characters and the consistency between the antemortem and postmortem shape is left, in part, to a subjective evaluation and to the experience of the operator.

Personal identification has been described in the literature for almost all the skeletal regions: frontal sinuses, cranial sutures, vertebrae, hip bones, osseous traits of the hands and feet, and even trabecular bone pattern (this last one only on high-quality hand and wrist X rays) [8–49]. In most instances, the examination is performed by a simple morphological comparison, at times with image superimposition, either of the bones with the antemortem X ray, or of the antemortem X ray with a postmortem X ray of the same skeletal region.

For some districts, the search for an "identification algorithm" has been attempted. The frontal sinus is perhaps the most studied one [12–17]. Apparently, the shape (Figure 2) of the frontal sinuses is so peculiar that it is even different in homozygous twins (like fingerprints). Different methods of classification of frontal sinus shape exist. One method (Yoshino's) is based on the attribution of a score for each of the following parameters: asymmetry, left sinus larger than the right one or vice versa, presence and number of indentations (and therefore arches) per septum, partial septa, presence of supraorbital cells, and so on. The entire procedure leads to a score, which is then translated in an "identification index". For the other skeletal districts such precise indications do not exist.

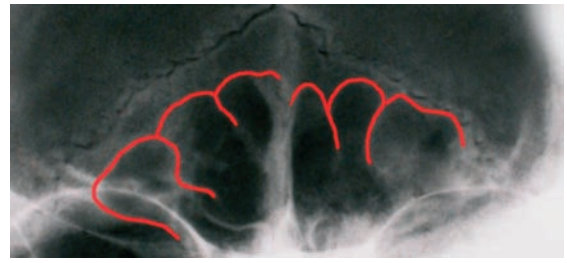

Figure 2 The red line delineates the outline of the frontal sinus in this X ray of the head. Comparison of the morphology of the antemortem and postmortem X ray can lead to positive individualization

Nonetheless, it is still possible to compare the forms of such other districts (Figure 3), such as the vertebrae and articular extremities. Of these, the transverse processes and the spinal process, which present very different shapes from one another, for example, are particularly useful. But there are no algorithms yet that allow a quantitative or semiquantitative estimate of the comparison. The answer is left to the morphological evaluation of the observer.

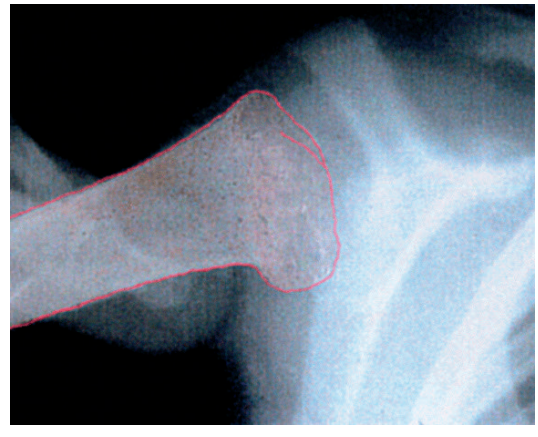

Figure 3 The radiograph represents a detail (humerus) of the antemortem thoracic radiograph of a skeletonized murder victim (a subadult). The thin line is the profile, once a similar orientation has been achieved, of the humerus from the skeleton

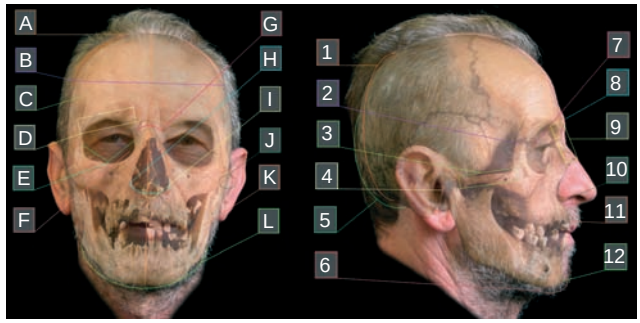

Figure 4 After having selected images of the missing person, proper spatial orientation of the skull and enlargement of the picture (trial and error) are achieved. Then superimpositions are usually performed in the frontal and lateral views. The figure shows an example of craniofacial superimposition in the frontal and lateral position. The letters (frontal) and the numbers (lateral) indicate the landmark for which the correspondence between face and skull is evaluated [36]. The observed criteria for the comparison in norma frontalis, marked with letters A to N are the following:

A: The length of the skull from bregma to mention must be included in the face. The bregma is generally covered with hair.
B: The width of the skull must match the forehead area.
C: The temporal line, if visible on the face, should correspond to the temporal cranial line.
D: The eyebrows generally follow the superior edge of the orbit to the medial and central third; they continue superiorly to the lateral third while the edge of the orbit deviates inferiorly.
E: The orbits contain the eye entirely.;
F: The lachrymal groove, if distinguishable on the photograph, lines up with the osseous groove.
G: The width of the nasal bridge must correspond in the two images.
H: The width of the nasal aperture falls within the external margins of the nose.
I: The nasal spine is situated above the inferior edge of the medial nasal crus.
J: The external auditory meatus is medial to the traghus. This can be adequately evaluated by a marker inserted in the ear.
K: The oblique line of the mandible, if visible on the face, corresponds to the same line on the skull.
L: The mandibular curve is similar to the curve visible on the face.

In norma lateralis:
1: The skullcap must coincide with the height of the head.
2: Sometimes it is possible to notice the margin of the frontal process of the zygomatic bone which should match the one on the cranium.
3: The margin of the zygomatic arch of the skull is also superimposable to that of the face.
4: The portion is slightly behind the traghus, and below the helix crus.
5: The occipital curve is placed inside the margin of the nape.
6: The anterior protuberance of the mandible is behind the chin. The chin form corresponds to the mandible form.
7: The lateral margin of the eye is situated within the orbit.
8: The profile of the glabella both of the skull and of the face must be similar.
9: The glabella, the nasal bridge, and the region of the nasal bones are the most significant. The prominence of the glabella and the depth of the nasal bridge closely follow the contour of the thin layer of overlying skin. The nasal bones fall within the margins of the nose.
10: The front nasal spine is situated posteriorly with respect to the base of the nose, close to the more posterior portion of the lateral septum cartilage.
11: The prosthion is posterior to the anterior margin of the superior lip.
12: The pogonion is posterior to the indentation noticeable in the chin where the orbicularis oris crosses the chin muscle

Since the antemortem material consists of radiological material, one should always be extremely careful in checking for proper orientation of the postmortem image, so that the two images can be comparable.

When there are no antemortem X rays with which to compare bone morphology, the last method the anthropologist can resort to is craniofacial superimposition (Figure 4). It consists of the

superimposition of a photograph of the skull onto a photograph, similarly oriented, of the face of the living person [36–43]. The correspondence between two subjects is evaluated on the basis of the correspondence of several anatomical landmarks that can be found on the skull and on the face. Although this procedure can be extremely useful and reliable for the dental area (in dental superimposition the same elements – teeth antemortem and teeth postmortem – are superimposed), it has far less credibility as a precise and accurate method when the soft tissues of the face are compared and matched to landmarks on the cranial skeleton. Figure 4 illustrates a general example that summarizes the method and whose aim is to demonstrate the difficulty in matching specific landmarks.

The supporters of this method report a reliability of 96%, whenever the possibility exists of both the frontal and lateral superimposition, but the discrepancy among numerous anthropologists concerning the degree of certitude supplied by this type of investigation is large.

Some authors have also tried to ameliorate the method by using photos in the oblique position as well, and checking the match of specific landmarks on three projections (frontal, lateral, and oblique). Others have even automated the system, and measured semiautomatically anatomical consistency between the digitized skull and face, as well as the distance between the landmarks and the thickness of soft tissues on the anthropometrical points; evaluation of matches has even been attempted by the use of polynomial functions and Fourier harmonic analysis for the forehead and mandibular line areas.
