that variable human iris color in humans is primarily determined by polymorphism in the Oculocutaneous Albinism 2 (OCA2) gene [13–15]. OCA2 was first discovered by researchers studying the human albino phenotype as a locus with mutations that affected iris melanin production but not skin melanin production (as well as other mutations that affect both). Recently, [13] built upon earlier reports [14–17] to identify 33 OCA2 SNPs associated with digitally quantified iris color independent from their ancestry information. As it is with many phenotypes (e.g., Figure 5), ancestry was itself correlated with the phenotype (Figure 6) and correcting the associations with respect to population structure was crucial for demonstrating that they were *bona fide* (that is, that the association was with iris color, not an element of population structure that is itself correlated with iris color; [3]). Though each of the 33 SNPs were marginally (independently) associated with iris color, none were very useful on their own as iris color classification features. However, when assembled into diplotypes, the alleles for these 33 SNPs were highly predictive for the overall eumelanin content of the iris; among 1100 diplotypes from individuals of European descent, there existed 96% concordance of iris colors among those samples with the same diplotypes [3, 13]. To predict the iris color of a given sample, this team thus built a database of phenotyped diplotypes, and then queried the database much as we do with the indirect method of phenotyping – though, in this case, with test diplotypes rather than admixture profiles. The return for this query provides an average iris color and range of iris colors as a point estimate and range of inferred color for the test diplotype. The results were satisfying; a validation sample provided a 96% accuracy rate (the inferred or predicted iris color for the unknown iris fell within the predicted range 96% of the time; Figure 8) and demonstrated that the method was capable of pinpointing the overall eumelanin content of the iris and often the particular shade, though not the pattern of iris pigmentation [13].

Particularly interesting from this work on iris color is what it teaches us to expect for other phenotypes. The predictive power of these SNPs required a consideration within the context of diplotypes. Not only were SNPs unable to provide predictive power on their own, haplotypes were equally insufficient and even diplotypes composed using smaller numbers of SNPs than these 33 (such as hap-tag SNPs) were insufficient to achieve good prediction results [13]. This illustrates the apparent historical and mechanistic complexity of even this relatively simple (predominantly single-gene) phenotype. A by-product of this complexity is the need for a massive database in order to handle most test samples; with so many SNPs part of the equation, the number of diplotypes in the human population is very large and the chances that a test sample from a crime scene would have a match in the database at its current size ($n =$ 1100, Summer, 2007) is about 10%. Nonetheless, the inferences for these 10% are highly accurate and based on this utility, the iris color diplotype database system has been developed as a forensic service by DNAPrint genomics under the trade name Retinome™ (DNAPrint genomics is the laboratory within which the author conducted much of the work

described here and throughout this article). So far the method has been applied to several homicide cases; however, due to the currently small size of the database, many detectives desiring to use Retinome™ have been unable to do so because their crime-scene samples did not have a match in the database. For this method of predicting iris color to have more of a broad impact on the investigative process, the size of the database will have to be increased substantially.

In spite of its limitations, the Retinome™ system was the first system for the direct inference of a complex human phenotype. Since its introduction on the lecture circuit in 2004, other OCA2 systems involving additional single nucleotide polymorphisms (SNPs) were described [23], and eventually, a single SNP was discovered in 2008 [24–26] that was so powerfully associated with the light/dark iris color dichotomy that it was posited to represent no less than a founder mutation – an evolutionarily instrumental mutation that not only explains but also represents the historical genesis of the crude light versus dark dichotomy extant throughout the world today. The strength of the association (nearly perfect, with respect to the dichotomy), functional studies with cultured melanocytes, the universality of the association (the C allele associated with lighter colors in individuals from around the world), and the location of the SNP in an important regulatory region of the OCA2 gene all combined to suggest that this hypothesis is indeed true. Although the SNP is only useful for crude predictions (lighter versus darker colors), the founder status of the mutation meant that prediction was suddenly possible for all samples – not merely a small fraction. Indeed, it is likely that some of the previously described SNPs were useful as components of a predictive tool through linkage with this founder mutation. However, others are likely to represent important pieces of the final solution for predicting precise colors and shades with economy and practicality. For example, one of the 33 Retinome™ SNPs (rs1800407) was demonstrated to be a penetrance modifier of the newly discovered founder mutation, and a minimalist set of OCA2 polymorphisms for the "ultimate" in forensics utility (precise color, perhaps pattern as well, for all crime-scene samples) will likely require a composite diplotype system involving the founder mutation and some number of the previously described SNPs in [3] and [23]. This "ultimate" system has not yet been developed, though integration of the founder mutation with those of the Retinome™ system in a newly available forensic service called Retinome™ 2.0 (DNAPrint genomics, Inc., Sarasota, Florida) represents a step toward this goal.

Hair Color

Hair color cannot yet be comprehensively predicted from pigmentation gene genotypes. The iris color polymorphisms just described are not associated with human hair color and association and linkage scans have so far been relatively fruitless in identifying other useful associations ([3]; Zhu G. and Martin N., Queensland Institute of Medical Research, Brisbane AU, personal communication, and T. Frudakis unpublished results). This may be due to the fact that unlike the crudest aspect of iris color – the quantity of eumelanin in the iris – the genetic basis for hair color is a function of significant locus heterogeneity and complex historical origin. However, it appears that red color may be an exception. Valverde *et al.*, [27] was the first to identify MC1R associations with pheomelanogenic red hair color (RHC), and subsequently, several other authors have extended these results to identify what are today called the *RHC* phenotype alleles (all SNPs, Box *et al.*, [28]; Duffy *et al.*, [29]; Smith *et al.*, [30]; Palmer *et al.*, [31]; Box *et al.*, [32]; Bastiaens *et al.*, [33]; Bastiaens *et al.*, [34]; Kennedy *et al.*, [35]; Flanagan *et al.*, [36] and reviewed by Sturm, [37]). The associations are sufficiently strong to enable good predictive power – with odds ratios ranging from 2.3 to over 100 (reviewed in Sturm, 2002; [3]). The United Kingdom's forensic science service (FSS) has condensed the major MC1R red-hair polymorphisms into a 12-marker test that is sold to the forensics community. This test is generally only useful in cases of homozygosity; individuals who are homozygous for any of these mutations, or heterozygous for any two separate mutations (called *compound heterozygotes*) are accurately predicted to be redheaded (accuracy = 96%, from a test with $n = 48$ subjects) and those without a mutation (homozygous wild type) are almost always not redheaded (accuracy = 100%, from a test with $n = 35$ subjects; [18]). Approximately 84% of redheads are detectable by these criteria. Predictive ability is lower in the case of simple heterozygotes (only one mutation present, in the heterozygous state), which is by definition the state in which most of these RHC SNP alleles are expected to be found, in which case 88% are not redheaded while 12% are redheaded ($n = 33$). Indeed,

we might expect that each of these mutations will have varying influences on the phenotype depending on the MC1R context within which it is found, and application of diplotype databases as described for iris color may be helpful in teasing more predictive power.

Other Phenotypes

Databases are not yet available for the direct inference of skin color, but this may change soon. [12] and Bonilla *et al.*, [38] used a process called *admixture mapping* to identify variants in the OCA2, MATP, ASIP, and TYR pigmentation genes associated with skin color in a manner that is independent from their ancestry information content. None of these appear to be strong enough to enable accurate prediction, but [19] convincingly described additional variants of the SLC24A5 gene that underlie additional variable skin pigmentation in humans (as well as other vertebrates). Diplotypes involving SNPs in these five genes may be sufficient for accurate inference of skin color within the context of the database systems we have been discussing, though such as database has not yet been constructed. Promising markers for human stature have also been identified in the RUNX2 gene [20] and RANK gene [21], but its unclear whether these two genes are sufficient for predicting this phenotype (especially since environment is likely to play such a role) and RUNX2/RANK variant databases for this phenotype have also not yet been constructed.

Ethical/Procedural Issues and Case Studies. Were the STR profile for each of the world's human inhabitants deposited into an international forensic DNA database, there would be no need to infer phenotype from crime-scene DNA since we would always be able to achieve a database match. Owing to ethical and procedural concerns, this is unlikely to come to pass in the foreseeable future. The ethical issues surrounding the inference of phenotype are extensively covered in [3], but for our purposes here, we can simply note that there is not a fundamental difference between learning about phenotype from human eyewitnesses versus DNA, except when DNA is available, it is more likely to provide reliable and falsifiable information. At some point, ethicists that decry the use of DNA for predicting phenotype as part of the investigative process will have to choose between the rights of DNA donors to remain anonymous and uncharacterized and the rights of future victims of these donors not to be future victims. Phenotype profiles may cause the inclusion of innocent individuals into suspect pools, which would cause inconvenience to these individuals but not increase the likelihood of a false conviction (their CODIS profile must still match that of the crime-scene sample, the probability of which is not reasonably a function of whether or not they are tested using the current state-of-the-art CODIS assays, and is irrespective of their phenotype). It could be argued that many such individuals would or should become suspects for other reasons – such as a life of crime, proximity to the crime scene and/or relation to the victim – and that information about phenotype merely hones attention to a subset of these individuals. Indeed, many investigators consider these other reasons adequate priors (bases) on their own for defining who is and is not of interest in an investigation and honing attention to a subset of them with DNA-based phenotype information could reduce unnecessary inconvenience for many not fitting the phenotype "profile". Notwithstanding, weighted against the death of innocent victims that could be caused by not applying intelligence provided by DNA-based methods, inconvenience caused to innocent individuals subsequently proven not to match the CODIS profile of a given crime-scene sample pales toward insignificant in comparison. Indeed, we seem to have made the decision to use physical information to shape investigations already – as it pertains to human eyewitness testimony; even with all of its pitfalls, its subjectivity, and poor performance rate, eyewitness testimony currently represents one of the most important cornerstones of the investigative process. The use of DNA-based methods promise only to improve this performance using DNA as an additional and/or alternative source for information, at least for cases where DNA is available. Even so, ethicists have complained that DNA-based phenotyping methods are akin to "racial profiling", but the difference between using physical information gleaned from a crime-scene specimen and "racial profiling" is the application of falsifiable science rather than prejudice. For example, focusing on an individual based on information extracted from a crime scene is an exercise based on evidence and data and the conclusions are falsifiable by other laboratories. In contrast, focusing on an individual based on a belief

that individuals of "group X" are more likely to be criminals – lacking specific data derived from a crime scene – is based more on prejudice and subjectivity than the scientific method and generally speaking, such correlations are not adequately powerful in a predictive sense to constitute meaningful priors when determining the likelihood of an individual's involvement in a crime.

The methods described in this article have been applied to numerous criminal investigations. The first application of the indirect method was for the Louisiana Multiagency Homicide Task Force Investigation (Louisiana Serial Killer Case) in the spring of 2003 [3, 22]. Investigators had adequate DNA from various rape/murder scenes throughout the state, but without a CODIS match, they were forced to target their investigation based on two eyewitness accounts that subsequently proved irrelevant to the case. Over a year passed with the task force looking for a "Caucasian" male (not only with standard investigative practices but also with DNA sampling dragnets) until a 73-AIM version of the DNAPrint 176-AIM genomic ancestry panel described in this article (which was also sold under the trade name DNAWITNESS™ as version 2.0) was applied and indicated that the donor was an individual of primarily African ancestry (85%) with a small amount of Indigenous American admixture (15%). In this particular case, the lack of European admixture was used to infer a relatively dark skin shade with respect to the average African-American in the United States (Figure 5a). The investigation was refocused with this data and within a couple of months, the newly refocused investigation lead to an ex-con in the area fitting this profile whose CODIS STR profile was subsequently matched to the crime scene. Were it not for the application of the phenotyping methods, the investigation would have continued on its misdirected path, and others would likely have been raped and murdered [22].

Another murder case in Napa California was initially focused on Hispanic suspects based on an eyewitness account. Napa detectives applied the 176-AIM panel discussed in this article and obtained a continental admixture result that was found from DNAPrint genomics' DNAWITNESS 2.5 database to be consistent with individuals of Continental European as well as Middle Eastern descent – not Hispanic. They then applied the DNAPrint Eurasian panel of 320 AIMs and the RETINOME™ iris color panel described earlier in this article and learned from database searches that the individual was most likely of Northern European ancestry and of light-colored irides. The investigation was focused appropriately, and the perpetrator of the crime in this particular case (who was of Northern European descent with blue eyes) was eventually identified and linked to the crime scene via the CODIS profile. As with human eyewitness data, DNA-based phenotype information does not always result in quick arrests of course, and of the hundred or so investigations that have employed the methods described herein, the majority remain open. However, even for these cases, investigators have saved money and time that would have been spent investigating individuals with phenotypes very different from the crime-scene DNA donor.

To advance the field, the SNP and AIM associations and databases currently available need to be amplified so that an inference for every sample can be obtained, and more research is needed so that additional phenotypes can be considered. In the near future, this may be an uphill battle, at least in the United States. For example, many US grant-funding agencies have not embraced much of the work described in this article – particularly those associated with indirect methods of phenotype inference and it seems most likely that the task of expanding this field will likely to be left to private enterprise or public laboratories outside the United States. Indeed, the work described in this article was funded with private capital, and though commercial demand for the products has not so far economically justified the investment, the work has at least provided some public service and could prove just as useful for other more commercially lucrative areas of research such as in drug development (where constructing a portrait of an ideal patient for a given drug could have a significant impact on the likelihood of clinical trial success). The institutional resistance in the United States toward the type of work discussed in this article is interesting and deserves some thought here. Some argue that the US justice system is not built for efficiency and is biased toward the interests of the accused. If true, this may explain why US budgets for solving crimes are often limited such that US investigators have difficulty funding basic CODIS processing of their crime-scene samples (which should always be done first since identity testing provides probative, not merely presumptive results). For example, backlogs of a year or more

and anecdotal reports of rape kits stacked to the ceiling awaiting funding for CODIS processing are not uncommon in the United States. For agencies experiencing such backlogs, budget allocation for phenotyping is likely to remain de-prioritized and until phenotyping methods have had more time to penetrate the field through continued demonstration of utility. Until the problems underlying the CODIS backlogs have been solved, the application of DNA-based phenotyping methods is likely to continue on a case-by-case basis, with emphasis on high-profile cases that investigators are under unusual pressure to quickly solve (such as serial homicide cases).

Acknowledgments

I would like to thank all of the volunteers who provided their informed consent to be part of our forensic databases here at DNAPrint genomics, Inc.

End Notes

[a.] Though, since all loci carry some ancestry information, calculations on the statistical certainty of such a match requires the use of appropriate population databases since they are based on allele frequencies that vary subtly from population to population.

Photography: Marks, Impressions, and Documents

Introduction

Photography plays a pivotal role in criminalistics by providing several key functions including nondestructive methods of detection, recording, preservation, and enhancement of physical evidence. Standard operating procedures for most forms of physical evidence require the evidence to be photographed either at the crime scene or in the forensic laboratory. In many cases involving crime scene investigation, the photographs of physical evidence obtained at the scene become the only form in which that evidence exists. The preservation of perishable forms of physical evidence places a higher emphasis on photographic methods to retain the evidence long after the scene has changed or the physical evidence has perished.

Some forms of crime scene photographs also under go a process of comparative analysis made directly from the photographic source. Evidence such as bloodstain patterns, footwear impressions, fingermarks, toolmarks, and tire impressions all require a forensic examination made directly from the images. These photographs become the primary source [1] of the forensic analysis, and the value of the physical evidence is a function of the quality and accuracy of the photographic evidence.

The application of photography certainly covers a broad range of activities and some specific taxonomy needs to be developed when attempting to model photography's purpose in the forensic sciences [2]. This section discusses the central technical aspects of photography when used in criminalistics. Information regarding basic camera operation or techniques for simplistic recording of items found at a crime scene are not provided in this section. It will, however, examine the aspects of photographing evidence that utilize photographs in the analysis of evidence by forensic criminalists. Aspects including accurate recording methods, specialized techniques, and optical enhancement of evidence are discussed.

Currently, photography can be divided into two separate forms: silver halide (film) photography and digital photography. Both the forms of photography are currently practiced in the forensic science domain and are considered the same in this section. The light-sensitive recording mechanisms are the most obvious differences between each technology; however, camera operation remains relatively the same (with some exceptions).

Digital imaging is a different concept that involves using digitized images on a computer platform and a distinction is made between digital photography and digital imaging. Digital photography is the practice of photography using a digital camera, while digital imaging is the processing or alteration of digital images using image editing software programs or the digitization of a photograph using peripheral computer equipment such as a scanner.

The practice of digital photography and digital imaging are naturally implicit. The application of image editing software (i.e., Adobe Photoshop™) is also an integral element within the overall digital photography workflow. It is important to recognize, however, that the improvement capacity of images using image editing software does not substitute for consistent quality photography techniques at the capture stage.

This section presents information regarding the optical enhancement of evidence in three separate components: (i) maintaining the image integrity, (ii) optical enhancement, and (iii) digital imaging enhancement.

Image Integrity

The debate regarding the legitimatization of digital images in law enforcement and forensic science has been an exhaustive process by several law enforcement working parties, committees, and organizations over the years [3–5]. Legal organizations have generally accepted the new technology and have adopted their own forms of operating procedures when using digital photography. Like all modes of physical evidence, continuity of the evidence is a critical component of the management of the evidence integrity. Photography should be not different to any other mode of evidence and sound procedural policy regarding forensic photography practices should be developed and maintained throughout all the forensic organizations. It is, however, not the function of this section to discuss those procedures.

Image integrity also refers to the ability of the image to represent the aspects of the photographic evidence accurately, reliably, and truthfully. The integrity of the photography evidence is a paramount consideration in criminalistics. The following attributes are considered in relation to image integrity for the photography of physical evidence that requires analysis directly from those photographs. More simplistic applications of photography to record the subjects *in situ* may not require such strict technical parameters.

Dimensional Integrity

The reproduction of three-dimensional subjects into accurate two-dimensional photographs is fraught with difficulty by the very nature of this dimensional transition. The need for accurate dimensional representation is, however, a consideration when examining evidence such as fingermarks, footwear impressions, toolmarks, and bloodstain pattern evidence. Conveniently, these evidence forms are mostly represented as two-dimensional (or very close to it) and photography can reproduce a fair representation in this dimensional exchange (two-dimensions into two-dimensions). Accurate reproduction in this situation is not, however, automatic and requires some technical considerations to exclude the aspects of image distortion. Figure 1 shows four photographs taken of the same subject, a wire frame. It demonstrates how different the same object may be represented in a photograph and the importance of accurate photography. The image in Figure 1(a) has correctly maintained the subject's dimensional integrity, while those in Figure 1(b–d) show keystoning or optical distortion.

Forensic photographs that are used in comparative analysis must maintain the integrity of the subject's dimensional aspects. Images that do not represent the subject's dimensions and shape accurately are considered to be distorted. Image distortion is caused by several visual conditions including: (i) the camera viewpoint in relation to the subject (perspective distortion), (ii) the optical characteristics of the lens (curvilinear distortion), (iii) the dimensional stability of the recording material (film), and (iv) incorrect resizing of images in digital imaging software.

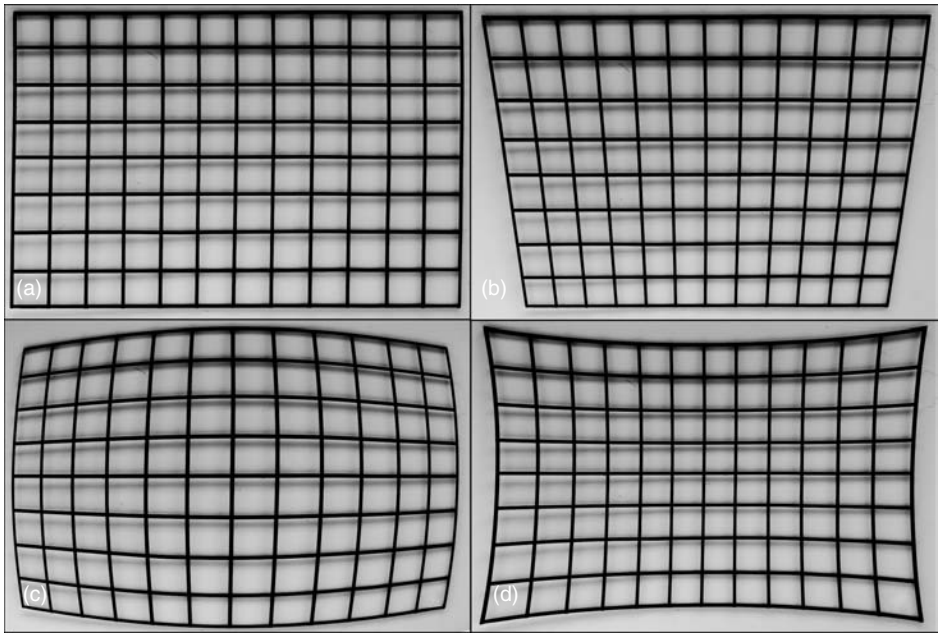

Figure 1 Four photographs of the same object displaying different representations of image dimensional integrity: (a) correctly photographed displaying good image dimensional integrity; (b) image displaying perspective distortion or keystoning; (c) image displaying barrel distortion; and (d) image displaying pincushion distortion

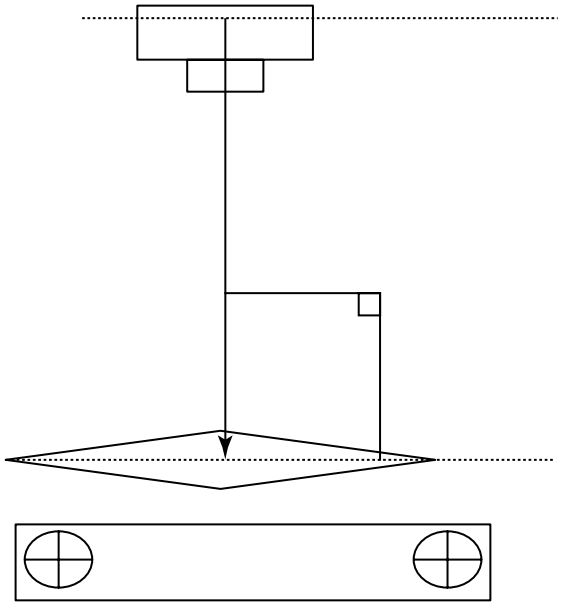

Figure 2 Camera position in relation to the subject. The lens axis is perpendicular to the subject and film planes while the film plane and subject planes are parallel

There are two essential requirements for the successful photography of physical evidence while maintaining the dimensional integrity of the evidence: (i) position the camera correctly to avoid perspective distortion (keystoning) and (ii) always use a distortion-free lens (Hard return). The camera viewpoint must be directly over the subject, which means the lens axis is perpendicular to the subject plane and the camera focal plane and subject plane are parallel [6]. Figure 2 illustrates the camera position in relation to the subject to avoid introducing perspective distortion while maintaining the integrity of the subject's dimensional aspects.

Several lens designs suffer from an optic aberration called *curvilinear distortion* [7], which will also corrupt the integrity of the image dimensional qualities. Curvilinear distortion is often described by the visual result that appears in the image and is referred to as either *barrel distortion* or *pincushion distortion* [8, 9] (see Figure 1). These effects are indicative of their descriptions and are caused by variations of image magnification across the field [1]. Curvilinear distortion can be minimized by using a symmetrical or quasi-symmetrical lens design. Lenses that are significantly asymmetrical in design, such as telephoto and retrofocus lenses, tend to suffer appreciably from curvilinear distortion [8]. Zoom lens are also prone to distortion aberration and generally display pincushion distortion at longer focal lengths and barrel distortion at shorter focal lengths [8, 10]. Lens designs that are distortion free are called *orthoscopic lenses* [8, 11]. A critical aspect of photographing physical evidence and maintaining the dimensional integrity of the evidence is to select a lens that is free from curvilinear distortion.

Macro lenses are designed for photography at shorter working distances than infinity (∞) or for a magnification range of 0.1–1.0 times [12]. They are also either symmetrical or quasi-symmetrical in design and are considered as highly corrected for curvilinear distortion aberration. All photography of physical evidence that requires a high standard of image dimensional integrity should be taken with a macro lens and never with a telephoto, wide angle retrofocus, or zoom lens. This aspect of forensic photography quality is imperative for evidence such as fingermark impressions, footwear impressions, physical fit evidence, toolmark evidence, and other forms of evidence requiring the examination of photographs. This aspect is naturally not as important for general recording of evidence such as *in situ* images at crime scenes. Zoom lenses are very useful for general crime scene photography but not for more critical forensic photography.

Some digital imaging software provides the facility to correct lens distortion. Even though lens distortion may be corrected using digital imaging software such as Adobe Photoshop™ [13, 14], digital correction of this image artifact should only be applied when it is absolutely necessary and should not replace the standard photography practices that avoid lens distortion. Prevention is better than the cure and it is certainly more preferable to avoid curvilinear distortion by using a lens that is considered as distortion free or orthoscopic in the first instance.

Representation of Scale

The incorporation of linear scales into physical evidence photographs is an essential practice when recording evidence. There are various linear scales available for different types of evidence. Linear scales are used as a reference to the size of the subjects photograph and this reference is used to enlarge the photographs to predetermined magnifications for

comparative analysis examination (1 : 1 for footwear impressions, 5 : 1 for fingerprint impressions, etc.). Linear scales are also used to calibrate the scale of digital images when using image analysis applications. Calibration is achieved when the amount of pixels are counted across a known length present in the image. Each pixel then represents a lineal value and several mathematical functions may be applied to the image.

Important considerations when incorporating linear scales include the following: (i) use an appropriate sized scale for the type of evidence photographed, (ii) make sure the scale does not hide the features of the evidence, and (iii) the position of the linear scale must be parallel to the subject and at the same height. Some linear scales also incorporate circular references to detect any perspective distortion that may have resulted from poor photography technique. Digital correction of perspective distortion may also be conducted using Photoshop™ and using the circular references as a standard.

Image Quality

The quality of the image is naturally an important aspect of recording evidence that will undergo further examination and analysis. Image quality for forensic purposes may be defined by several parameters including image sharpness or resolution, detail or clarity, image contrast, color fidelity and dynamic range, and dimensional integrity. Table 1 provides a list of those parameters and also describes what influences these considerations of image quality.

The maintenance of image quality needs to be carefully considered and embedded into the forensic practitioners working practice. Image quality forms a critical basis for forensic photography and is an essential requirement before further optical and digital enhancement techniques may be applied. Digital enhancement is not a correction for poorly executed forensic photography. Evidence enhancement techniques build on the foundation of sound image quality and permit further visualization and the application of forensic evidence.

Table 1 Image quality parameters and their causes

Quality parameter	Cause
Image sharpness and resolution	i) Lens focus ii) Depth of field iii) Camera shake and shutter speeds iv) Quality of optics
Detail and clarity	i) Image sharpness ii) Shadow and highlight detail controlled by camera exposure iii) Lighting technique iv) Color fidelity and tonal range v) Digital workflow
Image contrast	i) Lighting quality ii) Lighting ratios iii) Subject properties (and treatment) iv) Level adjustments (digital photography) or film processing (film photography)
Color fidelity and dynamic range	i) Color temperature balance between lighting and capture source (white balance for digital photography, film, and filter combinations for film photography) ii) Digital photography; color space, bit depth, file applications, and gamma settings iii) Color management and calibration of computer monitor
Image dimensional integrity	i) Camera viewpoint ii) Optics iii) Application of linear scales iv) Resizing digital images

Evidence Enhancement

The most common rationale to enhance physical evidence is to improve the visibility of the evidence. Contrast between the evidence and background can become problematic when evidence is found on items that are of similar color or tonal value. Increasing the difference of brightness values between the evidence and the background provides an increase of contrast. Evidence deposited onto material with complex patterns can also lower the visibility of the evidence and cause problems with interpretation of the evidence. An optical enhancement example is found in the two crime-scene photographs (Figure 3).

The photograph in Figure 3(a) is a bloodstained footwear impression made on a black ceramic tile found at a crime scene. This image displays very little visibility and contrast between the bloodstain impression and the black tile background. Figure 3(b) is the same footwear impression that has undergone chemical and optical enhancement to increase the contrast and improve the visibility of the evidence. The bloodstain footwear impression was first treated with a blood reagent called *Hungarian Red* and photographed using a monochromatic light source of 530 nm. A Wratten 25 barrier filter was attached to the camera lens.

Evidence enhancement may be achieved by using the following methods:

- chemical treatment (development or staining);
- optical enhancement;
- specialized lighting techniques; and
- digital imaging enhancement.

Enhancement may be conducted using a single method or a combination of methods as demonstrated in Figure 3(b). Chemical treatment to enhance or develop physical evidence is a practice that is well established in forensic science. The treatment may independently increase contrast due to chemical staining or it may combine physically with the deposited material and alter the spectral qualities of the material. Optical or photographic enhancement involves various techniques utilizing the optical properties of the evidence material and its relationship to the radiation source and spectral sensitivity

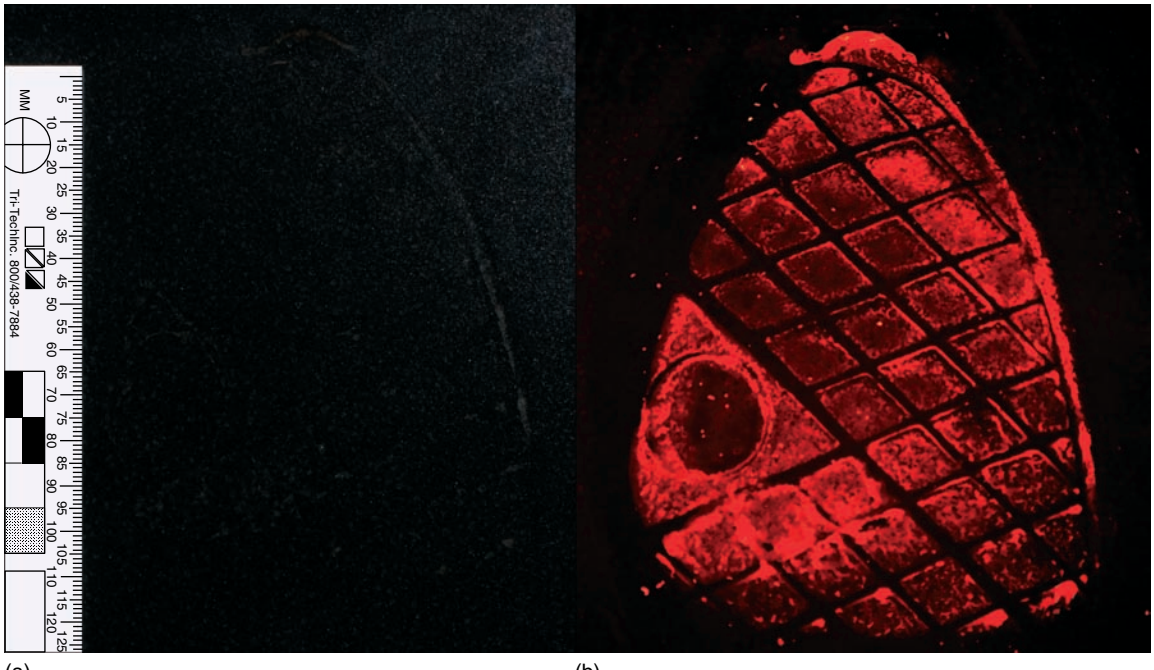

Figure 3 (a) Footwear impression in blood on a black ceramic tile. (b) Same impression treated with Hungarian Red and photographed with a 530 nm monochromatic light source and a Wratten 25 barrier filter on the lens

of the capture device. Digital imaging enhancement also utilizes digital imaging editing software such as Adobe Photoshop™. Optical and digital imaging enhancement are discussed in the next section.

Optical Enhancement

Chemical treatment of physical evidence (i.e., blood or fingermarks) will either stain the material to increase the contrast or make the material react to a light source of specific spectral output. Details regarding the various chemical treatments are discussed elsewhere in this section, however, the reaction of chemically treated specimens to certain wavelengths of light provides the basis of optical enhancement.

Optical enhancement of physical evidence provides the visualization of latent evidence or provides improved visibility by increasing the contrast between the evidence and its background. There are three essential elements that form the foundation for optical enhancement of physical evidence. These elements include: (i) the specific spectral distribution of the light source illuminating the specimen, (ii) the specimen's response when illuminated by the light source, and (iii) the spectral sensitivity of the capture device (film or digital sensor). Each component requires careful consideration when performing optical enhancement of physical evidence.

Spectral Distribution of Light Sources

The approximate spectral sensitivity range of human vision is between 400 and 700 nm, with higher sensitivity within certain ranges depending on the level of illumination. When light enters the eye and forms an image on the retina, nerve cells called *photoreceptors* [15] convert the light energy into a signal that is translated by the mind. There are two types of photoreceptors within the retina called *rods* and *cones* and these receptors react to different levels of illumination. Malacara [16] suggests there are approximately 100 million rods and 5 million cones. The cone receptors are used for bright light conditions and have a sensitivity peak at 555 nm, while the rod receptors provide vision in low light (night vision) and have a sensitivity peak at 505 nm [16–18].

Most digital cameras capture color by using a color filter array positioned over the camera's sensor. This array consists of a mosaic of red, green, and blue (RGB) filters known as a *Bayer filter*. The Bayer filter has twice the number of green filters as red or blue to produce color images that relate to the spectral sensitivity of vision [19].

The spectral output of a light source is called its *spectral distribution* and may be measured using a spectrophotometer. Optical enhancement techniques use various different light sources including natural sources such as direct sunlight and open shade, and artificial light sources such as incandescent tungsten, tungsten halogen, electronic flash, xenon arc lamps, and others.

White light containing a mixture of several colors is considered as a polychromatic light source. Polychromatic light is suitable for most general photography applications and essential for color photography. However, optical enhancement techniques often require a light source with a narrow spectrum or monochromatic light sources [20]. Monochromatic light sources are produced by filtering polychromatic light through an optical filter or filters. Lasers are another source of monochromatic light [21].

Specialized forensic lighting equipment such as the Rofin Polilight™ provides monochromatic light for a range of forensic applications including optical enhancement. These units use a high-intensity xeon light source with inbuilt interference filters to produce monochromatic light with bandwidth of ≈40 nm for most settings. The inbuilt interference filters are also tunable by adjusting the angle of the filter in relation to the transmitting light through the filter. A tuning rate of 30 nm may be achieved with a 45° tilt and the shift is always downtuned toward a shorter wavelength. Figure 4 provides details of the spectral distribution of the Polilight on the 590-nm setting. The monochromatic nature of the light output can be seen by the narrow shape of the spectrum.

Spectral Response of Specimen

Optical enhancement operates on the premise that specimens record in a particular way when they are irradiated by specific wavelengths from a monochromatic light source or transmitted through an optical filter over the camera lens. Optical filtering of the illuminating light to produce a monochromatic source isolates the response from the specimen. These effects can be achieved with polychromatic light sources; however, due to the broad nature of polychromatic

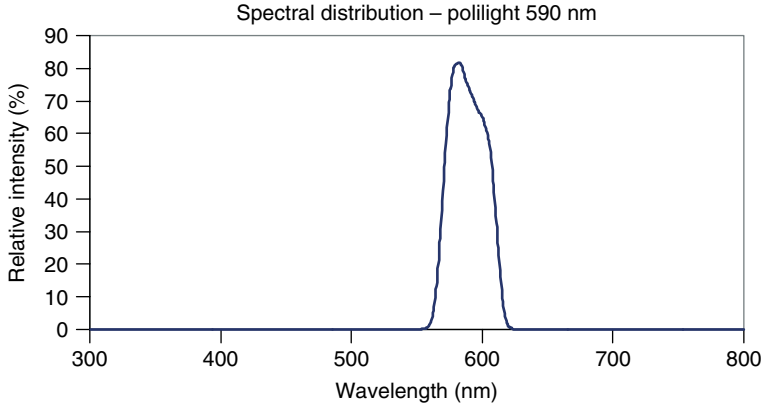

Figure 4 Monochromatic spectra from a Polilight™ forensic light source (setting 590 nm)

lighting, the effects are not seen or are masked by the other wavelengths.

Optical filters placed over the camera lens can also alter the properties of light transmitting through the optical system. Optical filters produce specific spectral responses from the specimen. The application of optical filters on the camera lens allows optical enhancement to be conducted in standard white light conditions, unlike using monochromatic light sources, which will need to be conducted in a darkened room. However, the monochromatic forensic light sources available today provide a narrower spectrum that is difficult to achieve when using a single optical filter over the lens.

Optical enhancement may produce four different conditions or responses from the specimen when illuminated by monochromatic lighting:

- the specimen may *absorb* the light and become darker;
- the specimen may *reflect* the light and become *lighter*;
- the specimen may *transmit* the light and become *transparent*; and
- the specimen may *luminesce* and become *fluorescent*.

These responses to certain wavelengths of monochromatic light may be referred to as *modes of optical enhancement lighting*. These modes may be described as (i) absorption mode, (ii) reflection mode, (iii) transmission mode, and (iv) photoluminescence mode. The purpose of optical enhancement is to make the specimen visible or introduce greater visibility by enhancing the contrast between the specimen and background. When monochromatic light sources are used in the optical enhancement of evidence, natural color rendition of the specimen is not possible due to the specific spectral range of the light used. Strong color casts are produced when using monochromatic light with color photography and this effect should be avoided because it often appears like a photographic error. Digital images photographed in color should be converted to a grayscale image or the color desaturated to – 100%.

Absorption and Reflection Modes. Absorption and reflection modes are chromatic effects that provide an increase of contrast between the specimen and its background. These modes operate on the principle of selective absorption or selective reflection of a colored specimen when illuminated with a specific monochromatic light source (or transmitted via an optical filter). When a monochromatic light source illuminates a color specimen, the specimen will either darken or become lighter in tone depending on the relationship between the color of the light source and the color of the specimen.

Absorption mode is a method of increasing the contrast between the specimen and the background by darkening the tonal value of the specimen or background. Absorption occurs when a colored specimen is illuminated by a monochromatic light that is an opposite color to that of the specimen [20]. The specimen darkens due to its selective absorption properties

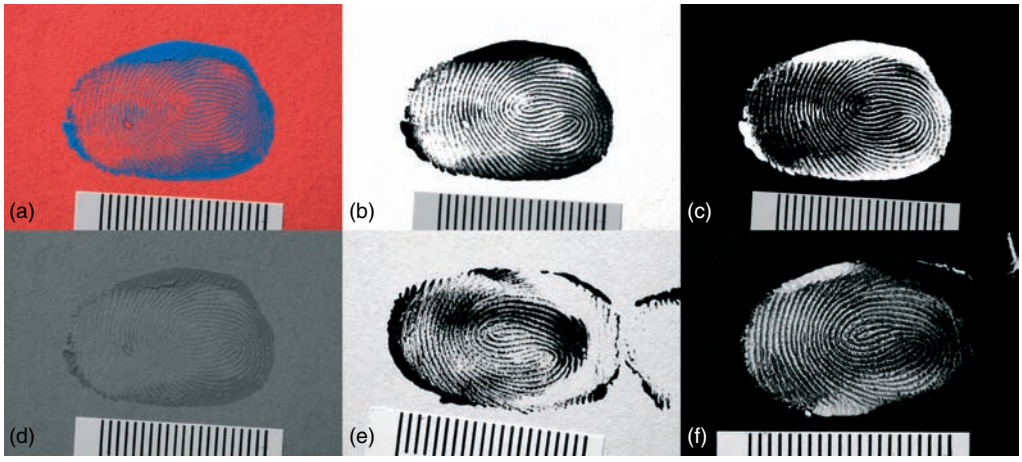

Figure 5 (a) Color image of a fingermark made in cyan-colored paint on a red background. (b) Absorption mode on a red background. (c) Reflective mode on a red background. (d) Grayscale image without enhancement. (e) Absorption mode on white background. (f) Reflective mode on black background

and this mode is most commonly used to increase the contrast.

Reflection mode is also a method of increasing the contrast, however, it lightens the specimen or background by selective reflection. Refection is also a chromatic condition and requires a colored specimen and a monochromatic light source of similar color to the specimen. Figure 5 is a photograph of a fingermark made in cyan colored paint found on a red document. Figure 5(a) is the color image using standard white light (electronic flash), while Figure 5(d) is the same image converted to a grayscale image. Figure 5(b) uses a red monochromatic light (650 nm central bandwidth) and darkens the fingermark due to the absorption of the red illumination. Figure 5(c) uses a blue monochromatic light (450 nm central bandwidth) and lightens the fingermark's tonal value. This series of images also demonstrates an ideal situation for absorption and reflective modes. The color of the background is opposite to that of the specimens. Although this ideal condition is rarely observed in reality, the examples provide an optimum result for this technique.

The general rule for selecting the color of the monochromatic light source for absorption or reflection mode is based on the selective absorption and selective reflection properties of the specimen [20]. It suggests that the color of the light source lightens its own color and darkens its opposing color. Figure 8(a) represents two models of color synthesis that are regularly used in photography and digital imaging. The two models are "additive" and "subtractive" color synthesis. Additive color synthesis uses primary colors such as red (R), green (G), and blue (B). In an ideal condition, if equal quantities of red, green, and blue light are added together, their combination will produce white light [8]. Hence, RGB primary colors are considered as additive and each color ideally represents one-third of the white light (visual) spectrum. The reproduction of color using the three components of red, green, and blue is called *trichromacy* and relates to the function of color vision known as the *Young* and *Helmholtz theory* [8, 15–17].

The subtractive color synthesis model is based on the subtraction of opposing primary colors (called *complementary*) from white light. Therefore, if green is taken out of white light, the resultant color will be magenta. Magenta light is considered as without the green component of white light due to its subtraction. Primary colors may be subtracted from the white light by using the subtractive color synthesis model comprising of the complementary colors, e.g., cyan (C), magenta (M), and yellow (Y). When an ideal complementary filter (cyan, magenta, or yellow) is placed over a white light source, one-third of the spectrum is subtracted (red, green, or blue) while two-thirds is transmitted. Therefore, subtractive color synthesis is a combination of the two remaining primary colors and makes up two-thirds of the

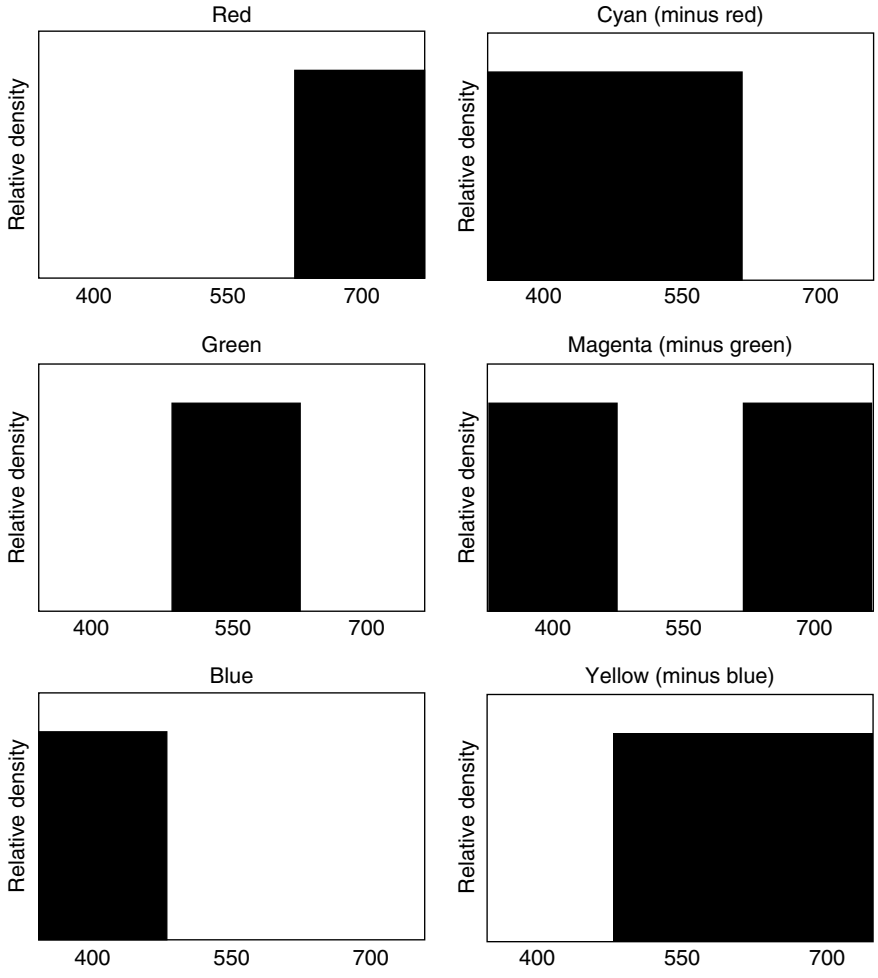

Figure 6 A representation of spectral output from ideal conditions for additive and subtractive color synthesis. The graphs on the left illustrate that each primary color (RGB) produces approximately one-third of the visual spectrum. However, the subtractive model comprising of CMY colors produce two-thirds of the white light spectrum

visual spectrum. Figure 6 illustrates the relationship between additive and subtractive color synthesis models. Each color in the additive color model (RGB) represents one-third of the visual spectrum, while each color in the subtractive model (CMY) make up to two-thirds of the white light.

Additive and subtractive models of color synthesis are also the basis of color film technology and digital imaging color modes [22, 23]. If you examine an image on a color negative film (minus the integral layer which is the amber base color of the film base) you will see that the color image is represented in its negative colors. That is, the reds will be cyan, greens will be magenta, and blues will be yellow. This effect can also be seen if you invert a color digital image. Figure 7 provides an insight into how these two modes of color synthesis are used in photography. The colors rendered in the inverted or negative image clearly show the relationship between additive and subtractive colors in photography.

Digital imaging also uses the same color modeling with RGB color and CMYK color modes. The "K" is an additional channel and represents black. RGB color is the standard for most digital photography applications, while CMYK is a color space often

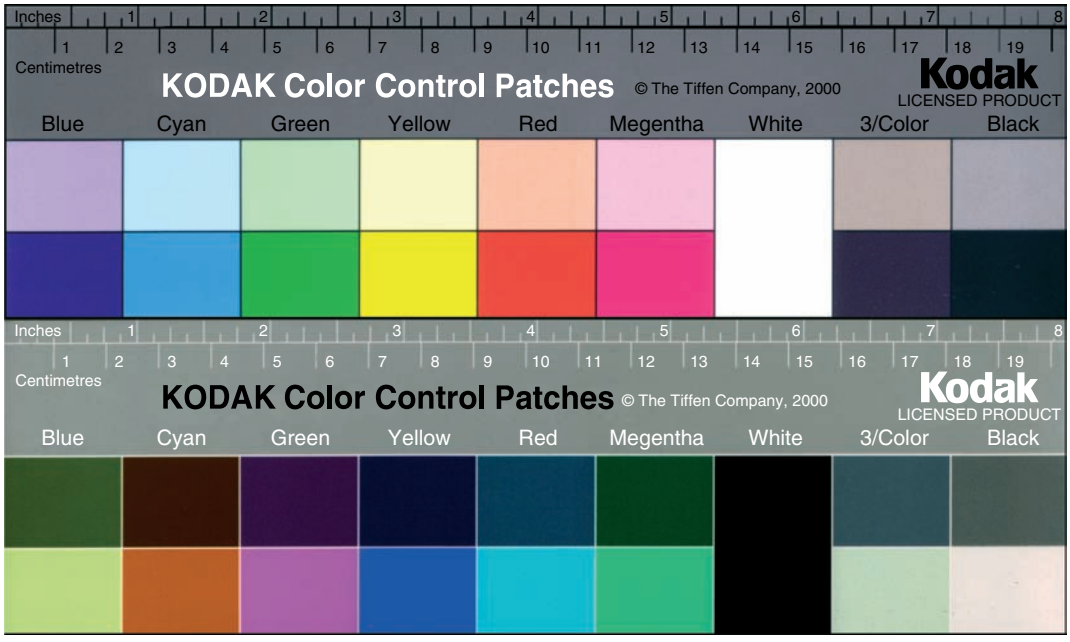

Figure 7 Positive and negative color images displaying the relationship between additive and subtract color synthesis in photography

used for photography used in graphic reproduction (reproduction of images in print media).

Figure 8(a) further displays the relationship between additive and subtractive color models and provides a guide for the selection of monochromatic light for absorption or reflective modes. Each triangle represents a color synthesis model, RGB or additive and CMY (without the K) or subtractive, to produce a color wheel or more appropriately a color star. Colors on the opposing points of the star (e.g., red and cyan) represent opposite colors, while the colors positioned on points next to the additive primary colors are their composites. The opposing colors will provide optimum absorption for specimens and selective monochromatic light sources or optical filters and will darken the specimen. The two adjacent colors next to each opposing color will also darken the specimen.

This diagram forms the basis for absorption mode and the specimens opposing color should be selected as the color of the monochrome light source or optical filter. While absorption mode is usually more effective to enhance contrast than reflective mode, selecting the same color monochrome light source as the color of the specimen will lighten the tonal value of the specimen. Color wheels as illustrated in Figure 8(a) are for photographic applications and are calculated based on the additive and subtractive models of color synthesis of light [22]. Color wheels that are designed for pigments and used in painting and graphic design are not the same and are not suited for optical enhancement or photography.

The color of the background is also a factor to consider when increasing the contrast using absorption and reflective modes. Neutral backgrounds such as white, gray, or black will display little change when illuminated by monochromatic light due to the achromatic (without color) character of these tones. However, if the background is colored, then the same absorption or reflection principles will occur to the background as it does to the specimen. Backgrounds, which are the opposite color to the specimen, have the potential to produce the highest degree of contrast when applying absorption or reflective modes. White backgrounds also work well with absorption mode because the specimen can be darkened against a light background. Black backgrounds work best with reflective mode by making the specimen lighter to enhance contrast. Figure 5(e) demonstrates the results of absorption mode with a white background, while

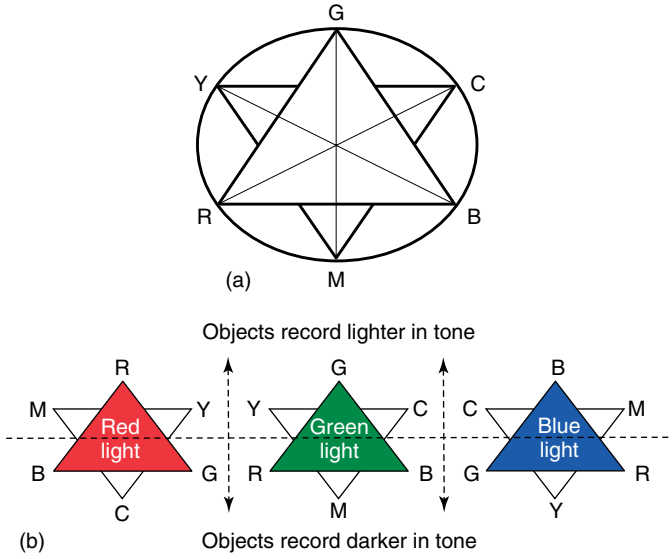

Figure 8 (a) Additive and subtractive color synthesis models demonstrating color opposites; (b) Additive and subtractive color synthesis models demonstrating the tonal changes when using monochromatic light sources. The object colors positioned above the horizontal line will record in a lighter tonal value, while the object colors indicated below the line will record darker in tone due to the absorption of the light

Figure 5(f) illustrates the effect of reflection mode on a black background.

As previously mentioned, absorption and reflective modes may also be achieved by using optical filters placed on the camera's lens and photographed using standard white light. This technique has a long history with black and white film photography. Optical filters, known as *contrast filters*, provide a similar effect as monochromatic lighting, except that the effect is influenced and controlled by the transmission properties of the optical filter with white light [24–26]. Filter factors must also be applied to the camera exposure to compensate for the loss of light caused by the absorption of light by the filter. The application of photographic filters may also be achieved digitally with Adobe Photoshop™. Digital imaging enhancement is discussed in the following section.

Transmission Mode. While an increase of contrast is the objective for absorption and reflective modes of optical enhancement, transmission mode has a different function. The function of transmission mode is to reveal evidence that may be obscured or not visible [27]. It uses the transmission properties of selective wavelengths of light incorporation with the spectral characteristics of the specimen and the spectral sensitivity of the recording medium. This enhancement mode allows the specific wavelengths of light to transmit through thin specimens of specific spectral qualities and renders the specimen transparent [6, 26–29]. When the specimen becomes transparent, items beneath the specimen can become visible. An example is shown in Figure 9 where the obliterated writing on a document has become visible due to the transparent properties of the ink covering the text.

Photoluminescence Mode. When specimens possessing certain properties are illuminated by specific wavelengths of monochromatic light, they may absorb the excitation light and then reemit light of a different wavelength. This effect is know as *luminescence* [29, 30]. There are two different results caused by luminescence: (i) fluorescence that emits light at a longer wavelength while the excitation source is illuminating the specimen and (ii) phosphorescence that emits light and continues to do so for a period of time after the excitation source ceases to illuminate the specimen [29, 31, 32]. The material painted onto watch dials that illuminate in the dark is an example of phosphorescence.

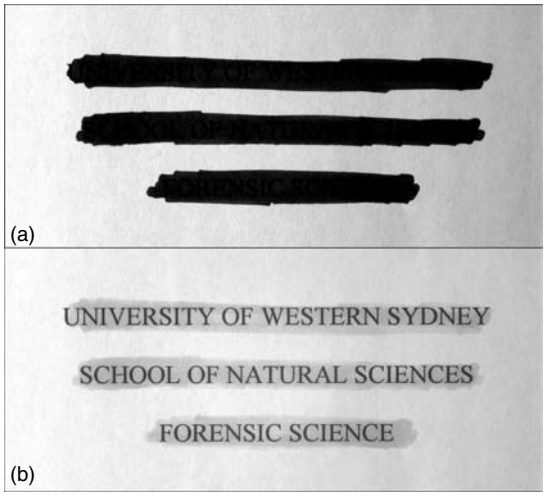

Figure 9 Transmission mode. The ink obliterating the text has become transparent and allowing the visualization of the text beneath the ink

There are also other forms of luminescence such as bioluminescence that is found in several organisms (e.g., glowworms) and chemiluminescence that is caused by a chemical reaction (e.g., luminol) [29]. Bioluminescence and chemiluminescence are caused without the presence of an excitation light source. Lennard and Stoilovic [31] suggest that luminescence caused by the absorption of light is called *photoluminescence* and this type of luminescence is often used in optical enhancement. Bioluminescence, chemiluminescence, and photoluminescence effects can all be photographed; however, due to the low level of light emission, these procedures must be conducted in a darkened environment [29].

Photoluminescence mode enables the specimen to fluoresce and the emitted light from the specimen can be recorded by a camera. Recording specimens using this type of luminescence is also called *fluorescence photography* [29, 32, 33]. This mode requires consideration of all aspects of the optical enhancement triangle including (i) the specific spectral output of the excitation light source, (ii) a photoluminescent response (fluorescence) from the specimen, and (iii) the spectral sensitivity of the recording device (film or digital sensor).

The selection of the specific excitation spectra will depend on the photoluminescent properties of the specimen material. Forensic evidence specimens such as seminal fluid, saliva, and urine fluoresce naturally when illuminated with certain excitation light sources [30, 33]. This naturally occurring phenomena is referred as *autofluorescence* [1, 29] and optical enhancement may be achieved without chemical treatment in these cases and is nondestructive. Other forms of evidence that do not naturally fluoresce (like blood) may be induced to fluoresce by chemical treatment with a fluorochrome [29]. This process is called the *secondary fluorescence* [1, 29] and treatments such as Rhodamine 6G, Indanedione, Diazofluorenone (DFO), and Hungarian Red are some of the common reagents used in posttreatment for photoluminescence mode [34].

Photoluminescence mode is often an alternative to other optical enhancement methods when the background does not suit the absorption or reflective modes. An example may be found in blood evidence. Absorption mode is generally the preferred method for blood evidence using a monochromatic light source at 415 nm, the maximum absorption of dried blood [33]. However, if the blood evidence is deposited onto a dark background, absorption mode will not provide an increase of contrast. Instead, it will darken the blood against a dark background, resulting in very little contrast. Figure 3(b) provides an example of photoluminescence mode for blood evidence.

Excitation ranges for photoluminescence mode vary depending on the autofluorescent characteristics of the specimen or the reagent used for posttreatment secondary fluorescent photography. Most forensic applications use spectral ranges in the lower order including ultraviolet (UV), violet, blue, and green region wavelengths. The resultant emitting light from photoluminescence mode is always longer in wavelength than the excitation source used. Therefore, most photoluminescence applications provide an emission light within the visual spectrum (400–700 nm). Some document examination applications are the exception where infrared luminescence methods produce an emission source further into the invisible spectrum. This method is generally outside the standard photography range and is conducted using specialized instrumentation called a *video spectral comparator* (VSC).

The emission light source produced by the photoluminescence is usually quite weak in brightness value and as previously mentioned requires photography in a darkened environment. Barrier filters are also applied to the camera lens to improve the contrast

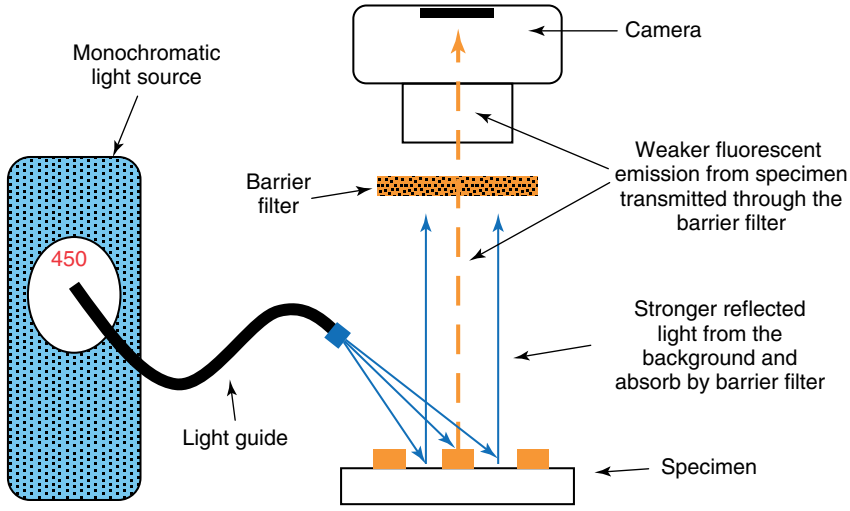

Figure 10 Photoluminescence mode displaying the application of a monochromatic light source, a specimen that fluoresces and a barrier filter over the camera lens

between the specimen and background. The rule for applying barrier filters for photoluminescence mode is to use a filter of the same color as the emission source. This provides maximum transmission of the fluorescence and will also darken any opposing background reflected light. For example, when a blue-colored light source is used to produce an orange-colored fluorescence, an orange barrier filter transmits the orange colored emission and darkens the reflected blue light of the background.

Photoluminescence mode requires the following parameters: (i) an excitation source suitable for the specimen material, (ii) a specimen that provides fluorescence (naturally or induced), (iii) a barrier filter to improve contrast, and (iv) the appropriate spectral sensitivity of the recording device (usually within the visual spectrum). Figure 10 illustrates the requirements of photoluminescence mode. Figure 11 is a fingerprint dusted with a green fluorescent fingerprint powder and photographed using a 540 nm excitation source. Figure 3(b) is a bloody footwear impression treated with Hungarian Red reagent excited by 530 nm excitation source from a Polilight and a Wratten 25 (red) barrier filter on the camera lens.

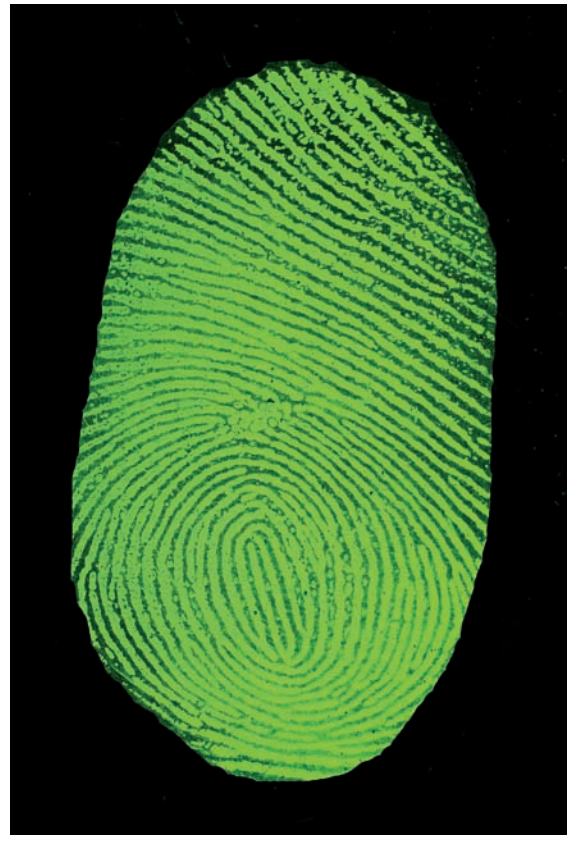

Figure 11 Fingermark using photoluminescence mode

Spectral Sensitivity of Capture Device

The spectral sensitivity of the recording mechanism (digital sensor or film) is the spectral range that the

device or material is able to record. Spectral sensitivity is an essential consideration when conducting optical enhancement methods. The recording device must be capable of recording in the spectrum used in the enhancement method.

The spectral sensitivity of film may be examined using wedge spectrograms. Wedge spectrograms are graphs that plot the spectral response of the film. These graphs are produced by exposing film to a dispersed light that has passed through a diffraction grating and then a neutral density wedge, which is placed on the film's surface.

Tripack color films have a spectral sensitivity range within the visual spectrum (400–700 nm). These films are not sensitive in the infrared region and an UV absorption layer is situated before any of the RGB sensitivity layers which prohibits any recording in the UV region. Generally, color films are not used in optical enhancement techniques. They produce a color cast when using monochromatic lighting or using a colored optical filter and are not sensitive outside the visual spectrum.

Film emulsion is the suspension of silver halides in gelatin to form a light sensitive emulsion. It is naturally sensitive only to UV and blue wavelengths and early film remained only sensitivity in these regions. In 1873, Vogel discovered that film emulsions can be made sensitive to blue and green spectra by adding a dye to the emulsion [8]. This process of dye sensitization was later refined and emulsions spectral sensitivity were extended into the red and infrared spectra. Black and white films are regularly used in optical enhancement and are still available in various spectral sensitivities. There are five classes of black and white films with different spectral sensitivity ranges. These classes are as follows:

- blue sensitive – only sensitive to UV and blue wavelengths;
- orthochromatic – sensitive through to the green region;
- panchromatic – sensitive through to red or covering the visual spectrum up to ≈650 nm;
- extended red sensitivity – extends further into the red spectrum up to ≈750 nm; and
- infrared – sensitive into the infrared region up to ≈900 nm.

For a more detailed examination of the film's spectral sensitivity, consult wedge spectrograms for each film type. Film manufactures readily publish this information with the product description.

The spectral sensitivity of digital cameras is more difficult to obtain from most of the camera manufacturers. There are generally three different types of digital sensors, also called *semiconductors*, used in digital cameras:

- charged coupled device (CCD);
- complementary metal oxide semiconductor (CMOS); and
- Foveon.

Single-shot digital cameras using CCD or CMOS sensors use a Bayer filter, which is a mosaic of RGB filters placed over the pixels. Foveon sensors, however, use a system of three different layers of semiconductors stacked together to form a multilayer sensor. These sensors design replicates that of the tripack color film, which consists of three different color sensitive layers (RGB). Each layer is suspended in a silicon wafer and the longer wavelengths are able to penetrate through the previous layer/s [35]. The advantage of Foveon sensors is that they do not require demosaicing interpolation like systems using a Bayer filter and the physical size of the sensor is not divided by each color channel (therefore, increasing sensor resolution).

Digital sensors have spectral sensitivity characteristics like all the light sensitive devices. CCD and CMOS sensor's spectral sensitivity works very differently to that of silver halide film. While film is naturally sensitive to UV and blue light and is made sensitive to other spectral regions using dye sensitization, digital sensors are more sensitive to the infrared (IR) region with very little sensitivity in the blue and UV spectral regions. The lower sensitivity in the blue region is the cause of higher noise levels found in the blue channel. Digital sensors are monochromatic and color is produced by processing of the image using trichromacy (combination of RGB). To improve chromatic aberration effects on the optics, most digital cameras also place an infrared blocking (absorbing) filter over the sensor to limit the spectral sensitivity to the visual spectrum. The spectral sensitivity of digital cameras is therefore a combination of (i) the spectral response of the monochromatic semiconductor, (ii) the absorption properties of the IR blocking filter, and (iii) the transmission properties of the Bayer filter.

Various digital cameras are available for forensic photography. Excluding the standard low-end consumer compact digital cameras, cameras suitable for forensic photography include: standard digital single-lens reflex (SLR) (pro and proconsumer models), digital SLR cameras with the IR blocking filter removed (modified for infrared photography) and scientific-based monochrome digital cameras. These scientific types of digital cameras provide various ranges of spectral sensitivity and generally publish the response data. Standard SLR camera manufacturers rarely publish the spectral sensitivity data and are generally only considered for applications within the visual spectrum (400–700 nm), although some cameras will perform slightly outside this range.

Specialized Lighting Techniques

Photography readily exploits light and its interaction with the surfaces of objects. The term *lighting* is used in photography as a way of describing the "visual effect" that results when this interaction of surfaces and light energy manifests. Some lighting techniques provide aesthetic elements to a photograph, while some others may enhance aspects of the physical evidence. Lighting may provide a visual representation of shape, line, form, subject texture, detail, aerial perspective, and many more visual aspects [35]. The topic of photographic lighting is an expansive consideration and cannot be fully justified in this section of the text. However, four specialized lighting techniques used for the enhancement of physical evidence are discussed in this section, which are as follows:

- axial illumination;
- near-axial illumination;
- diffuse reflection method; and
- oblique lighting.

Axial Illumination

Axial illumination is the light that illuminates the specimen from the camera's optical axis [36]. This form of lighting produces no shadow visible by the camera and is a form of shadowless lighting. Owing to its directionality, it may be used successfully to photograph specimens in cavities when getting light into small crevices is difficult. Axial illumination is used to detect topographical variances found on flat metal surfaces including coins or medals. It is also a technique that may also be used to photograph untreated fingermarks found on metal or reflective surfaces.

Axial illumination is a similar technique as epi-illumination used in photomicroscopy [18, 36]. This form of illumination is produced by using a collimated (parallel) light source directed onto a thin semitransparent (semisilvered) mirror beam splitter positioned at a 45° to the lens axis [36, 37]. Thin semitransparent mirrors are more suitable than plane glass because the mirror surface increases the illumination efficiency and reduces the double-image effect, which is more visible on plane glass beam splitters. A slight double image results due to the separation between the two surfaces of the beam splitter (front and back). Thicker beam splitters produce a greater shift between each image that makes this artifact more obvious. Other ambient light must also be carefully controlled to avoid extraneous light reflecting off the beam splitter's reflective surfaces. In particular, reflected light transmitting through the beam splitter and illuminating other objects within the room can produce a reflection on the near side of the beam splitter and cause a reflection of the object within the image space. A light absorber such as black velvet cloth should be used to absorb this light (see Figure 12). Figure 12 illustrates the components of axial illumination.

Near-Axial Illumination

Near-axial lighting produces a similar lighting effect as axial illumination. The light source is positioned close to the lens axis [36] producing a light quality that is void of form, texture, and shadow. The intent of near-axial lighting is to illuminate an object or scene evenly. Several portable light sources, including portable flash, may be used to produce this form of illumination. Ring light attachments (see Figure 13) attach to the camera lens and can also produce a diffuse near-axial illumination [36].

Diffuse Reflection Method

When light reflects off a surface, the properties of the surface will affect the type of reflection produced. There are two types of reflected light possible: diffuse reflection and direct reflection [8, 17, 38]. Direct reflection (also referred to as *specular reflection*) results from light reflected off polished surfaces.

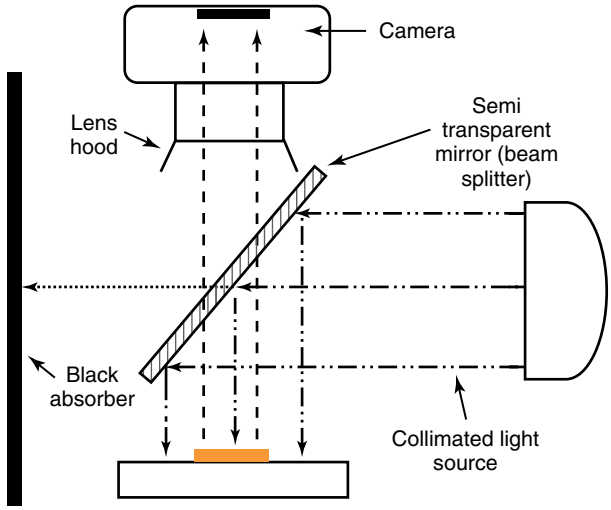

Figure 12 Axial illumination lighting diagram

Figure 13 A ring flash attachment on a digital SLR camera used for near-axial illumination

Direct reflection follows the first law of reflection which states that the angle of incidence equals the angle of reflection ($i = r$) [8, 12, 17, 22].

Diffuse reflection is the scattering of reflected light caused by a matt surface. The uneven nature of matt surfaces reflect the incident light in different directions by maintaining the first law of refection ($i = r$). The effect produces reflected light in multiple directions causing a diffuse effect (see Figure 14b). Diffuse reflection may also be considered as partly diffuse or totally diffuse [22]. Totally diffuse reflected light is perfectly diffuse meaning the spread of reflected light forms evenly across the entire surface. Totally diffuse reflections obey Lambert's law and the surface is considered to be a *Lambertian surface* [8, 12, 22].

Diffuse reflection lighting method exploits the outcomes of both direct and diffuse reflection. Figure 15 is a photograph of an untreated (undeveloped) fingermark on a highly polished flat surface, which is a computer hard drive. This subject produces two different surfaces: the highly polished surface of the hard drive and the matt surface of the fatty deposit of the fingermark. When incident light is applied to both surfaces simultaneously, a direct reflection will be produced off the hard drive and a diffuse reflection from the fingermark.

The relationship between the position of the camera lens, the position of the incident light source, and the position of the specimen are all critical aspects of this technique. Their positions are also interrelated and careful consideration is essential. The camera should be positioned perpendicular (90°)

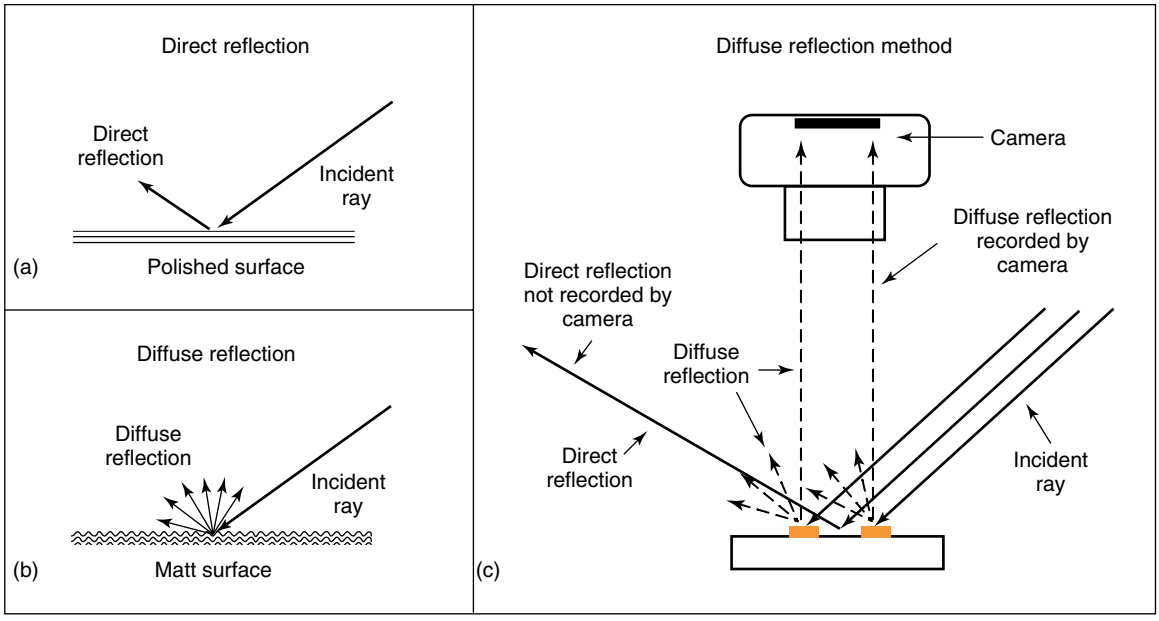

Figure 14 (a) Direct reflection from a polished surface ($i = r$), (b) diffused reflection from a matt surface, and (c) lighting, illustrating diffuse reflection method seen in Figure 15

Figure 15 Untreated fingerprint found on a highly polished computer hard drive and photographed using diffuse reflection method

to the subject plane. The incident light source is positioned at ≈45° angle from the specimen, which will also result in a ≈45° angle from the lens axis (see Figure 14c). The visualization of the fingermark is achieved due to the differences between the reflected light values from the diffuse light reflected from the fingermark and the direct light from the polished surface. Owing to the law of reflection ($i = r$), ≈100% of the direct reflection will reflect away from the camera lens and not record in the camera. This will result in the polished surface having no light entering the camera and producing a dark toned surfaced in the photograph. The diffuse reflection emanating from the fatty deposit of the fingermark will direct some reflected light into the camera lens and record in the photograph. The result is illustrated in Figure 15 whereby the fingermark records a light tone against a dark background. Diffuse reflection method is a simple and effective method of recording fingermarks on polished surfaces without having to treat or develop the mark.

Oblique Lighting

Oblique lighting (also referred to as *side lighting*) is one of the most valuable lighting techniques used

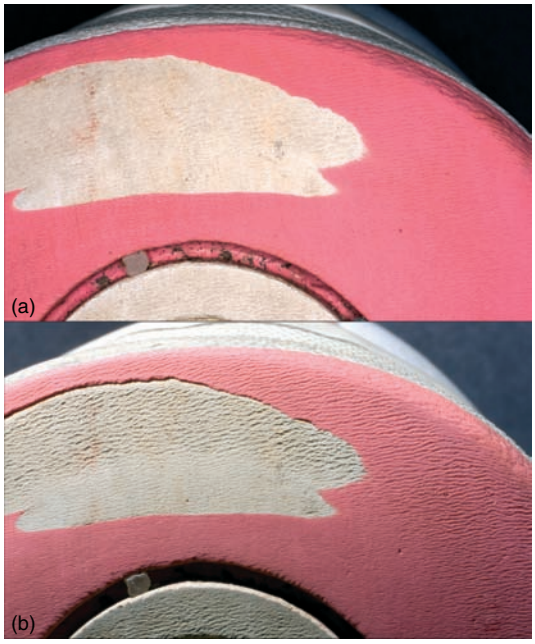

Figure 16 (a) Photograph depicting the heel of a shoe using near-axial illumination (ring flash). (b) Same shoe using oblique lighting. Schallamach patterning becomes more visible with oblique lighting

when photographing mark evidence. Oblique lighting may provide a significant increase in detail and provide the visualization of individual identification characteristics that may be crucial to the examination. Oblique lighting is achieved by positioning the light source at an oblique or low angle to the specimen. The lighting direction runs across the surface of the specimen and essentially increases the local contrast or variations of highlight and shadow on the surface of the specimen. This effect increases the topographic detail and provides further visual information to examine.

Figure 16 provides an example of the differences between oblique and near-axial illumination. The Schallamach patterning found on the heel of a shoe is greatly emphasized by oblique or side lighting. Figure 16(a) was photographed using a near-axial portable flash, while Figure 16(b) uses oblique lighting. Oblique lighting has increased the local contrast on the surface of the heel making the Schallamach pattern more visible.

Digital Imaging Enhancement

Digital enhancement of physical evidence is the application of computer software to make adjustments to digital images of evidence. Digital enhancement provides several similarities to the techniques used in digital photography and optical enhancement. The most significant advantage digital imaging has provided forensic science is its ability to make fine adjustments to image parameters such as contrast, color, sharpness, image noise, and many other adjustments. Items in images can also be quantified by counting, measuring, and making mathematical calculations using image analysis applications. The advantages of digital imaging for forensic science are expansive. This section examines two common practices of digital enhancement using such controls as contrast and the chromatic modification of specimens.

Digital enhancement of physical evidence should not be considered as a process of correcting poorly executed digital photography. Digital enhancement of evidence requires the input of quality digital photography and the enhancement techniques provide further tools for the forensic scientist. Concepts of quality include sharpness, image dimensional integrity, lighting, exposure, and dynamic range.

Digital images record brightness linearly unlike film which responds to light nonlinearly [39]. Film's nonlinear response to light may be seen in the "S"-shaped characteristic curves that plot their exposure and density parameters. Obtaining quality digital images with a higher dynamic range is preferable when performing digital enhancement. Essentially, the more inherent information the digital image contains, the more control image enhancement offers. Best practice suggests digital images should be captured (camera or scanner) using a 16 bit (or a 14 bit for some cameras) and RAW images are better processed using Photoshop processing appliances such as Camera Raw™ than in-camera processed JPEGs.

Compression applications such as the JPEG captured and processed in-camera at an 8 bit offers significant less information and enhancement control. Digital enhancement processing in Photoshop should also be carried out using the 16 bit per channel for improved results [13, 19]. There is a significant difference in pixel depth between 8 and 16 bit per channel modes. The 8 bit per channel provides 256 variations per channel that results in approximately 16 million possibilities for RGB files. While the

16 bit per channel images contain 65 536 variations for each channel and results in billions of color and tonal representation possibilities.

Contrast Adjustment

Digital imaging can provide adjustments to image contrast with significantly more control and ease than more traditional film-based technology. Visualization of evidence is predominately made possible by the contrast between the evidence and its background. Fingermark evidence is a good example and is most reliant on contrast between the friction ridge detail and the substrate background. Like optical enhancement, digital imaging enhancement using contrast adjustments in Photoshop is an effective method of improving the detail and visualization of evidence.

There are various methods in Adobe Photoshop™ that allow contrast adjustment. The most suitable method is using the "curves" function located in the "Image > Adjustments > Curves" menu. In Photoshop versions greater than CS3 the exposure histogram is also embedded into the curve graph. Figure 17 is an example of how curves may adjust to the contrast of the specimen. The image is of a fingermark on a glass window and developed in black powder. To avoid specular reflections, the fingermark was the photograph using brightfield illumination that combined a small sheet of white Perspex situated behind the fingermark and a portable flash positioned behind the mark was used as the illumination source. The original image displayed high levels of detail but with low contrast and the contrast was enhanced using the "curves" adjustment. The inserts situated in each image provide details of the before and after curve adjustments.

The first graph shows a straight line (curve) diagonally across the graph which represents the linear nature of digital images. The gradient of the curve influences the degree of image contrast. The greater the gradient (more steeper the curve) the less variation there is between certain sections of the shadow and highlight regions resulting in more image contrast. Lowering the gradient (flatter curve) reduces the contrast. The second insert found in Figure 17 shows an increase in the gradient of the curve that has resulted in the increase of contrast. The shadow and highlight regions were also "clipped" slightly which also added to the contrast improvement. Contrast enhancement adjustments using "curves" may be conducted in each channel separately or as an alpha channel indicated as "RGB".

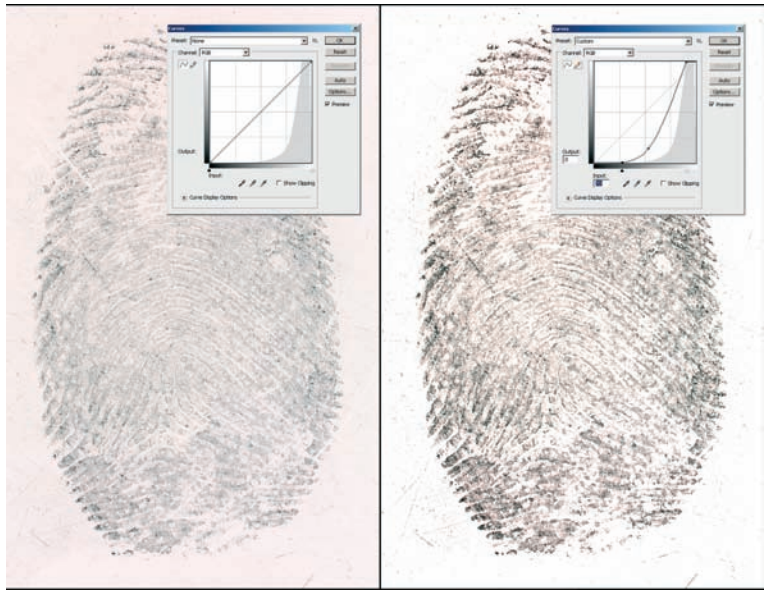

Figure 17 Before and after fingermarks when contrast is enhanced using Photoshop curves

Chromatic and Tonal Modification

Adjustments to the spectral response of color may also be modified in digital imaging software in a similar way to optical enhancement techniques. When working with Adobe Photoshop™ there are always several different methods to obtain the same or similar result. Changing the chromatic aspects of specimens can also be achieved using several Photoshop functions; however, the "Black & White" adjustment is most likely the simplest. The "Black & White" adjustment automatically converts the image to a monochrome image while maintaining the file in RGB mode, so that modification of the colors, now tones, can be adjusted. As previously explained, when using optical enhancement techniques using monochromatic lighting or colored optical filters over the camera, the image should be converted to a monochrome image to avoid color casts.

The "Black & White" function can be found on Photoshop versions higher than the CS3 and work on the principles of black and white contrast filters (see optical enhancement). It may be found on the Photoshop menu "Image > Adjustment > Black&White". Like contrast filters used on the camera with monochrome film, the "Black & White" function alters the brightness of tonal values by altering the spectral reflective and absorption properties. Logically, the digital imaging application is altering the spectral response artificially by adjusting the brightness values of each color and its resultant tonal value in monochrome (unlike optical enhancement). The "Black & White" function provides individual darkening or lightening of the following colors; red, green, blue, cyan, magenta, and yellow. These are the colors previously mentioned in the additive and subtractive models. There are three options when operating this function: (i) the custom option which uses slider bars to modify the tonal value of each color, (ii) use preset filters in the drop-down box, and (iii) develop your own presets. The custom function offers more control over the tonal values of each color and is considered more suitable for evidence enhancement. The image must be in RGB mode to operate "Black & White" and it does not operate in grayscale or CMYK modes. As previously mentioned, working with 16 bit per channel images provides a distinctive advantage for this method due the more subtle changes possible between tonal adjustments.

Figure 18 provides and example of how the "Black & White" adjustments function can enhance evidence by selective contrast variations of tones due to their original color. The blue ink of the stamp was lightened by moving the blue slider bar to the right to increase its brightness value. The red ink of the handwriting was darkened slightly by moving the red slider bar left or lowering the brightness value of the red color. The result is a remarkable difference in contrast difference between the blue and red inks and the blue stamp has almost disappeared. The signature can now be examined without the interference of the overlaying blue stamp.

The Black & White function is also useful for removing colored backgrounds that interfere with developed fingermarks. Figure 19 is a ninhydrin

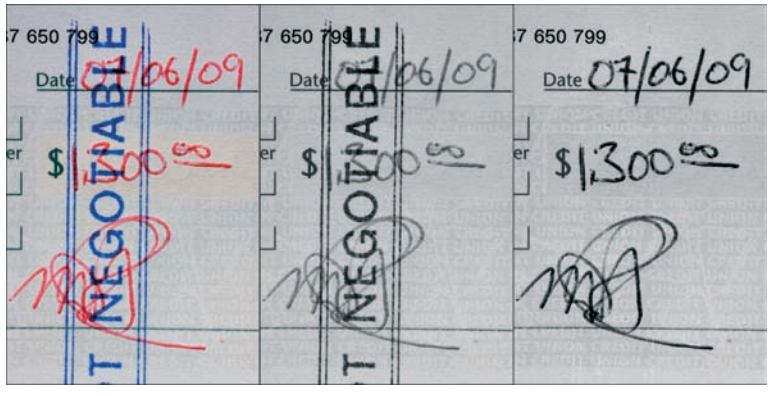

Figure 18 The handwriting on the bank check was written in red ink. The blue stamp has obliterated components of the signature and check amount. The Black & White adjustment has lightened the blue stamp and darkened the writing slightly to increase the contrast between the two inks (stamp and pen)

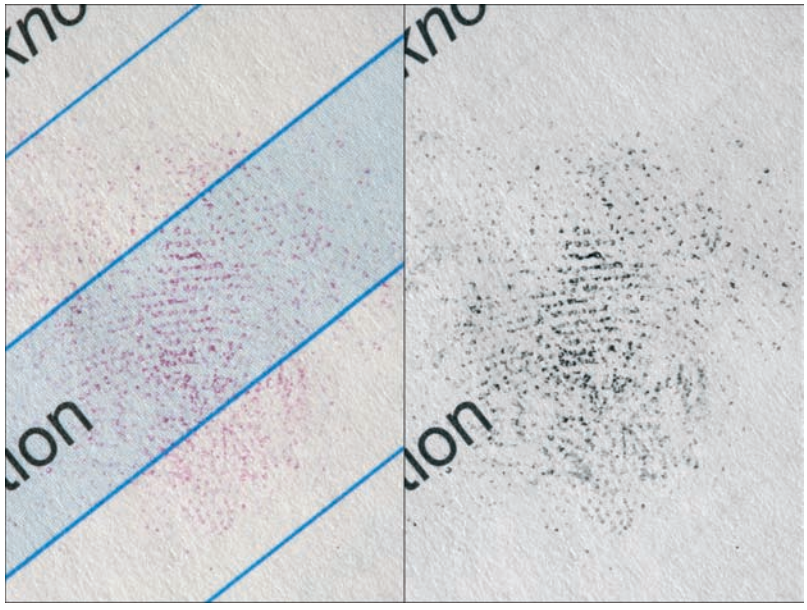

Figure 19 (a) Color photograph of a ninhydrin developed fingermark; (b) The same fingermark with the blue lines and blue area of the document removed and the ninhydrin fingermark darkened

developed fingermark on a document with strong blue lines and blocked sections of blue. The blue lines and blue background were removed using the "Black & White" filter application and the magenta color of the ninhydrin print darkened to enhance the contrast between the fingermark and the background. This process takes approximately 20–30 s to complete once the image is loaded into Photoshop™, making it a highly efficient method of evidence enhancement.

Poisons: Detection of Naturally Occurring Poisons

Introduction

A large number of plants produce compounds that may cause serious illness, injury, or even death. Some plants contain toxic compounds in all parts, whereas other plants are poisonous in some parts and edible in others. Examples include potatoes and tomatoes, which contain toxic alkaloids in the green parts of the plant, but these alkaloids are not present in the ripe potato tuber and tomato fruits.

A comprehensive list of toxic plants is not possible because of the large number of poisonous substances. Although many plants contain toxic substances, only a few species cause poisonings in humans. The actual

number of cases of plant poisoning is hard to determine. Even the numbers of fatal poisoning by plants is not always very obvious. Severe or even deadly poisonings with plants are relatively rare; the frequencies and the plants involved are regionally different.

A published report of the Poison Information Centre in Chile showed that only 0.43% of the medical consultations from January 1998 to June 2000 were with respect to intoxications with plants or mushrooms [1]. Compared to Chile, the Poison Information Centre of northern Germany reported in 2005 that 12% of medical consultations were related to the use and misuse of plants or plant products. Most of these consultations were due to accidental ingestion of the plant material or the misuse of herbal drugs of abuse [2].

Severe and fatal poisonings by plant materials are very rare.

The Poison Information Center, Mainz, Germany, has recorded 31 severe and fatal poisonings caused by plants from January 1995 to July 2007 [3]. The majority of these cases (55%) were caused by an abuse of plant material; only five cases (16%) were a suicide attempt. A total of 5 of the 31 severe poisonings were recorded as fatal.

A study analyzing the self-poisoning fatalities in rural Sri Lanka from March 2002 to March 2003 has shown that 44 of 198 people died from ingestion of the plant oleander [4]. The higher number of plant poisonings in Sri Lanka compared with other countries may also reflect the availability of drugs or poisons used in suicide attempts.

In Australia, the National Coroners Information Service (NCIS) recorded that 9 persons of 131 400 recorded deaths had died from plant or mushroom poisoning in the period between July 2000 and July 2007 [5]. In general, severe or fatal plant poisonings are not very common and are limited to a small number of poisonous plant species.

Manner of Poisoning with Plants

Unintentional Ingestion of Plants and Plant Material

Unintentional ingestion of plant material not only occurs in children, especially younger ones, but also in adults. It is obvious that the reason for accidental ingestion in different age groups is completely different. Whereas children discover their environment by trying bits of plants that appear attractive to them, adults ingest them accidentally [6].

For children, the attractive parts of plants are mostly fruits and seeds with colorful seed coats. Examples include the fruits of deadly nightshade, which look similar to cherries, and the red seed coats of the yew. In the case of yew, the seed coats are very sweet and are not poisonous, but the seeds inside are very poisonous. Children can also be attracted by fruits that are similar to edible plants. A good example is the fruit of laburnum, which looks like peas or beans.

For adults, the reason for an unintentional ingestion of plant material is usually a mix-up. Poisoning occurs as a result of ingestion of poisonous plant due to confusion. The affected persons are usually looking for alternative sources of food or self-medication with herbal drugs. A common example is the collection of meadow saffron instead of wild garlic. Also the mix-up of mushrooms is very common. Many case reports have shown that the deadliest mushroom is the death cap, which looks similar to edible champignons [7].

Accidental ingestion of plant material is also possible by taking herbal medication that has been either incorrectly prepared or in which the wrong plant material has been used. A common problem is the use of aconitum in traditional Chinese medicine, which can be toxic when prepared incorrectly.

Intended Ingestion of Plant Material

Besides unintentional ingestion of plant materials, plants have always been, and are still, used in homicides and suicide attempts. Historical records show that plant materials have caused the death of many famous personalities. An example is the death of Socrates, which was caused by the application of the plant hemlock [8]. But even today, poisonous plants are used from time to time in homicide cases. However, the suicidal ingestion of natural poisons is more common. In developed countries, drug- or poison-related suicide attempts are mostly in connection with prescriptive drugs. However, case reports describe the use of very poisonous plants like deadly nightshade, aconite, and yew in suicides. These patients are often well educated and know about the toxicity of the plants they use. As an example, one patient was growing aconite in his garden, harvested the root of the plant, and prepared an extract, which he ingested and injected. He had

studied literature about the toxicity of this plant and had even shown the literature to an emergency physician [3].

In rural parts of developing countries, suicidal ingestion of plants is far more common due to a lack of availability of prescription drugs [4].

Ingestion of Plant Material Due to an Abuse

The use of plants and plant material for psychoactive effects has been known and recorded for millenniums. The knowledge of the psychoactive effects and the toxic side effects were extensively observed by shamans and other users and has been passed down from generation to generation. In recent years, the use of herbal drugs for their psychoactive properties has become increasingly popular among illicit drug users. The reasons for this increase are diverse. Some of the herbal drugs are not scheduled, and are generally easily accessible, and are sometimes considered to be safe since they are natural.

The assumption of less toxicity is simply not true. Plants often contain pharmacologically highly active compounds. In addition, using hallucinogenic poisonous plants carries the danger of an overdose. The amount of active ingredients in the plant is strongly dependent on geographical and climate conditions. A consumption of two leaves in spring might be hallucinogenic, whereas the consumption of two leaves in autumn may be fatal [6].

Overdoses due to an abuse of plant materials are often described for plants like deadly nightshade [9], datura [10], and kath [11].

Even a nonoverdose situation might cause dangerous behavior. It is well known that the anticholinergic syndrome triggered by atropine or scopolamine causes hallucinations and dry, hot skin. The drug users therefore try to cool down by jumping into water, risking a death by drowning. Hallucinations can also sometimes cause self-inflected injuries. The NCIS (Australia) recorded two cases of death due to self-induced stab wounds under the influence of magic mushrooms [5].

Description of Selected Plants and Fungi

In the following sections toxicologically important plants and some fungi are described in detail. To avoid confusion, scientific names of the plants are used. The scientific names have the advantage that only one name exists for each plant, whereas the commonly used names may not be unique and can be used for more than one plant. Table 1 translates the most commonly used English names of the plants into their scientific names. In the following sections, selected plants and fungi, which are often involved in plant-related poisonings, are described in monographs. The monographs are listed in alphabetical order of the scientific names of the plants. Figure 1 provides representative photographs of some poisonous plants.

Table 1 List of common names of poisonous plants and their associated botanical names

Common English name	Botanical name
Aconite	*Aconitum napellus*
Angel's Trumpet	*Datura stramonium*
Autumn crocus	*Colchicum autumnale*
Belladonna	*Atropa belladonna*
Castor bean	*Ricinus communis*
Castor oil plant	*Ricinus communis*
Deadly nightshade	*Atropa belladonna*
Death cap	*Amanita phalloides*
Devine cactus	*Lophophora wiliamsii*
Dwale	*Atropa belladonna*
European yew	*Taxus baccata*
Golden chain tree	*Laburnum anagyroides*
Hemlock	*Conium maculatum*
Jimson weed	*Datura stramonium*
Kath	*Catha edulis*
Kava	*Piper methysticum*
Laburnum	*Laburnum anagyroides*
Laurier rose	*Nerium oleander*
Magic mushroom	*Psilocybe mexicana*
Meadow saffron	*Colchicum autumnale*
Mescal button	*Lophophora wiliamsii*
Miraa	*Catha edulis*
Monkshood	*Aconitum napellus*
Naked lady	*Colchicum autumnale*
Oleander	*Nerium oleander*
Peyote	*Lophophora wiliamsii*
Poison hemlock	*Conium maculatum*
Quat	*Catha edulis*
Thornapple	*Datura stramonium*
Wolf's Bane	*Aconitum napellus*
Yaqona	*Piper methysticum*
Yew	*Taxus baccata*

Aconitum Napellus

The herbaceous perennial plant *Aconitum napellus* (Figure 1), known as aconite or monkshood, grows to

Figure 1 Flower and leaves of *Aconitum napellus*

a height of 1 m, and is native to western and central Europe. The English name "monkshood" is derived from a part of the dark blue flower of *A. napellus* that has the shape of a cylindrical helmet. The toxicity of *A. napellus* is mentioned in Greek mythology, where it is described as the first poisonous plant. In fact, aconite is the most poisonous plant in central Europe due to its alkaloid-like aconitine.

All species of the gender *Aconitum* are highly toxic and have been used for many centuries as arrow poison or common poison in homicides. Roots, leaves, flowers, and seeds are all exceedingly poisonous to man and livestock. The main active alkaloid in plants from the genus *Aconitum* is aconitine [6].

An accidental poisoning due to a mix-up with other nutrient plants is quite unlikely owing to the lack of similarity. Also, children are not attracted by the plant very often. However, aconite is a source of many fatal poisonings described in case reports [12]. The most common causes of a poisoning with plant material of the genus *Aconitum* are either a suicide attempt or an incorrect preparation of the plant in traditional Chinese medicine. Aconite is used in the traditional Chinese medicine [13], and can be freely purchased from herbal shops around the world. An incorrect preparation, or a wrong dosage of the plant material, may produce a fatal dose of the toxic alkaloid.

Amanita Phalloides

Amanita phalloides is a deadly poisonous mushroom, commonly known as *death cap*. This mushroom appears after periods of rain from late summer to the end of autumn. Death cap originates from Europe, but can be found worldwide. The fungal fruiting body of *A. phalloides* has a convex yellowish or greenish cap, usually 5–15 cm across. The stem is up to 20-cm long. The flesh of the fruiting body is white. With similarities to champignons, parasol mushrooms, and paddy straw mushrooms, this fungus can be confused with other fungi. The toxicity of *A. phalloides* has been extensively studied since the largest number of deadly mushroom poisonings are caused by this species. All parts contain amatoxins and phallotoxins, and the toxin most responsible for the deadly effects is alpha-amanitin [14]. The peptide alpha-amanitin is a very stable compound and even prolonged cooking or maceration with salt does not decrease the toxicity. The toxin acts by inhibition of RNA polymerase II and therefore blocks protein synthesis.

The lethal dose of amanitin is only 0.1 mg kg^{-1}, which means that a medium-sized mushroom can cause the death of a human. Death caps have been reported to have a pleasant taste, and a mix-up cannot be recognized by the taste. The symptoms of a poisoning with *A. phalloides* are initially gastrointestinal in nature. Colicky abdominal pain, vomiting, and watery diarrhea characteristically start approximately 8 h after ingestion. These symptoms resolve in a period of two or three days, giving the false sign of a remission. After a few days, a hepatic and renal failure causes symptoms like jaundice, delirium, seizures, and coma. Death occurs usually 6–16 days after ingestion of the mushroom.

The treatment of a poisoning with death cap includes gastric lavage, activated charcoal, the correction of metabolic acidosis, and an intravenous antidote treatment with silibinin. Silibinin is extracted from blessed milk thistle (*Silibum marianum*) and is supposed to prevent the uptake of amatoxins into liver cells. In some cases, liver transplants have been necessary.

Atropa Belladonna

The perennial plant *Atropa belladonna* (Figure 2) is commonly known as *deadly nightshade*. Other common names such as dwale, death's herb, or witch berry give an impression of its toxicity and use in the middle age. The toxicity and pharmacological effects of the plant are part of the etymology of the botanical name. The genus *Atropa* is named after the goddess

Figure 2 Berry and leaves of *Atropa belladonna*

Atropos, who is known in Greek mythology to cut the life thread. The species name *belladonna* is Italian for beautiful lady and originates from its historical use of the berry juice by women to dilate their pupils [6].

All parts of *A. belladonna* contain toxic tropane alkaloids. Even though the root contains that highest alkaloid concentration, the most dangerous parts, in terms of accidental intoxication, are the berries because of their attractive look and sweet taste. Besides accidental ingestion, poisonings are reported after an abuse of *A. belladonna* due to the hallucinogenic properties of the tropane alkaloids.

The main alkaloids present in *A. belladonna* are l-hyoscyamine and l-scopolamine. Even though only l-hyoscyamine is present in the plant, l-hyoscyamine is converted to a racemic mixture of 50% l-hyoscyamine and d-hyoscyamine. This conversion is either as a result of extraction or release after ingestion. This racemic mixture is called *atropine*.

Atropine acts pharmacologically via blocking acetylcholine receptors of the muscarine subtype. The blockage of these receptors causes symptoms like tachycardia, dilated pupils, decreased gastrointestinal motility, dry hot skin, and dry mouth due to a decreased sweat and saliva production. Apart from these peripheral effects, atropine also affects the central nervous system and causes agitation, disorientation, and hallucinations [15].

Catha Edulis

The evergreen shrub *Catha edulis*, which is native to tropical East Africa and the Arabian Peninsula, is known as *khat* or *qat*. In these countries, the use of khat for therapeutic and recreational purpose has been an integral part of the local culture for centuries. In the second part of the twentieth century, the consumption changed to an uncontrolled abuse and spread throughout other continents. For example, more than 2300 kg of khat was confiscated at Frankfurt Airport (Germany) in 1998 [16]. This new aspect of khat consumption has raised increased concern in international organizations. In 1980, the World Health Organization classified khat as a drug of abuse that is able to produce dependence.

The main psychoactive alkaloids of khat are cathinone and its metabolite cathine, also known as *norpseudoephedrine*. Cathinone was found to have a pharmacological profile closely resembling that of amphetamine. Cathinone acts as a central nervous system stimulant and shows sympathomimetic effects by releasing catecholamines from presynaptic storage sites. Experiments have shown that cathine acts like cathinone, but is less effective. Both substances are controlled substances in many countries due to khat abuse.

Colchicum Autumnale

Colchicum autumnale is a perennial plant that grows from corms. The most common English names are autumn crocus, naked lady, and meadow saffron. These names represent the similarity of the flower to crocuses. However, this similarity is limited to the appearance of the flowers. In contrast to most other plants, the plant flowers in autumn, long after the leaves have died back, and therefore the English name naked lady. The fertilized fruits emerge from the ground with the new leaves appearing the following spring [6].

Colchicine is the main active alkaloid of *Colchicum*. It is present in all parts of the plant, but particularly in the corm, seeds, and flowers. Colchicine inhibits the function of microtubules and therefore acts as a cytotoxic. It also reduces the activity of leukocytes and lymphocytes. This mechanism of action is suspected to be the reason for its success in the treatment of gout. The plant has been used to treat gout for more than 2000 years. Although colchicine has many side effects, it is still recommended as a treatment for acute gout [17].

Figure 3 Habitus of *Conium maculatum* [Image by Thomas Schoepke – http://www.plant-pictures.com]

Conium Maculatum

The 1.5–2-m tall biennial plant *Conium maculatum* (Figure 3) is known as *hemlock* or *poison hemlock*. The smooth green stem of hemlock is characteristically spotted with purple on the lower half. The leaves are finely divided and the white flowers are small and clustered in umbels. The plant is similar to fennel, parsley, or wild carrot. The root of hemlock, white and fleshy, is often unbranched and shows a similarity to parsnip. The toxicity of hemlock has been known in Greece since 399 BC, as the symptoms of the lethal poisoning of Socrates were described by his pupil Plato. In the middle ages, the medicinal use of hemlock was very limited due to its known high toxicity [8]. *Conium maculatum* is native to Europe but has been introduced and grows as a weed in Asia, North America, and Australia.

All parts of the plant are poisonous. The highest concentrations of the toxic alkaloids are found in unripe seeds, but concentrations vary significantly depending on temperature, moisture, and the season. The main toxic alkaloids of hemlock are coniine and γ-coniceine. The exact mechanism of action of these toxic alkaloids is not known. The primary action is on the central nervous system with symptoms similar to nicotine poisoning. The most common symptoms of hemlock poisoning are problems in movement, dilation of pupils, slow and weak pulse, heavy salivation, and nausea. After a severe poisoning, coma and death from respiratory failure are possible [18].

Figure 4 Flower, leaves, and unripe fruit of *Datura strammonium*

Datura Stramonium

The annual plant *Datura stramonium* (Figure 4), which is often found in nutrient-rich soils, grows to a height of up to 1 m. This plant of the nightshade family is commonly known as *thornapple, Jimsonweed*, or *Angel's Trumpet*. The large flowers of *Datura* are white, erect, and tubular. The tubular shape and its psychoactivity are related to the name Angel's Trumpet. The name thornapple is related to the fruits, which are spiky large green capsules containing numerous black seeds. The plant is distributed generally throughout temperate and subtropical regions. The *Brugmansia* species are similar to *Datura* in botanical appearance and are often cultivated in pots as house plants [6].

All parts of *Datura* and *Brugmansia* are toxic and contain tropane alkaloids. As already described for *A. belladonna*, the main alkaloids are l-hyoscyamine and l-scopolamine. Owing to the presence of these alkaloids, these plants are often abused for their hallucinogenic properties. This increasing misuse has forced a prohibition by law in Florida against planting Angel's Trumpets.

The symptoms of a poisoning as well as the treatment are similar to those described for *A. belladonna*.

Laburnum Anagyroides

Laburnum anagyroides (Figure 5), also known as *laburnum*, grows as a shrub or a small tree. The plant has yellow flowers in pendulous racemes, and therefore it is known in German as "Goldregen", which is often translated as golden rain acacia.

Figure 5 Flower of *Laburnum anagyroides* [Image by Thomas Schoepke – http://www.plant-pictures.com]

Because the plant is attractive and frost tolerant, laburnum is very popular as ornaments in parks and gardens. The fruits are silky hairy pods; the unripe pods are similar to bean or pea pods. The seeds are similar to small beans [6].

All parts of laburnum are toxic and contain quinolizidine alkaloids. The main toxic alkaloid is cytisine, with the highest concentration detected in the ripe seeds and seed pods. Knowing about the toxicity, laburnum has been used in traditional medicine by American Indians, who have consumed the seeds for their emetic effects during rites and magical practices. During the Second World War, the leaves of laburnum were used as a tobacco substitute due to its similar effects. Studies have also shown that cytisine is effective as an aid to smoking cessation [19].

Cytisine binds with a high affinity to nicotinergic acetylcholine receptors. Like nicotine, cytisine acts as a blocking agent on the central nervous system via an overstimulation of these receptors. Owing to the mechanism of action, the symptoms of a poisoning are similar to a nicotine overdose. The central-stimulating effects can cause delirium and convulsions [19]. Death is possible through a respiratory paralysis or failure of the circulatory system. The treatment of a poisoning with laburnum is symptom orientated, with no specific antidote available [6].

Lophophora Williamsii

The small spineless cactus *Lophophora williamsii* is commonly known as *peyote*. This cactus grows extremely slowly and flowers sporadically. It takes in the wild up to 30 years to reach the size of a golf ball and to produce the first flowers. The small pink fruits of peyote are sweet tasting and delicate. The cactus is native to southern United States and Mexico, but is cultivated all over the world.

A recent study has shown prehistoric use of peyote by native North Americans. A radiocarbon study dated dried cacti, so-called mescal buttons, to the time interval 3780–3660 BC. Because in these dated buttons psychotropic alkaloids were present, it was concluded that they were used for their psychoactive effects [20].

The main reason for the psychoactive effects of peyote is due to the presence of the phenethylamine alkaloid mescaline. The effects of peyote and mescaline in humans are well studied. Native peyote cults used the cactus because it produces rich visual hallucinations. These effects were also used in psychiatric studies as a chemically induced model of mental illness. The mechanism of action is similar to that of lysergic acid diethylamide (LSD) or psilocin. These substances act as partial agonists at 5-hydroxytryptamine (5-HT) receptors. Although the acute toxicity of peyote or mescaline is not as high as other herbal alkaloids, fatalities have been described. Owing to the strong hallucinations, fights among drug abusers or self-harm situations are not uncommon.

Nerium Oleander

The evergreen shrub *Nerium oleander* (Figure 6), simply known as *oleander* is native to northern parts of Africa and the Mediterranean region. The scientific name is deduced from their preference to grow near water; Nero is the Greek word for water. The leaves of oleander are thick and leathery, dark green and narrow lanceolate, and up to 20-cm long. The leaves grow typically in pairs or whirls of three. The flowers of oleander are white, pink, or yellow, are up to 5 cm in diameter, and grow in clusters. Even though the flowers of *N. oleander* can be slightly yellow, the so-called yellow oleander is *Thevetia peruviana*. Both oleander and yellow oleander can easily be grown in warm subtropical regions and are extensively used in parks and roadsides worldwide [6].

Both plants are highly toxic and contain cardiac glycosides of the cardenolide type in all parts. The highest glycoside concentrations were detected in the

Figure 6 Flower and leaves of *Nerium oleander*

seeds of oleander, and the main glycoside present in these plants is oleandrin. Oleandrin acts like other cardiac (cardiac) glycosides of the cardenolide type by inhibition of the sodium potassium exchange, which causes an increased calcium level in heart cells, which increases contractions of heart muscle cells. An overdose of the cardiac glycosides causes dysrhythmia and a possible heart block. The first scientific study showing the therapeutic usefulness of cardiac glycosides was published in 1785 by Withering [21]. The therapeutic range of the cardiac glycosides is narrow. Many fatal and severe poisonings have been reported after ingestion of oleander or other plants containing cardiac glycosides, such as *Digitalis purpurea* (foxglove), *Adonis vernalis* (pheasant's eye), or *Convallaria majalis* (lily of the valley). The typical symptoms of an overdose with cardiac glycosides are dizziness and vomiting, followed by cardiac arrhythmias [6].

The treatment of an overdose is dependent on the severity of the poisoning. For treatment of severe poisonings, an antibody-based antidote has been developed to specifically remove the glycosides. In case of poisoning with plants or self-prepared extracts, this antidote is unfortunately poorly effective. The antidote removes therapeutically applied pure glycosides, but it is likely that some cardioactive glycosides are not removed [6].

Piper Methysticum

The common English name for the western pacific plant *Piper methysticum* is kava. Other names for the plant are 'awa', used in Hawaii, or 'yaqona', common in Fiji. Kava is an evergreen bush growing up to 3 min height, with heart-shaped leaves up to 20 cm in length. The plant is closely related to black pepper (*Piper nigra*) and also has a spicy taste. Kava is psychoactive, indicated by the scientific species name *methysticum*, which is Greek for intoxicating. Kava is consumed on many western pacific islands and Australia [6]. Traditionally Kava is prepared by grinding or chewing the rhizome, which is mixed with water or coconut milk. The effects after consumption of kava are talkative and euphoric behavior, anxiolytic effects, sense of well-being, clear thinking, and relaxed muscles. The plant contains a mix of kavalactones and kavapyrones. Extracts of the plant were introduced into modern medicine as a mild anxiolytic. After the report of some deaths due to its medicinal use, kava medicines were banned. Kava-containing medicine causes acute liver failure [22]. The traditional use of kava by Pacific Islanders and by some aboriginal communities is not believed to be associated with liver damage. A recent study has shown that kava feeding in rats does not cause liver damage [23]. Further investigations are necessary to demonstrate the long-term safety of kava preparations.

Psilocybe Species

The small brown mushroom genus *Psilocybe* sp is best known for their psychoactive properties and are therefore called "magic mushrooms". The fruiting bodies of the magic mushrooms are small to medium in size and typically show a brown coloration. Hallucinogenic species of *Psilocybe* can be found in temperate regions throughout the world [24]. The psychoactive species contain as active ingredients psilocin and psilocybin. These compounds are structurally related to serotonin, a neurotransmitter in the central nervous system. Psilocin and psilocybin cause effects like the synthetic drug of abuse LSD. The effects of intoxication with magic mushrooms are mainly hallucination; the acute toxicity of the compounds is low. However, the consumption of these compounds is dangerous. Severe hallucinations can cause self-inflected injuries. Deaths due to self-induced stabbings following consumption of magic mushrooms have been recorded [5]. Two patients died from the wounds after they had stabbed themselves in the chest while under the influence of magic mushrooms.

Figure 7 Leaves of *Ricinus communis*

Figure 8 Fruit and leaves of *Taxus baccata*

Ricinus Communis

Ricinus communis (Figure 7), the castor oil plant, is cultivated all over the globe for oil production. The annual bushy shrub is believed to have its origin in tropical Africa, but grows nowadays worldwide. The plant with glossy palmately divided leaves is often used for ornamental purposes in gardens. The fruit of *R. communis* is a soft, spiny capsule with three almost oval seeds, which are the so-called castor beans. The attractive seeds have a hazelnut-like taste and contain 45–55% of fatty oil. The seeds also contain up to 25% protein. The protein fraction contains the highly toxic lectin ricin, which is poisonous via ingestion, inhalation, or injection. Ricin acts via an inhibition of protein synthesis. As a lectin, it binds to glycoproteins, facilitating the entry of the toxin into the cytosol [25].

After ingestion of ricin, the symptoms are nausea and diarrhea. In severe poisonings, liver and renal dysfunction, and possibly death, occurs. After inhalation, coughing and dyspnea can occur. These symptoms can progress to respiratory distress and death. The injection of ricin causes symptoms of general weakness and myalgias. Death is possible due to hypotension and multiorgan failure.

Ricin poisoning is possible by accidental or suicidal eating of the seeds. After oral ingestion of the seeds, the toxicity depends on how well the seeds are chewed. Some factors make the castor beans dangerous, such as their attractive appearance and the stability of ricin toward proteolytic enzymes. The treatment of a poisoning with ricin is recommended to be symptomatic. No specific antidote for ricin poisoning is available [25].

Taxus Baccata

The conifer *Taxus baccata* (Figure 8) is widely known as yew, and is often considered to be the oldest plant in Europe. The age of some yew trees is estimated to be 5000 years. The plant is a small to medium-sized tree, which grows relatively slowly. The leaves of this conifer are dark green and lanceolate, with a length of up to 4 cm. The plant has very characteristic single seed cones surrounded by a bright red colored berrylike structure, called an *aril*. All parts of the plant are highly toxic, except the arils. This enables the cones (including the arils) to be eaten by birds, but the seeds remain undamaged in the bird's droppings. The plant contains pseudoalkaloids of the taxane type. The main compound responsible for the toxicity of the European yew (*T. baccata*) is taxine B [6].

Some taxane-type pseudoalkaloids are also important in the treatment of cancer. In recent years, Taxol®, which contains paclitaxel, has become of particular interest in the treatment of ovarian, breast, and non-small-cell lung cancer. Paclitaxel has been isolated from the Pacific yew, *Taxus brevifolia*. Because of the extensive use of Taxol® and the fact that more than 1000 trees are needed to obtain 1 kg of paclitaxel, pharmaceutical companies have found an alternative source of the drug. A precursor of paclitaxel is isolated from cultivated European yew plants, and paclitaxel is synthesized using this precursor. The mechanism of action of taxanes is an inhibition of cell division by stabilization of the microtubuli. Therefore, these substances have cytotoxic effects.

In the case of an overdose with yew plants, the symptoms are nausea, dizziness, abdominal pain,

shallow breathing, and tachycardia. Death can occur as a result of respiratory paralysis, with the heart in diastolic arrest. The treatment of a poisoning with yew is symptomatic, with no specific antidote available [6].

Analytical Methods

Because of the diversity of the toxic compounds in plants and mushrooms, a general laboratory screening procedure is not possible. Therefore, various specific methods for detection have been developed. Table 2 summarizes the major active compounds and the most common detection methods of the plants described in this article.

Table 2 List of botanical names, the corresponding main toxic compounds, and the common detection of these compounds in biological fluids

Scientific name	Main toxic compound(s)	Common detection in biological fluids
Aconitum napellus	Aconitine	HPLC, LC-MS
Amanita phalloides	Amanitine	Immunoassay, LC-MS
Atropa belladonna	Hyoscyamine, scopolamine	GC-MS, LC-MS
Catha edulis	Cathinone	GC-MS, LC-MS
Colchicum autumnale	Colchicine	HPLC, LC-MS
Conium maculatum	Coniine	GC-MS, LC-MS
Datura stramonium	Hyoscyamine, scopolamine	GC-MS, LC-MS
Laburnum anagyroides	Cytisine	LC-MS
Lophophora wiliamsii	Mescaline	GC-MS, LC-MS
Nerium oleander	Oleandrine	Immunoassay, LC-MS
Piper methysticum	Kavaine	HPLC
Psilocybe mexicana	Psilocin, psilocybin	GC-MS
Ricinus communis	Ricin	Immunoassay
Taxus baccata	Taxine B	LC-MS

Methods for detection of naturally occurring toxic compounds include high-performance liquid chromatography (HPLC), liquid chromatography mass spectrometry (LC-MS), gas chromatography mass spectrometry (GC-MS), and various immunoassay techniques. The use of HPLC is common for detection of compounds like aconitine, colchicines, and the ingredients of kava. Kavalactones and kavapyrones are commonly used for the detection of aconitine and colchicine. The modern and more sensitive LC-MS techniques have been applied to many naturally occurring substances, especially if low concentrations have to be detected. The use of GC-MS techniques is applicable if the substances are thermostable and provides a powerful tool for detection of alkaloids like atropine, cathinone, and mescaline. While GC-MS techniques are useful, LC-MS techniques are preferred for the detection of low concentrations in blood.

The use of immunoassay techniques is possible for some poisonous compounds of herbal origin. It has been shown that the cardiac glycosides of oleander can be detected using an immunoassay technique for cardiac glycosides. This technique is not able to differentiate between the cardiac glycosides. A differentiation is possible using HPLC techniques. Also the detection of ricin is commonly performed using immunoassay techniques, such as radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA). Owing to the physicochemical properties of the protein ricin, chromatographic techniques are more challenging and cannot at the present time be easily confirmed by conventional chromatographic techniques due to its large molecular size.

Detection methods using immunoassay techniques were also developed for the proof of death cap poisoning. Amanitin can be detected in urine up to 24 h after ingestion by the use of immunoassay techniques.

A postmortem detection of the toxic substances is often challenging. Determination of these is often likely in urine, but for some compounds like colchicine bile is the most useful specimen for postmortem analysis. Some toxins like amanitin are unlikely to be detected in postmortem specimen because death occurs many days after ingestion.

Some substances like psilocin and psilocybin are chemically unstable; hence concentrations need to be interpreted carefully.

See **Toxicology: Initial Testing** for further information on general drug detection techniques.

Summary and Conclusions

Fatal plant and mushroom poisonings are relatively rare. The diversity of poisonous compounds and their widespread occurrence in plants and fungi makes a comprehensive list of dangerous flora impossible. Besides, the majority of fatal cases are limited to a small number of plants and mushrooms. These poisonings can occur either after unintentional or intended ingestion or after abuse for their hallucinogenic effects. While plants and fungi can be dangerous to humans, fatal cases are avoidable. However, the analytical detection of a poisoning from an unknown plant or fungus can be a challenge for toxicologists.

Police Interviews and Interrogations *see* Confessions: Evidentiary Reliability of

Police Use of Force

Traditionally, the hallmarks of policing involve officers responding to criminal and noncriminal calls for police service, detecting and preventing criminal activity, investigating past crimes, and enforcing laws. To carry out these activities, the police have institutional authority to use force. Such authority, power, or legal right comes from rules of law, which recognize that the police must sometimes use coercive action against law-violating citizens to accomplish legal objectives. Because police agency records and published statistics such as the annual figures reported by the Bureau of Justice Statistics consistently show that some citizens are willing to violate the law, use of force by the police remains a central part of their occupation (*see also* **Policing and Critical Incident Teams**).

When the police use force, they have the discretionary power to choose from a range of possible responses available in a given law enforcement activity. Responses can include the police using their presence or show of authority to using deadly force to deal with law-breaking behaviors by citizens. Whenever the police invoke their legal right to use force against citizens, there are court decisions regarding legal standards for making the right force choice.

Courts in the United States, where the use of force by police is subject to constitutional restraints, generally apply three major legal decisions that clarify standards surrounding the appropriateness of police use of force: *West v. Atkins* [1], *Graham v. Connor* [2], and *Tennessee v. Garner* [3]. Under the umbrella of *West v. Atkins*, the police must act under color of law to be liable for use-of-force actions against citizens that amount to violations of police authority. The police must make objectively reasonable use-of-force choices under the *Graham* rules, which include a balancing test, subjective, objective, hindsight, and totality of circumstances tests. If the police decide to use deadly force against law-violators, then the *Garner* rules highlight three conditions in which deadly force may be reasonable: deadly force is necessary, suspects are dangerous, and the police are able to warn suspects.

Standards Governing Acting Under Color of Law

Before courts consider allegations that the police used wrongful or excessive force against citizens, they make legal determinations on whether the police were acting in their official capacity; that is, whether the police used force while "acting under color of law" whereby they exercised a power or right granted by law [1]. Generally, the use of force by the police against law-violating citizens is a law enforcement activity normally carried out under color of law.

Not all uses of force by the police, however, amount to acts under color of law. The question of official conduct is not always clear especially during off-duty hours, during acts of self-defense that happen in personal circumstances [4], or during acts of force that occur in secondary employment settings such as security venues. When making color of law determinations in these situations, courts weigh heavily the nature of the officer's behavior [5]. They have considered behaviors such as flashing of a badge [6], wearing a police uniform [7], identifying themselves as police officers [4], driving a marked police vehicle [6], or brandishing a department issued weapon [8], in concert with force as acts under color of law. Courts may also consider off-duty police acts within their jurisdiction and on which they file

official police reports as behaviors that constitute acting under color of law [9].

Although sometimes the question of official conduct is ambiguous, courts have employed a three-prong test in color of law determinations: public function test, state compulsion test, and nexus test [10, 11]. For example, under the public function test, the court would consider whether an officer's use of force was a state action normally reserved for the police and usually performed by them during their official duties, or a personal action [12]. Making investigatory stops, arrests, or performing searches are uses of force that the police usually carry out under color of law [8, 13].

Under the state compulsion test, the court would determine whether the state or government compelled the officer to use force to enforce a government interest such as arresting a citizen who commits a crime of domestic violence. The central question is whether the use of force was an action required by law or police department policy [7]. Finally, the nexus test would involve the court's consideration of whether the officer's use of force involved conduct closely linked to or associated with the state [14]. For example, the action of an off-duty officer who grabs and arrests a citizen who commits a larceny may constitute state action because there is a sufficiently close nexus between the officer's conduct and the state's regulation of arrest powers.

While courts have employed the police function, state compulsion, and nexus tests in making legal decisions about police uses of force that fall under color of law, they have not used them in a formulaic fashion. Instead, they have considered the totality of circumstances surrounding each particular use of force case when employing them. To hold the police liable for wrongful uses of force that amount to constitutional violations, courts must first find whether they were clothed with official authority.

Standards Governing Objective Reasonableness

Whenever the police use force while acting under color of law, they must ensure that their use-of-force tactics do not violate the constitutional rights of citizens. Police uses of force against free citizens mostly occur in the course of an arrest, investigatory stop, or other seizure. The Fourth Amendment and its "reasonableness" standard is the precise constitutional right that provides free citizens protection against unreasonable seizures or excessive force by the police. In *Graham v. Connor* [2], the court established five substantive tests for judging the reasonableness of police use of deadly or nondeadly force against citizens: balancing test, subjective test, objective test, hindsight test, and totality of circumstances test.

Using the balancing test, courts weigh the rights of free citizens under the Fourth Amendment against the interests of the government to take action against them. For example, an officer has a legal interest to stop or seize a motorist who travels through a stop sign without stopping. Yet, the motorist has a right to travel freely along the highway without police interference if the officer cannot substantiate a legal interest to carry out the traffic stop.

Where the police establish a legal interest to take action against citizens, the Fourth Amendment recognizes that the interest carries with it the need to use some degree of physical coercion or threat [15]. Built into the application of the balancing test is a principle of proportionality: Is the officer's act of force in the correct relationship to the citizen's violation of law? For example, a suspect disobeys an officer's verbal commands during an arrest. This form of behavior is less severe than is the suspect shooting at the officer. Both suspect behaviors require some degree of force by the officer to handle them and complete the arrest, but at obviously different levels. Therefore, courts balance the amount of force the police use against the amount of force they need to use in a particular situation [16].

When employing the objective test, courts consider whether another well-trained officer under the same set of circumstances would observe and conclude that the use of force by the police was reasonable. It requires a retrospective investigation and opinion by the well-trained officer (or expert) who has special knowledge of issues surrounding police use of force. Both carrying out the investigation and giving an opinion involve seeing through the lens of the officer on scene: what the officer's observations were; what the officer's observations meant; what the officer's experience and situational knowledge were; and what the officer's realty was. The expert weighs heavily the citizen's behavior because it has a large degree of power in influencing the officer's choice of force [17]. In the light of the particular circumstances, the expert conveys to the court whether he or she

believes that the officer's choice of force was within the range of objectively reasonable options available because there is no precise formula for determining a single or best force option.

Under *Graham*, the subjective test discounts the personal motivations of the police because they have no value in the court's application of the Fourth Amendment's reasonableness standard. For example, an officer's evil intentions do not raise a Fourth Amendment claim of excessive force when his or her use of force was objectively reasonable. Alternatively, the officer's good intentions do not make an objectively unreasonable use of force constitutional.

Using the hindsight test, courts would not consider every grab or push by the police even if they later seem unnecessary as violations of the Fourth Amendment's protection against unreasonable seizures. Courts make allowances for errors by the police who must at times make split-second decisions about using force in situations that are tense and uncertain, and that evolve rapidly. What gives rise to constitutional violations are more than police acts that amount to mere mistakes. For example, having probable cause to arrest a person but arresting the wrong person, or having a warrant to search a house but carrying it out at the wrong house would not in every case violate the Fourth Amendment's reasonableness standard. The hindsight test takes into account police mistakes and uses the at-the-moment perception of another well-trained officer on scene as the basis for a reasonableness inquiry and not the after-the-fact perception of others.

The last *Graham* test – totality of circumstances – involves evaluating the circumstances of a use of force event. Because the Fourth Amendment's reasonableness standard is not capable of an exact definition, its application requires attention to the totality of circumstances. The central question is whether the totality of circumstances justifies a particular use of force by the police. Circumstances that the police know before and when they use force are relevant in courts' determinations of reasonableness [18].

In *Graham*, the court suggests careful attention to the severity of the crime; whether the suspect poses an immediate threat to the police or others nearby, the suspect attempts to escape police custody, or the suspect fights against arrest. On the face of these circumstances, deciding to use deadly force to shoot a suspect of a felony crime who resists the police and attempts to escape arrest might seem permissible. The calculus of reasonableness in deadly force cases, however, requires some attention to the *Garner* [3] rules because *Graham v. Connor* is a nondeadly force case.

Standards Governing Deadly Force

The only US Supreme Court decision that deals directly with the use of deadly force by the police is *Tennessee v. Garner* [3]. Under the *Garner* rules, police may use weapons or other use-of-force tactics that amount to deadly force to prevent the escape and make the arrest of fleeing felons under three conditions. First, the police have probable cause to believe that a suspect poses a threat of significant physical harm to them or others: the danger condition. The immediacy of the threat and the dangerousness of it are the cornerstones of this condition. The dangerousness element suggests that suspects who threaten the police or others with weapons "or" suspects who commit crimes where they cause or threaten to cause significant physical harm are dangerous because of their violent or potential violent behavior. Under *Garner*, the "or" aspect of dangerousness suggests that the possession of a weapon or the threat to use one is not necessary to satisfy dangerousness. Courts, however, have considered suspects armed with guns, knives, or flashlights, and suspects who have used a vehicle as a weapon against an officer or have attempted to seize an officer's weapon as dangerous [19–24]. They have recognized murder, bank robbery, and armed robbery as felony crimes that demonstrate dangerous behaviors that justify the use of deadly force [25–27].

The immediacy element of a suspect's physical threat to the police or others suggests that the period during which the threat occurs and the threat actually happens is important. Unfortunately, not all courts measure this period the same. Some may apply an "imminent" yardstick whereby significant physical harm is about to happen such as a suspect pointing a handgun at an officer [28]. Others may use more than a yardstick whereby they consider the "unpredictability" of a dangerous suspect, which is not easily foreseeable and measurable [29]. Nevertheless, courts carefully examine the totality of circumstances in all cases when making determinations about immediacy.

Second, the police may only use deadly force against a dangerous suspect when necessary: the

necessary condition. Unless the suspect satisfies the danger condition, deadly force is unnecessary. What is necessary or needed, however, may invite hindsight arguments. For example, in *Plakas v. Drinski* [30], Plakas ran at an officer and tried to use a fireplace poker to kill him. The officer shot and killed Plakas. In this case, the plaintiff argued that the officer had nondeadly force options available and that the officer did not try them. The officer could have used a spray or a police dog to disarm Plakas; deadly force was unnecessary. At both the district and federal court levels, the courts ruled in this case that the officer's force was reasonable. The Fourth Amendment's reasonableness standard does not require police to use less intrusive uses of force. Federal courts have rejected necessary arguments that the police could have used nondeadly force options when deadly force ones were reasonable [31].

Third, the police must warn – where feasible – a suspect of their intention to use deadly force: the warning condition. Unless the suspect satisfies the danger condition, both a warning and deadly force are unnecessary. The use of deadly force may also be unnecessary if a dangerous suspect submits to an arrest after a warning.

Whether the police make decisions to use deadly or nondeadly force options to seize free citizens, their choices must fall within the range of objectively reasonable options available in particular situations. The Fourth Amendment's reasonableness standard is the appropriate test in claims that the police used excessive force in the course of an arrest, an investigatory stop, or other seizures. However, not every police abuse of force occurs under these conditions. An officer who uses excessive force against a prisoner would violate either the Fourteenth Amendment's due process clause or the Eighth Amendment's prohibition against cruel and unusual punishment. It is important then to identify the specific constitutional right that is the precise textual source of an officer's use-of-force conduct [2].

Policing and Critical Incident Teams

Police calls for service occasionally require the police to resolve high-threat or special-threat situations such as barricaded suspects, hostage situations, drug raids, or warrant services. Although infrequent, these events are significantly different from usual police work that is often less dangerous: They require some degree of

special handling. In US law enforcement circles, such special teams have become known by the acronym SWAT, which stands for special weapons and tactics. In other countries, such special teams may be designated by other terms. Since the 1965 Watts riots in Los Angeles, California, the need for SWAT teams (at times called *police paramilitary units, critical incident teams, special response teams*, and other names in the police literature) to deal with special-threat situations that regular officers are traditionally unprepared to handle has become popular among American law enforcement agencies [1].

Police departments of all sizes have working SWAT teams and some are developing them [2, 3]. They most often employ, when available, their SWAT teams to deal with rare high-threat police call outs. Officers who are SWAT members receive special training to work as a team and to use special weapons and force tactics to handle the most dangerous call outs. Because their behaviors involve special uses of force, there are some common risks related to the legal process.

The adequacy of a SWAT team and its training in particular uses of special weaponry, technology, and tactics to confront the most dangerous situations may give rise to a legal action when the team fails to train in the proper use of issued equipment and use of force tactics. When a SWAT team uses force, its choices must be "objectively reasonable." In cases of alleged use of excessive force, criminal and civil liability can attach itself in the form of a team's wrongful actions under Titles 18 and 42 of the US Code respectively. There are legal risks surrounding the intervention of a SWAT team to control and overcome hostage takers where the main concern is the protection of human life and the avoidance of hostage and bystander injuries.

Adequate Training

Police departments that have SWAT teams often call upon them to resolve the most dangerous police–citizen contacts. SWAT teams commonly carry out high-threat warrant services where the police believe that suspects are armed and dangerous. They execute high-threat narcotics search warrants where drug dealers seem likely to defend their drugs and homes using weapons. Sometimes, SWAT team interventions require team members to confront, disarm, and arrest suspects who hold citizen prisoners.

To assist SWAT teams in handling and controlling extreme police callouts, police departments employ their SWAT team members with special weaponry that are not available to regular officers. For example, some police agencies issue high-powered rifles, automatic firearms, diversionary devices, ballistic shields, and chemical munitions [4]. They authorize their SWAT teams to carry out tactical operations that involve the use of special tactics such as warrant, warrantless, or "no-knock" forced building entries. Because police departments arm their SWAT teams with special weapons and tactics to help them to enforce laws and make arrests, they need to train them on their appropriate uses. A failure to train may amount to a "conscious choice" or "deliberate indifference" to the constitutional rights of citizens to be free from unreasonable uses by SWAT teams [5].

Without training, SWAT teams are likely to make mistakes when deploying SWAT such as using diversionary devices to help them to carry out no-knock warrants. It is not reasonable to expect common officers to know the right force option without training [6]. SWAT teams must receive training in specialized tasks they are likely to perform on-the-job [5]. A failure to train them might give rise to a federal cause of action. Community stakeholders could consider police agencies to be deliberately indifferent to the needs of SWAT teams to receive specialized training.

In resolving the responsibility to train, police departments must focus on the adequacy of its training programs to meet the plausible conditions under which its SWAT teams works [5]. Courts suggest that training require officers to make judgments on the use of varying degrees of force [7] and present officers with situations that reflect real-life work conditions [8]. Knowing the prevalence of SWAT team call outs and the unique facts surrounding them can be the basis for making informed training decisions. Use of expert witnesses on the proper application of guidelines enacted by a department often provides the crucial factual information to courts when litigation ensues.

Reasonable and Excessive Force

Free citizens raise a Fourth Amendment claim when they allege that a SWAT team used excessive force against them in a law enforcement capacity (*see also* **Police Use of Force**). The Fourth Amendment prohibits unreasonable searches and seizures. It protects

free citizens from the police using excessive force against them. There is no prevailing definition of what is excessive force. The Supreme Court, however, imposed an "objective reasonableness" standard for reviewing claims of excessive force by the police [9]. In such cases and under the *Graham* rules [9], the trier (or judge) or triers (or jury) of facts must first weigh the rights of free citizens under the Fourth Amendment against the interests of the government to take action against them (or balancing test). The Fourth Amendment recognizes that the right to take action against free citizens is associated with the need to use some degree of physical coercion or threat [10]. Second, consider whether a well-trained officer under the same set of circumstances would observe and conclude that the actions by the police were reasonable (or objective test).

Third, discount the subjective motivations of the police because they have no value in a court's appraisal of excessive force (or subjective test). Evil intentions do not raise Fourth Amendment claims when force options were objectively reasonable. Good intentions do not make objectively unreasonable force options constitutional. Fourth, evaluate the circumstances of the police call out. That is, what is the severity of the crime, does the suspect pose an immediate threat to the police or others nearby, and is the person actively resisting or fleeing arrest (or totality of circumstances test). Because the "objective reasonableness" standard is not capable of providing an exact definition, its application requires attention to the totality of circumstances. Only circumstances known to the police before and at the time they use force are relevant [11]. The central question is whether the totality of circumstances justifies a particular use of force by the police.

Fifth, recognize that not every push or shove by the police even if it later seems unnecessary violates the Fourth Amendment (or hindsight test). The standard of "objective reasonableness" makes allowances for errors made by the police who must at times make split-second decisions about force in situations that are tense and uncertain, and that evolve rapidly [12].

Finally, examine carefully at whether the severity of force by the police puts suspects at risk of death "or" serious bodily harm (or deadly force test). Under the *Garner* rules [13], police may deploy weapons or use tactics that amount to deadly force in three conditions. First, if deadly force is necessary to prevent escape (or necessary condition). Second, if the police have probable cause to believe that a suspect poses a significant threat of death "or" serious bodily harm to them "or" others nearby (or dangerous condition). In this condition, the court suggests that suspects who threaten the police or others with weapons and suspects who commit a crime and cause or threaten to cause serious bodily harm are dangerous because of their violent or potential violent behavior. Third, if possible, the police must warn a suspect of their intention to use deadly force against him or her (or warning condition).

Whether SWAT teams use deadly or nondeadly force options against suspects of crimes, allegations of excessive force are possible especially when tactical operations involve the use of SWAT not employed by regular officers. For example, plaintiffs have argued that the uses of certain police tactics such as deploying diversionary devices are excessive. In numerous court cases, however, the courts have suggested that uses of diversionary devices are permissible under the *Graham* rules [9] when the totality of circumstances support their use, when the police use discretion and do not deploy them routinely as a matter of custom, and when the police receive training in their appropriate use [14–16].

A high-risk forced building entry by a SWAT team also raises concern of excessive force. In general, police need consent, exigent circumstances, or an arrest or search warrant to enter buildings. Carrying out a forced building entry will trigger a judicial review of its lawfulness and excessiveness especially when any injuries occur. The more on-scene time a SWAT team has with a police call out such as negotiating with a barricaded suspect, the less the team can rely on exigency to carry out a warrantless entry, search, or seizure. A SWAT team avoids some excessive force liability for using forced building entry tactics when it obtains prior judicial approval.

Questions about excessive force may occur when police regularly execute as a matter of policy or custom warrantless building entries in critical incident situations regardless of the totality of circumstances. For example, in *O'Brien v. City of Grand Rapids* [17], the court held the city liable for a warrantless entry into the home of an armed barricaded suspect with whom the police had contact time for 6-hours. The police here had a custom of executing warrantless building entries in critical incidents regardless of the circumstances.

Sometimes, when police fail to reevaluate prior to entry the circumstances justifying a no-knock warrant, it may be unreasonable or excessive to carry out the warrant. For example, in *United States v. Singer* [18], the court said that if during the period between obtaining a no-knock warrant and executing it the police receive reliable information that exigent or dangerous circumstances no longer exist, the police must reevaluate their plan of entering a home without first knocking and announcing.

In cases of alleged use of excessive force, criminal and civil liability can attach itself in the form of a team's wrongful actions under Title 18 of the US Code section 242 and Title 42 section 1983 respectively. Commonly referred to as *sections 242* and *1983*, police shall not deprive any citizen within their jurisdiction of any rights secured by the Constitution and laws while acting under the color of law. In an action of law (criminal action for deprivation of rights) or redress (civil action for deprivation of rights), police are liable to any persons injured under sections 242 and 1983. Civil liability can also come in the form of specific state statutes that are similar to those of the federal government. For those members of SWAT teams, call outs are at times fraught with certain legal – criminal or civil – problems, dangers, or difficulties.

Hostage and Bystander Injuries

Police have the responsibility to safeguard the well-being of the community. There is the possibility of injuries, however, when tactics to handle dangerous police call outs involve the use of physical force to capture and arrest law violators. Generally, no deprivation of rights occurs when the police use reasonable care, but accidentally shoot hostages or bystanders during police–citizen encounters. For example, in *Green v. Denison* [19], a suspect fired a bullet that shattered glass, which blinded a bystander. An officer fired a bullet that accidentally hit the suspect's girlfriend. Both injured persons sued and claimed that the police had a duty to protect them from harm. The court dismissed the claims and held that police officers are not liable for injuries or damages to the general public that arise from their acting within the scope of their authority or duty. It distinguished duty owed to the public from duty owed to particular persons targeted by the police. Protecting the police or giving them official immunity from personal liability arising from making discretionary or best judgment decisions allows them to perform their job without distractions.

In *Lee v. Williams* [20], a police deputy unintentionally shot a hostage during a shootout with armed suspects. Postincident litigation brought about a § 1983 civil deprivation of rights claim against the deputy. The court ruled that there was no Fourth Amendment seizure of the hostage because the deputy did not intend to shoot him, but did intend to shoot the armed suspects.

For officers involved in making tactical decisions about handling hostage situations, the courts have established a philosophy of "human life is the main concern." For example, in *Downs v. United States* [21], a Federal Bureau of Investigation (FBI) SWAT team carried out a forceful assault against armed suspects who hijacked an airplane, held passengers as hostages, but released some of them during negotiations. The outcome of the assault approach was the deaths of hostages. The court ruled that the safety of hostages is more important than the arrest of suspects.

There is no constitutional obligation to have specially trained SWAT teams deal with nonnormal police calls for service such as hostage situations [22]. Actions by regular or non-SWAT officers, who generally do not possess the same training, experience, and equipment that SWAT officers posses to handle the most dangerous police call outs, might not automatically result in injuries or police behaviors that would shock the conscious of courts. For SWAT and non-SWAT officers involved in making tough tactical decisions, (*see* **Aggression**) postincident outcomes might involve criminal or civil action for deprivation of rights. Fourth Amendment principles (*see* **Seizures: Behavioral**) are equally applicable (*see* **Threat Assessment: School**) to both SWAT and non-SWAT officers who might injure citizens.

FRANK J. GALLO

Pollen *see* Palynology

Polymorphism: Genetic

Natural genetic variation, within a population, is seen by the existence of more than one type of allele for a locus. Loci with several commonly occurring alleles are useful for profiling purposes because, although some individuals may share the same at alleles at a locus, the probability of them sharing the same alleles at all loci reduces dramatically as the number of loci considered increases. For profiling purposes, scientists use loci that comprise sequences with simple tandem repeats (STR) (*see also* **Short Tandem Repeats**). These are regions of DNA that have short sequences of DNA that are repeated as multiple blocks, like carriages of a train. Any one person will have two copies (alleles) of the locus, one from mother and one from father, and each allele will have its own number of STRs. These may be the same (homozygote) or different (heterozygote).

DNA profiling tests the polymorphism, or variation, of the alleles at a set of loci for a sample. For the sake of convenience, the different alleles of any one locus are given a name that is the same as the number of STR contained within the allele's DNA sequence. Thus, a person with profile D3/13,16 is a heterozygote with one allele at D3 that has 13 repeats and a second allele that has 16 repeats.

Polymorphisms in a population have evolved as a result of mutations and the passage of time. In the case of STR, mutations are thought to be due to a low rate of slippage of DNA synthesis of the repeated sequences during the process of making sperm and egg cells. Such mutations are then passed on to a new generation and over time become a measurable proportion of a population. A rule of thumb for a polymorphism is that it occurs in at least 0.05% of a population. Exactly, how common any allele is depends on many factors, including chance, selective breeding, population size, intermingling of populations, and so on. The allele frequencies of a polymorphic locus will remain stable if the population is in Hardy–Weinberg equilibrium (*see also* **Hardy-Weinberg Equilibrium**), but are often different for different populations.

Postmortem Biochemical Examinations

Introduction

Functional Causes of Death

The diagnosis of *functional causes of death* is, on one hand, based on mostly sparse postmortem findings and, on the other hand, considerably on postmortem biochemical alterations, which frequently originate from illnesses with internal causes and subsequent dysregulations such as diabetes mellitus, alterations of kidney and liver function, and imbalances of water and electrolytes. It is not rare that combinations of such dysregulations with problematic overlappings are seen due to close physiological and biochemical links [1–4] (*see also* **Cardiac and Natural Causes of Sudden Death**; **Natural Causes of Sudden Death: Noncardiac**).

Postmortem Biochemical Estimations and Differences to Clinical Biochemistry

Postmortem biochemical analyses may represent the main clue to the diagnosis of functional causes of death. One of the main problems is to be able to apply clinical biochemical values on postmortem conditions. On one hand, there are big unpredictabilities regarding general postmortem changes in body fluids. On the other hand, biochemical values in postmortem specimen may well represent more or less the results of changes taking place during agony or the early postmortem period. Contrary to clinical biochemical estimations, values obtained postmortem do not necessarily allow conclusions regarding the mechanism of death. Postmortem diagnostic procedures, therefore, require a critical way of looking at them [5].

Obtaining the Appropriate Specimen

Body fluids are usually obtained during postmortem examination. In cases with a limited external examination specimen (e.g., cerebrospinal fluid (CSF), vitreous humor, blood, and urine) can also be taken by cannulation (suboccipital access, puncture of an eyeball, dissection of a femoral vein, and puncture of the urinary bladder). The cranial cavity and the eyeballs provide a relatively good protection of the enclosed body fluids against decomposition effects. After obtaining vitreous humor, the eyeballs should be refilled with water due to cosmetic reasons.

The volume of CSF to be found varies from 50 ml (baby) to 135 ml (adult). A few milliliters are sufficient for the postmortem biochemical analyses and there is usually no problem to get blood-free CSF. Approximately 1–2 ml of vitreous humor can be obtained by the puncture of both eyeballs. Aspiration of small parts of the retina is of no further relevance. Postmortem blood should be taken from the heart and a (peripheral) femoral vein and urine from the bladder immediately after dissection (a few milliliters per specimen) [6].

"Near-Table" Methods

During the postmortem examination, several screening tests with stripes and tablets can be carried out regarding glucose, bilirubin, or acetone. Furthermore, there are a number of electronic test devices on the market, which can be used for screening purposes. These "near-table" methods are useful to confirm or exclude certain differential diagnoses at the time of the autopsy (further information: http://www.roche-diagnostics.com).

Glucose Metabolism and Diabetes Mellitus

General Aspects of Diabetic Coma

Diabetic coma is a life-threatening complication of diabetes mellitus. Owing to a relative or an absolute insulin deficit, there is a typical rise of blood sugar with the possibility of acute complications or damage to blood vessels and nerves after longer duration. Depending on the age group, the incidence of diabetes mellitus varies between 2 and 5%. Causes for coma may be the onset of an unknown diabetes, lack of insulin injections, or increased requirement of

Table 1 Postmortem biochemical values in case of alterations of glucose metabolism

Dysfunction	Parameter	Compartment	Results
Coma (in general)	Sum value[a]	Cerebrospinal fluid	$\sum > 415\,\text{mg dl}^{-1}$[b]
		Vitreous humor	$\sum > 410\,\text{mg dl}^{-1}$[c]
	HbA_{1c}	Blood	>12.1%[d]
	Glucose	Urine	$>25\,\text{mg dl}^{-1}$[e]
Ketotic coma	Acetone	Blood, cerebrospinal fluid	$>21\,\text{mg dl}^{-1}$[f]
		Vitreous humor	$>5\,\text{mg l}^{-1}$[f]
		Urine	
Hypoglycemia	Sum value	Cerebrospinal fluid	$\sum < 50–80\,\text{mg dl}^{-1}$
		Vitreous humor	$\sum < 100–160\,\text{mg dl}^{-1}$

[a] According to Traub: concentrations of glucose and lactate
[b] Mean value = $500–600\,\text{mg dl}^{-1}$
[c] Mean value glucose = $300–950\,\text{mg dl}^{-1}$; mean value lactate initially = $80–160\,\text{mg dl}^{-1}$, after 20 h = $210–260\,\text{mg dl}^{-1}$
[d] Mean value = 13–15%, nondiabetics = 9.15%
[e] Most of coma cases $>50\,\text{mg dl}^{-1}$, partly $2000–4000\,\text{mg dl}^{-1}$
[f] Coma: mean value = $100–150\,\text{mg l}^{-1}$

insulin due to acute infections, poor diet, operations, gastrointestinal diseases, or myocardial infarction. Twenty-five percent of all diabetic comas are so-called manifestation comas with previous unknown diabetes. Infections are the most frequent triggers for coma onset (approximately 40% of the cases). The frequency of fatal coma among known diabetics is between 0.5 and 1.5% with a peak in the age group of 40–60 years. The overall lethality from coma varies from 5 to 25% and rises to 70% with coma of longer duration. Lethality of diabetic coma is tenfold in 70-year-old individuals compared to 30-year-old patients. Furthermore, the risk for coma in juveniles is four- to sevenfold higher than in adults [1, 2] (see Table 1).

Types of Diabetic Coma

Typically, diabetes mellitus type I is associated with ketonemic coma, whereas hyperosmolar coma normally results from type II diabetes mellitus. A lack of insulin causes a rise of blood glucose with subsequent loss of fluids and electrolytes. In addition, increased lipolysis is used to compensate the deficit of energy resulting from the inhibition of glucose metabolism leading to increased levels of ketone bodies with metabolic acidosis. The latter may be excessive ($500–1000\,\text{mg l}^{-1}$ acetone or higher), whereas hyperglycemia remains mostly moderate ($250–600\,\text{mg dl}^{-1}$). Hyperosmolar coma is more rare (approximately 10–20% of the cases) and associated with relative lack of insulin causing reduced peripheral utilization of glucose with simultaneous release of glucose from the liver. Low levels of insulin prevent ketosis due to inhibition of lipolysis. Therefore, it is typical to find excessive hyperglycemia (often above $1000\,\text{mg dl}^{-1}$) with lacking or only mild ketosis.

Diabetic coma may lead to fatal outcome via different pathophysiological pathways. There is a cardiovascular type with leading oliguria or a renal type with acute kidney failure. Moreover, there exists pseudoperitonitis type with the symptoms of an acute abdomen. Typical accompanying diseases of fatal diabetic decompensation may be myocardial infarctions, apoplexy, embolism, pneumonia, pancreatitis, pyelonephritis, and a predisposition for lactic acidosis [5].

The most important body fluids for postmortem diagnostic purposes are CSF and vitreous humor using the so-called sum value according to Traub, which provides a combined calculation to compensate postmortem alterations of blood glucose level due to glycolysis, accordingly [7].

Glucose

The hourly metabolic decrease of glucose in CSF is about $10–15\,\text{mg dl}^{-1}$ but may vary between approximately 5 and $45\,\text{mg dl}^{-1}$. The hourly rate is below $1\,\text{mg dl}^{-1}$ 100 h postmortem. Given normal metabolic conditions, therefore, zero levels are reached after 10–12 h. Longer persisting glucose levels are indicative of antemortem hyperglycemia [8].

The speed of postmortem glycolysis depends on a number of factors, e.g., the temperature and duration of body storage. Postmortem glycolysis is slower in diabetics compared to nondiabetic individuals, whereas obesity accelerates degradation of glucose. Isolated assessment of elevated glucose levels in CSF requires critical reserve (normal range: *ca.* 50–90 mg dl^{-1}), because multiple other dysregulations may be accompanied by the same symptom as carbon monoxide poisoning, acute cardiac death, brain trauma, strangulation, protracted agony, asphyxia, pneumonia, and pancreatitis. This aspect has also to be taken into account regarding other body fluids [6].

Lactic Acid (Lactate)

The product of postmortem glycolysis is lactate (normal level in CSF *ca.* 9 mg dl^{-1}). Its concentration increases postmortem with a rate of approximately 10–15 mg dl^{-1} up to the 10th hour after death. After this time, the increasing rates vary considerably. Under differential diagnostic aspects also other disorders may cause hyperlactacidemia, e.g., tumors, respiratory insufficiency, severe chronic inflammations, uremia, especially inflammations of the central nervous system or alcohol-induced with lack of thiamine, physical strain, and alimentary factors (e.g., strict fasting).

Sum Value

This combined method, according to Traub, compensates arithmetically for the postmortem production of lactate from glucose by using a "sum value". It is based on the fact that 1 mol of glucose produces, via glycolysis, two moles of lactate so that the concentrations can be added using milligrams per deciliter. If the "sum value" exceeds 362 mg dl^{-1} in CSF, the probability of fatal diabetic coma is about 89%, if other, e.g., toxicological and morphological, alterations can be excluded. In cases of diabetes mellitus, the "sum value" remains almost stable up to the 200th hour postmortem. If there are nondiabetic causes of death, the "sum value" increases up to the 30th hour postmortem, but remains nearly stable afterwards. Although the formula, according to Traub, has to be used under critical view, the "sum value" may be considered the most important criterion for the diagnosis of fatal diabetic coma. However, the author's research has revealed that it is more realistic to increase the limit "sum value" in CSF to 415 mg dl^{-1} (upper limit of the 95% confidence interval in cases of cardiac death), with cases of diabetic coma ranging on average between *ca.* 500 and 600 mg dl^{-1} [9, 10].

Vitreous Humor

The calculation method according to Traub may also be applied on vitreous humor. The glucose level herein is about 50–85% of the serum glucose. Values for postmortem glucose concentrations vary from 20 mg dl^{-1} (nondiabetics) to 90 mg dl^{-1} (known diabetics), but wide variation ranges have to be taken into account. Owing to slower glycolysis in vitreous humor compared to CSF, normal glucose values may be found as long as two days postmortem. In cases of fatal coma, glucose values between *ca.* 300 and 950 mg dl^{-1} may be found. Lactate values are already around 80–160 mg dl^{-1} in the intramortal period and between 210 and 260 mg dl^{-1} approximately 20 h postmortem. The upper limit value is 410 mg dl^{-1} and if this is exceeded, it can be taken as a strong indication of fatal diabetic coma, given the condition that other possibly competing mechanisms can be excluded. The procedure is said to be applicable until the 10th postmortem day [11–15].

Blood Glucose

Blood sugar levels alone are only of low diagnostic relevance, if at all limited to blood from the femoral veins within the 1st and 2nd hour postmortem in which the level is *ca* 40–100 mg dl^{-1}. Contrary to this, glucose levels in central blood (right ventricle) may easily reach 1000 mg dl^{-1} and over due to postmortem hepatic glycogenolysis. Normally, postmortem glycolysis (approximately 13 mg dl^{-1} h^{-1}) results in complete metabolization of the blood glucose within 6–8 h. This leads to a corresponding increase of lactate up to 180 mg dl^{-1} after 1 h and *ca.* 450–680 mg dl^{-1} after 12–24 h. Especially due to postmortem diffusion of serum and its components from surrounding tissues into blood vessels, the "sum value" cannot be used [10].

Hemoglobin A_{1c}

This glycosylated fraction of hemoglobin represents an important parameter regarding a basic diagnosis of

diabetes mellitus. Owing to the fact that kinetics of its formation is depending on time and concentrations, HbA_{1c} can be used as a long-term indicator of diabetic conditions (so-called blood sugar memory for *ca.* 120 days). Levels of 6–8% (maximum of 10%) are consistent with a normal glucose metabolism, whereas higher concentrations are indicative of inappropriate metabolic conditions (hyperglycemias in the past). Periods of increased blood sugar have to last 6–8 h minimum to cause significant rises of HbA_{1c} due to its slow reaction kinetics. Furthermore, the prefinal and postmortem drop of the pH value in blood, due to formation of lactate, are likely to result in a reduction of HbA_{1c} because of separation of its unstable component. Blood sugar also decreases rapidly after death. The stable part of hemoglobin A_{1c} makes up approximately 90% of the whole. For example, hyperglycemia around 360 mg dl^{-1} takes around 12 h to cause an increase of HbA_{1c} of 1.3% absolute. In reverse, a reduction of around 5% needs around seven days.

There has been found a positive connection between "sum value", urine glucose concentration, and HbA_{1c} level. This means that there usually is a coincidence of elevated "sum value", high urine glucose, and HbA_{1c}. Hemoglobin A_{1c} has proven to be relatively stable versus autolysis especially in hemolyzed blood and can be measured postmortem in frozen samples and also in samples stored in a normal fridge. It has been revealed that storage at temperatures between +4 and −80 °C does not cause any relevant changes to the HbA_{1c} concentrations. The result is independent from the actual total hemoglobin level because HbA_{1c} is measured as percentage of the current hemoglobin value [16].

Falsely elevated hemoglobin A_{1c} concentrations can be found due to increased HbF levels in cases of thalassemia or advanced renal failure. In principle, HbA_{1c} has proven to be a reliable parameter for the basic diagnosis of diabetes mellitus without being too liable for interferences. It is also possible to measure other glycosylated proteins such as fructosamine, but assessment is rather difficult. The mean levels of HbA_{1c} in cases of diabetes mellitus differ considerably from those in nondiabetic individuals and are around 12.1% in diabetic coma (range: ~13–15%). However, the lower portion of the range in case of diabetes mellitus may overlap with the upper portions of the range in nondiabetic cases as it has been shown for the "sum value" [17].

Ketone Bodies

The ketotic type of diabetic coma is characterized by an increased level of ketone bodies in blood and other body fluids (acetone and acetylacetate *ca.* 25–35%, β-hydroxyl-butyrate *ca.* 65–75%; normal values for acetylacetate 0.8–2.4 mg l^{-1}, for β-hydroxyl-butyrate 2.5–9.8 mg l^{-1}). Estimation of acetone may easily be carried out in connection with blood alcohol analysis using headspace chromatography. The normal concentrations for free acetone range from 2.3 to 2.5 mg l^{-1} in nondiabetic patients and may reach 23 mg l^{-1} in diabetics. The levels are almost independent from the postmortem interval [2, 5].

The level of acetone in CSF with diabetes mellitus differs considerably from those seen with nondiabetic causes of death, especially in cases of diabetic coma, with an obvious association regarding an elevated "sum value". If other causes can be ruled out, acetone levels exceeding 5 mg l^{-1} are suspicious of diabetes mellitus. Ketotic coma may be associated with levels higher than 100 mg l^{-1}, but ketonemia is rarely seen if the blood glucose concentration is only 200 mg dl^{-1} and below. According to the author's research, acetone levels in ketotic coma exceed 21 mg l^{-1} in most of the cases, with mean values in this group of 100–150 mg l^{-1}. Single cases may show levels of more than 1000 mg l^{-1}. Nondiabetic factors that might cause elevated ketone levels are, e.g., chronic hepatic and renal diseases, pancreatitis, shock, chronic alcoholism and isopropanol poisoning (levels up to 160 mg l^{-1}) as well as protracted fasting (acetone levels may exceed 5000 mg l^{-1}) [18].

Urine

As the fourth column of postmortem diabetes mellitus diagnostics, an examination of urine can reveal important clues. Urine glucose levels higher than 25 mg dl^{-1} (maximum in healthy individuals) may be indicative of diabetes. Diabetic coma is sometimes associated with urine glucose concentrations above a few 1000 mg dl^{-1}, but usually higher than 500 mg dl^{-1}. These excessively high values only show very small overlapping with other cause of death groups, although positive findings for glucose in urine alone are only of lower value. Glucosuria is a rather frequent nonspecific symptom, e.g., due to brain trauma, myocardial infarction, intoxication, apoplexia, and leukemia. Likewise, glucosuria may

be absent even in cases of manifest diabetes mellitus caused by diabetic glomerulosclerosis itself or postmortem degradation. Ketone bodies are likely to be found in urine longer than 24 h postmortem. Concentrations exceeding $0.5\,mg\,dl^{-1} = 5\,mg\,l^{-1}$ of free acetone may be indicative of ketotic dysregulation. However, a positive test for ketonuria is not a proof for ketonemia, because the kidneys have a relatively high clearance rate for ketone bodies. Furthermore, there are multiple conditions that might cause considerable ketonemia (see above). Hyperosmolar coma is typically characterized by a lack of ketonemia (approximately 30% of diabetic comas) [1, 2, 5].

Lactic Acidosis

There are some secondary effects of lactic acidosis that might gain special forensic medical relevance. For example, moving potassium to the extracellular space may cause hyperkalemia (see below). Acidosis decreases the reactivity versus catecholamines with a negative-inotrope effect on the heart. Severe acidosis may result in massive reduction of the kidney blood circulation leading to acute renal failure. Diabetic coma can also cause acidosis by production of β-hydroxyl-butyrate and acetylacetate (see above). Lactic acidosis plays an important role, particularly regarding overlapping with postmortem diagnosis of diabetes mellitus. Considerable amounts of lactic acid are being released during shock and hypoxia, due to poor perfusion caused by diabetes mellitus, following renal failure, hepatic diseases, and ethanol/methanol intake, rarely as complication of a treatment with biguanides or due to severe lack of thiamine with chronic increased alcohol intake. The conditions can be exacerbated by chronic renal failure due to reduced excretion of acids and also by an increased loss of bicarbonate resulting from diarrhea and/or vomiting.

The central causal mechanism is an increased concentration of pyruvate from protein catabolism together with a lack of oxygen, so that energy can still be provided by glycolysis. Accumulation of lactate happens more frequently in diabetics than in other patients what is due to disturbances of oxygen supply and alterations of metabolic activities. The clinical picture is characterized by gastrointestinal discomfort, muscular spasms, central nervous disturbances and deep frequent respiration. The severe type of biguanide-induced lactic acidosis shows a lethality rate of over 50%.

Patients suffering from chronic alcoholism represent a special risk group regarding fatal lactic acidosis and ketotic coma as well. There are often only very few and/or nonspecific morphological findings. On one hand, considerable ketonemia may follow acute alcoholization (free acetone from 74 to $400\,mg\,l^{-1}$), but, on the other hand, high "sum values" may also result in this condition. Their range (*ca.* $294–594\,mg\,dl^{-1}$) can also be associated with fatal diabetic coma. Given the precondition that diabetes mellitus and other competing mechanisms can be ruled out, ketotic coma or lactic acidosis has to be considered as a cause of death in such cases. The lower limiting values for the "sum value" are *ca.* $300–400\,mg\,dl^{-1}$, for acetone in blood around $90\,mg\,l^{-1}$ and 6% for HbA_{1c} [19, 20].

Hypoglycemia (Endogenous vs. Exogenous Hyperinsulinism)

Although fatal hypoglycemia appears to be a rather rare event among forensically examined death cases, they might be the source of serious diagnostic problems. Under clinical conditions, hypoglycemia is diagnosed if the blood glucose level lies below $40\,mg\,dl^{-1}$ *or* if the so-called Whipple's triad can be found. It comprises blood glucose level below $45\,mg\,dl^{-1}$, symptoms of hypoglycemia, which disappear under administration of glucose. Multiple circumstances may be responsible for hypoglycemia in individuals with an empty stomach, e.g., insulinomas and other tumors, severe hepatic diseases, uremia and glycogenoses. The initial manifestation of diabetes mellitus may also be accompanied by reactive hypoglycemia as well as alterations of gastric mobility, vegetative instability, or massive alcohol intake with simultaneous lack of food due to inhibition of gluconeogenesis. The autonomous or glucopenia-associated spectrum of symptoms includes hyperorexia, nausea, restlessness, sweating, tachycardia, endocrine neuropsychologic disorder, primitive automatisms, risk of convulsions, and focal signs with apoplectiform symptoms. The final state with somnolence, coma, and central alterations of respiration and circulation until death has forensic medical relevance.

Hypoglycemias due to exogenous causes are mostly seen with an existing diabetes mellitus. Important mechanisms are accidental or intentional overdosage of insulin or sulfonyl-urea derivates with

subsequent reactive hypoglycemia. Such a situation may arise from lack of regular alimentation due to intercurrent diseases without changing the doses of antidiabetic drugs. Other possibilities for hypoglycemias can be interferences with drugs which decrease the blood sugar level indirectly or unusual physical strains. However, types of hypoglycemia with a forensic medical impact are those caused by overdosages of antidiabetics.

The so-called factitious hypoglycemia needs special attention. It is caused by (unnecessary) administration of insulin or sulfonyl-urea derivates and can be seen in connection with psychic alterations (e.g., borderline personality disorder) or suicidal intention. It is rare to find a primary criminal background, e.g., cases of homicide. The most important diagnostic criterion of this type of hypoglycemia is that it happens independently from alimentation. Affected persons often have relations to professional health care or are relatives of known diabetics [21].

The calculation procedure regarding a "sum value" can also be used for the diagnosis of hypoglycemia. Consequently, low sum values in CSF in vitreous humor below *ca.* $50-80\,\mathrm{mg\,dl^{-1}}$ or rather $100-160\,\mathrm{mg\,dl^{-1}}$ are strongly indicative of fatal hypoglycemia. This conclusion is particularly supported by simultaneously high insulin levels suggesting that estimation of insulin levels and also of c-peptide postmortem is essential. In case of endogenous secretion, insulin and c-peptide are both found elevated. If there is exogenous hypoglycemia due to administration of insulin, the level of c-peptide will be noted as much lower than normal. Contrary to this, there are usually increases of insulin and c-peptide concentrations following an intake of sulfonyl-urea derivates, but, in diabetic individuals, often rather high insulin levels can be seen without any indication of hypoglycemia. The procedure has also proven to be reliable in cases of suspected hypoglycemia in car drivers [22, 23].

Postmortem estimations of insulin levels can be carried out by radioimmune assay (RIA) and have revealed levels very similar to those of healthy individuals in blood from a femoral vein and also from the heart. Nevertheless, postmortem concentrations of insulin in blood from the right ventricle may be increased to about 10-fold of normal values due to release of insulin after death. Putrefaction may cause problems as well. Furthermore, single estimations have a wide variation and, therefore, cannot be used as the only criterion for the diagnosis of insulin-based hypoglycemia. Sometimes it is possible and useful to have a proof of suicidal insulin injection by analyses of the tissues close to the injection site. It is a strict rule that the postmortem diagnosis of hypoglycemias must be based on a combined assessment of different criteria and can only be made "per exclusionem". According to this, especially cardiac diseases, cerebral hemorrhages, pulmonary embolism, strangulation/asphyxia, ruptures of vessels and intoxications have to be ruled out. Estimations of insulin should always be carried out in peripheral venous blood or CSF/vitreous humor because diffusion of insulin from the pancreas via the portal vein might take place postmortem. The "sum value" calculated from glucose and lactate levels is of special importance (see above) [24, 25].

Alterations of Liver Function

In case of an advanced stage of *hepatic cirrhosis* from different causes, it is not rare that there develops an alteration of liver metabolism, often resulting in potentially reversible complications, due to retention of neurotoxic substances in blood with decompensation and final *hepatic failure*. Suspicion may arise from the previous medical history, desolate housing conditions, known alcohol abuse, and sometimes the presence of jaundice. Acute deterioration of hepatic insufficiency with a danger of hepatic coma originates from an increased production of ammonia due to a high portion of proteins in the intestinal contents that may be caused by gastrointestinal hemorrhages (especially esophageal varicosis due to alcoholism), protein-rich nutrition, febrile infections with increased protein catabolism and drugs (e.g., benzodiazepines, analgesics). Clinically, the advanced stage is characterized by permanent drowsiness but patients can be woken up, later on hepatic smell, and electroencephalogram (EEG) alterations. This picture leads to coma with unmistakable "foetor hepaticus" and massive EEG changes until fatal outcome with total hepatic failure [1, 2].

The terms *acute hepatic insufficiency* or *endogenous hepatic coma* describe a failure of the liver function *without previously existing chronic liver disease.* Contrary to the chronic hepatic failure, decompensation can occur suddenly without any indications from the medical history. Important morphological findings are dermal and scleral jaundice

and, clinically, disturbances of blood coagulation and consciousness (somnolence, coma). It is especially the fulminant type with a duration of less than seven days, which may gain forensic medical relevance. Important causes are viral hepatitis (65%) and hepatotoxic substances (30%) such as medication (Paracetamol), drugs, chemicals (CCl_4), or poisons from mushrooms (Amanita phalloides). This elucidates the importance of accompanying *toxicological analyses.* Potentially fatal complications may be brain edema (80%; most frequent cause of death), gastrointestinal hemorrhages (50%), as well as hypoglycemia and renal failure with electrolyte imbalances.

The typical enzymes of liver metabolism represent important parameters, which can also be examined postmortem, as well as bilirubin. The daily bilirubin production comes to approximately 510 $\mu mol\,l^{-1}$ (30 $mg\,dl^{-1}$; normal value up to 1.1 $mg\,dl^{-1}$). Hepatic failure is typically associated with an increased level of serum bilirubin causing jaundice if it exceeds 34 $\mu mol\,l^{-1}$ (2 $mg\,dl^{-1}$). A differentiation between direct bilirubin bound to biglucuronide and nondirect bilirubin bound to albumin is only useful under clinical aspects. *Postmortem bilirubin levels* may well be compared with those obtained antemortem. Differences are only ranging in the area of 0.1 $mg\,dl^{-1}$, especially in death cases showing jaundice. During the postmortem period, there can be seen a slight but steady increase (*ca.* 0.2 $mg\,dl^{-1}$ after 2 h and 0.7 $mg\,dl^{-1}$ after 20 h). Furthermore, there is an increase of *enzymes typical for the liver* (*GPT glutamate pyruvate transaminase, GGT gamma glutamyl transferase, and AP alkaline phosphatase)* as well as of *ammonia* (>100 $mg\,dl^{-1}$; normal value below 0.05 $mg\,dl^{-1}$) primarily not only in blood but also in other body fluids (CSF, vitreous humor). However, clinical reference ranges of values can only be used as a basis for assessment. Most of the bilirubin in CSF belongs to the conjugated type, often associated to hypokalemia and hypoglycemia [6].

Disturbances of Kidney Function

Chronic renal failure represents the result of a nonreversible reduction of the function of both kidneys. Important causes are, e.g., diabetes mellitus (nephropathy, *ca.* 35%), hypertension (*ca.* 25%), chronic inflammations (*ca.* 15%) and abuse of analgetics (*ca.* 1%). The chronic reduction of the renal function can also show acute decompensation leading to unexpected sudden death, which is not an unusual development during diabetic coma. The *compensated chronic phase* showing only a functional reduction of a low degree and the phase of *compensated retention* (azotemia, creatinine levels up to 6 $mg\,dl^{-1}$) are not associated with symptoms of uremia. Preterminal renal failure with creatinine levels above 8 $mg\,dl^{-1}$ plus symptoms of uremia is called *decompensated retention. Terminal renal failure* (uremia) showing creatinine levels over 10 $mg\,dl^{-1}$ is associated with massive symptomatology of uremia. During the phase of *decompensated retention* (preterminal phase), there may be seen edematous changes, cardiac failure, gastroenteritis due to uremia and neuropathy. The *terminal phase* is characterized by acute life-threatening symptoms, such as neuropathy and encephalopathy, overhydration with pulmonary edema, bleeding tendency, coma, and death (see Table 2).

Acute renal failure or acute renal insufficiency represents a mostly *reversible reduction of the renal function* with loss of urine production and increasing retention parameters (urea, creatinine). Fifteen percent of the cases with acute renal failure show polyuria or normuria with an increase of retention values being the only symptom. Without sufficient therapy, e.g., dialysis, acute renal failure mostly has a fatal outcome. Sometimes bilateral necroses of the renal cortex can be seen. There are multiple possible causes for *acute renal failure,* such as alterations of the blood circulation, toxins, medication (antirheumatics, cytostatics, and antibiotics), chemicals (glycols), and inflammatory or vascular processes.

The most critical clinical phase is the third one with polyuria and extensive loss of water/electrolytes and simultaneous increase of urea and creatinine. Fatal complications may occur associated with other organs, e.g., shock lung, cardiac failure and arrhythmia, and cerebral edema with further central nervous complications. The most significant biochemical changes of acute and chronic renal failure are increased levels of urea and creatinine, electrolyte imbalances (often decreased with acute renal failure) and also a reduced concentration of urine [1, 2, 6].

Creatinine

Under postmortem conditions, an increased level of creatinine in CSF and vitreous humor can be indicative of renal failure (normal value 0.6–1.4 $mg\,dl^{-1}$).

Table 2 Postmortem biochemical values in cases of renal failure (insufficiency)

Dysfunction	Parameter	Clinical values	Compartment	Results
Compensated retention	Creatinine	$\leq 6\,mg\,dl^{-1}$		
Preterminal failure (f)		$>8\,mg\,dl^{-1}$		
Terminal failure		$>10\,mg\,dl^{-1}$		
RF ruled out			CSF/VH	Creatinine $<2.5\,mg\,dl^{-1}$
RF possible				$2.5–4.0\,mg\,dl^{-1}$
RF primary fatal				$>4.0\,mg\,dl^{-1}$
Normal values (urea–nitrogen)/urea[(a)]			Blood (heart)	Maximum 179 (83) $mg\,dl^{-1}$ (mean value = 102 (47) $mg\,dl^{-1}$)
			CSF	Maximum 197 (92) $mg\,dl^{-1}$ (mean value = 89 (41) $mg\,dl^{-1}$)
Uremia (urea–nitrogen)/urea[(a)] dysfunction[(b)]		(First 13 hpm)	Blood and CSF	$>200\,mg\,dl^{-1}$ (93)
		CSF/blood (heart)	CSF	Blood (heart)
RF ruled out		Urea $<100\,mg\,dl^{-1}$	Creatinine $<2.5\,mg\,dl^{-1}$	Creatinine $<3.5\,mg\,dl^{-1}$
RF possible		$100–200\,mg\,dl^{-1}$	$2.5–4.0\,mg\,dl^{-1}$	$3.0–4.5\,mg\,dl^{-1}$
RF primary fatal		$>200\,mg\,dl^{-1}$	$>4.0\,mg\,dl^{-1}$	$>4.5\,mg\,dl^{-1}$

RF, renal failure; CSF, cerebrospinal fluid; VH, vitreous humor; pm, postmortem

[(a)] Urea–nitrogen $\times$ 2148 ($mg\,dl^{-1}$) = urea ($mg\,dl^{-1}$)

[(b)] Different method of assessment (see text and references)

During the early postmortem interval, the creatinine concentration is rather stable. In healthy individuals, the mean values are $1.6\,mg\,dl^{-1}$ (8 h postmortem), $1–2\,mg\,dl^{-1}$ (12 h postmortem) and $3–4\,mg\,dl^{-1}$ (24 h postmortem). Therefore, reliable assessment is possible for pathological levels if the specimens are obtained during the early postmortem period.

Renal failure can be ruled out if the creatinine level is below $2.5\,mg\,dl^{-1}$. It is possible if its concentration ranges between 2.5 and $4.0\,mg\,dl^{-1}$ and renal failure is to be considered as the primary cause of death with levels exceeding $4.0\,mg\,dl^{-1}$, given CSF being obtained within the first hours postmortem. After death, the normal relation between creatinine levels in serum and CSF remains almost the same.

On one hand, problems may arise from a connection between renal damage and creatinine level. On the other hand, high creatinine values are seen without any or only slight alterations of the kidneys. However, there is also the possibility that advanced kidney damage coincides with levels below $4\,mg\,dl^{-1}$. It must be pointed out that disturbances of the circulation and toxicemia may cause creatinine retention but that partial renal function can still be in place during uremia [6].

Urea

In case of renal failure, there exists a close relation between the levels of urea in serum and CSF (normal range: $13.8–34.6\,mg\,dl^{-1}$). The urea level in CSF is approximately three fourths of the serum value. However, there have been reported reduced levels in CSF and also slight increases in blood from the femoral veins and also in liquor compared to antemortem values and also independent from the cause of death. If renal diseases can be excluded, such changes may be due to agonal or postmortem effects. Furthermore, there is a rising difference between the

concentrations of urea in liquor and blood with the postmortem interval increasing. Often postmortem values are slightly higher compared to intravital estimations. However, this increase is lower if the intravital concentration has been rather high. In case of manifest renal insufficiency, possibly with uremia, there are usually considerable differences to the levels found in healthy individuals.

There is an arithmetical connection between urea–nitrogen and urea, which is as follows: urea–nitrogen $\times$ 2.148 (mg dl^{-1}) = urea (mg dl^{-1}). Urea levels in CSF above 20 mg dl^{-1} (9.3 mg dl^{-1} urea–nitrogen) are indicative of renal disease, whereas the postmortem "normal values" for blood from the heart is 179 mg dl^{-1} maximum (83 mg dl^{-1} urea–nitrogen), with a mean value of 102 mg dl^{-1} (47 mg dl^{-1} urea–nitrogen). The corresponding concentrations in CSF are 197 mgYdl^{-1} (92 mg dl^{-1} urea–nitrogen) with a mean value of 89 mg dl^{-1} (41 mg dl^{-1} urea–nitrogen). Contrary to this, urea levels in CSF and blood from the heart do usually exceed 200 mg dl^{-1} (93 mg dl^{-1} urea–nitrogen) during the first 13 h postmortem in the case of uremia from all imaginable causes [26].

Diagnosis

Postmortem estimation of creatinine and urea levels in blood from the heart (left ventricle preferred) and CSF have important relevance regarding the postmortem diagnosis of renal failure. The following ranges of values can be differentiated for a practicable combined diagnostic procedure:

Urea below 100 mg dl^{-1} in CSF/blood, creatinine below 2.5 mg dl^{-1} in liquor and below 3.5 mg dl^{-1} in blood: renal failure can be excluded.

Urea 100–200 mg dl^{-1} in CSF/blood: renal failure possible if there is an additional creatinine level of 2.5–4.0 mg dl^{-1} in liquor and of 3.0–4.5 m gdl^{-1} in blood from the heart. Urea above 200 mg dl^{-1} in CSF or blood: renal failure represents the primary cause of death if creatinine levels in liquor simultaneously exceed 4.0 and 4.5 mg dl^{-1} in blood from the heart [2, 6].

Water- and Electrolyte Imbalances

The regulation of the water and electrolyte balance aims to maintain *isotonia* and *isovolumia* within the intravasal space. Sodium, chloride, and bicarbonate show the highest extracellular concentrations, whereas potassium and phosphoric esters predominate in the intracellular space. Owing to the fact that the relation between extracellular fluid volume and water exchange is much lower in *infants* than in adults, water imbalances may develop much earlier and be life-threatening.

It is not rare that electrolyte imbalances occur due to other diseases such as diabetes mellitus, chronic alcoholism, and nutritive disturbances. There are some types of dysregulations, which can lead to sudden unexpected death and may therefore be of forensic medical relevance. *Isotonic dehydration* is characterized by extracellular loss of sodium and water in isotonic relation, e.g., during the polyuric phase of acute and chronic renal failure, vomiting and diarrhea, pancreatitis and peritonitis, and due to dermal loss (following burn injuries). The main mechanism of *hypotonic dehydration* is salt depletion together with extracellular deficit of water. Delirium and convulsions are typical cerebral symptoms, which have to be considered as causes of sudden death. *Hypertonic dehydration* (with hypernatremia) leads to a deficit of free water in the extracellular and also in the intracellular space and is caused e.g., by a lack of water supply, dermal loss (sweating), and also via the lungs (e.g., hyperventilation from infections and fever), the kidneys (diabetic coma), and the gastrointestinal tract (diarrhea, vomiting). The typical morphology comprises tinting of the skin, sunken eyes, dry surface of the galea and/or dry cutting areas of organs. A biochemical pattern was proposed as diagnostic tool. The so-called dehydration pattern consists of an elevation of sodium $>$155 mmol l^{-1}, chloride $>$135 mmol l^{-1}, and urea $>$40 mg dl^{-1}. Persisting imbalances also result in corresponding alterations within the CSF (osmotic gradient) [27, 28].

Regarding the postmortem diagnosis of *water and electrolyte imbalances,* measurements of the pH is of no value. Estimations of electrolytes in CSF and vitreous humor can only be of limited meaningfulness. On one hand, the pH strongly depends on the state of the body, and, on the other hand, liquor often becomes sanguinolent when it is obtained so that there may be considerable alterations especially to electrolytes. Centrifugation may be of certain help, but cannot remove all components originating from damaged erythrocytes. This is why liquor from the lateral ventricles should be obtained, because after

12–24 h there are no differences to lumbar liquor [29].

Potassium

Disturbances of the potassium balance can gain forensic medical relevance because they have been described to occur not only isolated but also in connection with other diseases and sudden death (acute myocardial failure due to arrhythmias). Particularly, intestinal or renal loss or insulin treatment of diabetic coma are likely to result in *hypokalemia* ($<3.6\,\text{mmol}\,l^{-1}$). The main causes of *hyperkalemia* ($>5.0\,\text{mmol}\,l^{-1}$) are acute renal failure, chronic renal insufficiency, or extensive tissue damages. The main possible complications are disturbances of conduction, ventricular flutter, and fibrillation, which may lead to asystolia (acute danger to life with potassium levels $>6.5\,\text{mmol}\,l^{-1}$) [1, 2, 6].

Estimation of potassium in blood and serum specimens obtained postmortem have proven not to be reliable due to extremely fast and intense potassium release from cytolysis. In CSF, the potassium value can reach up to sevenfold of the normal level within the first 10 h postmortem, but the range of variation is rather wide. The potassium content of liquor is, to a large extent, independent from the serum level and in infants lower than in adults (normal range: *ca.* $2.1–4.6\,\text{mmol}\,l^{-1}$). Contrary to this, the increase of the potassium concentration in vitreous humor has been reported to be regular. This can provide certain conclusions regarding the time of death within the first 12 h postmortem. There seem to be no other relevant disturbances from other diseases on the potassium content of vitreous humor except hepatic failure. Furthermore, there do not exist any comprehensible associations between the concentration differences of sodium and potassium, which appear to allow further reliable conclusions [30–34].

Sodium/Chloride

There is an extracellular decrease of *sodium* parallel to an increase of potassium (see above) postmortem. As a general rule, there is a variation of the sodium level within CSF mostly corresponding to the serum concentration (*ca.* $128–157\,\text{mmol}\,l^{-1}$), except situations with severe infections of the central nervous system.

Without differentiation regarding the mechanisms of death, sodium levels in CSF and serum are usually found within the normal range, but the variation range differs considerably from intravital values (*ca.* $123–205\,\text{mmol}\,l^{-1}$). Although there is a distinct decrease of sodium in CSF and serum after death, its concentration in vitreous humor remains rather stable up to 30 h postmortem, followed by an almost linear decrease in the following 50 h. Sodium levels above $155\,\text{mmol}\,l^{-1}$ and below $130\,\text{mmol}\,l^{-1}$ in adults and larger differences outwith the normal range in children can be indicative of hypernatremia or hyponatremia antemortem. Sodium levels in *fluid obtained from the pericardial sac* show distinct correlation to the postmortem interval, namely, a decrease of approximately $0.4\,\text{mmol}\,l^{-1}$ during the first 85 h after death, but also with a wide range of variation.

The level of *chloride* in CSF is approximately 20% higher compared to serum and shows a range of *ca.* $110–129\,\text{mmol}\,l^{-1}$ in healthy individuals. The postmortem changes of chloride are comparable to those of sodium (see above), so that there happens also a typical decrease of the chloride concentration in plasma and CSF. The levels of chloride and sodium in vitreous humor appear to be almost "parallel" and remain nearly constant for over 30 h postmortem. However, any close correlations between chloride values and causes of death or time could not be identified postmortem.

Calcium

The homoeostasis of calcium has an important impact onto the neuromuscular conduction. *Hypocalcemia* (total Ca $<2.2\,\text{mmol}\,l^{-1}$, ionized Ca $<1.1\,\text{mmol}\,l^{-1}$) results in pathological reflexes or arrhythmia. Causes of *hypocalcemia* (total Ca $>2.7\,\text{mmol}\,l^{-1}$, ionized Ca $>1.3\,\text{mmol}\,l^{-1}$) are chronic osteolytic or endocrine processes in most of the cases, which may be the reason for sudden unexpected deaths via electrolyte imbalances with arrhythmias, somnolence, and coma.

Under postmortem conditions, the serum calcium concentration is constant for *ca.* 10 h with a slight increase thereafter (normal range in healthy individuals: $1.96–2.60\,\text{mmol}\,l^{-1}$). The calcium contents of CSF reflect approximately the serum level of ionized calcium. In vitreous humor, calcium levels are much more stable and there is less influence of agonal and postmortem effects [1, 2].

Diagnosis

Postmortem diagnosis of imbalances of electrolyte and water metabolism cannot be based on isolated single parameters. Assessment must always include a synopsis of different values. Furthermore, the postmortem interval has to be taken into account in each case. Postmortem biochemical analyses regarding electrolyte imbalances are believed to be most successful in cases being characterized by elevations of parameters such as states of dehydration. One main disadvantage are the wide range of variation referred to single analyze results. This requires a combined interpretation of different values with consideration of all morphological and toxicological findings as well as the possibility of combined dysregulations (e.g., kidney and glucose metabolism).

High Excitation and Hypothermia

A state of *high excitation* is characterized by a massive release of catecholamines, especially in situations with mechanical restraints and also in cases of prolonged agony. Such stress situations can be classified by estimation of adrenaline and noradrenaline levels using high performance liquid chromatography (HPLC) in serum, CSF, and vitreous humor. Analyses in different compartments is useful to achieve semiquantification of the intensity of stress and its impact on the mechanism of death.

Particularly increased noradrenaline levels in CSF and vitreous humor are indicative of a protracted stress reaction. The author's research has revealed massively increased catecholamine concentrations, partly exceeding the normal ranges many times (adrenaline values in vitreous humor and CSF 100–8000 $ng\,l^{-1}$; noradrenaline levels 4000–70 000 $ng\,l^{-1}$ (normal ranges in serum: adrenaline 20–120 $ng\,l^{-1}$ and noradrenaline 150–170 $ng\,l^{-1}$)). Especially high noradrenaline levels indicate a longer duration of stress [35–37].

Hypothermia can also cause a massive release of catecholamines in the sense of intense stress. The levels are within the ranges of high excitation with the noradrenaline concentrations being considerably higher than those of adrenaline (10- to 32-fold) comparable to cases with prolonged agony. Contrary to this, adrenaline levels often exceed those of noradrenaline in death cases with short agony. Death due to hypothermia results in mean quotients adrenaline/noradrenaline considerably <1, whereas quotients >1 are typical for short agony (e.g., myocardial infarction, head trauma) being indicative of higher adrenaline levels [38].

Additional analyses of volatile substances (ethanol, methanol, propanol-1, propanol-2, and acetone) usually show elevated acetone concentrations in all compartments being indicative of hypothermia, but basically only in cases that are ethanol-free. Acetone and propanol-2 are then altered equally. If relevant alcoholization is found, both substances can only be found in very low or physiological ranges that is indicative of an antilipolytic effect of ethanol (acetone $>35\,mg\,l^{-1}$ if blood alcohol level is $<10\,mg\,dl^{-1}$ vs. $<5\,mg\,l^{-1}$ if blood alcohol level is $>185\,mg\,dl^{-1}$) [39].

Conclusions and Final View

Regarding the postmortem diagnosis of *fatal diabetic coma,* morphological findings are only of indicative value. Therefore the diagnosis "death due to diabetic coma" always has to be a *synopsis comprising medical history, macromorphology and histology completed by postmortem biochemistry.* Specimens (CSF, vitreous humor, blood, and urine) should be obtained if there is any suspicion on disturbances of the glucose metabolism. Parameters of major relevance are "sum value" and hemoglobin A_{1c}, which are found to be elevated in most cases of fatal coma (above $415\,mg\,dl^{-1}$ and 12.1%, respectively). The level of free acetone usually exceeds $21\,mg\,l^{-1}$ and urine glucose concentration exceeds $500\,mg\,dl^{-1}$. A correct diagnosis always requires a combination of a minimum of three positive values e.g., increased "sum value", hemoglobin A_{1c} positive, and elevated acetone concentration *or* increased "sum value" and several indicative findings within macromorphology and histology (*see also* **Natural Causes of Sudden Death: Noncardiac**).

Under forensic medical aspects, the diagnosis of fatal diabetic coma can only be made *per exclusionem.* Consequently, other mechanisms of death, e.g., intoxications, have to be ruled out. However, overlapping with other causes of death appears to be rather typical and common. Owing to the fact that the whole diagnostic procedure can only be carried out *per exclusionem,* the only area of overlapping causing problems is that with "natural

causes of death" because myocardial infarctions or pulmonary embolism may both represent real complications of diabetic coma and can as well cause metabolic decompensation to preexisting diabetes mellitus. Especially in cases with acute myocardial infarctions differentiation may be problematic, but contrary to such acute changes, the situation is different with chronic alterations as e.g., narrowing coronary arteriosclerosis or myocardial scars. With such preconditions, the higher the relevance of positive biochemical findings is, the more intensive they appear to be (very high "sum value" and acetone level, etc.).

Postmortem biochemical examinations can also provide help in cases without morphological causes of death outwith the field of diabetes mellitus so that specimens of body fluids should also be obtained. Often analyses on certain parameters sensibly complement postmortem morphological diagnostics as in cases of liver disease, chronic renal failure, and electrolyte imbalances. Preliminary studies have also been carried out on the usefulness of other body compartments (e.g., synovial fluid) for a range of examinations as well as for further biochemical parameters (e.g., troponin T) [40, 41].

It has to be mentioned that urea levels in blood and CSF are likely to be elevated in case of *chronic kidney disease* and furthermore slightly following death, but this increase has been found to be considerably lower in liquor compared to blood. Postmortem diagnosis of renal insufficiency can be made with urea levels above $200\,\mathrm{mg\,dl^{-1}}$ (urea-nitrogen in excess of $93\,\mathrm{mg\,dl^{-1}}$). Creatinine concentrations seem to remain widely unaltered in all body fluids postmortem. The most reliable examinations are possible in CSF with a level below $1.6\,\mathrm{mg\,dl^{-1}}$, expected to be typical in individuals without kidney disease. However, postmortem biochemistry can only represent one pillar of the procedure to establish the cause of death as such results are unsuitable to be used as the only diagnostic criterion.

Especially, a combined spectrum of postmortem biochemical values is of most relevant meaningfulness, regarding the diagnosis of fatal metabolic disturbances. They may be strongly indicative of chronic or acute mechanisms and diseases, although, of course, no clinical diagnoses based on postmortem findings can be made. *Exclusion of any competitive mechanisms* is of special importance. A final diagnose regarding the cause of death can only be made by the inclusion of medical history, macromorphology, histology findings, postmortem biochemical results, and toxicology and *per exclusionem* only.

GERHARD KERNBACH-WIGHTON

Postmortem Interval: Anthropology

One of the most difficult tasks for the forensic anthropologist is establishing the postmortem interval (PMI) – i.e., time since death. The determination of PMI on skeletal remains is affected by enormous limitations, which have to do with the great variability in decomposition rates.

Postmortem phenomena (such as putrefaction and other types of decomposition) severely alter markers, which are essential for the evaluation of the PMI (along with identification of the body, interpretation of manner of disposal of the body, and the manner of death, in particular signs of trauma). To correctly and thoroughly read and interpret human remains in this sense, intrinsic factors (pertaining to the body) may not be sufficient and it is becoming increasingly evident that the environment (i.e., extrinsic factors such as plants, pollen, algae, moulds, macrofauna, and microfauna) may be crucial for answering the question of PMI [1–8]. Much of the difficulty in determining the time since death and/or permanence of a body in a specific environment stems from the lack of systematic observations and research on the decomposition modalities in different environments of the human body. Postmortem changes have been dealt with extensively in the literature but are very specific and bear too little an interdisciplinary approach [1–28]. Many physicochemical changes begin to take place in the body immediately or shortly after death and progress in a fairly orderly manner until the body disintegrates. Each change has its own time factor or rate. Unfortunately, these rates of development of postmortem changes are strongly influenced by unpredictable endogenous and environmental factors. Consequently, the longer the PMI, the wider is the range of estimate as to when the death probably occurred. In other words, the longer the PMI, the less precise is the estimate of the time of death. Shortly after death, enzymes that occur naturally in the body begin the degradation processes (autolysis), subsequent decay by bacteria and fungi is purely aerobic and, ideally, leads to the entire skeletonization of the corpse. According to an old rule of thumb, 1 week of putrefaction in air is equivalent to 2 weeks in water, which is equivalent to 8 weeks buried in the soil, given the same environmental temperature. The interval between the time of death and final skeletonization is governed by the environment in which these processes occur, while the processes of degradation on the soil surface, which is biologically highly active, usually reach completion within several weeks, the time required for the decomposition of interred bodies takes between 3 and 12 years under favorable conditions. Under unfavorable conditions, the processes might require up to a hundred or even thousands of years before completion [29–43]. Once severe decay sets in, tools for determining PMI and permanence in a specific environment move from forensic pathology to forensic anthropology and taphonomy (i.e., the study of decaying organisms over time and the effects environmental factors may have on them) and to the multidisciplinarity of other forensic sciences, more or less well known, such as forensic entomology, forensic botany, zoology, hydrology, etc. In fact, forensic entomology is the only one of these disciplines that has been thoroughly investigated, but may not be sufficient. Taphonomy and other disciplines (such as even biomolecular diagenesis) must take their stand in the medicolegal world in order to solve the above-mentioned issues. This means that a multifactorial approach dealing with intrinsic and extrinsic factors must be sought. Very few studies exist in this sense, perhaps, because the world of natural sciences, anthropology, taphonomy, and forensic medicine are still too far apart. Until now, the following steps have been taken. Tenessee's body farm has led to several observations on decomposition processes of human remains in specific environments, but these deal mainly with macroscopic observations, entomological, and chemical ones. As regards human decomposition processes, sporadic case studies exist on this issue, on the surface, in soil, and in water, which, however, only deal mainly with body intrinsic and entomological factors. Even useful chemical aspects still need to be explored. For example, the articulated processes including physical, chemical, biochemical, and microbiological changes occurring during postmortem events have to be held responsible for the onset of odour. Odour, a complex mixture of volatile compounds, is a complicated and difficult attribute to measure. The electronic nose is an instrument that comprises an array of electronic chemical sensors with a partial specificity and an appropriate recognition system capable of recognizing simple or complex odors. Substantial work has been done to

Figure 1 Human remains of a young woman found in a woody area in northern Italy. Much mummified tissue still clings on to the bone surface. Postmortem interval was known to be eight months. Remains were found in spring

apply electronic nose technology for environment and food quality monitoring and evaluation in order to identify, recognize, and discriminate different odors. In food, animal species for human nutrition, spoilage odors as key indicators for fresh or not fresh fish (in conjunction with other factors, such as oxidative changes and growth of microrganisms), and time development of these volatile components in both fish and cereals have been identified. However, no studies are available on the precise identification and possible quantification of odorous molecules from corpses, and this argument at present is the domain of dog conductors, who train dogs to recognize a possible grave localization utilizing their ability to track decomposition odors. The repeatability of cadaver decay in animal models has been treated in an experimental study on the effect of freezing and thawing and on the decomposition of organic matter. Some work has been done for intrinsic changes of the pig body (and some entomology) particularly in forests and in a marine environment, but very few reports combine the data on intrinsic and extrinsic factors. From these few reports, interesting data emerge: the great variability of decomposition and the need to combine decomposition with environmental data. Botany (roots, leaves, and pollen) and zoology (diatoms, plankton, etc.) seem to have a crucial role (Figures 1, 2). The significant contribution of annual growth in woody tissue for PMI estimation has been proven and many have stressed the importance of extrinsic factors – however, the world of combined extrinsic and intrinsic factors still remains uninvestigated.

For the case of skeletonized or partly skeletonized human remains, it is frequently difficult to say whether such remains belong to someone who

Figure 2 Botanical remains can be of crucial importance. The image shows a grain of pollen in microscopy that denotes the season of deposition on human remains, and therefore a term *antequem non* since death

died 5, 10, 20, or even more years before. Variables dependant on the environment, climate, location, and even animal intervention can seriously modify decomposition rates and preservation of human remains in an unpredictable manner. The exposition to the sun, temperature, climatic rainfall, and wind conditions as well as soil chemical characteristics influence bone surface appearance and may alter PMI estimation.

A rough distinction at times can be made between archaeological and forensic remains. Some scientists claim that it is possible to distinguish among recent bones (less than 10 years), old bones (less than 50 years), and ancient bones according to a more or less dry appearance of the bone. In the past, PMI on bones

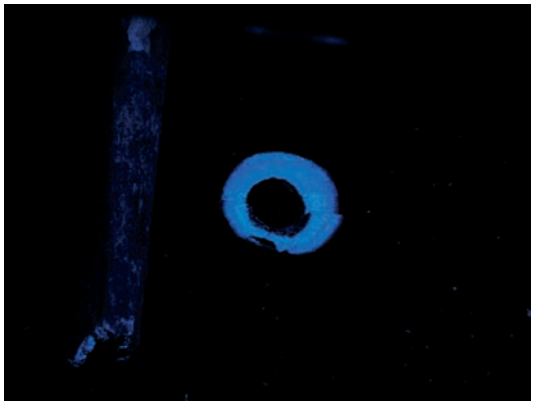

Figure 3 Cross section of a femur with a PMI of 5 years showing a greater degree of fluorescence with UV light

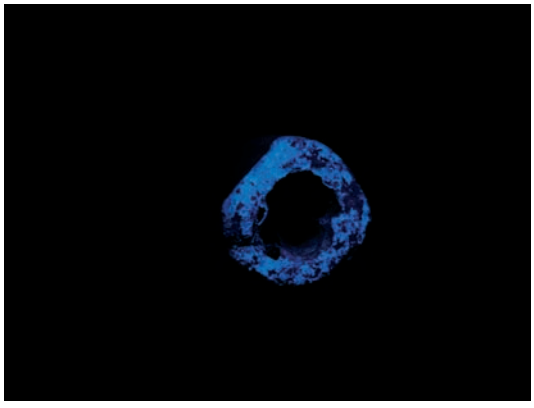

Figure 4 Cross section of a femur with a PMI of 50 years showing a lesser degree of fluorescence with UV light

has also been estimated according to the quantity of organic material still visible within the bone matrix by illumination with UV light (Figures 3 and 4) or the microscopic appearance of bone (Figures 5 and 6).

These methods, such as the macroscopica appearance, are, however, dependant on too many variables affecting degradation, which may not reflect the actual length of PMI. In other terms, a skeleton with a short PMI may look more degraded, if it was exposed to harsh environmental factors, than a skeleton with a longer PMI with less severe environmental variables. In spite of attempts to standardize fluorescent and microscopic patterns, these tests give no unequivocal classification, and therefore can provide only indicative data on PMI.

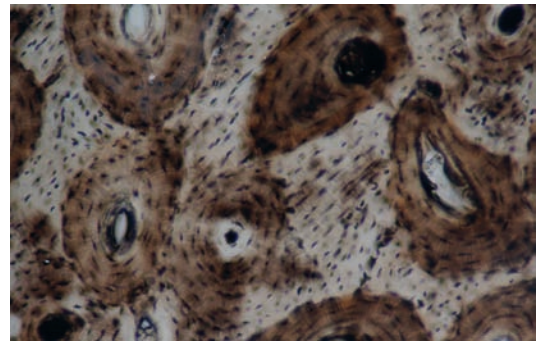

Figure 5 Microscopical aspect (100×) of fresh bone (PMI of several months). The structure of bone is clearly visible

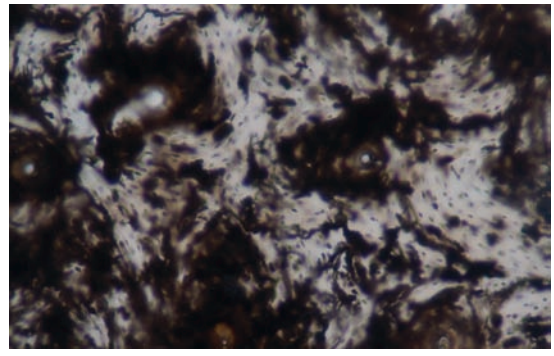

Figure 6 Microscopical aspect (100×) of old bone (PMI of 50 years) that shows severe degradation, destruction of the microscopical structure, and fungal infiltration

This is why in cases of retrieval of skeletal remains, the context becomes fundamental. The botanical analysis of leaves, roots, and seeds on and around the remains, for example, can give a *postquem non* or *antequem non* temporal limit by studying the elements that have colonized the site after the deposition. A PMI indication can also be reached throughout the analysis of clothes and personal belongings found at the site. Entomological study of insects colonizing remains may provide a more accurate indication about the age of deposition; corpses are in fact colonized by different insect populations in accordance with season, climatic conditions, environmental characteristics, and decomposition stage.

Radiochemical tests are another, more expensive, tool by which the anthropologist may try to determine PMI [35–43]. These are based on the decay rates of radioisotopes fixed in bone during life. The

use of Carbon-14 provides accurate information about the PMI in case of archeological remains, but its importance in forensic material is reduced because its before period (BP) date refers to the 1950s. Strontium 90 may also be useful; its high atmospheric concentration is due to massive explosions and nuclear weapon pollution that occurred during World War II. Another method benefits from the high levels of artificially introduced Carbon-14 in terrestrial organisms by thermonuclear devices between 1950 and 1963. It is based on the observation that different tissues of the body have a diverse time of development and a diverse turnover rate. Quantifying radiocarbon values in different tissues and placing these values in the bomb-curve, taking care of noting the age of the individual and other factors, allows an estimation of the date of death.

All such methods, however, still need calibration and testing for contamination – and remain exclusive to few laboratories and are quite expensive.

Postmortem Toxicology: Artifacts

Introduction

In unnatural, sudden, violent, or unexpected deaths, the investigator often needs evidence whether a foreign compound is present in autopsy material. Moreover, quantification of a drug is necessary to state whether its amount is sufficient to cause, prevent, or be involved directly in the death [1]. The interpretation of an analytical result is often the most difficult aspect of forensic toxicology. It is different from the situation in clinical toxicology, and largely dependent on the type and quality of specimens provided as well

as on storage and analytical procedures [2, 3]. Interpretation and evaluation may become more difficult in decomposed or embalmed cases. Nevertheless, in these cases, drug degradation or formation of artifacts is more likely to be expected [4, 5].

Artifacts in forensic postmortem toxicology are substances or drug concentrations present in body fluids or tissues during analysis that do not correspond to the genuine drug or drug level present in the body at the time of death. Because of the immediate history of the treatment of the deceased, the postmortem time period as well as the collection, storage, processing, and analysis of postmortem specimens, these artifacts remain an inherent part of postmortem forensic toxicology. For the analyst, postmortem artifacts may be an intricate and demanding challenge. To avoid errors in the evaluation of an analytical result, it is essential to be aware of and to identify artifacts.

This article illustrates various individual artifacts, explains their origin, and discusses techniques to recognize them and minimize their effects.

Antemortem Factors

In death investigation, quantification of a foreign substance is often necessary to state whether the amount of a particular compound is compatible with fatal poisoning or more in accordance with therapeutic concentrations in the underlying case [6]. In living beings, basic pharmacokinetic concepts and models provide estimates of the quantitative relationship between the dose of a drug and the observed blood or tissue concentration. This field is concerned with drug liberation, absorption, distribution, metabolism, and excretion as well as the relationship of these processes to the intensity and time course of the drug's therapeutic and adverse effects. A large pharmacologic variability can be observed in living individuals. Factors likely to contribute to the individual's response to a drug and to influence the disposition of a drug are given in Table 1 [1, 2].

In acute poisoning, death may usually occur before steady state has been reached, and the arterial blood concentration can be appreciably higher than the venous blood concentration. Studies on arteriovenous differences in drug concentrations during lifetime are rare, most comprehensive data for humans are provided by Chiou [7]. For example, arterial plasma concentrations of amitriptyline were found to be up to fourfold greater than venous concentrations during the absorption/distribution phase. With diazepam and lidocaine, the initial arteriovenous differences were of approximately 2 orders of magnitude and lasted for about 60 min after dosing.

Table 1 Factors likely to contribute to pharmacokinetic variability [1, 2]

Different preparations of the drug and clandestine manufacture
Dose, route of administration, and frequency
Pharmacokinetics
Age, gender, race, and genetic disposition
Body weight, exercise, nutrition, condition, and disease state
Genetic variation in drug metabolism
Tolerance
Coadministration of other drugs or alcohol

Disease affects the way drugs are absorbed, distributed, metabolized, and excreted. The liver and the kidneys play a central role in the disposition kinetics of most drugs [8]. Patients with renal disease excrete considerably less unchanged drugs than patients with normal renal function. If a drug is only eliminated by hepatic metabolism, however, its clearance should not be markedly altered. This rather simple theory does not apply to all metabolized drugs. For example, patients with impaired renal function may experience severe and prolonged respiratory depression when treated with morphine. Although morphine's metabolism and excretion is not impaired in renal insufficiency, accumulation of morphine-6-glucuronide occurs. There is evidence that morphine-6-glucuronide is an active metabolite [9]. Sulfonurea drugs, such as glibenclamide, are likely to cause significant hypoglycemia due to accumulation of the active metabolite in renal insufficiency [10]. The effects of liver disease on the pharmacokinetics of drugs are unpredictable due to multiple effects that liver disease produces. In alcoholic cirrhosis, the half-life of diazepam is increased about fourfold over control values [11]. An impaired metabolism and changes in the apparent volume of distribution with chlordiazepoxide have also been observed in severe liver disease, but not with oxazepam and lorazepam, whose elimination involves glucuronidation only [12]. Liver dysfunction also affects hepatic blood flow, which is important in the disposition of drugs with a high hepatic extraction ratio [13]. For example, the coefficient of variation for morphine

serum concentrations during four consecutive days of stable oral morphine treatment at stable clinical symptoms ranged from 13 to 103% [14]. This day-to-day variation has been attributed to fluctuations in hepatic blood flow [15].

Not only is a high degree of variability routinely found between subjects, but a wide range of blood levels may also be seen in the same subject taking a drug on different occasions. The renal clearance of digoxin is significantly lower during a period of immobilization than during a period of normal physical activity leading to an artifactual increase in digoxin concentration [16]. A large pharmacokinetic variability is consistently observed with drugs that are subject to a substantial presystemic metabolism and/or a high hepatic clearance such as desipramine, where plasma levels differed by 30-fold in patients treated with 25 mg desipramine orally three times a day [17].

Alcohol is a common finding in medicolegal death investigations. Many drugs interact with alcohol, thereby altering the mechanism or effects of the alcohol and the drug involved [18]. Dorian *et al.* [19] have shown that the area under the curve of both amitriptyline and nortriptyline was increased in the presence of ethanol because of a reduction in amitriptyline hepatic clearance.

At present, drug–drug interactions are widely recognized, although the underlying mechanisms are still far from being fully evaluated [20]. A great deal of variability, both pharmacokinetic and pharmacodynamic, has been seen with midazolam in patients on mechanical ventilation in an intensive care unit [21]. The half-life of midazolam ranged from less than 2 to about 10 h. In addition, it was difficult to establish a relationship between consciousness and the concentration of the drug. These differences were associated with the state of the patient and the variety of coadministered drugs. Far less is known about drug–nutrient interactions resulting in therapeutic failure or drug toxicity [22]. For example, the activities of cytochrome P450 (CYP) 3A4, CYP2C9, and CYP1A2 may be increased by use of St. John's Wort, and kava may inhibit CYP1A2, CYP2D6, and CYP3A4 [23]. Carbamazepine causes a loss of biotin, which may lead to poor seizure control, and plays a role in the drug's adverse effects [24].

In drug overdose or critically ill persons, pharmacokinetics of a drug are likely to be very different from the common subjects of pharmacokinetic reports, due to diminished cardiac output, falling blood pressure, decreased tissue perfusion, impaired ventilation, tissue hypoxia, acidosis, dehydration, as well as renal and hepatic failure. With few exceptions, there is little information on this point. Major changes in the clearance and volume of distribution of morphine were found in trauma and burned patients, and sepsis may induce a decrease in the hepatic metabolism of drugs [25].

Also, formation of endogenous compounds may be considered. An elevated blood isopropanol concentration, which is usually attributed to alcohol misuse, can be observed following physical exercise. Isopropanol is also detectable under pathophysiological conditions in diabetes mellitus, and in liver and gastrointestinal diseases. In these cases, the blood acetone concentration is also increased [26]. In ketotic states, isopropanol may function as a shunt regenerating NAD^+, thus contributing to the maintenance of metabolic stability.

Not only analytical results may be biased by clandestine manufacture of drugs, which are frequently impure or adulterated, but substances present with these drugs can also be classified as diluents, adulterants, impurities of manufacture, and impurities of origin. Adulteration may occur by the addition of bulking agents or to fake the pharmacological effect. For example, lidocaine is a common adulterant in cocaine preparations [27]. A comprehensive overview on clandestine drug synthesis including pharmacological activities associated with the analogs and impurities is given by Soine [28].

The presence of tolerance will usually make interpretation of results difficult. Tolerance may result from a decreased efficacy at the receptor site or an increased metabolism due to enzyme induction. The presence of a drug analyte in blood or urine can be used to document recent exposure only. By providing information on exposure to drugs over time, hair analysis may be useful [29]. Although there are still controversies, particularly concerning drug incorporation, the influence of cosmetic treatment, and external contamination, long-term information on an individual's drug use may be accessible through hair analysis [30, 31].

Effects of treatment during resuscitation or hospitalization may produce artifacts. In persons who have undergone emergency medical treatment, the medication given by the emergency physician should be provided, for, even without restoration of the heart

action during cardiopulmonary resuscitation, high concentrations of lidocaine in the left cardiac chamber were observed. Obviously, substantial amounts of intubation-related lidocaine had been absorbed by the trachea during cardiac massage [32]. Treatment with intravenous fluids for a period of time before dying often presents interpretative problems in alcohol and drug findings, and blood and tissues may even be devoid of detectable amounts. Devices that automatically deliver medication by the parenteral route can lead to artificially high blood concentrations postmortem [33]. Transdermal patches, e.g., fentanyl containing devices left on the body, will give rise to locally high drug concentrations of the drug [34].

All these factors affect a drug concentration that will be found in the body after death. However, experience has told that there are many additional and even unique aspects of postmortem changes, which are discussed in the following passage.

Changes Occurring after Death

Postmortem Redistribution

Drug concentration is likely to change after death. Early indications that a change does exist are from Curry and Sunshine [35] reporting large differences in the concentrations of barbiturates in blood obtained from different anatomical sites. A comparison of ante- and postmortem drug levels already indicates that postmortem drug concentrations do not necessarily reflect concentrations at the time of death. A study on six cases revealed postmortem blood concentrations as high as, or higher than the antemortem circulating blood concentration [36]. For example, an 11.7-, 3.9-, and 2.6-fold increase could be noticed for dothiepin, amitriptyline, and methadone in postmortem blood. In general, drugs with wide concentration ranges observed in central (c) and peripheral (p) blood exhibiting a high c/p ratio tended to have a high postmortem/antemortem concentration **Postmortem Toxicology: Interpretation**. In contrast, no significant difference was observed in samples taken at admission and autopsy in heroin fatalities [37]. At present, the attempt to estimate antemortem concentrations from postmortem measurements is prone to considerable error [38–42].

Knowledge on the mechanisms causing artifactual increases or decreases in drug concentration during the postmortem period is still limited. These changes are gathered under the generic term of *postmortem redistribution*. The underlying mechanisms of postmortem redistribution as far as known have been reviewed by Pelissier-Alicot *et al.* [43], Yarema and Becker [44], and references cited therein. The physicochemical and pharmacokinetic properties of a drug are probably favoring factors. Organs such as the gastrointestinal tract, the lungs, the liver, and the myocardium are major sources of postmortem redistribution. Cell and tissue modification during agony, autolysis, and putrefaction are also involved.

Potential factors that have been recognized to govern postmortem redistribution are summarized in Table 2. It appears that drugs that have an apparent volume of distribution $>3\,l\,kg^{-1}$, and are sequestered in tissue and present in extracellular fluid are candidates for postmortem redistribution. Accordingly, amitriptyline exhibited significant postmortem distribution, whereas morphine and its glucuronides indicated only a trend for higher concentrations in heart blood compared with femoral or subclavian blood [37, 45, 46].

Many drugs are sequestered antemortem in organs, and postmortem redistribution may either occur by diffusion through blood vessels or from the lumen of a body cavity toward surrounding organs. The vascular pathway may depend on the blood remaining fluid after death. Investigations on postmortem

Table 2 Major factors governing postmortem drug distribution

Physicochemical and pharmacokinetic properties of the drug	Size, shape, charge, pK_a, partitioning behavior, lipophilicity, volume of distribution, binding to proteins and/or red cells, affinity toward tissues, decreasing or residual metabolic activity during the perimortem and early postmortem time period
Environmental conditions	Initial concentration, pH, orientation of solute flux, temperature, time, blood coagulation and hypostasis, blood movement due to pressure and fluidity changes, position of the corpse, lysosomal enzyme activities, and bacterial invasion

diffusion from gastric residues in a human cadaver model using amitriptyline, paracetamol, and lithium carbonate revealed high concentrations in liver and lungs, whereas diffusion into gallbladder bile, cardiac, and aortic blood was less severe [47]. Diffusion of ethanol from the stomach into blood is not a problem in alcohol analysis. For an intact stomach containing 400 ml of 10% ethanol, contamination of a femoral vein sample was minimal [48]. However, it should be considered that regurgitation of alcohol or drugs from the stomach, esophageal sphincter relaxations, and severe blunt trauma resulting in the rupture of internal organs, especially of the stomach, facilitate postmortem diffusion processes. These circumstances may favor artificially elevated blood concentrations [49, 50].

Drugs accumulated in lungs are rapidly released inducing elevated drug concentrations in thoracic and heart blood samples as well as in liver specimens. These changes were assessed in animal and cadaver models, and were, e.g., also seen in methamphetamine-associated deaths [51]. Redistribution from the lungs seems more intense than redistribution from the gastrointestinal tract due to the large surface of the alveoli, the thin membranes, and the high vascularization. The early rise in dothiepin levels in thoracic blood in a rabbit model reflects postmortem redistribution from the lungs, where the drug was heavily concentrated [52]. Fuke *et al.* [53] observed that torso blood samples showed less toluene after gastric instillation than after tracheal instillation. Also, a higher toluene concentration was present in the left lobe of the liver than in the right with gastric instillation. The pleural and peritoneal fluids are regarded as vehicles for drug exchanges between the lungs and the liver [43].

The redistribution effects from the liver are far more complex, and may occur via the hepatic vessels or directly to adjacent organs, such as the stomach or the gall bladder [39]. Postmortem decreases in concentrations of fluoxetine and norfluoxetine, in both liver and lungs, occurred along with increases in blood concentrations in a dog model [54]. In rats, administered amitriptyline in the liver lobes had high but variable drug concentrations among tissues. Lobes lying closest to the stomach had the highest drug concentrations [55]. In general, a great part of the surface of the left liver lobe being in close contact with the stomach wall will be more involved in postmortem redistribution. Also, it may be difficult to correctly assign the source of hepatic concentrations postmortem [43].

A substantial increase in heart blood could be noticed for drugs, such as calcium channel blockers or cardiac glycosides, which are highly bound to cardiac tissue. In a series of digoxin cases, the drug concentration was invariably higher in heart blood specimens than in peripheral blood samples [56, 57]. The lungs, the liver, and the stomach may serve as further drug sources. A useful compilation of drug concentrations in heart and femoral blood has been published by Dalpe-Scott *et al.* [58].

Variations in postmortem drug concentration largely depend on both the time since death and the site of blood collection. Differences in drug concentrations collected from different anatomical sites have been reported for numerous drugs including imipramine, diphenhydramine and codeine [59], methadone [60, 61], doxepin, clomipramine, barbiturates [39], amitriptyline [45], cimetidine [62], methamphetamine [51], cocaine [63], digoxin [56], zopiclone [64], methylenedioxymethamphetamine, and methylenedioxyamphetamine [65]. A review on site-dependent differences is given by Prouty and Anderson [41] and Baselt [38].

It is evident that postmortem redistribution is governed by the postmortem time interval. Compared to studies on site-dependent differences, only few data on time-dependent differences are available. In a fatal case of dihydrocodeine intoxication, site-to-site differences of the parent drug and major metabolites were very small, probably due to steady state, an apparent volume of distribution of $1.0-1.3\,l\,kg^{-1}$ for dihydrocodeine, the fluidity of blood as well as very early postmortem blood sampling [66].

Some case reports have determined that there is little evidence of time-dependent variability, which may be due to delayed sampling. Temporal changes in drug concentrations that have been studied in animal models revealed significant changes to occur already during the early postmortem period [55, 67–70]. The level of dothiepin in cardiac and pulmonary blood samples steadily increased to reach 400% of its original concentration at 8-h postmortem [71]. In a dog model, 2-h postmortem concentrations of fluoxetine and norfluoxetine were 2.2- to 6.0-fold higher than antemortem concentrations, but did not significantly differ from 12-h postmortem concentrations [54]. An overview on drugs in which redistribution is likely to occur or in which postmortem redistribution probably

does not occur is provided by Drummer [3], Leikin and Watson [4], and Baselt [38].

Major Changes of the Media and the Analyte Occurring after Death

General Remarks. As indicated in the section "Postmortem Redistribution", body fluids and tissues as well as drugs present in these specimens are subject to fundamental changes during the postmortem time period. Alterations of the media may considerably impact drug analysis. Decomposition of a corpse involves the processes of autolysis and putrefaction. Enzymes naturally present in the body induce autolytic changes; putrefaction is due to destruction by microorganisms. The onset of autolysis is rapid in cells with high concentrations of hydrolytic enzymes, such as the pancreas and the gastric mucosa, and is slower in the cells of the heart and the liver. Being the specimen of choice for detecting, quantifying, and interpreting drug concentrations, a more detailed review of postmortem changes in blood is given.

Postmortem Changes of Blood with Regard to Drug Analysis. Blood is a complex mixture that contains solubilized proteins, dissolved fats, solids, and suspended cells. Serum or plasma is traditionally used in clinical settings because blood affords advanced handling in the laboratory procedures [6]. Drug concentrations provided in literature are usually determined from these fluids. Analytical results obtained from postmortem blood are compared valuably with levels previously reported in therapeutic and toxic conditions [38, 72–74]. However, separation of red blood cells from postmortem blood is usually not possible, and its composition may remarkably differ from a blood sample obtained from a living person.

Changes may already occur during agony [75]. Hypoxia reduces the intracellular pH value, thus inducing an increased accumulation of basic drugs into the cells. Neutral or acidic drugs are less affected. Intracellular acidification and changes in ionic strength lead to a damage to the lysosomal membrane, and, subsequently, to enzymatic digestion of the cell membrane and components. Drugs that are concentrated in the cell are redistributed at this stage into the extracellular compartment. After death had occurred, there is a rapid progress in postmortem redistribution processes due to disintegration of physiological and anatomical barriers (see the section "Postmortem Redistribution"). Postmortem vascular permeation has been shown in an *in vitro* model using morphine and its glucuronides [76].

In addition to the immediate postmortem dropping of the pH value up to 5.5, a decrease in blood–water content can often be observed [75, 77]. There exist strong variations in the water content of postmortem blood ranging from 59 to 89%. Both hemoconcentration and altered partition behavior affect original drug levels.

As the permeability of all cell membranes increases, hemolysis occurs. In addition to hemolysis seen with most specimens, blood coagulates postmortem, and then becomes liquid again. The effectiveness of these two processes will determine whether postmortem blood is clotted, fluid or partially clotted, and partially fluid [78]. Blood clots distribute unevenly in the body. A few hours after death, hypostasis occurs by sedimentation of blood and serum to the lower parts of the body due to gravitation. As a result, concentration measured for any drug exhibiting unequal distribution between red cells and serum may be biased by blood hypostasis, irregular clotting, and hemolysis.

Average distribution ratios between whole blood and plasma are given for major drugs in Table 3 [61, 79–88]. Further data of blood-to-plasma concentration ratios are provided by Baselt [38] and Iten [89]. For some drugs, varying blood-to-plasma ratios have been observed between individuals. In patients, chlorpromazine erythrocyte concentrations tended to correlate with plasma concentrations, but the erythrocyte/plasma concentration ratio varied from 0.61 to 2.00 among patients [90].

Ratios may not only vary between drugs but also differ between a particular drug and corresponding metabolites. Some caution is advisable using these data. Most of them are derived from *in vitro* partition experiments using systems composed of plasma water, plasma proteins, and erythrocytes. When spiked blood is diluted with autologous plasma water, erythrocytes always discharge the compound overproportionally, compared to plasma proteins [91, 92]. Also, ratios may differ depending on whether the sample had been collected from a living person or a corpse. For example, the plasma-to-whole blood concentration ratios of cannabinoids were found to

Table 3 Blood-to-plasma concentration ratios for some drugs of forensic interest

Drug	Ratio	Reference
Amitriptyline	1.0–1.1	[79]
Nortriptyline	1.5–1.7	
Cocaine	1.00	[80]
Diazepam	0.70	[79]
Oxazepam	1.00	[81]
Ethanol	0.74–0.90	[82]
Methadone	0.75	[83]
	1.00	[61]
Morphine	1.02	[84]
Morphine glucuronides	Dependent on hematocrit	[85]
Δ^9 - Tetrahydrocannabinol	0.55, 0.66	[86, 87]
11-Hydroxy-Δ^9-tetrahydrocannabinol	0.57, 0.58	[86, 87]
11-Nor-9-carboxy-Δ^9-tetrahydrocannabinol	0.62	[88]

be very similar and their individual coefficient of variation to be very low in samples taken from living individuals. However, data obtained postmortem suggest that the distribution of cannabinoids is scattered over a wider range of values compared to those determined in living subjects. Also, cannabinoids favored postmortem "serum", the mean ratio between the blood supernatant and whole blood being 2.4, but only 1.6 in samples collected from living people [88]. Generally, the differences observed between blood or plasma are considered to be less important compared to the changes in concentration that may occur prior to sampling.

Invasion of intestinal flora into tissues and body fluids occurs rapidly after death, especially at ambient or elevated temperatures. Postmortem blood samples taken 6 h after death in patients who had died of causes other than infectious diseases were tested positive for bacteria [93], whereas in a study on heart blood samples collected 85 h after death bacteriologic cultures gave negative results [94]. Microbial enzymes hydrolyze and transform lipids, carbohydrates, and proteins. As a result, the pH value of blood slowly increases again during the postmortem interval [75, 95].

Postmortem Alterations in Drug Concentrations. Degradation as well as formation of drugs during the postmortem interval as competing processes to postmortem redistribution has been observed. Drugs concentration may change due to chemical and physical degradation, metabolic formation or breakdown (Table 4). Problems also arise from interfering substances that are endogenously produced during autolysis and putrefactive processes (see the section "Postmortem Redistribution").

Systematic investigations on the time dependence of detectability of drugs or poisons in a putrefying body do not exist. Some case reports revealed that drugs such as morphine or atropine may be identified in specimens from exhumed corpses or from stored tissues many months after death [96]. Comprehensive data on positive drug findings in putrefied bodies had been published by Arnold *et al.* [97]. For example, phenobarbital, bromazepam, sulpiride, and promethazine could be successfully identified in highly putrefied materials. The interpretative value of these measurements is limited, however.

Recovery of organophosphorous pesticides, such as parathion or malathion, was less successful compared to paraquat, whereas recovery of organochlorine compounds was >72% from putrefactive materials [99, 100]. Stevens [95] studied the stability of 56 drugs and drug-related compounds added to drug-free liver homogenates. Degradation was elevated in samples exposed to fly-borne bacteria. From the results, the following molecular structures are assumed to be prone to putrefactive decomposition: oxygen that is bonded to nitrogen as in nitro groups or *N*-oxides, sulfur, which forms part of a heterocyclic ring, and aminophenol structures. A variable decomposition rate, which was observed for dothiepin in bacteria-contaminated liver and blood specimens, was suggested to be due to differences in bacterial activity [52].

Table 4 Possible mechanisms operating on drugs postmortem, examples modified according to [98]

Mechanism	Example(s)
Chemical instability	
Hydrolysis	Heroin, cocaine, *O*-acyl-, and *N*-glucuronides
Oxidation	Sulfur-containing drugs and morphine
Metabolic instability	
Esterases (endogenous)	Hydrolysis of ester-type drugs Hydrolysis of phase-II metabolites Reduction, e.g., of nitrobenzodiazepines Oxidation, e.g., of thioridazine
Metabolic production	Ethanol, γ-Hydroxybutyrate, carbon monoxide, and cyanide

The possible role of enteric bacteria in the bioconversion of nitrobenzodiazepines was studied in detail by Robertson and Drummer [101]. It is well known, that in deaths involving flunitrazepam, considerably higher concentrations of 7-aminoflunitrazepam than that of the parent compound can be detected in blood [102]. The conversion of the respective 7-aminometabolites of nitrobenzodiazepines by individual bacteria in blood was species dependent. Significantly higher rates were found for obligate anaerobic species than for facultative anaerobic species, and there was little difference among the species for their ability to metabolize nitrazepam, flunitrazepam, or clonazepam. The conversion rate was slowed down by keeping the corpses at 4 °C. The effect of pH variation on the metabolic activity of different bacterial species was variable.

Postmortem degradation does also concern acid-labile conjugates, such as the ester glucuronides of 11-nor-9-carboxy-Δ^9-tetrahydrocannabinol, propofol, or diflunisal [103, 104] as well as the more stable ether glucuronides [105]. Conversion of morphine glucuronides to free morphine by residual glucuronidase activity or some bacterial enzymes is a most prominent example [106]. The bacteria most likely involved are originating from the gastrointestinal tract. Being the most prominent among them, *Escherichia coli* is an important source of β-glucuronidase activity. Preferential hydrolysis of morphine-3-glucuronide to free morphine by bacterial enzymatic activity was ascertained in *in vitro* experiments, and was shown to depend on storage time, temperature, and initial degree of putrefaction [107].

Bacteria, yeast, and fungi can also produce some compounds in the postmortem blood, the most prominent representative being ethanol. In contrast to drug metabolism, which may persist some time after death, the physiological metabolism of ethanol is assumed to cease at the time of death [108]. A considerable site-dependent variation of the ethanol concentration in blood samples had been observed even in cases where signs of putrefaction could not be noticed [109]. These differences were mainly attributed to death occurring during the absorptive phase where differences between arterial and venous blood exist. Ethanol absorbed from the gastrointestinal tract distributes throughout the body according to the water content of the corresponding tissue or body fluid. The postmortem change in blood alcohol content closely following the change in blood water content, correction for water content has been recommended [110]. In principle, the water content of blood decreases with the time after death. However, there are some exceptions, e.g., drowning experiments with animals indicated a dilution of alcohol in blood [111].

Postmortem changes of ethanol are well documented [112]. The majority of the cases attributed to neoformation did not have significant ethanol concentrations (<0.07%). However, there are a few case reports demonstrating that a significant amount of ethanol up to 0.22% may be produced [113, 114]. The amount of ethanol formed during the postmortem time interval depends on the antemortem conditions, the species of microorganisms present, the availability of substrates, and the storage conditions of the body prior to collection of samples for toxicological analysis **Alcohol: Analysis**. In bodies that were stored refrigerated, even in the presence of microbial species capable to produce ethanol, alcohol formation

could not be established within 4–24 h after death [113, 115]. Comprehensive reviews on the variety of organisms capable of producing ethanol and on the microbiology and biochemistry of postmortem ethanol formation are given by Corry and Huckenbeck [116, 117]. Potential substrates are carbohydrates, glucose, lactate, ribose, and amino acids, and glycolysis is thought to be the primary process for ethanol production [116, 118].

For postmortem synthesis of ethanol is difficult to be accurately established, further putrefactive products have been suggested as indicators to differentiate postmortem-formed ethanol from antemortem-ingested ethanol. Along with ethanol, other short chain alcohols, such as 1-propanol, isopropanol, 1-butanol, 2-butanol, isobutanol, and isoamylalcohol, are produced by microorganisms. Methanol is considered not to arise from microbial synthesis. In case reports, *in vitro* and animal studies, most commonly 1-propanol, could be detected [113]. Estimation of the ethanol synthesis based on the 1-propanol or other short chain alcohol levels seems questionable due to their highly variable formation rates as well as for they may derive from ingested alcoholic beverages. Huckenbeck [117] found that different Clostridium and Proteus species produced α- and γ-aminobutyric acid and δ-aminovaleric acid along with ethanol, but a quantitative relationship between postmortem ethanol and putrefactive amino acid production could not be established.

Postmortem cyanide production could give improper estimation of cyanide poisoning from blood analysis. Seto [119] suggested that cyanide is released from methemoglobin cyanide complex by heat denaturation, and diffuses out of the blood vessels via plasma during which it encounters albumin. Also, liberation by superoxide anion radical oxidation of proteins has been assumed. However, these pathways have been judged to be of minor importance compared to cyanide production during storage or as an analytical artifact.

γ-Hydroxybutyrate (GHB) has been widely abused. It is also a naturally occurring compound present in the mammalian central nervous system. Small amounts are formed from γ-aminobutyric acid with subsequent reduction to form GHB again. Besides its premortem production, GHB can be produced as a postmortem artifact [120]. When GHB concentrations are low at a postmortem time interval of more than a few hours, they may be falsely implicated as a cause of death [121].

Artifacts in Specimens Stored in Formaldehyde or Collected after Embalmment

Sometimes it is necessary to perform analysis on pathologic specimens stored in formaldehyde or on samples that have been collected from an embalmed body. The embalming procedure may have diluted the blood, and/or may have partially or completely removed drugs or poisons present at the time of death from major blood vessels [122]. Embalming fluids are typically based on formaldehyde with final concentrations of 5–20% at acidic or neutral pH values, and may usually also contain alcohols [123]. Formaldehyde is a highly reactive chemical agent, and may mask, alter, or destroy a drug during the fixation or embalming process. Previous studies have demonstrated that formalin can react with various drugs including, e.g., amphetamines [124], barbiturates [125], and benzodiazepines [126] in a time, pH value, and formalin concentration-dependent manner. Most likely, reaction pathways are through hydrolysis and/or methylation via the Eschweiler–Clarke reaction. In addition, body fluids and tissues are difficult to extract due to denaturation.

Results from liver tissue specimens collected from drug-related suicides indicated that some methylation of nortriptyline to amitriptyline had occurred during formalin fixation and storage, but consistent ratios could not be established [122]. In a different study, conversion of nortriptyline to amitriptyline was confirmed [127]. For the formation of amitriptyline was only proportional to the loss of nortriptyline at a pH value of 9.5, it was suggested that the metabolite may be susceptible to degradation in formaldehyde containing solutions at lower pH values. *N*-methylation has also been reported for amphetamine, methamphetamine, and fenfluramine. Disappearance of fenfluramine was higher at elevated formaldehyde concentrations, and an increase in pH directly correlated with the appearance of *N*-methyl fenfluramine [128].

Some drugs appeared to be reasonably stable in formalin. In a study examining chemically fixed tissue specimens of poisoned rabbits, a formalin solution containing 10% formaldehyde (pH 7.4) was found to be most suitable for diazepam- and

chlorpromazine-containing tissues for at least 28 days with respect to the recovery of the analytes [129]. Succinylcholine only slowly degraded in embalmed rat tissue samples [130]. It appears that the embalming fluid maintaining acidic conditions contributed to the drug's stability in fixed tissue, whereas succinylcholine is very rapidly hydrolyzed in blood. However, some compounds, such as alprazolam and midazolam, decompose more rapidly under acidic conditions [126].

Stability of volatile substances in formalin-fixed tissues was tested for ethanol, diethyl ether, chloroform, and toluene in a rabbit model by the intravenous route [131]. All volatile compounds were still detectable after a 14-day fixation period. Compared to nonfixed materials, in the fixed tissue samples concentrations had decreased in the following order: ethanol > diethyl ether >> chloroform > toluene.

Leaching of drugs into the fixing/storing solution is evident. In a sildenafil-related death, a comparison of the quantitative values of sildenafil in fixed tissues and those in the same tissues at autopsy revealed a mean decrease of 74%. However, the total recovery from both the fixed tissue and the particular formalin solution was 95% with regard to the original quantity in the same tissue before fixation [132]. Similar observation was reported on the detection and quantification of morphine and strychnine in fixed samples and formalin solutions [133, 134].

Analysis of fixed samples may create problems with regard to the isolation of the analyte and damage of the technical equipment. Iffland *et al.* [135] succeeded in determining carbon monoxide in clots of heart blood collected from an embalmed body following release of carbon monoxide from the sample by nitric acid. Phenobarbital was detected in fixed brain tissue as well as in the formalin solution in a poisoning case using ultraviolet (UV) spectrometry and thin layer chromatography, whereas gas chromatography (GC) was not applicable due to interferences and damage of the column [136].

Acquisition of Specimens

General Considerations

The purpose of sampling is to provide a representative part of the whole that is suitable for analysis and reliable interpretation. Sampling is the most important step in drug analysis because an analytical result will never be better than the sample from which it is derived. Specimens available in postmortem toxicology investigations can be numerous and variable, and may be selected on the basis of the case history, requests, legal aspects, and availability in a given case. So far, a harmonized protocol for sampling in suspected poisoning or drug-related death has not been established [49, 137]. Generally, the specimens routinely collected at autopsy include fluids, such as blood from peripheral sites and heart blood, urine, bile, cerebrospinal fluid, vitreous humor and gastric contents, and organs, particularly liver [49, 138]. The main collection artifact is contamination, but can be reduced by sampling before the autopsy, if appropriate. It is difficult, if not impossible, to acquire quality specimens once autopsy has been completed. An appreciation of how contaminants may be introduced is also important.

Sampling Artifacts

Incorrect Selection and Acquisition of Samples. Samples taken for analysis should always be chosen bearing in mind the disposition of the drug in the body. An incorrect or insufficient sampling will severely affect case investigation **Toxicology: Analysis**. In fatalities requiring quantitative determination, a blood specimen is preferably taken from the femoral vein prior to autopsy, for contamination may be avoided, and this site is less affected by postmortem changes (see the section "Changes Occurring after Death"). If the femoral vein is ligated prior to sampling, the sample is likely to be relatively uncontaminated by blood from the major organs [40]. Cardiac blood is regarded as unsuitable for quantitative analysis of drugs. Diffusion out of the stomach can artificially raise the cardiac blood concentration, and a sample may equally contain blood that has drained from the lungs, the vena cava inferior, the aorta, and the subclavian veins. If a heart blood specimen is sampled through the chest wall, one should be aware that the sample is contaminated with thoracic fluid and gastric contents. Postmortem specimens obtained from patients who have died several days after a drug-related episode are likely to give negative results [2]. It is essential to perform toxicology investigations on specimens obtained on or soon after admission to hospital. In fire victims, blood that is not collected from body regions excluded from severe burning can contain falsely elevated carbon monoxide levels due

to diffusion of environmental carbon monoxide and binding to hemoglobin. Relying on a result from a single specimen may be misleading. It is recommended to collect blood from at least two different sites or, if not available, along with other specimens, at least.

Urine is a valuable specimen, because it can easily be tested, and drugs and drug metabolites are usually found in high concentrations **Drug Testing: Urine**. A sample collected during autopsy may be contaminated by blood and should preferably be taken prior to autopsy by puncture of the abdominal wall. A positive identification indicates recent drug use, but does not indicate when or how much drug was ingested. There is little correlation between urine and blood concentrations. If death takes place quickly, urine findings can be negative. Analysis of a specimen may not be a reliable means to reveal ingestion of drugs, e.g., sertraline and norsertraline, which are present in very low concentrations or were not renally cleared [38]. Analysis of a urine specimen may reveal exposure to organophosphate compounds or analysis of toluene, xylene, and trichloroethylene via identification of their major metabolites in cases where blood analysis will fail to detect these compounds [38]. Local anesthetics, e.g., lidocaine, which are used on catheters, are a common finding in urine samples.

Gastric contents are a useful specimen to rapidly discover drug overdose, for oral ingestion is the major administration route of prescribed drugs. The total amount of a drug or poison remaining in the gastric contents is far more important than its concentration. A low absolute amount does not rule out the possibility of an overdose. Also, a low drug concentration in the stomach may arise from passive diffusion from the blood into stomach contents. This phenomenon is frequently observed in drugs being weakly basic in nature [33]. Since the gastric contents can be largely inhomogeneous, the entire specimen should be submitted or mixed before an aliquot is taken. The odor of gastric contents or colored material can potentially point to a specific agent, although, e.g., blue stains may result from parathion or flunitrazepam ingestion.

Bile represents a collection and storage depot for many xenobiotics and corresponding metabolites that have a biliary excretion and are subject to enterohepatic cycling. To avoid contamination of surrounding tissues, the gall bladder should be tied off before removing from the liver. Drug concentrations can be significantly higher in bile than in blood. The mean bile to blood ratios varied from about 1 for acetaminophen and amphetamine to about 2000 for desmethylclobazam. In several cases, a drug could be identified in bile, but was not detectable in blood [139]. A qualitative finding in bile may indicate previous or chronic exposure to a drug or poison.

Cerebrospinal fluid and vitreous humor are aqueous and transparent fluids, which are useful to screen for a variety of drugs [140]. Both cerebrospinal fluid and vitreous humor also contain very little proteins. Therefore, drugs highly bound to proteins or lipophilic in nature tend to be found in lower concentrations in these fluids than in blood [49, 141]. A major limitation to the use of cerebrospinal fluids is the small database of reference values [142], whereas vitreous humor has been used to analyze a larger number of drugs [143–150]. Many studies have stressed the usefulness of vitreous humor for alcohol analysis [151]. However, the wide variation of vitreous humor to blood ethanol ratios must alert when results from vitreous humor are used to estimate the concentration in femoral venous blood [152].

Tissue specimens collected for postmortem toxicology investigations include liver, kidney, lung, brain, skeletal muscle, and adipose tissue [49, 151]. Tissue samples may be useful in cases with an extended postmortem time period and whenever body fluids are not available. Extensive data had been published for liver and kidney, less for brain and lung specimens [38, 153]. Drug concentrations in liver were found to be site dependent (see the section "Postmortem Redistribution"), and sampling from deep within the lobe has been recommended [154]. Concentrations in brain may also significantly vary from one region to another [155]. The within-case variability of drug levels observed in muscle specimens supports the opinion, that drug analysis on skeletal muscle is rather qualitative than quantitative in nature. Muscle specimens had also been considered for alcohol analysis, but the muscle to blood–ethanol concentration was found to depend on the time course of ethanol absorption, distribution, and elimination [156]. A skin specimen or a cube of muscle may support evidence of the route of drug administration [49]. As skin acts as a temporary drug reservoir, the specimen should always be excised together with a

random specimen preferably taken from a similar site to act as control [157].

Hair is an ideal specimen for determining, e.g., chronic arsenic and mercury poisoning [158]. Also, numerous drugs and poisons have been detected in hair in recent years (*see* **Hair: Toxicology**) [159, 160]. The amounts deposited in hair are functions of both ingestion/exposure and of the metabolic regimen. Segmentation of the hair can assist in estimating the time of exposure. A decrease in drug concentration in the proximal sections of hair may indicate a decrease in tolerance to the drug. There are many factors that influence drug concentrations in hair: biological factors such as hair structure and pigmentation, individual factors such as drug use, customs culture or race including hair care, environmental factors, and also methodological factors [30]. External uptake of drugs from blood, vomit, or putrefactive fluids leads to artificially elevated drug levels in hair, which will not be fully removed by common wash procedures [31].

Specimen Containers and Preservation. The use of appropriate specimen containers and preservatives can be critical with regard to ultimately identify a substance in an individual specimen. Specimens must be collected in separate, clean containers, which should be filled up to minimize evaporation of volatiles and oxidative losses of drugs.

The best materials to collect and store fluids or tissue specimens are glass containers. Sampling into a glass container is a must, if solvent abuse or an anesthetic death is suspected. Essential are also aluminum foil- or Teflon-lined lids to prevent gas escaping and to minimize drug adsorption. Solid tissue samples may also be placed in nylon bags, which are tightly sealed [138]. Most types of plastic containers are suitable for the collection of tissue specimens in drug-related fatalities. Disposable hard plastic tubes or Nalgene® bottles with screw caps are also recommended for collection of body fluids for breakage of these containers upon freezing had not been observed [161]. The use of evacuated tubes is less desirable, for sample contamination from plasticizers used in their manufacture may occur. For collection tubes containing gel separators, a gross contamination by toluene, 1-butanol, ethyl benzene, and xylene has been reported [162]. Evaluating the container before routinely collecting specimens in it might reduce production of artifacts.

Obligatory recommendations for specimen preservations do not exist. Specimen preservatives are generally not required for specimens other than blood. In addition to a preserved blood sample, an unpreserved specimen available to the toxicologist is optimal, for preservation strategies depend on the target analytes and are not unique. Fluoride preservation with a final concentration of 1–5% sodium fluoride by weight is recommended for postmortem analyses of alcohol, cocaine, cyanide, and carbon monoxide. Postmortem synthesis of ethanol can be effectively inhibited, whereas hydrolysis of cocaine can only be slowed down by fluoride preservation [163]. A general problem with ester-type drugs is the presence of esterases; as degradation takes place even at 4 °C, immediate freezing of specimens is recommended [164]. Artificial production of GHB has been observed in blood samples not collected in fluoride-containing tubes [165], and also in specimens collected in citrate buffer [121]. Fluoride preservation must not be used when organophosphorous chemicals are involved. For example, rapid degradation of metrifonate (dichlorvos) was found to be favored by the presence of sodium fluoride, esterases, elevated temperatures, and alkaline condition [166]. Early acidification of the specimen and storage at −80 °C was recommended by Heinig *et al.* [167].

Acidification may also stabilize cocaine or labile conjugates such as *N*-glycosides [5, 168]. Ascorbic acid may be used as an antioxidant. For example, losses in olanzapine during storage at 4 °C may be reduced by the addition of 0.25% ascorbic acid [169]. Apomorphine, like most catechols, is prone to oxidation to quinones, unless ascorbic acid is added as an oxidant [170]. However, the presence of an antioxidant may have reverse effects. During storage reduction of the *N*-oxide metabolites of chlorpromazine, of samples containing antioxidants, resulting in an increase in the concentration of the parent drug, has been observed [171]. Anticoagulants are not recommended for postmortem blood samples because these additives may also affect drug concentration. Blood concentration of morphine in ethylene diamine tetraacetic acid (EDTA) tubes was 4.8% higher than in heparin tubes [172], which also contain phenolic preservatives such as cresol [171].

Stability During Storage

In clinical chemistry, stability is defined as the capability of sample material to retain the initial value of a measured quantity for a defined period within specific limits when stored under defined conditions. The individual maximal permissible instability is preferably linked to the criteria of analytical imprecision, and is expressed as the critical difference [173]. This procedure allows defining the maximum permissible storage time for an analyte in a particular specimen at a given condition.

In postmortem investigations, such consideration starts at the time of sampling and covers the time until analysis. The presence and extent of alterations since the time of death can only be estimated, part of them even cannot be avoided, and they cannot be undone. Therefore, knowledge on degradation mechanisms in a particular matrix and on resulting breakdown products is important.

A review on poisons, drugs, and heavy metals suspected to be unstable is given by Leikin [4] and Ellenhorn [174]. Unfortunately, the particular biological matrix, which may play a role in the stability of an analyte, has not been considered. For example, in urine, cocaine is chemically stable at a pH of less than 7.0. In blood samples, even acidic conditions do not prevent cocaine to be metabolized by residual esterase activities. Interestingly, cocaethylene seemed to be more stable in postmortem specimens than cocaine. Muscle as well as brain tissues were considered to be the specimen of choice for testing both cocaethylene and cocaine [168]. Valuable information on artifacts is provided by Baselt [38] and Drummer [175]. Comprehensive data on the stability of drugs of abuse in blood were reported by Levine and Smith [176] already in 1989. A recent update was given by Skopp and Pötsch [177]. Data on the stability of drugs in tissues are rare.

In principle, all volatile compounds such as aerosol propellants, anesthetic gases, carbon monoxide, ethanol, and organic solvents are unstable during storage. Losses of up to 25% of blood toluene have been observed in glass tubes stored unopened for 7 days at room temperature, and considerably higher losses were noted in glass tubes with rubber stoppers [178]. There is an artifactual rise in carbon monoxide level in unpreserved blood specimens since bacterial action can result in both the production of carbon monoxide and the denaturation of hemoglobin [38]. The formation of toxicologically significant concentrations of cyanide in postmortem tissue has been demonstrated, which was attributed, in part, to conversion of thiocyanate to cyanide and breakdown of proteins [179, 180]. Conversely, a significant decrease in blood cyanide concentration has been attributed to mechanisms that include evaporation, thiocyanate formation, and reaction with specimen components [181]. Temperature and cyanide concentration are apparently important factors in these changes [182].

Another important consideration when measuring drugs is the stability of corresponding metabolites. Highly labile metabolites such as sulfate conjugates and *N*- and acylglucuronides may rapidly be converted back to the unconjugated compound and consequently result in falsely elevated concentrations. Examples are the *N*-sulfate metabolite of minoxidil, *N*-glucuronide metabolites of nomifesine, and 11-nor-9-carboxy-Δ^9-tetrahydrocannabinol glucuronide [103].

Some of the degradation mechanisms seen during storage are similar to those observed during autolysis and putrefaction (see the section "Major Changes of the Media and the Analyte Occurring after Death"). Generally, degradation of a drug occurs through hydrolysis, oxidation or reduction processes, and is generally slowed down by decreasing storage temperatures and preservation of the sample (see the section "Specimen Containers and Preservation"). These processes are due to endogenous enzyme activities, e.g., esterases still operating in the sample, chemical reactions or to enzyme activities such as glucuronidase following bacterial invasion during the postmortem interval (see also Table 4) [98].

Experimental investigations on time-dependent changes give information on the reaction type involved in drug degradation [183], and may guide to a more proper estimation of the drug level at the time of sampling. Hydrolysis of ester-type drugs generally exhibited an apparent first-order reaction kinetic, whereas an oxidation can often be described by a second-order reaction kinetic. Investigations on the reaction type involved in the degradation of forensic relevant drugs have already been performed, e.g., for morphine, morphine glucuronides, cocaine, benzoylecgonine, ecgonine methyl ester, lysergic acid diethylamide (LSD), and 11-nor-9-carboxy-Δ^9-tetrahydrocannabinol glucuronide [103, 105, 163, 184].

The mechanisms involved in the breakdown of benzodiazepines are poorly understood. Hydrolysis and reduction are suggested to be involved in their degradation. Degradation of nitrobenzodiazepines occurs very rapidly, whereas other benzodiazepines do not appear to be as unstable [101, 185]. Besides bacteria, major influence factors in the degradation of nitrobenzodiazepines are an increased temperature and the absence of sodium fluoride [186]. Chlordiazepoxide tends to form desoxychlordiazepoxide during storage, and further degrades to nordiazepam, which also represents a metabolite and an artifact in the analysis of the parent drug by GC [187].

Terbutaline was shown to be stable in spiked postmortem blood at room temperature for 7 days. In contrast, a loss of 83% was observed for fenoterol in spiked postmortem blood at the same conditions. Only 7% of the initial concentration was present after 6 months at 4 °C. The instability of fenoterol is most likely a result of the presence of the phenolic group attached to the side-chain nitrogen atom, which is susceptible to oxidation [188].

There is evidence that different degradation mechanisms operate in blood depending on its source, either obtained from living individuals or collected from corpses. An experimental investigation on morphine and its glucuronides in spiked fresh blood and plasma revealed that oxidation primarily affected drug stability, whereas in postmortem samples stored under the same conditions, hydrolysis of morphine glucuronides was assumed to be the predominant reaction [105].

Sometimes, metabolites or breakdown products are far more stable than the parent drug. Complete degradation of furazolidone occurred in muscle tissue stored at 4 °C during 24 h. Even storage in liquid nitrogen did not fully stabilize furazolidone [189] indicating that analysis of a metabolite, which is reasonably stable, may be favored [190]. The poor stability of cocaine, benzoylecgonine, and ecgonine methyl ester is well documented [163, 183, 191]. Alternate analysis for ecgonine representing a rather stable breakdown product may be performed in highly putrefied specimens or specimens stored for long periods of time.

Most drugs or poisons are probably stable in biological materials for months, particularly if frozen and special arrangements may prevent loss of an analyte by degradation (see the section "Specimen Containers and Preservation").

Analytical Artifacts

Although the history of a sample appears to be most relevant to the production of artifacts, analytical artifacts may also be considered during the isolation and identification of an analyte. For most drugs and poisons, a two-stage testing is usually employed, comprising a preliminary screening test followed by confirmatory analysis, which should offer a higher degree of specificity for the analyte than the first test. A gross overview on common methods used in postmortem toxicology investigations has been given by Hearn and Walls [1] as well as by Drummer [3]. There is little to differentiate in analytical procedures used in other forms of forensic toxicology with respect to postmortem toxicology investigations.

Available immunoassays can yield positive results in urine for metabolites from most of the common benzodiazepines, except lorazepam and flunitrazepam [1]. These drugs may not be detected until hydrolyzed [192]. Interaction with putrefactive amines is commonly seen in immunoassays for amphetamine-type drugs [193]. Interactions are not limited to matrix effects or the structural and conformational similarity of compounds. Further information on cross-reactivity and potential mechanisms is given by Richardson [2]. In addition, turbid, highly colored, or opaque specimens can interfere with the detection principle affording an intensive preextraction step.

Chromatography has been the mainstay of drug analysis for many years. Often, a special pretreatment or homogenization according to the specimen's nature and/or a more sophisticated cleanup extraction of putrefied materials is required for all forms of chromatography. Extraction into an organic solvent for partial purification of a biological fluid or a tissue homogenate is still widely used. Lipophilic compounds will be readily extracted by nonpolar solvents. The more polar solvents being partially miscible with water will also remove water-soluble materials. As a result, drug conjugates are also transferred into the organic phase. If phase-II metabolites are subsequently hydrolyzed, this will lead to erroneously high levels of the parent drug [103, 194]. The phenomenon of conjugate instability is most common with labile conjugates such as *N*- or *O*-acyl-glucuronides [103, 104].

The chemical properties of a solvent can give rise to chemical reactions of the solvent itself and the insidious breakdown products or stabilizers it

may contain. For example, the effect of phosgene in chloroform has been reported as a cause of artifactual formation of carbamate derivatives during extraction of tricyclic antidepressants [195].

The problems associated with solvent extraction can be minimized by using solid-phase extraction. Because of its far greater variability, one must be well informed on the mechanisms of interaction to maintain proper control on the separation. If blood cells are not disrupted or if particles are still present in the sample, flow rates and reproducibility are altered.

The extraction efficiency of a drug or metabolite from a postmortem specimen may be variable from case to case, or even from site to site within the same corpse. It may also be markedly different than from a particular blank specimen used for calibration. The use of stable isotope internal standards may provide a higher degree in the accuracy of the analytical results. Unfortunately, few deuterated standards are commercially available for drugs, metabolites, or artifacts.

It is often necessary to evaporate extracts to reconstitute them into small volumes for transfer to chromatography. The most common routes of sample loss are adsorption onto glassware and volatilization of the drugs, e.g., of amphetamines. Adsorption losses can be prevented, e.g., by silanization of glassware or by including a polar solvent, such as amyl alcohols, as an additive to the extracting solvent or prior to evaporation. The problem of amphetamines' volatilization can be solved by converting them to their nonvolatile hydrochloride salts [6].

Gas chromatography coupled to mass spectrometry (GC/MS) is generally accepted as unequivocal identification for most drugs, and provides best confirmatory information. Also, liquid chromatography coupled to mass spectrometry(LC/MS) is an emerging technique [3]. There are several drawbacks with GC/MS analyses; some of them are included in Table 5.

It is now recognized that determination of major metabolites and degradation products along with the parent drug is essential to avoid misinterpretation of the data due to artifacts [196]. Such a stability-indicating assay is one that can accurately and selectively differentiate the intact drug from its potential decomposition products.

Table 5 Potential problems with GC/MS analyses[(a)]

Erroneous identification at a low analyte concentration
Misidentification due to interfering substances
Inadequate information due to similar (barbiturates) fragmentation behavior
Production of low mass fragment ions only (tricyclic antidepressants)

Conclusions

Artifacts must be accepted as an integral part of postmortem toxicology, frequently interfering with a straightforward interpretation of the analytical results.

Reporting all the details of the scene investigation and terminal events as well as of the social and medical history will aid to recognize important issues that may occur during the antemortem phase with respect to postmortem findings.

There is general agreement that drug concentrations are site dependent and tend to change with time, most significant alterations occurring already perimortem or rapidly after death. Heart blood concentrations are often higher than those of peripheral specimens. However, there does not appear to be a way to predict the relationship between drug levels derived from various specimens nor the manner in which the concentrations may change with time. To circumvent the problem of postmortem redistribution, it is recommended that blood be sampled from a peripheral vessel along with at least a second specimen taken from a different site, liver from deep within the right lobe and lung rather from the apex than the base. Tissue samples can be of value to assess the significance of a drug in the death of an individual provided that a sufficiently large database has been established.

Tables of therapeutic, toxic, or fatal ranges or correcting for blood-to-plasma ratio cannot be applied without restrictions. As the exact mechanisms of postmortem redistribution are not fully understood and most likely a combination of several factors, exact estimates of the dose are unreliable.

Postmortem degradation as well as formation of compounds have been observed, and may vary between tissues and body fluids as well as from drug to drug. For example, ethanol may be formed in postmortem blood in variable and nonpredictable amounts. In severely putrefied, embalmed, or formalin-fixed tissue, fundamental changes of both the matrix and the drug should be considered. Complete degradation or even removal of a drug may have occurred.

Sampling poses a high risk of contamination and/or production of artifacts. Correct sampling prior to or during autopsy is as essential as is the use of appropriate containers and preservatives including deep freezing. Some drugs or metabolites may undergo further decomposition during storage for several months.

Changes in materials and target analytes often require modifications of routinely applied analytical procedures; the most valuable appears to be a stability-indicating assay.

A thorough cooperation of the pathologist and toxicologist will enable to handle some of the problems addressed above. Some postmortem artifacts will never be resolved, whereas others are amenable to further elucidation from both case reports and experimental studies.

Postmortem Toxicology: Interpretation

Introduction

The detection of drugs and other substances in biological tissues, such as blood, represents the first stage in the application of toxicology to the forensic sciences. The presence of drug including situations where quantitative data are available requires careful interpretation.

With few exceptions, interpretation requires a thorough understanding of the circumstances of the case and an advanced knowledge of how the substances detected by the analyses interact with the body. Thus, knowledge of both the pharmacokinetics (effect of drug) and the pharmacology of the substance is required and must be carefully related to the known circumstances of the case.

This article provides an overview of the basic pharmacokinetics of drugs and how route of administration and the overall health of the person can influence the interpretation of toxicological results. Several examples are included to illustrate how toxicological data can be misinterpreted.

Other articles in this encyclopedia provide details of the expected effects of substances; see sections on drug classes: alcohol, amphetamines, cocaine, benzodiazepines, and the opioids (opiates). (*See also* **Behavioral Toxicology**).

Basic Pharmacokinetics

To understand the way substances such as drugs are absorbed and the time course of their presence in the body, it is necessary to understand some basic effects of drugs in the body, known as *pharmacokinetics* [1, 2].

The main pharmacokinetic phases can be segregated as follows: absorption, distribution, and elimination.

Absorption

Drugs that are swallowed rely on the release of the drug or other dose form in the stomach or small intestine. This can occur through disintegration of a tablet or through a controlled release of drug from the tablet matrix. Controlled release of drugs is designed to slow the absorption, to (usually) prolong the drug's actions, or sometimes to protect the stomach from potentially harmful drug (i.e., enteric-coated tablets). Except for some acidic drugs (e.g., acetylsalicylic acid), drugs are primarily absorbed in the small intestine and then mainly in the upper sections (jejumen). The delay from swallowing to first appearance of drug in the blood stream can be typically 15–30 min and will occur over many hours.

The time to the maximum blood (or serum) concentration is termed T_{max} (units: time such as hours), while the concentration at this time is termed C_{max} (units: mass per volume, i.e., milligrams per liter).

Many drugs once absorbed (or their subsequent metabolites) can be excreted into the bowel through bile and become reabsorbed further down the gastrointestinal tract. This is known as *enterohepatic recirculation* and can lead to an apparent delay (or even a second peak) in the absorption of drugs. Morphine is a common example in which morphine glucuronide metabolites secreted into bile find their way back into the bowel and are subsequently reabsorbed.

Unabsorbed drug is present in feces and can represent a significant proportion of the administered drug.

A number of pharmaceutical formulations provide a controlled release of drug from a tablet matrix. This is used to control the absorption of drug into the body and provide a longer duration of action of the drug. This is typically used for drugs with short biological actions and has the net result in reducing the need for repeated doses within a 1-day period. For example, morphine and oxycodone can be given twice daily rather than four times daily when formulated into a sustained delivery tablet or capsule.

Distribution

Once the drug is absorbed and has entered the blood stream, it is distributed to all parts of the body. The uptake of drug into tissues and organs will depend on access of drug to all parts of the tissue (e.g., blood supply) and the relative affinity of the drug-to-tissue components. There is considerable variation of drug uptake for different drugs and also between individuals. For some drugs, the affinity of drug to a tissue can be manyfold higher than the blood (e.g., THC in fat and muscle tissue).

The distribution phase is variable but usually requires some hours or days of exposure before some form of steady-state situation is reached.

Elimination

All foreign substances are eventually removed by the body; the rate depends on the drug and its ability to be metabolized (e.g., by liver) and excreted by the kidneys and other organs. Some drugs, e.g. cocaine, are rapidly metabolized to less active compounds and excreted within hours, whereas methamphetamine may only be excreted within days. The metabolism of drugs can be quite complex and often involve multiple pathways. In some cases, metabolites are also biologically active and contribute to the pharmacological response in a person (e.g., methamphetamine is metabolized to the active amphetamine) [3].

The time to halve the blood concentration (following the peak concentration) for methamphetamine can be over 1 day. This time is called *half-life*. This value applies to the terminal elimination phase once the drug has been fully absorbed and distributed to bodily tissues. There is considerable variation in half-lives among individuals, even for the same drug. Half-lives measured before the terminal elimination phase is dominant will generally underestimate the terminal elimination rate.

Some pharmacokinetic data including terminal elimination half-lives for common drugs of abuse are given in Table 1.

The term *clearance* is often used as another measure to quantify the removal of drugs from the body and represents a composite of all forms of drug removal. This includes a combination of kidney excretion, liver metabolism, and other sources of drug removal.

For volatile substances, elimination can also occur through expiration, e.g., alcohol (ethanol), solvents, although this is still a relatively minor source of elimination compared to metabolism and excretion through the kidneys.

Route of Administration and Bioavailability

The proportion of drug available to the body when compared with another route of administration is termed *bioavailability*. This term usually refers to the comparative availability of drugs that are orally taken compared with the same dose given intravenously. Drugs that have a bioavailability of 100% are completely absorbed orally and are not metabolized prior to entering the blood supply. For example, morphine has a bioavailability of 25% when given orally as tablets, meaning that only 25% of morphine is available to the body after oral administration. In total, 75% is either not absorbed or is metabolized prior to entering the blood. When morphine is given by intravenous injection, the bioavailability is 100%. Moreover, the injection has delivered the drug to the blood stream almost instantaneously by passing the absorption phase. Drugs given by intravenous injection will have an immediate intense effect on the person. In abuse situations, such as in the use of heroin, this can precipitate a cardiorespiratory collapse and sudden death [4].

Substances given by other modes of administration, e.g., nasal insufflation (snorting), inhalation (volatile substance abuse), smoking, etc., have different rates of drug absorption.

Table 1 Typical pharmacokinetic data for some common drugs

Drug	Dose range (mg)[a]	Typical blood concentrations ($mg\,l^{-1}$)[b]	Half-life (days)[c]
Alprazolam	0.5–4	0.05–0.2	0.3–1
Amphetamine	From 10	0.1–0.2	0.3–1.5
Diazepam	5–40	0.1–0.6	0.8–2
Cocaine	From 25	0.1–0.5	0.6–4
Codeine	8–60	0.1–0.3	0.1–0.2
MDMA	50–150	0.1–0.3	0.4–1
Methadone	5–120	0.1–0.3	0.6–3
Methamphetamine	From 10	0.05–0.2	0.5–1.5
Morphine	From 5	0.1–0.4	0.1–0.4

[a] Usual dose range
[b] Typical blood concentrations following common doses seen in forensic cases
[c] Pharmacokinetic half-life of terminal elimination phase
MDMA, 3,4-methylenedioxymethamphetamine

Single versus Multiple Doses

The pharmacokinetics of drugs do not generally change with repeated doses of drug; however, depending on the time between doses, there can be carryover from previous dose(s). For example, a drug with a half-life of 12 h will need about five times this

for the drug to be removed from the body. Hence, the administration of a further dose earlier than 60 h (5 × 12 h) will result in some accumulation of drug from dose to dose. In practice, multiple doses are given at least daily, and sometimes two or three times daily; hence, drugs with half-lives of more than a several hours will result in larger pharmacological responses on repeated dosing [1].

Methadone, a drug related to morphine, is used widely to treat dependency to heroin and other opioids. It has a half-life of about 24 h and when given once daily, the blood concentrations increase substantially over the first 5 days of treatment. This can cause potentially fatal toxicity if the initial doses are too high for the established tolerance to opioids [5]. To avoid this phenomenon, low starting doses are recommended, with daily monitoring for the first week of treatment to ensure optimal safety (and response) for the subject.

The interpretation of blood concentrations in a person on a drug such as methadone is further complicated by the accumulation of drug with repeated doses. Hence, the only way a toxicological result can be properly interpreted is to establish whether the drug was likely to have been taken as one (larger) dose or by repeated (smaller) doses.

Predicting Blood Concentrations

There is considerable variation in the way humans respond to drugs. A standard dose, even when corrected for body weight, will show considerable pharmacokinetic variability from one person to another and will even vary in the same person when the substance is given on separate days. This is because any one of the three processes (absorption, distribution, and elimination) will affect the plasma concentration *versus* time profiles. This difference is increased when the drug is given orally when compared with injection, since variability in absorption also occurs.

Figure 1 illustrates schematically what would be expected of typical person-to-person variability for an orally administered drug when both T_{max} and C_{max} are quite different, and the overall area under the plasma concentration *versus* time profile indicates the amount of drug available to the body.

It is important to understand that each drug has its own pharmacokinetic properties. These include the rate of absorption, the degree of distribution in bodily tissues, and the rate of metabolism and elimination. Standard texts provide details of the relevant pharmacokinetic factors to provide a guide as to the effects of the particular drug [2, 6].

A number of physiological factors can further affect blood concentrations of drugs. These include any disease that alters absorption, distribution, and elimination. The most common diseases are those of the liver and the kidneys, since these are the most important organs involved in the elimination of drugs. Liver is a major organ that metabolizes drugs to (more water soluble) metabolites that are more likely to be excreted by the kidneys [7]. Heart disease, such as congestive heart failure, can also affect drug clearance since blood flow through vital organs is reduced. Advanced age (over 70 year) will usually result in reduced organ function, leading to a reduced ability to process drugs. Older (but otherwise

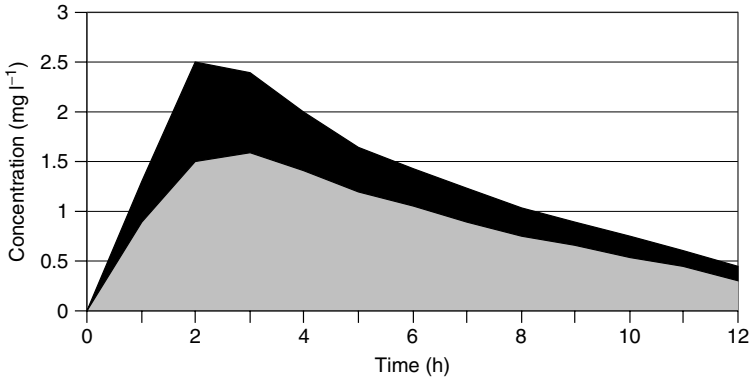

Figure 1 Stylized blood concentration *versus* time profiles showing possible diverse profiles in two different persons given the same dose of drug orally

healthy) persons will often require lower doses for their weight than their much younger counterparts.

The net consequence is that there is substantial variability in blood (and plasma/serum) concentrations for a given dose of substance even if the time of administration is known. In a great proportion of forensic cases, the time of dosage is unknown and in many instances the mode of administration (e.g., oral, intravenous, nasal insufflation, etc.) is usually assumed.

Postmortem Artifacts

In situations involving the interpretation of toxicology results in deceased persons, it is probable that concentrations of drugs (and other substances) would have changed from the time of death [3, 8].

These changes have been described in **Postmortem Toxicology: Artifacts**.

Postcollection Artifacts

Some substances are unstable chemically and can degrade postcollection, particularly, if optimal storage conditions are not maintained. This applies not only to volatile substances such as alcohol but also to nonvolatile substances that are not chemically stable under the storage conditions and, in particular, biological matrix.

These changes have been described in **Postmortem Toxicology: Artifacts**.

Examples

Table 2 summarizes examples of how a particular drug concentration in blood can be differentially interpreted based on the available information.

See **Cocaine**; **Opioids**; **Amphetamine**.

Repeated Use of Drugs

In the case of methamphetamine, where the drug can accumulate with repeated use and produce much greater concentrations than after single doses, it is not possible to infer from a concentration the likely consequence of the drug.

Similarly, with long-acting opiates such as methadone, accumulation occurs from one dose to another, leading to apparent elevated concentrations after some days of use. The interpretation is further compounded by the neuroadaptation that occurs to drugs with repeated use, leading to tolerance of potentially harmful effects [5].

The context of the death is critical to understanding the role, if any, of the drugs detected. For example, a person can die from the effects of using too much cocaine (usually from an adverse effect on the heart), but equally well a person can die from a

Table 2 The effect of circumstances on the interpretation of toxicology results

Drug	Blood concentration ($mg\,l^{-1}$)[a]	Circumstances	Likely interpretation[b]
Methamphetamine	0.5	Single oral dose, 2 h postdose	Moderate-to-high doses (<50 mg)
		Several doses over a few days, oral, 2 h postdose	Low-to-moderate doses (~50 mg)
		Single oral dose, 24 h postdose	High dose (>100 mg)
Morphine	0.5 (free)	Single oral dose of morphine, 2 h postdose	Moderate dose, potentially toxic (>50 mg)
		Single intravenous dose of heroin, 2 h postdose	Moderate dose, potentially toxic (>50 mg)
		Multiple oral doses of sustained release morphine (days)	Low-to-moderate doses, likely to be safe (<50 mg doses when given a number of times daily)
Cocaine	0.5	Single oral dose, 1 h postdose	Moderate-to-high doses (<50 mg)
		Single snorted dose, 2 h postdose	Low-to-moderate doses (~50 mg)
		Multiple snorted doses over 4 h	High dose (>100 mg)

[a] Peripheral clinical blood collected without reference to any postcollection artifacts

[b] Doses are only guides and should not be taken literally and will also depend on health and size of person

completely unrelated event such as a fatal shooting or motor vehicle crash and have the same concentration of cocaine (and its metabolites) as the person who died from the effects of cocaine. There is no relationship between the concentration of drug and an outcome for most substances when assessed in isolation.

This lack of relation between blood concentration and response is also seen with other drugs of abuse as well as most prescription drugs.

Natural Disease

As one might expect, the presence of natural disease can complicate the interpretation of drug effects. For example, a person with heart disease, such as an enlarged heart or atherosclerosis (blocked arteries), is more likely to suffer from an adverse reaction to amphetamines than an otherwise healthy person. In fact, the use of chronic amphetamine is linked to the premature development of heart disease itself [9].

Lung disease including infections, such as pneumonia, can increase the harmful effects of opioids by further weakening the ability to withstand compromised respiratory function caused by the opioids themselves (e.g., morphine and heroin).

Multiple Drugs

In most forensic cases, more than one substance is present in the person concerned [3]. When this occurs, it is likely that the combined effects need to be considered. The use of cocaine in a person using an opioid (e.g., heroin) is more dangerous than either drug alone, even though one drug is a stimulant and the other is a depressant.

Commonly, alcohol is seen in the presence of another drug. Unless the concentration of alcohol is toxicologically insignificant ($<0.02\,\mathrm{g}\ 100\,\mathrm{ml}^{-1}$), alcohol will enhance the effects of the other drug(s). Benzodiazepines that are ordinarily relatively safe drugs will be substantially more toxic in the presence of significant amounts of alcohol. Combined drug use is also more likely to lead to behavioral changes. (*See also* **Alcohol**; **Benzodiazepines**; **Behavioral Toxicology**).

Summary

In summary, in a forensic case, a large range of factors affects the interpretation of a drug concentration. It is essential to gather as much information as physically feasible as well as to interpret the information in the context of the case. There is no substitute to proper collection of both medical and forensic evidence.

Postmortem Toxicology: Laboratory Analysis

Introduction

As a major application of forensic toxicology, postmortem toxicology assists pathologists, coroners, and/or judges (in criminal matters) in determining the cause and manner of death. It assists in the assessment

of whether injury, toxicity of drug(s) or poison(s) or natural causes (e.g., disease) has any relevance to the death. On the other hand, the circumstance in which the death occurs determines the manner of death, i.e., misadventure, suicide, homicide, etc.

There are several situations that usually require postmortem toxicological analysis:

1. when the direct cause of death is suspected to be drug or poison related;
2. when the cause of death is suspicious or unknown, and investigation is needed to establish cause and/or manner of death (including drug or poison related);
3. when the cause of death is known, toxicological analysis is needed to clarify the manner of death. For instance, in a fatal traffic accident, an investigation is needed to ascertain any influence of alcohol and/or drug(s) on driver;
4. when involvement of drugs or poisons need to be ruled out to support negative pathological findings during autopsies;
5. when detected drugs may give clues as to any underlying disease process, i.e., anticonvulsant drugs, antidiabetic drugs, etc.;
6. when there is a statutory requirement for autopsies and subsequently toxicological examinations are deemed necessary by an authority such as coroners.

The use of postmortem analysis as a crucial evidence in court can be dated back to 1840 when Dr Mattheiu Orfila, a Spanish-born French physician, was asked by the court to investigate a case of Marie LaFarge for the murder of her husband using arsenic, a common poison used in those days [1, 2]. Before Orfila's investigation, toxicological analysis of arsenic was found positive in the food but was not detected in the stomach content of the victim using Marsh test [3]. However, Orfila discovered that the test had been inappropriately performed, and arsenic was later detected in the victim's body. As a consequence, Marie was found guilty of murder.

According to the history of poisons written in an Egyptian manuscript, Ebers Papyrus, approximately 1500 BC, mandrake, hemlock, opium, aconites, and certain metals from the natural sources were known for their poisonous properties and they had been used as weapons or in torture [4]. A poison can be defined as any substance that when taken in a sufficient quantity will cause intoxication or even death. This dose-dependent relationship was first explained by Paracelsus (1493–1541) with the statement "Sola dosis facit venenum" (only dose determines the poison). For instance, even the well-known deadly poison such as cyanide (CN), arsenic, or carbon monoxide may not be harmful if it is inhaled or ingested in a minute quantity. On the other hand, substances as innocuous as drinking water or minerals such as potassium or sodium, if taken in excessive quantity, could induce death. To analyze postmortem samples for a wide variety of potential intoxicants, which are unknown to the toxicologist in most of the cases, is a challenging task.

Specimens for Toxicological Analysis

The collection of specimens in an autopsy is the first and most important step in toxicological examination as the availability of proper biological specimens can maximize the chance of obtaining meaningful analytical findings to assist in determining the cause and manner of death. Since deterioration of specimens increases with postmortem time interval, biological specimens should be collected as soon as practicable after death. Additionally, in most cases, autopsy can only be performed once; the collection of specimens after autopsy is rarely possible.

Unlike in clinical toxicology, where serum/plasma and urine are usually available, the choice of specimens in postmortem toxicological investigation can be extensive and variable. The specimens selected for analysis can vary depending on the case and the information provided to the pathologist during the investigation. Additionally, the instrumentation and methodologies available to the laboratory will also determine what a laboratory can do. Importantly, the specimens obtainable will play a major role, since some specimens may not be available such as urine (if bladder is emptied or because of decomposition) [5, 6]. Generally, the pathologist has the final say on the specimens collected. Prudent facilities will collect a full set of specimens even if not immediately needed since they can be kept and stored if analysis is not immediately required.

The most common specimens used for general toxicological examinations of drugs and poisons in postmortem cases are blood, urine, and vitreous

Table 1 Suggested postmortem specimens to be collected[a]

Type of cases	Specimens collected
General cases	Blood
	Urine
	Vitreous humor
General cases (blood not available)	Cavity fluid (for screening)
	Liver
	Urinary bladder washing (if urine not available)
	Vitreous humor (if any)
Drug- or poison-related cases (suicide cases)	Plus gastric contents
Drug- or poison-related cases (suspicious cases)	Plus gastric content and liver
Gaseous or volatile substances	Plus lung and brain tissue
Heavy metal poisoning	Plus liver, kidney, and hair

[a] Other specimens can also be collected if deemed necessary

humor. When these are not available, tissue samples such as liver, brain, lung, muscle, and bones and body fluids such as bile, pleural effusions, and other specimens (e.g., hair and nails) are all useful in postmortem analysis. Table 1 summarized the specimens recommended, if available, to be collected on the basis of the types of cases.

Blood

Blood is often the specimen of choice for detecting, quantifying, and interpreting drug concentration in postmortem toxicology as most of the literature data are based on their examination in blood [7–10]. Drug concentration in blood is useful for establishing any recent ingestion of the drug in question and to determine the effect of drug on the deceased at the time of death. Blood sample is preferentially taken from peripheral sites such as the femoral (upper leg) or subclavian region rather than from the cardiac region in order to avoid contamination from abdominal fluids and contents, and to reduce artifactual rises in blood concentration due to postmortem redistribution [11]. However, diffusion of drug from urinary bladder to femoral blood can take place if a large amount of urine contains high concentration of the drug [12]. For cases involving hospital treatment before death, clinical specimens obtained soon after admission and immediately before death, whenever appropriate, should also be investigated particularly when poisoning is suspected before admission into hospital (*see* **Postmortem Toxicology: Artifacts**).

If vascular blood cannot be obtained, sampling can be made from the thoracic or the abdominal cavity. However, the composition of these samples will be markedly different from the whole blood and should therefore only be used to qualitatively determine the presence of drugs or poisons. In case of advanced putrefaction, pleural fluid should be collected for screening [6].

Urine

Urine is a convenient specimen for toxicological screening. This is because (i) a relatively high concentration of drugs and their metabolites accumulate in urine and (ii) the drug detection time window in urine is usually longer than that in blood, thereby facilitating detection of any possible exposure to potential drug(s)/poison(s). Immunoassay can be performed directly on urine specimens for the detection of certain drug classes, especially for those commonly abused drugs. However, there is no correlation of urine drug concentration with pharmacological effects because of the time difference between drug absorbed into the bloodstream and drug eliminated into the urine. In addition, in acute drug-related deaths where survival time (probably less than 15 min) is short, drug may not be excreted into the urine. Therefore, when both urine and blood are available, blood cannot be substituted by urine for the screening of drugs and poisons, and if found, the quantitation of drugs or poisons should preferably be performed on blood. Unfortunately, urine cannot be collected in cases due to perimortem voiding or decompositional changes.

Liver

Liver is the major organ for detoxification. Many toxic substances are present in the liver in higher concentrations than in the blood. It is easily collected and can be readily homogenized. Consequently, liver is used to supplement the blood concentration data, or may also be the only specimens available in cases of advanced putrefaction. Usually, the liver from deep within the right lobe is preferred to avoid possibility of gastric diffusion from stomach or from mesenteric circulation [13]. Liver should be finely diced and homogenized in water or a dilute buffer with a minimum water/buffer-to-liver ratio of 1 : 1. The usual method for extraction of biological fluid can be applied to liver homogenate, provided it is properly validated. However, the more complicated matrix present in liver may require additional cleanup to allow better instrumental detection. Unfortunately, the limited toxicological data from the literature limit the ability to interpret liver concentration data [14].

Vitreous Humor

Vitreous humor is the major fluid component of the eye, and is well protected inside the eyeball so that it is less subject to contamination and bacterial action and has little protein content. In conjunction with alcohol levels in blood and/or urine, quantification of alcohol in vitreous humor is useful to assist in distinguishing between alcohol intake before death and postmortem alcohol formation. In addition, this specimen is particularly useful for determining common antidepressants, digoxin, sodium, chloride, glucose, and metabolites related to renal functions (e.g., urea nitrogen, uric acid, and creatinine). Thus, it should be collected whenever possible.

Gastric Contents

As oral ingestion is a major route of drug administration, gastric contents are important to investigate potential poisoning and in case of overdose or acute poisoning, high concentration of drugs or poisons will be detected. In many cases of acute poisoning, undissolved capsules or tablets may be discovered through visual inspection of the contents, allowing relatively simple drug or poison identification. The total amount of a drug or poison present in the gastric contents is more important than its concentration. When supported by blood and/or tissue findings, a large quantity of the parent drug in the gastric contents as compared to the prescribed dose would indicate drug overdose. Therefore, the total volume of gastric contents should be measured. Recent intake of strong alkali or acids prior to death can easily be determined by pH measurement. In addition, an alkaline pH may also be due to the ingestion of CN and screening test for CN, such as Ferroin test [15], should be considered. The presence of a characteristic odor in gastric content can be a useful indicator for certain toxic substances. Some of the examples are listed in Table 2.

Other Specimens

Sometimes analysis of specimens other than those mentioned may be more appropriate. For instance, bile can be useful for screening of drugs and poisons as a number of drugs, such as morphine, benzodiazepines, and their glucuronide metabolites, ketamine, etc., are present in higher concentrations in bile than in blood. Bile can also be considered as an alternative screening specimen when urine is not available. Lung tissue is particularly useful in the analysis of volatile substances, such as hydrocarbons and other solvents or gases. Brain is useful for the detection of drugs such as antidepressants, narcotics, and halogenated hydrocarbons that act primarily on the central nervous system. In deaths due to chloroform poisoning, a high chloroform concentration can be found in the brain [16]. Kidney is useful in the investigation of heavy metal poisoning. The high concentration of metal deposited in kidney is often associated with structural damage that may be characterized histologically. As the growth rate of hair is approximately 0.6–1.4 cm per month, it provides a longer drug surveillance window, in a scale of weeks to months, than that of urine and blood. Hair is used

Table 2 Example of characteristic odor in relation to common toxic substances

Odor	Indication
Alcohol	Ethanol
Bitter or burnt almond	Cyanide
Garlic	Organophosphate insecticides
Antiseptic	Chloroxylenol

to evaluate prior exposure to heavy metals, such as arsenic, lead, and mercury, and is now extended to the analysis of a wide range of organic drugs and poisons to provide information on the chronic use or long-term exposure to toxic substances [17].

In case of serious putrefaction, body fluids and tissues including blood, urine, and liver may no longer be available. Under such circumstances, other alternative specimens like muscular tissue, hair, or bone should be considered for toxicology screening but the quantification of drugs and poisons in these samples will be of limited toxicological significance (*see* **Hair: Toxicology**).

Table 3 lists the recommended amount, if available, of specimens taken for analysis and their intended purposes.

All specimens collected should be stored in tightly sealed containers at low temperatures (usually below 4 °C for short-term storage during analysis and −20 °C for longer term storage). Except for blood, there is no special preservation required for specimens collected. For blood samples, one of the bottles collected should be preserved by addition of at least 2% w/v of sodium fluoride or equivalent to suppress the postmortem production of alcohol, γ-hydroxybutyrate, CN, and carbon monoxide and reduces hydrolysis of some drugs, such as cocaine to benzoylecgonine [6, 18].

Additional Information Required Prior to Analysis

Most drug- or poison-related deaths do not present characteristic features pathologically as those found in many disease-oriented deaths, such as cancers. Strategy for postmortem sampling and subsequent analysis should be based on a detailed knowledge about the case in respect of the presence of any foreign substances suspected to be related to the fatality. To facilitate toxicologists in devising the appropriate analytical methods, interdisciplinary discussions between professionals involved in the case (at least between forensic pathologist and toxicologist) prior to commencement of toxicological investigation is recommended. The following information should be provided if available:

1. Evidence(s), such as drug paraphernalia (e.g., syringe), poisons or medications, empty containers, and/or packaging inserts, suspected to be related to drugs or poisons found at the scene

Table 3 Minimum recommended amount of specimens taken for postmortem analysis

Specimen	Where to obtain (amount)	Principal uses
Blood	Peripheral (femoral or subclavian preferred) (2 × 10 ml)	Useful to confirm recent drug use and concentration, if a drug found, is useful for toxicological interpretation
	Peripheral (preserved using 2% w/v sodium fluoride or equivalent) (at least 2 ml)	Mainly for alcohol and for analysis of some drugs requiring preservation
Urine	(>10 ml)	Useful for broad class of drug screening but may not be useful on timing of drug administered
Liver	Deep within right lobe preferred (>100 g)	Useful solid tissue samples to supplement blood data especially when blood is not available but limited literature data available
Bile	(At least 5 ml or whole gall bladder)	Useful fluid for drug screening especially when urine is not available
Vitreous humor	(All available ~2–5 ml)	Useful in alcohol analysis and, if necessary, some other drugs (e.g., digoxin, glucose, urea nitrogen, uric acid, creatinine, and antipsychotic drugs)
Gastric contents	(All)	Indicative of recent drug administration
Hair	Identify distal and proximal end (>50 mg)	Drug use history provide information of drugs/poisons and metal exposure in scales of months
Lung	(50 g)	For volatile substances (such as H_2S and chloroform poisoning)
Brain	(50 g)	Brain may be useful in infant drug deaths or for volatile poison cases

should be seized as analysis of these items may be valuable for determining the subsequent type of analysis to be performed on the biological specimens. In some cases, household products, such as caustics, solvents, or pesticides, may also provide useful clues. While circumstantial evidence can provide hints, it can never substitute the analysis of body fluids or tissues because substance(s) found at the scene may not necessarily be connected to the death and often other substances are detected that are not obvious from the circumstances.

2. A comprehensive list of medications (especially recent medications prescribed) given to the deceased with relevant medical history should be provided.
3. Any physical abnormalities identified during autopsy may be indicative of intoxication or poisoning and a list of examples is given in Table 4 [6]. In this case, additional analysis targeting for the presence of possible toxic substances may be required.

Analytical Aspects in Postmortem Toxicology

Ingested substances are metabolized, being broken down or transformed into other species before they are excreted. Hence, identification of the original ingested material often involves considerable complications, for example, heroin is first metabolized into 6-acetylmorphine and then to morphine, while Δ^9-tetrahydrocannabinol (THC), an active ingredient in cannabis, is first converted to 11-hydroxy-Δ^9-tetrahydrocannabinol and then to 11-nor-Δ^9-tetrahydrocannabinol-9-carboxylic acid.

In addition, the active constituent in a regular dose ranging from grams or milligrams is diluted to a concentration usually in the range of micrograms or nanograms per milliliter of body fluids or per gram of tissue by way of dispersion throughout the body. The analytical method to be utilized must be capable, both in terms of sensitivity and specificity, of detecting the target substances at low concentrations and in complicated biological matrices (*see* **Postmortem Toxicology: Artifacts**).

Table 4 Useful findings related to toxic substances observable during autopsy

	Possible Indication
Color of skin	
Cherry red to bright red	Carbon monoxide or cyanide
Grayish to brownish	Nitrate, nitrite or aniline
Nasal/oral cavity	
Residues of powder or colored material	Intransal drug use (e.g ketamine, cocaine), ingestion of tablet or capsule residues
Oral cavity/ gastointestinal tract	
White, corrosive staining	Hydrochloric acid
Black-brown, corrosive staining	Sulphuric acid
Glass-like, reddish necrosis	Alkaline agents (e.g. sodium hydroxide)

Analytical Techniques

There are a wide variety of analytical techniques available for the analysis of toxic substances in biological specimens. The most common techniques used in modern toxicology laboratories include various immunoassays with different detection principles, color tests (e.g., Ferroin for CN, Marsh test for arsenic, etc.), instrumental chromatographic techniques using high-performance liquid chromatography (HPLC) and gas chromatography (GC) coupled with various detectors. To effectively apply chromatographic techniques, an extraction procedure is required to separate the intended drugs/poisons from biological matrices followed by reconstitution in appropriate solvents compatible with the requirements of the intended instrumentation.

Immunoassays. A number of immunoassays intended for antemortem analysis can also be used for postmortem analysis especially when urine is available. Immunoassay is based on the principle that the drug is detected by its ability to displace or block the binding of a fixed amount of labeled drug molecules present in the reagent. The label can be a fluorescent molecule (e.g., fluorescence polarization immunoassay (FPIA)), an enzyme (e.g., cloned enzyme donor immunoassay (CEDIA), enzyme multiplied immunoassay technique (EMIT), and enzyme-linked immunosorbent assay (ELISA)), a radioactive isotope (e.g., radioimmunoassay (RIA)) or other substance that can be detected by means of instrumentation. Some assays can distinguish between bound

and free labeled drug in a mixture are known as *homogenous immunoassay*, such as CEDIA, EMIT, and FPIA. For heterogenous immunoassays, such as ELISA and RIA, they require a washing step to separate the bound labeled complex from free labeled reagent prior to analysis. Thus, homogenous immunoassays are easier to be automated and less labor intensive than heterogenous ones. In general, immunoassays are fast, sensitive and, in homogenous immunoassays, direct detection can be achieved without sample purification. It is used for screening of common abused drugs, such as opiates, amphetamines, cocaine, cannabinoids, phencyclidine, and barbiturates. In addition, prescribed drugs, such as propoxyphene and tricyclic antidepressants, can also be screened with the use of specific reagents. For postmortem screening, antibodies having broad drug selectivity within a class of drugs (e.g., sympathomimetic amines) are preferred over those that are sensitive to a specific drug (e.g., methamphetamine) as it allows the screening of drugs within the same class. The sensitivity can be further increased by prior hydrolysis of glucuronide or sulfate conjugates of some drug classes, such as cannabinoids, opiates, and benzodiazepines.

Cutoff values, often applied to workplace drug testing, especially for abused drugs should be used cautiously in postmortem cases since the presence of low drug concentrations can be of forensic significance. In an acute drug-related death, for instance, the drug may not have sufficient time to be excreted into urine before death resulting in a low drug concentration in urine. False positives may occur, either from structurally related drugs or from metabolites of other drugs that are recognized by the antibodies. For instance, phenethylamine, a common putrefactive product from decomposed bodies, can cause a false-positive response to the amphetamines class test when using immunoassays. Cross-reactivity can also be due to chemicals with similar structures to the intended analytes. For example, pholcodine gives rise to a positive response to the opiates reagent of FPIA. Thus, for those samples, which give positive screening results, confirmation tests should be performed, preferably using chromatographic techniques with MS detection.

Extraction Techniques. The usual extraction techniques involve either liquid–liquid extraction (LLE) or solid-phase extraction (SPE).

LLE involves the selective partitioning of the compound of interest into one of two immiscible phases by a judicious choice of extraction solvents. Although there are some developments in SPE techniques, in recent years [19], the traditional LLE technique is still a common extraction method used in postmortem specimens. The method has the advantage of efficient extraction of drugs and poisons present in a wide concentration range and the absence of adsorption loss frequently associated with a solid surface. However, for some postmortem blood or tissues, problems associated with the formation of stable emulsion, variable extraction efficiency and endogenous interferences due to autolysis may occur. To extract acidic and basic/neutral drugs from biological fluids or tissues using LLE, separate extractions using appropriate organic solvent(s) with the addition of acidic and basic buffer, respectively, are required. Various methods using LLE for drug extraction in postmortem specimens show that there is a wide choice of solvents or mixture of solvents with similar extraction efficiency and selectivity [18, 20].

The mechanism of SPE based on the selective partition of one or more components between two phases, one of which is a solid sorbent while the second, mainly a liquid, is more complicated than LLE. Extraction is accomplished by adsorption of the analytes onto the solid sorbent followed by washing with an appropriate solvent to remove the unwanted matrix before eluting the analytes. Compared with LLE, SPE has the advantages of low solvent consumption, provision of cleaner extracts, and ease of automation and high extraction efficiency for certain specific drugs requiring a smaller sample volume. Thus, it provides an excellent alternative to the traditional LLE for the extraction of postmortem samples. Unlike LLE, untreated sample cannot be applied directly onto SPE. Pretreatment procedures, e.g., protein precipitation and centrifugation, may result in a significant loss of analytes due to adsorption or occlusion onto the precipitated constituents. Ion exchange resins have shown to be efficient in the extraction of acidic drugs [21]. On the other hand, mixed-mode SPE, being capable of extracting acidic, basic, and neutral drugs, is suitable for general unknown screening (GUS) [22] (*see* **Toxicology: Initial Testing**).

Chromatographic Techniques. GC and HPLC, coupled with various detectors, are common instrumentations to screen for a wide range of organic toxic

substances. A combination of mass spectrometry with either GC or, more recently, HPLC is the definitive technique to establish proof of structure of unknown substances. With the extensive development of commercial MS technology at an affordable cost, gas chromatography mass spectrometry (GC-MS) and high-performance liquid chromatography mass spectrometry (HPLC-MS) (or liquid chromatography mass spectrometry (LC-MS)) become increasingly popular tools employed in toxicological analyses.

GC is one of the most frequently used techniques for separating, identifying, and quantifying a parent drug and its metabolites, other coadministered drugs and endogenous compounds. This technique can be coupled with various detectors from the more universal flame ionization detector (FID) to specific detectors such as electron capture detector (ECD) and nitrogen phosphorus detector (NPD).

FID is useful for the detection of alcohol, other volatile organic compounds and many other organic drugs and poisons. NPD is sensitive to nitrogen- and phosphorus-containing compounds and is useful for the detection of drugs and poisons, such as antidepressants, antipsychotic drugs, benzodiazepines, opiates, cocaine and its metabolites, organophosphorus insecticides, etc. The use of FID and NPD either alone [23–25] or in a combination of both [26] has been shown to be useful for GUS of organic drugs and poisons. ECD is particularly sensitive to halogenated compounds (e.g., chlorinated insecticides), nitriles (e.g., CN) or nitrogen-containing compounds (e.g., benzodiazepines, nifedipine, and zopiclone). Unfortunately, the above detectors can only provide retention time data without any additional information for structural identification. Thus, more sophisticated techniques, such as GC-MS or LC-MS, are recommended for confirmation (*see* **Confirmation Testing: Toxicology**).

The high separation power of capillary GC coupled with a highly selective MS detector has been currently regarded as the "gold standard" in GUS for drugs and poisons. The availability of a well-established and standardized ionization technique (electron impact (EI) at 70 eV) has facilitated the construction of large databases of reference mass spectra for library search and many useful spectral libraries relevant to toxicological screening are now available. However, GC is not suitable for direct analysis of polar compounds although derivatization can partly solve the problem and mass spectral libraries containing a practically complete coverage of trimethylsilyl (TMS) derivatives are available commercially [27].

HPLC is capable of dealing with the analysis of a wide range of both volatile and nonvolatile compounds. The reversed phase mode column is at present the most common separation method applied in toxicological screening. Unlike GC, derivatization is not necessary for the analysis of polar and thermolabile compounds and this advantage certainly promotes HPLC as a better alternative for compounds not amenable to GC. Detection is often aided by diode-array detectors (DAD), which acquire UV–visible spectra continuously during a chromatographic run and the chromatogram is extracted and plotted at preselected wavelengths. The combined technique of high-performance liquid chromatography diode-array detector (HPLC-DAD) is another suitable technique for GUS of compounds, covering a wide range of polarity, stability, and molecular masses. Since metabolic transformation, in many cases, does not affect the ultraviolet (UV) chromophores of the molecule, one of the added values of this technique in GUS for drugs and poisons is that the low selectivity of DAD facilitates the detection of metabolites. In addition, compounds belonging to the same class with similar chemical structures often display similar absorbance patterns allowing unknown compounds not previously identified are tentatively assigned for further analysis. However, one of the drawbacks of HPLC-DAD is that the resolution of HPLC is usually inferior compared with GC, and UV spectroscopy is less sensitive than that of MS. In addition, for compounds possessing weak UV–visible or without any characteristic UV–visible absorbency, identification using HPLC-DAD is difficult in terms of both sensitivity and specificity.

LC-MS is useful for the analysis of compounds that are not amenable to GC-MS. These compounds include lysergic acid diethylamide (LSD), glucuronide conjugates, such as morphine-3 or 6-glucuronide or for some very potent or large molecules that other techniques are not sufficiently sensitive for detection (e.g., colchicines, cardiac glycosides such as digoxin and digitoxin, β-agonists such as salbutamol and terbutaline) [26].

The most common ionization mode used in LC-MS techniques is atmospheric pressure ionization (API), which mainly comprises of different versions of electrospray ionization (ESI) and atmospheric

pressure chemical ionization (APCI) interfaces. With simpler sample preparation, LC-MS is extended to certain analyses originally performed by the less-specific HPLC-DAD or even GC-MS. For these reasons, LC-MS, which combines an almost universal separation process with the most specific and sensitive type of detector, has become a promising alternative approach to GC-MS and HPLC-DAD in toxicological analysis [28–30].

However, there are several drawbacks in the use of LC-MS. First, the ion-suppression effect, especially when operating in the ESI mode, is a well-known problem: signal of the intended analyte is often suppressed because of the presence of coeluting compounds/interferents so that the intended analyte may be underestimated or even overlooked. Thus, the effect of ion suppression on the signal of the intended analyte should be cautiously evaluated before use. If ion suppression does occur, changes in experimental conditions, such as the sample cleanup method, chromatographic conditions relating to the mobile phase, the elution column, and the internal standard, should be considered. Moreover, only certain volatile buffers and mobile phase can be used for LC-MS to be compatible with the MS requirement. Thus, the separation efficiency is often inferior compared with HPLC-DAD although it may not be a problem for tandem MS because separation of analytes can be made in the MS/MS mode.

Systematic Toxicological Analysis

The usual practice in toxicological examination begins with the preliminary identification of alcohol and screening of a wide spectrum of acidic, neutral, and basic organic drugs or poisons. If a toxic substance(s) is detected, confirmatory and, if necessary, quantitative testing has to be performed. In general, a positive identification is achieved using at least two independent analyses and preferably based on different analytical principles. Using GC-MS or LC-MS, confirmation and quantification can be simplified into one single analysis. Quantification of drugs in blood, liver, and gastric content as dictated by the case, provides more meaningful interpretative information. Reference concentrations of many compounds in blood in therapeutic, toxic, and even fatal levels have been published [7–10]. Although limited, useful references are also available for some compounds in liver [14]. It should be noted that while substances found in excretory fluids such as urine or bile are useful qualitatively, quantification of drugs and poisons in these fluids usually has limited interpretative values.

A comprehensive and systematic analysis for the presence of chemical substances of toxicological significance is termed systematic toxicological analysis (STA). There are thousands of potentially harmful substances ranging from poisonous gases (e.g., carbon monoxide and hydrogen cyanide (HCN), and hydrogen sulfides), food (e.g., ethanol), deadly poisons (e.g., CN salts and arsenic), abused drugs, pesticides, toxins from natural sources, a wide variety of prescribed drugs and even household products, etc. It is impossible to design a single analytical scheme to cover all these substances with distinctly different chemical and physical properties. Screening for a wide scope of drugs and poisons is, however, possible by grouping substances of similar properties for analysis. The most effective strategy includes a series of standard general screening procedures supplemented by as many special methods as required. A combination of immunoassays with chromatographic techniques is usually employed to detect a wide range of substances. Immunoassays detect classes of drugs with similar structures while chromatographic techniques detect large groups of drugs with similar extraction properties, polarity, and detection characteristics.

General toxicological screening usually involves the following tests:

1. alcohol determination;
2. immunoassay screening;
3. GUS of organic drugs and poisons;
4. other specific tests as required such as carboxyhemoglobin, CN, etc.

Table 5 shows the suggested screening tests based on different case nature. Since it is virtually impossible to screen for all toxic substances in every case, a rational selection of case-specific analysis in addition to STA will be necessary. In general, the additional analysis to be conducted is primarily based on the information provided or specific requests made by the relevant parties such as pathologists and the police.

An example of an analytical scheme used for general toxicology screening and scope of analytes likely to be detected is shown in Figure 1.

Alcohol Determination. Alcohol or ethyl alcohol (ethanol) is the most common drug found in

Table 5 Suggested analysis for sample collected[(a)]

Type of cases	Test conducted	Specimen tested
General cases	Alcohol	Blood, urine, and vitreous humor
	Immunoassay drug screening	Urine
	General organic drugs/poisons screening	Blood (urine)
General cases (blood not available)	Alcohol	Urine and vitreous humor
	Immunoassay drug screening	Urine
	General organic drugs/poisons screening	Liver/cavity fluid
Drug or poison suspected cases	Plus general organic drugs/poisons screening	Gastric content
Fire death	Plus carboxyhemoglobin, cyanide	Blood
Heavy metal poisoning	Plus metal analysis	Blood, kidney, and liver
Gaseous and volatile organic related	Plus sulfide	Blood, lung, and brain
	Plus volatile organic	Blood, lung, and brain

[(a)] Specific test(s) not covered may be added if deemed appropriate.

postmortem toxicology cases. In particular, ethyl alcohol is one of the leading causes of death by poisoning. In contrast to alcohol determination in living subjects, which is generally more straightforward, analysis of body fluids taken from cadavers is more likely to be contaminated with volatile substances, such as methanol and formaldehyde used in embalming processes, and abnormal metabolic products, such as acetone resulting from fasting or diabetic ketoacidosis. Therefore, techniques for analyzing postmortem alcohol are recommended to allow separation of most, if not all, low-boiling compounds eluting in the same range as ethyl alcohol [31].

Headspace GC coupled with FID is usually the method of choice and it can be used for simultaneous analysis of methanol, acetaldehyde, ethanol, isopropanol, and acetone using either *n*-butanol or *n*-propanol as an internal standard. A combination of blood (preferably femoral region), vitreous humor, and urine, if available, should be used for alcohol analysis to aid in the interpretation of the state of absorption and to avoid misinterpretation of blood alcohol concentrations due to diffusion of undigested alcohol from the stomach, and postmortem alcohol production due to bacterial action. The presence of significant amount of alcohol in blood together with the absence of alcohol in urine and vitreous humor cast doubt in the ingestion of alcohol prior to death and is indicative of endogenous alcohol production (*see also* **Alcohol: Analysis**).

Immunoassay Screening. Screening for drugs by immunoassays in urine is commonly pursued for the main classes of abused drugs (Figure 1), which include amphetamines, benzodiazepines, cannabinoids (metabolite of cannabis), benzoylecgonine (metabolite of cocaine), and opiates (morphine and codeine). The scope for drug screening can be extended to include opioids (e.g., methadone), barbiturates, and tricyclic antidepressants (e.g., amitriptyline/nortriptyline).

As urine is not always available in postmortem cases, screening for drugs and poisons, especially abused drugs, in blood or plasma may be considered and may even be desirable to establish what substances may be affecting the person. Blood, plasma, or even specimens such as bile or liver homogenate can be screened by the urine-based immunoassay test kits, but pretreatment with solvent or protein precipitation are required and validation should be made before use. In addition, techniques intended for analysis of blood, such as RIA and ELISA can be used on postmortem samples, and they tend to be more sensitive than those kits designed for detecting drugs in urine but modified for testing blood. Screening of potent drugs like digoxin or structurally related cardiac glycosides, such as bufadienolides present in Chansu (a remedy from toad venom), can be effectively performed in plasma using a digoxin reagent by various immunoassay techniques [32].

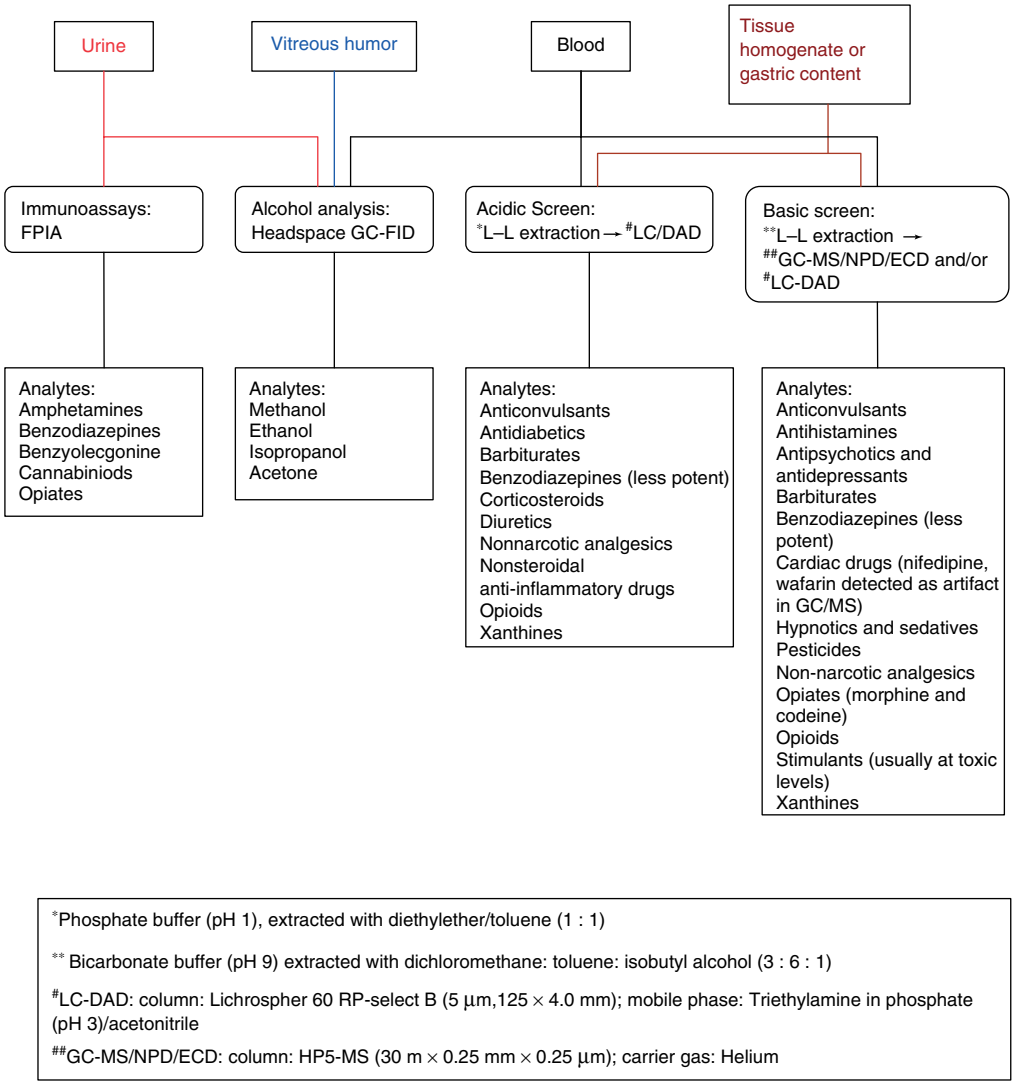

Figure 1 An example of general toxicology screening scheme

General Unknown Screening (GUS) for Organic Drugs and Poisons. As shown in Figure 1, acidic drugs can be extracted by adding an acidic buffer such as phosphate buffer (pH 1) to the samples followed by extraction with toluene: diethyl ether (1 : 1). Other methods, such as protein precipitation of blood with acetonitrile [33] or ammonium chloride salting-out of blood and other tissues with ethyl acetate followed by a washing step with hexane [34] can also be employed for the analysis of acidic and some neutral drugs. Analysis is usually made by HPLC-DAD using a reverse-phase column in conjunction with a mobile phase at acidic pH with gradient elution. Identification is accomplished by automatic library search based on a preinstalled, commercially available, or an in-house developed UV–visible spectral library. The retention times are useful to aid in identification but it should be established in-house using authentic standards according to the type of column and the mobile phase used. Nonnarcotic analgesics (e.g., paracetamol, salicylic acid, mefenamic acid, and sometimes propoxyphene), nonsteroidal anti-inflammatory

drugs (e.g., celecoxib, naproxen, and ibuprofen), diuretics (e.g., furosemide and hydrochlorothiazide), anticonvulsants (e.g., carbamazepine, phenobarbital, and phenytoin), antidiabetics (e.g., glicazide), opioids (e.g., methadone), barbiturates (e.g., secobarbital), corticosteroids (e.g., hydrocortisone), the less potent benzodiazepines (e.g., midazolam, diazepam, and sometimes estazolam), and xanthines (e.g., caffeine and theophylline) can be detected using HPLC-DAD after acidic extraction.

Drugs and their metabolites usually have similar UV–visible spectra because metabolic transformations, such as desmethylation and hydroxylation, do not usually affect the chromophores of the drugs. Yet, a drug and its metabolites usually have different retention times (e.g., midazolam and α-hydroxymidazolam, clomipramine, and desmethylclomipramine). Although it may be useful to extend the detection capability to drug metabolites even without the authentic standards, one should exercise caution to avoid misinterpretation when a peak slightly different in retention time and UV–visible spectrum from the parent drug is observed. As many drugs and poisons do not have characteristic UV–visible spectra, retention time becomes the main identification parameter. Thus, whenever standards of parent drugs and/or their metabolites are available, their retention times should be established in-house and their authenticity preferably confirmed by other techniques, such as GC-MS.

Extraction of basic drugs is accomplished by a carbonate buffer (pH 9) followed by extraction with a dichloromethane/toluene/isobutyl alcohol (3 : 6 : 1) mixture. Other combinations of alkaline buffers and extraction solvents such as borate buffer (pH 8.5) extracted with dichloromethane/isopropanol (9 : 1) [35], and using SPE with suitable cleanup procedures compatible with GC analysis [18–20] are also applicable. The use of more than one type of detectors (e.g., NPD and MS) coupled to GC would definitely give a greater coverage of possible drugs and poisons. The extracted sample could be analyzed sequentially by injection into two GCs equipped with different types of detectors or by splitting the effluent of the sample from one GC into two different detectors for simultaneous detection.

Examples of drugs and poisons found in the basic fraction include hypnotics and sedatives (e.g., zopiclone and zolpidem), benzodiazepines (e.g., diazepam, midazolam, estazolam, and bromazepam), antihistamines (e.g., chlorpheniramine, brompheniramine, and promethazine), antipsychotics and antidepressants (e.g., amitriptyline/nortriptyline, cyclobenzaprine, sertraline, clomipramine, and trihexylphenidyl), opiates (e.g., codeine, acetylmorphine, and sometimes monomorphine), opioids (e.g., methadone and meperidine), anticonvulsants (e.g., carbamazepine, phenobarbital, and phenytoin), and pesticides (e.g., melathion, dimethoate, and tetramethylene disulfotetramine). Stimulants such as amphetamines and cocaine may be detected when present at high concentrations. In addition, artifacts due to the presence of certain cardiac drugs such as warfarin and nifedipine may be encountered.

Some basic drugs that are too polar or thermally labile cannot be detected by GC and are not acid extractable for HPLC-DAD analysis. In such case, the basic extract can be analyzed using HPLC-DAD in addition to GC. Typically, the method permits the detection of cardiac drugs (e.g., warfarin, metoprolol, propranolol, dipyridamole, and amiodarone), anti-inflammatory drugs (e.g., ofloxacin), and herbal ingredients (e.g., tetrahydropalmatine).

Alternatively, derivatization prior to GC analysis can increase the volatility and hence thermal stability for those drugs that are not easily detected by GC or GC-MS [36]. Among the available derivatization procedures, trimethylsilylation is the most common method because of its versatility for derivatizing many different functional groups such as hydroxyl, carboxyl, amidic, and some amine groups under relatively mild conditions. Furthermore, the additional mass gain by silylation improves the specificity of the mass spectral information [37]. Typical examples include morphine and sympathomimetic amines. Other derivatized agents such as trifluoroacetylation for basic and neutral drugs, and extractive methylation using methyl iodide or formation of ethereal diazomethane for acidic drugs are also applicable [38, 39].

Some compounds do not exhibit characteristic mass spectra in GC-MS. In this case, unambiguous identification can be difficult if mass spectral matching is solely relied on because many compounds can give seemingly high matching scores. Typical examples include amino-containing compounds with predominant base peaks at m/z 44 ($C_2H_6N^+$) (e.g., amphetamine, methylenedioxyamphetamine MDA), 58 ($C_3H_8N^+$) (e.g., doxepin, cyclobenzaprine), 72 ($C_4H_{10}N^+$) (e.g., methadone, promethazine), or 98

($C_6H_{12}N^+$) (e.g., trihexylphenidyl, thioridazine) and usually associated with very low intensity fragments in the high mass range. If these compounds are well separated chromatographically, they can only be identified on the basis of their differences in retention time. For those substances having similar retention time in GC, however, another technique should be considered for confirmation.

The application of LC-MS to GUS is still not extensive in spite of its versatile analytical capability as well as sensitive and specific detection of a wide range of drugs and poisons. One of the problems is the soft ionization of LC-MS, which produces mass spectra that are not compatible with those generated by EI at standardized 70-eV ionization potential. Hence, the very large libraries of standardized EI spectra of chemicals, drugs, poisons, and their metabolites applicable to GC-MS are not valid for LC-MS. Thus, a totally different strategy for mass spectral identification of compounds is required for LC-MS.

Many efforts have been made to build up large mass spectral database applicable for GUS of compounds of toxicological interest on different types of LC-MS and promising progress has been demonstrated. Identification has been based on single quadrupole, ion trap, triple quadrupole, hybrid linear ion trap, and time of flight (TOF) [28–30]. The hybrid linear ion-trap LC-MS/MS showed promising development for building up a reference MS/MS library for the same type of instrument. This LC-MS/MS technique is unique in that the third quadrupole of the triple quadrupole MS can be operated in either a standard quadrupole MS for multiple reaction monitoring (MRM) experiment or as linear ion trap to produce highly sensitive enhanced product ion (EPI) scan in an information-dependent acquisition (IDA) experiment [40, 41]. The first detection step involves IDA survey scan containing a number of preselected MRM target drugs and metabolites where ions are accumulated and then filtered in the third quadrupole. In case of a signal above a preset intensity threshold is detected for an MRM transition, the EPI scan of the precursor ion is triggered to yield product ion mass spectra at various preselected collision energies. Finally, the resulting EPI mass spectra are then searched against a prebuilt mass spectral library for identification of drugs present in the sample. Alternatively, LC-MS/TOF has provided a novel approach for comprehensive drug screening. The use of LC-MS/TOF method has the advantages to provide a relatively high mass accuracy (~5 ppm) with reasonable resolution (5000–10 000 full width at half maximum). In this approach, a library is established to contain toxicological relevant compounds that consist of molecular formula and calculated monoisotopic accurate masses. Identification of drugs/metabolites was based on their accurate mass, retention time if a reference material is available, and drug metabolite patterns. Furthermore, the matching of theoretical and measured isotopic patterns of a compound introduces an additional parameter to allow unambiguous identification of compounds present in the sample. This approach allows substance identification even without any reference standards and retention time data [42] (*see* **Confirmation Testing: Toxicology**).

Other Specific Tests

When analysis of specific types of drugs or poisons that are not covered under the general toxicology screening scheme is required, additional tests will have to be performed. Figure 2 shows some of the examples on the analysis of certain specific types of drugs and poisons.

Drug-detection Techniques

Acid Back-Extraction. Although many basic drugs with amine functional groups such as those basic psychotropic drugs and antihistamines can be detected using aforementioned basic screening, an additional acid back-extraction after basic extraction can further improve GC-MS detection by producing a cleaner extract. Examples of psychiatric drugs include tricyclic antidepressants, phenothiazines antipsychotic drugs, tetracyclic antidepressants, butyrophenones, and serotonin reuptake inhibitors. In addition, better detection of other drugs like antiparkinson drugs (e.g., trihexylphenidyl) can also be achieved using this method (Figure 2).

Ketamine, amphetamines, and their analogs can be detected at moderate-to-high level in the basic extract using GC-MS/NPD (Figure 1). To increase the detection sensitivity down to therapeutic or even subtherapeutic levels, a simple acid back-extraction cleanup after basic extraction with diethyl ether (Figure 2) coupled with LC-MS/MS (ion-trap MS) analysis can be considered.

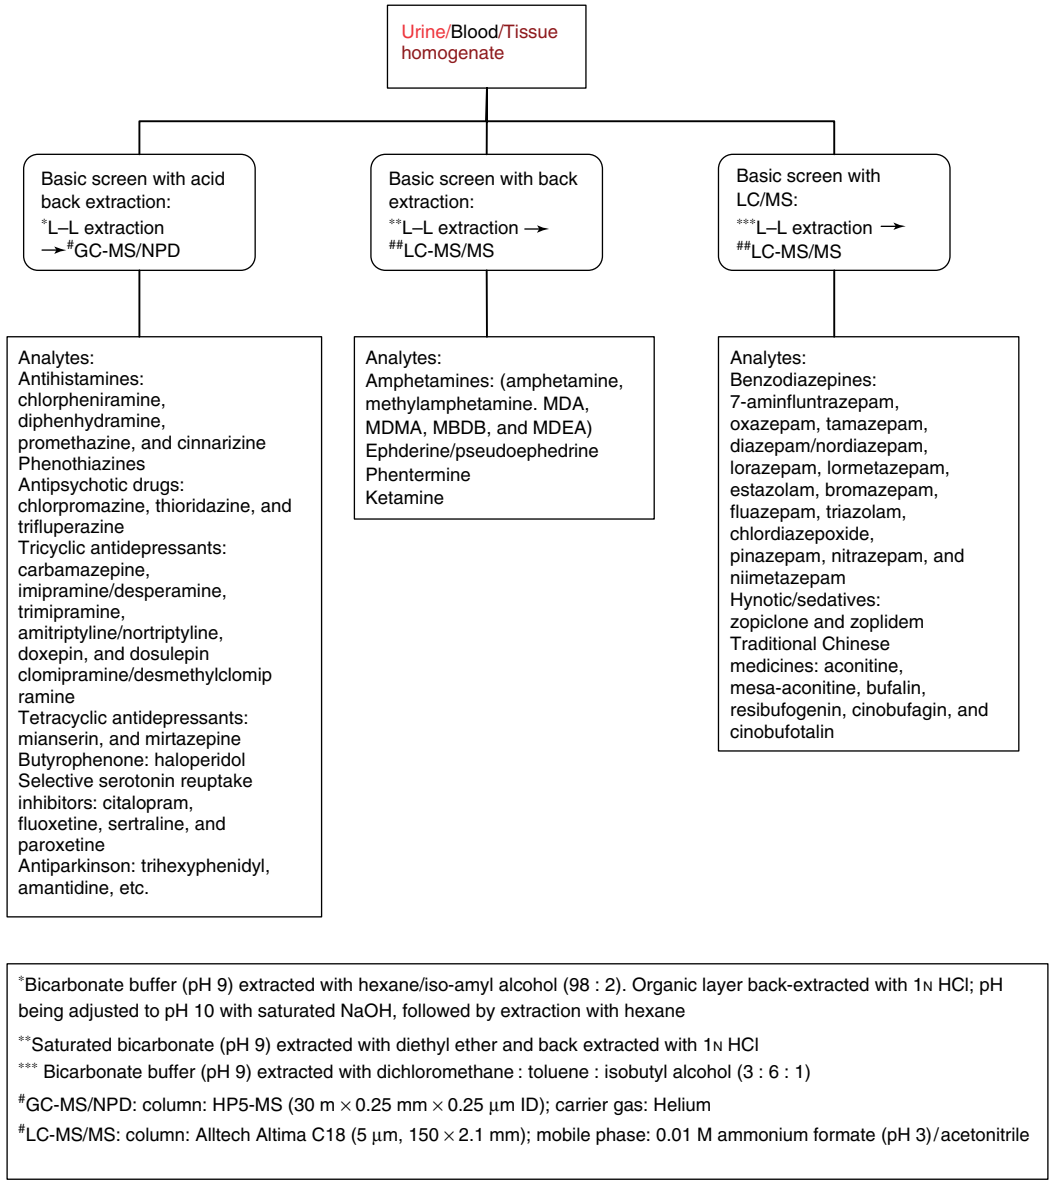

Figure 2 Examples of additional specific drug tests

Basic Extract Analyzed by LC-MS. LC-MS is complementary to the analysis of nonvolatile and thermally labile drugs/poisons that are not amenable to GC or GC-MS. In addition, LC-MS provides a superior sensitivity compared with the HPLC-DAD method, a good example being the LC-MS analysis of benzodiazepines: a structurally diverse class of pharmaceuticals. It is available as prescribed drugs with some of them (e.g., diazepam, midazolam, and nimetazepam) having been widely abused. Benzodiazepines and their metabolites represent one of the most common drug types found in postmortem specimens. While the relatively less potent benzodiazepines (e.g., midazolam and diazepam/nordiazepam) can be screened by the general screening procedures, many

potent or thermally unstable benzodiazepines (e.g., lorazepam, triazolam, and oxazepam) cannot be readily detected by standard screening techniques (Figure 1). To cater for a more comprehensive screening of benzodiazepines, the basic fraction from general toxicology screening can be reconstituted into aqueous methanol and subjected to LC-MS analysis (Figure 2). The same extract can also be used for the analysis of a wide range of targeted basic/neutral drugs and poisons including traditional Chinese medicines (e.g., aconitine and mesa-aconitine) and toxic ingredients found in Chan Su (e.g., bufalin, resibufogenin, cinobufagin, and cinobufotalin).

Analysis of Poisoning by Small Molecules. Carbon monoxide (CO), CN, and sulfide are well-known small and highly toxic molecules. Analysis of these molecules should be considered whenever poisoning due to these compounds is suspected.

Carbon Monoxide (CO). Determination of carbon monoxide poisoning will be required when a known source of CO, such as coal gas, burnt charcoal, or automobile exhaust, is located at the scene. On the other hand, it would be of forensic interest to decipher whether a fire victim had died because of CO poisoning, or had already died before the fire broke out. The saturation ratio of carboxyhemoglobin (COHb) in blood is determined by (i) simultaneous spectrophotometric (e.g., CO-Oximeter) measurement of COHb level and total hemoglobin in blood [43] or (ii) analysis of COHb through the release of CO by adding saponin and potassium ferricyanide to blood, followed by catalytic conversion of CO to methane, which is quantified by gas chromatography flame ionization detector (GC-FID) [44]. Analysis of COHb should be made using blood samples; other biological fluids, such as pleural effusion, are not recommended because a considerable amount of postmortem CO can possibly be generated in these samples by bacterial action on hemin [45].

Hydrogen Sulfide (H_2S) and Its Metabolites. Analysis is performed when H_2S poisoning is suspected, usually in industrial accidents, sewers, or ship holds where H_2S poisoning together with oxygen deficiency is suspected. Analysis is mainly based on the detection of H_2S or its metabolite, thiosulfate. Sulfate is also produced due to H_2S exposure but endogenous levels of sulfate in blood and urine are relatively high making it not an analyte of choice. GC-MS analysis can be performed for the ionized form of H_2S after derivatization using pentafluorobenzyl bromide [46]. The pH of the derivatized mixture is made acidic to suppress the production of sulfide in the blood due to decomposition of sulfur-containing compounds, such as cysteine. A similar derivatization procedure prior to GC-MS method can also be used for the analysis of thiosulfate with the exception that tetradecyldimethylbenzylammonium, a phase-transfer catalyst used in H_2S determination is substituted by ascorbic acid/sodium chloride [46, 47].

Cyanide (CN). Potassium or sodium salts of CN are used in metallurgy and electroplating industries and are relatively easy to obtain. Thus, its involvement in suicide and even homicide is not uncommon in some parts of the world. In addition, incomplete combustion of nitrogen-containing compounds such as urethane at fire scenes can produce HCN as one of the poisonous gases. Thus for fire victims, in addition to measuring the COHb saturation, CN levels in blood should also be determined. Inhalation of HCN or ingestion of CN can be fatal through inhibition of cytochrome oxidase causing cellular anoxia. CN in blood can be determined by automated headspace gas chromatography electron capture detector (GC-ECD). Blood is acidified with sulfuric acid in the presence of silver sulfate to produce HCN, which is diffused into the headspace to react with chlorine produced by chloramine-T to form cyanogen chloride, which is analyzed by GC-ECD [48].

Volatile Analysis. In addition to the analysis of alcohols, determinations of other volatile chemicals including various organic solvents are also of forensic significance. Sudden death due to volatile substance abuse (VSA) is not uncommon particularly for an inexperience user because controlling of dose is often difficult. Solvent from thinners (e.g., toluene and xylene), halogenated solvents (e.g., chloroform and dichloromethane), hydrocarbons (both aliphatic and aromatic) such as gasoline and kerosene, and fuel gas (e.g., butane) are commonly abused substances. Apart from VSA, analysis of volatile substances may also be required in certain circumstances. For instance, chloroform is commonly used for industrial purposes such as solvent and extracting reagents, and death

can occur accidentally and sometimes, in homicide cases, with the intent to incapacitate the victims. In addition, analysis for ingredients present in kerosene and gasoline may be useful in fire death cases.

Most volatile substances are stable in blood. The specimens should be stored at low temperature (i.e., less than 4 °C) in tightly sealed glass container, preferably with anticoagulant such as heparin. Analysis of tissues such as brain and lung may prove useful since high concentrations of volatile substances may be detected.

Headspace GC-FID is the method of choice for volatile chemical analysis. If structural identification is required, GC-MS should be employed. The method used for alcohol determinations can be extended for the analysis of other volatile chemicals using same columns (e.g., Elite-BAC1 or BAC-2) with some modification of experimental settings. Examples of compounds that can be analyzed are hexane, dichloromethane, chloroform, hexane, toluene, xylene, diethylether, and ethylacetate. For the analysis of low-boiling hydrocarbons, such as methane, ethane, propane, butane, and pentane, specific columns (e.g., GC-GASPRO) intended for analysis of volatile compounds can be used.

Heavy Metal Analysis. Although many metals are known to cause toxic effects, only a few are regarded as important toxic hazards: these include arsenic, lead, cadmium, thallium, and mercury. In addition, lithium is a psychiatric drug used for the treatment of manic-depressive disorder. There are many methods available for metal analysis in biological specimens, such as electrochemical, atomic absorption, and flame emission spectrophotometry, inductively coupled plasma coupled with either emission spectroscopy (ICP-AES) or inductively coupled plasma coupled with mass spectrometer (ICP-MS). ICP-MS after digestion of the biological specimens with concentrated mineral acid, such as nitric acid, is recommended. It is because ICP-MS allows a simultaneous screening of both metals and nonmetals as well as selective quantification of a single element with low detection limits. The availability of stable isotopes for most of the metal further enhances the accuracy of metal quantification by isotope dilution method.

Quality Systems and Assay Validation

A proper quality assurance program is an essential element for any analytical laboratory in order to ensure that the results generated are accurate, reliable, and traceable. It is even more important for a forensic toxicology laboratory since the results will be closely scrutinized in the courts of law. A quality manual pertaining all policies and procedures relevant to the reliability and traceability of the analytical results should be clearly written. Criteria affecting the quality of analytical results include the quality of materials used (such as reference standards, reagents, and chemicals), analytical methods adopted such as procedures and instrumentations used and their validity, sampling, and the chain of custody.

All analytical methods used must be properly validated. Suitable internal standards should be used in chromatographic assays, so that any systematic errors affecting the analyte can be compensated for by the internal standard. Compounds with chemical structures similar to the targeted analyte (e.g., deuterated analog) are preferably selected. For a batch of qualitative analyses, a negative control and a control representative of the analytes should be included. Any possible interfering factors that might adversely affect the analysis should be indicated. Quantitative analytical methods must be validated by determining the limit of detection, linearity range, precision, accuracy, and selectivity.

Postmortem redistribution (PMR) refers to the change in drug concentrations after death leading to differences in drug concentrations of postmortem blood samples taken from different sites. PMR arises from incomplete distribution of the drugs and/or poisons at the time of death, passive release or from vascular pathway from major organs such as gastrointestinal tract, liver, lungs, and myocardium, and later on cell autolysis and the putrefactive process.

Postpartum Psychosis

Introduction

Postpartum psychosis (PPP; also known as *puerperal psychosis*) was perhaps first described by Hippocrates in the fourth century BC. He described an acute onset of confusion, hallucinations, delirium, and insomnia [1, 2]. In 1865, the French physician Marce published his observations and study of perinatal disorders [3]. By the 1800s, symptoms of PPP were believed to be related to lactation, and the term *milk fever* was even used [1]. This "lactational insanity" was the basis for many Infanticide laws across the world. *The Yellow Wallpaper*, a monograph from 1899 [4], though controversial, may illustrate a woman's struggles with PPP.

The time in a woman's life when she is at greatest risk of psychosis or mental illness is in the postpartum period [5]. Fortunately PPP is rare, occurring after approximately 1–2 per thousand births. PPP often has a dramatic presentation, within the first several weeks of childbirth [6], but may begin within just days of giving birth. Early on, symptoms may include sleep disturbance and restlessness. Symptoms may evolve to include either depressed or elevated mood or both, agitation, delusions, hallucinations, and depersonalization. Women may believe they are being persecuted by the baby. Risks may include suicide, child neglect, or infanticide. PPP is considered a true psychiatric emergency, and mothers often require psychiatric hospitalization. Some specialized treatment units allow mothers to be hospitalized with their infants.

The Diagnosis of Postpartum Psychosis

Though cases may begin during pregnancy [2], more often they begin shortly after childbirth. Most cases of PPP begin within a couple weeks of delivery, with an abrupt onset [1, 2, 7]. By this time the mother has most often been discharged home with her fragile infant, rather than remaining in the hospital. Sleep deprivation is a potential trigger [8].

Risk of PPP may be related to hormonal shifts after birth (primarily the drop in estrogen) [7], stressors (such as marital problems), biology (bipolar disorder), and family history – genetic studies are underway [9], and can also be triggered by menstruation or cessation of lactation [2]. Some researchers have reported that the first pregnancy is a risk factor for PPP [2, 10]. Reports of recurrence rates of PPP after further pregnancies range from one in seven to women with bipolar disorder or schizoaffective disorder have a 50% risk of another episode of PPP [7, 11]. However, this rate is modified by prophylactic medication treatment [12]. Delivery complications may also elevate risk [10].

Common symptoms of PPP include symptoms of psychosis, with an impaired concept of reality and fluctuating delirium. Confusion, bizarre delusions (fixed, false beliefs) and behavior, hallucinations (unusual perceptual experiences that can be tactile, olfactory, or visual in addition to auditory), mood lability (ranging from depression to euphoria), and disorganized thinking may occur [1, 13]. For example, a woman might be delusional that she has special powers, that God has chosen her baby to be sacrificed, or that the baby is defective. Because of the lack of insight, suspicion, or conspiracy theories, women may not reveal their symptoms to others.

Among women with PPP, 72–88% have bipolar disorder or schizoaffective disorder, while 12% have schizophrenia [7]. In distinction to PPP, in schizophrenia delusional thinking and hallucinations often have a more gradual onset.

The psychiatric reference book DSM-IV-TR [14] does not list a specific diagnosis for PPP. Some debate exists within the field. According to the DSM-IV-TR, brief psychotic disorder or psychotic disorder not otherwise specified are diagnoses used for PPP, or a woman's symptoms may meet criteria for an affective (mood) episode [14]. Further even, the postpartum period is also defined differently depending on the group defining it; postpartum is 4 weeks according to the DSM-IV-TR, 6 weeks for ICD-10, 3 months in some epidemiological studies, and up to 1 year in some investigations [15].

Comparison with Postpartum Depression and Other Disorders

Postpartum blues or "baby blues" occur in approximately half to three-quarters of mothers [7]. Baby blues are not synonymous with postpartum depression (PPD); they are transient and not as severe. Symptoms usually occur in the first week after giving birth, and are self-limited. Symptoms may include anxiety, mood swings from sadness to irritability, and insomnia.

PPD symptoms are not the same as those of PPP. Approximately 10–15% of mothers experience PPD [3, 7]. Symptoms may occur within a few weeks to a year after giving birth. In PPD, a woman's predominant mood is sad or depressed, and she may lose enjoyment in her activities. Other symptoms may include insomnia, even an inability to sleep when the baby is sleeping. Her appetite may be abnormal. She may be fatigued and have difficulty concentrating. She may lack the interest in caring for her appearance, or even for her baby. She may experience feelings of worthlessness or hopelessness, and may have difficulty bonding with the infant. She may experience suicidal thoughts or thoughts of harming the infant. Symptoms of anxiety often also occur.

Psychiatrists must also differentiate psychotic thoughts and behavior from obsessive thoughts, which are also common in the postpartum [5, 7]. In obsessive compulsive disorder (OCD) or other anxiety disorders, women may experience intrusive thoughts that they have difficulty getting out of their head. These thoughts often represent worries, and the women, in distinction to women with psychosis, are not out of touch with reality. If these women have thoughts or fears, for example of harming someone, they usually realize that these thoughts are not of something that they would ever do and try to avoid the thoughts.

In the evaluation of a postpartum woman with psychiatric symptoms, physicians may consider that the differential diagnosis includes medical problems such as thyroiditis, Late Onset Tay Sachs disease, and vitamin B_{12} deficiency. Laboratory tests, computed tomography (CT) scan, or magnetic resonance imaging (MRI) of the brain may be indicated to rule out alternative organic diagnoses.

Treatment of Postpartum Psychosis

Because of the rapidly evolving and devastatingly severe nature of symptoms, PPP is often a psychiatric emergency. Women with a history of PPP or bipolar disorder have a 100-fold increase in psychiatric hospitalization during the postpartum [1]. In this disorder, treaters will often need to enlist help of family and other support. In some cases, child protective services may need to become involved.

Mood stabilizing medications (such as valproate or lithium) are mainstays of treatment, related to the frequently underlying bipolar disorder. Electroconvulsive therapy (ECT) is another consideration. Though not without risks of its own, ECT may provide for a rapid symptomatic improvement. Atypical antipsychotics such as olanzapine may have a role in the treatment of PPP as well [15]. (These agents are increasingly being used for not only the treatment of psychotic disorders but also of mood disorders.) Typical (older) antipsychotic agents may not lead to remission of symptoms [5]. Side effects of medications, such as sedation, which could impair her ability to respond to her infant, should be considered.

Because of the rarity of PPP, compared to other psychiatric disorders, there are fewer studies regarding evidence-based treatment. PPP is often considered to be a bipolar disorder unless proven otherwise.

Whether the mother is bottle-feeding or breast-feeding is another consideration, as different medications present different potential risks to breast-fed infants. The infant may require monitoring by a pediatrician. Other mothers may prefer to bottle-feed, to avoid any potential risk. With a supportive partner, bottle-feeding at least at night may have the added benefit of allowing the mother with PPP to sleep through the night.

Healthcare providers should educate patients about PPP. Support of families may help alleviate some of the stress associated with PPP [11]. It is important to consider prevention of episodes in future pregnancies/postpartum periods. Women with bipolar disorder are often treated prophylactically, where possible, with lithium or another mood stabilizer [7].

Risks in PPP

Mothers who experienced delusions that the baby is evil or a devil or not truly theirs were more likely to be abusive toward the infant [16]. Mothers with PPP "are at risk of injuring their children through practical incompetence or misguided delusions". [1, p. 106] Women with childbearing-related onset of psychiatric illnesses have reported homicidal ideation more frequently [13]. Risk of suicide is also present in PPP [17].

Neonaticide is specifically the murder of the neonate by the parent in the first 24 h of life [18]. Obviously, as most PPP has not yet begun at the time of birth, but rather has an onset several days to weeks later, there is a lack of relation of PPP to neonaticide in the great majority of cases. However, some cases of neonaticide do involve psychotic mothers [19].

Infanticide is often considered to include the murder of infants less than 1 year of age at the hands of the parent. (However, infanticide is a nonspecific term; in Biblical times, murder of a child at the hand of the state may have been considered infanticide.) Filicide, more precisely, is the murder of a child by the parent. If a woman is suffering from PPP, the physician should consider her risk of harming herself and/or her infant. Though there have been reported cases of infant murder while in the hospital [20], the overwhelming majority of cases occur outside the hospital. In psychiatric studies, mothers who kill their children often have

experienced psychosis, suicidality, and depression [21]. Often, alcohol or substance use, limited social support, and a maternal history of abuse are found as well.

The mother's motive for killing her infant or child may fall into any of several categories: *altruistic, acutely psychotic, fatal maltreatment, unwanted child*, or *spouse revenge* [22]. In an altruistic filicide, the mother kills her child out of love. A mother who sees her child suffering from cerebral palsy or leukemia may feel that the loving thing to do is spare the child from suffering. Though difficult to fathom, because of her depressed or psychotic outlook on life, another mother may believe that it is in the child's best interest to go to Heaven, rather than living an awful life on earth. The mother may be suicidal and not wish to leave her child in the hopeless world that she is departing. She may be psychotic, believing that if her child were to live, he or she would be tortured or raped or kidnapped, and may reason that the only humane choice is to kill him.

Alternatively, in an acutely psychotic filicide, the mother kills her child for no comprehensible reason. She may be responding to hallucinated voices commanding her to kill. She may kill in the throes of epilepsy or the confusion of delirium. She may put the baby in the oven instead of the dinner, for no rational reason but borne out of severe confusion and illness.

Fatal maltreatment filicide is the most common type of filicide overall. A child may die because of chronic abuse or chronic neglect. Certainly mothers suffering from psychosis or depression may be abusive, but so may many other mothers who do not have a mental illness. Too, mothers who are severely mentally ill and out of touch with reality may have difficulty providing for their infants' many needs. In an unwanted child filicide, a child who is not desired is killed. In a spouse revenge filicide, the rarest type, a child is killed in order to cause emotional pain in the other parent.

Newborns have a total dependence on their caregivers. If their caregiver is a woman with unidentified PPP, lacking in social support, that is highly concerning. A 4% risk of infanticide has been estimated in untreated PPP [23]. Even if a woman with PPP has support from her social network, if those who care do not understand the risks associated with PPP, there is cause for concern.

Infanticide Laws and Defenses

The British Infanticide Act was initially enacted in 1922, and was reformulated in 1938. The Act allows a woman, still recovering from giving birth, who kills her infant in the first 12 months of life to be charged with infanticide (akin to manslaughter) rather than murder, because "the balance of her mind is disturbed by reason of her not having fully recovered from the effect of giving birth to the child" [24].

Infanticide laws exist in over two dozen other nations, including Canada and Australia [25]. However, the legal criteria for infanticide vary across nations, including in New Zealand the murder of children up to age 10 [26]. In Luxembourg, there is a stricter penalty for child homicide.

However, a causal connectional between mental illness and the crime does not always occur in practice [27]. And, if a psychotic postpartum mother kills her infant and her older child, she could be charged for murder of the older child and infanticide for the killing of the infant. Also, one acutely psychotic mother who killed her 13-month-old baby might not qualify for infanticide though another mother who killed her 11-month-old baby *via* fatal maltreatment borne out of frustration might.

In the United States, there is no such infanticide legislation. The wake of the Andrea Yates child murder case led to proposals for American infanticide legislation [3, 28]. In the United States, the not-guilty-by-reason-of-insanity (NGRI) defense is used in some cases of maternal filicide. Throughout the United States and the world, there are various laws regarding NGRI (*see* **Insanity: Defense**). NGRI laws often include that a mental illness caused an actor not to know her act was wrong, and may include that she was unable to conform her conduct to the requirements of the law.

The diagnosis of PPP may be the mental illness on which the insanity defense is predicated. A woman with PPP and an alternative sense of reality may delusionally believe that she is doing what is right in killing her infant. Another woman may be unable to control her behavior because of manic psychosis. Still another may kill, believing that the hallucinations telling her to do so are from God. However, a mother who fatally abuses her infant may be unlikely to qualify for an NGRI finding because of the aforementioned requirements.

PPP can be difficult to prove in the legal sense – symptoms may have rapid resolution prior to psychiatric evaluation, and there has existed disagreement in the field as well. Psychiatric evaluation may be expedited in cases where PPP is believed to be related to the murder.

Summary

PPP may consist of symptoms including hallucinations, delusions, confusion, insomnia, mood swings, and loss of contact with reality. It must be differentiated from depression, anxiety, and medical disorders. Mothers may decompensate rather rapidly, within several weeks of delivery. Early recognition may be critical. These mothers often merit emergent treatment. Risks may include infant neglect, abuse, infanticide, or maternal suicide. Mothers with PPP who kill their infants may qualify for infanticide or insanity defenses.

Posttraumatic Stress Disorder

Exposure to psychological trauma is thought to be a risk factor for the development of many mental health disorders including posttraumatic stress disorder (PTSD), acute stress disorder (ASD), other anxiety disorders, depressive disorders, somatic disorders, substance abuse disorders, and psychotic disorders. The specific mental health symptoms that typically become manifest following exposure to trauma appear to vary from culture to culture [1–3] and from era to era, e.g., somatic and psychotic symptoms were much more common in the traumatized World War II (WWII) combatants [4] than they were in traumatized Vietnam combatants [5]. The term *PTSD* was first introduced into the official Western classification of psychiatric disorders in 1980 with the publication of the third edition of the Diagnostic and Statistical Manual for Mental Health Disorders or DSM-III [6]. Prior to 1980, the disorder was referred to by a number of names including soldier's heart in the Civil War, shell shock and traumatic neurosis in WWI, combat fatigue and war neurosis in WWII, and gross stress reaction in the 1970s [7]. PTSD has also been referred to by a number of somewhat pejorative terms to include secondary gain neurosis, compensation neurosis, and litigation neurosis owing to its association with malingering and factitious disorder [8, 9]. Malingering involves the intentional production or substantial exaggeration of physical or psychological symptoms and/or dysfunction in order to secure external incentives, e.g., avoiding work, evading criminal responsibility, and obtaining disability compensation [10]. Factitious disorder also involves intentional feigning or exaggeration of physical or psychological symptoms or dysfunction, but the motivation for doing so is to maintain the sick role, the victim role, or the wounded soldier role rather than obtaining external incentives [10]. Malingering and factitious disorder often coexist; and for the sake of brevity, the term *malingering* henceforth will be used to denote both malingering and factitious disorder.

Six criteria currently define PTSD per the most recent edition of the DSM, the DSM-IV [10]. First, the person must have experienced, witnessed, or have been confronted with a traumatic event that involved an actual or threatened death or serious injury of someone, or involved a threat to the physical integrity of self or others. In addition, the person's emotional response to the traumatic event must have involved intense fear, helplessness, or horror. Second, the person must persistently reexperience the traumatic event in the form of nightmares, intrusive recollections during the waking state, flashbacks (illusions and hallucinations) in which the person feels as if the event were reoccurring, and/or intense psychological distress or physiological reactivity upon exposure to stimuli that resemble an aspect of the traumatic event. Third, the person must persistently avoid stimuli associated with the traumatic event and/or experience a numbing of general responsiveness. Fourth, the person must experience persistent hyperarousal symptoms, e.g., hypervigilance, exaggerated startle reflex, and irritability. Fifth, the person must manifest reexperiencing, avoidance/numbing, and hyperarousal symptoms for more than one month posttrauma. Sixth, the person must manifest clinically significant distress or impairment in social, occupational, or other important areas of functioning. The diagnostic criteria for ASD are very similar to those for PTSD – the major differences being the presence of dissociative symptoms in ASD, but not in PTSD, and the PTSD symptom triad of reexperiencing, hyperarousal, and avoidance/numbing symptoms are experienced for less than one month in ASD, rather than for more than a month as they are in PTSD [10].

A voluminous amount of research has been conducted over the course of the past 25 years on psychological trauma, ASD, and PTSD. One of the

more surprising findings is that most individuals in the United States will be exposed to one or more traumatic events in the course of their lifetime – between 68 and 90% depending on the criterion and measurement methods used [11–14]. Perhaps even more surprising is the finding that only a relatively small percentage of those individuals exposed to trauma go on to develop PTSD – between 9 and 14% depending on the stressor criteria and measurement methods used [11–16]. Individuals with certain characteristics have been found to be at greater risk than others to develop PTSD subsequent to trauma – namely, women [17] and individuals with a history of psychiatric disorders as well as individuals with a family history of psychiatric disorders [11–16]. Conversely, individuals with other characteristics appear less likely to develop PTSD subsequent to trauma – namely, men [17] and individuals with good intelligence [5, 15, 18] as well as those individuals with a substantial amount of a personality trait termed *hardiness* [19–22]. Hardy individuals are those who stay committed to life (as opposed to being alienated), who believe in their own ability to control and influence the course of events (as contrasted with a sense of being powerless), and who view negative life events as challenges to be met and overcome (as opposed to view these events as insurmountable threats). Similarly, some individuals respond to traumatic events and PTSD with enhanced mental health, altruism, empathy, spirituality, and prosocial values or what has been termed *posttraumatic growth* [23, 24].

Some types of trauma appear to be more pathogenic than the other types. The most pathogenic appears to be trauma that is repetitive and prolonged (as opposed to a single and brief), man-made (as opposed to natural catastrophes), and particularly gruesome such as is often found in combat, war atrocities, and torture situations [24–27]. Single, brief, and time-limited traumatic events also vary in terms of their pathogenic potential. For example, a situation in which an 18-month-old child is run over in his own driveway by a neighbor and thereafter dies shortly in the arms of his mother is far more likely to provoke PTSD in the neighbor and the mother than the bystanders who are horrified as they witness the tragedy but who have no personal involvement with the child, the mother, or the neighbor [24–27].

Another somewhat surprising finding is that those individuals who develop PTSD subsequent to trauma often spontaneously remit or improve over time without the benefit of formal treatment to the point that they no longer meet the criteria necessary to be diagnosed with PTSD. Estimates vary, but approximately 50% of those with PTSD appears to spontaneously remit within two years posttrauma with the majority of the remission taking place in the first year [5, 12, 16, 28–31]. Those who do not remit spontaneously and who do not remit by way of treatment have an elevated risk to develop other mental health disorders and substance use disorders [11, 12, 14]. Those who do remit are at no greater risk to develop other mental health disorders than those who were never traumatized in the first place [11, 12, 14].

Another important finding is the level of vocational and social dysfunction varies considerably in the PTSD-afflicted individuals. Some individuals function at a high level vocationally and socially, and only experience occasional episodes of acute PTSD symptoms typically provoked by trauma anniversary dates or by severe situational stressors such as the death or serious illness of a loved one. Still others with PTSD are severely and chronically incapacitated emotionally, socially, and vocationally. This usually occurs when the individual has been exposed to a particularly severe trauma or to multiple traumas, has severe psychopathology prior to the trauma, and/or when severe comorbid disorders develop subsequent to the PTSD such as addictions, personality disorders, or psychosis [11–14].

Assessment

Prior to the publication of the DSM-III in 1980 [6], PTSD was frequently misdiagnosed in the form of false negatives (PTSD was present but not diagnosed) simply because it was not recognized as a valid diagnostic entity. Since then, it appears that the frequency of PTSD diagnoses have steadily risen as has the misdiagnosis of PTSD in the form of false positives (PTSD is diagnosed as present when it is not). Described below are some of the errors that are frequently being made today.

Trauma

One of the more common diagnostic errors being made is to equate stressful life events with trauma.

For example, a highly contentious divorce, being fired from a job, being betrayed by a close and trusted family member, or observing a tragic and deadly event unfold on television are often highly distressing and can generate many PTSD-like symptoms; but such events lack the critical element of being personally life-threatening and thus fail to meet one of the essential criteria necessary to diagnose PTSD [27]. For the same reason, being fearful while on sentry duty in a noncombat zone and learning of the deaths of other soldiers killed in a helicopter crash (but not being personally involved with them nor witnessing their deaths) generally does not constitute trauma. Malingers often fabricate traumatic events or they may fabricate their involvement with actual traumatic events. In either case, their stories often have inconsistencies in their retelling, inconsistencies with factual accounts of the traumatic events or in the events leading up to them, and/or implausibilities embedded within their stories [27]. For example, a malinger claiming to have been a sniper in Vietnam could not recall the manufacturer or power of the scope that was mounted on an unlikely weapon he said he employed – a rifle commonly used in Vietnam by infantrymen but generally considered to be inaccurate at long distances.

PTSD Symptoms

Another common error is to diagnose PTSD on the basis of the presence of reexperiencing, hyperarousal, or avoidance/numbing symptoms by themselves [27]. None of these symptoms are unique to PTSD and all can be found in several other mental health disorders to include generalized anxiety disorder, phobia, panic disorder, and substance-induced mood and anxiety disorders. A causal link must be established between this triad of PTSD symptoms and a traumatic stressor before other mental health disorders can be safely ruled out and PTSD diagnosed. To do this, the triad of PTSD symptoms must have first become manifest after trauma exposure has occurred, not before. Most individuals who develop PTSD following trauma exposure will experience the initial onset of the triad of PTSD symptoms within days or weeks of trauma exposure. Occasionally individuals do delay the initial onset of PTSD symptoms for as long as a year or so posttrauma, but reports of delayed onset several years after trauma exposure should be suspect, particularly if the individual reports his or her mental health to be sound in the intervening period. The triad of PTSD symptoms typically wax and wane in concert with situationally induced stress once the symptoms first become manifest. Reports of severe PTSD symptoms that show little variability across time, stress, and situations should be suspect. Flashbacks wherein an individual with PTSD relives a traumatic experience in a delusional state and out of contact with reality do occur, but they are rare. When flashbacks do occur, they are typically provoked by high levels of situational stress coupled with substance abuse and poor sleep in individuals with a history of severe trauma and severe PTSD symptoms. Reports of frequent, prolonged, and unprovoked flashbacks should be suspect. Reexperiencing symptoms in the form of nightmares, in which the traumatic experiences are veridically recapitulated in the PTSD-afflicted individuals' dreams, are typical. PTSD nightmares usually are accompanied by substantially more body movement than is found in conventional nightmares. PTSD nightmares also normally contain little in the way of fantasy at the outset; although as time progresses, PTSD nightmares may come to incorporate contemporary problems and issues in them as well as some fantastic elements. Conventional nightmares are largely fantastic and contain little in the way of realistic trauma material. Individuals with PTSD typically avoid situations that are connected with, or similar to, the traumatic events. Malingers generally do not avoid such reminders to the same extent. For example, malingers often relish telling war stories and often watch war movies and war footage on the news – things that most individuals with combat-induced PTSD would generally try to avoid. Malingerers tend to over-report or exaggerate the severity and frequency of hyperarousal and reexperiencing symptoms, and they tend to report these symptoms in interviews in an overly dramatic or histrionic fashion. On psychological tests that are sensitive to malingering, malingers tend to endorse obvious PTSD items but not subtle PTSD items; they also tend to endorse extreme but rare PTSD symptoms, and they tend to produce overall "fake-bad" test profiles. For a thorough review of the literature regarding psychological testing and malingering, see the article on forensic matters [32] in the text by Wilson and Keane [27].

Disability

The level of psychological, social, education, and vocational dysfunction related to PTSD varies considerably from one person to the other [27, 32]. Uncomplicated PTSD that is induced by a single, time-limited traumatic event in a mentally healthy adult who has good social support and who resides in a safe and healthy environment generally produces psychological distress in the neurotic (moderate) range along with mild to moderate dysfunction in social/educational/vocational functioning. The level of psychosocial dysfunction tends to markedly increase in those PTSD-afflicted individuals who heavily rely on substances and/or high levels of avoidance to cope with their PTSD symptoms [29, 30]. More psychosocial dysfunction is also generally seen in PTSD-afflicted individuals who have low social support and reside in unsafe, impoverished environments. The most severe psychosocial dysfunction is generally found among those PTSD-afflicted individuals who have substantial pre-existing psychopathology and/or develop such pathology subsequent to the PTSD, e.g., substance abuse disorders, psychotic disorders, and personality disorders. Severe psychosocial dysfunction is also likely to be found in the PTSD-afflicted individuals whose PTSD was induced by prolonged, repetitive, and particularly gruesome trauma, e.g., atrocities, and torture. Psychosocial dysfunction should never be assumed if PTSD is present. It should always be independently assessed across vocational, educational, social, and recreational domains. Malingers tend to exaggerate their psychosocial dysfunction, and they often have marked discrepancies between their capacities for work and play. For example, a malinger claimed high levels of PTSD-related vocational dysfunction yet coached his son's soccer team and routinely hosted social events in his home and in the community for team members and their parents.

Malingering

Few, if any, studies have rigorously examined the prevalence of malingering in either clinical or forensic settings. There are, however, a number of case studies and studies that have employed samples of convenience that have estimated the prevalence to vary from 1% [33] to 50% [34] depending on the setting and the population being examined. For a review of the literature in this regard, see the article on forensic matters [32] in the text by Wilson and Keane [27]. In most clinical settings, mental health professionals rely almost exclusively on individuals' self-reports to diagnose PTSD that are taken by the way of unstructured interviews or structured interviews such as the Clinician-administered PTSD Scale [35]. Given clinicians' general lack of skepticism and their desire to give clients the benefit of the doubt, many malingerers appear to be able to feign PTSD symptoms and trauma exposure well enough in such interviews to avoid being detected. This generally does not pose a problem provided the prevalence of malingering is low as it is in most clinical settings. However, in a few clinical settings and nearly all forensic settings, malingering is likely to be prevalent. This necessitates taking additional assessment measures to rule maligning out. Such measures usually entail collaborating clients' self-reports of trauma exposure, collaborating their self-reports of PTSD symptoms, and collaborating their self-reports of psychosocial disability by way third party reports, reviews of public and private records (e.g., media accounts, police records, military records, and medical records), and the administration of structured interviews that are sensitive to dissimulation such as the Structured Interview of Reported Symptoms [36] as well as psychological tests that have scales that are sensitive to dissimulation such as the Minnesota Multiphasic Personality Inventory 2 (MMPI2) [37]. Gathering such information usually adds considerable time and expense to the assessment process.

It is generally a good idea to rate individuals in terms of the malingering indicators listed below before diagnosing them with PTSD. The more malingering red flags that are present then the greater the likelihood of malingering. The number of red flags that should trigger efforts to collaborate individuals' self-reports will vary from setting to setting depending on the costs for misdiagnosing PTSD if malingering is overlooked *versus* the costs for conducting the more thorough assessment necessary to rule out malingering. The costs will also be strongly influenced by the relative prevalence rates of PTSD versus malingered PTSD in the population of interest, which are likely to vary from time to time. For instance, malingered PTSD was probably relatively rare in veterans who approached the United States

Department of Veteran Affairs for services throughout the 1980s – about 5% according to one estimate [38]. Thus, the costs of occasionally misdiagnosing PTSD because malingering was overlooked were relatively small then. But clinical observation and some empirical evidence [39–41] now suggest that malingered PTSD is far more common in veterans seeking services from the US Department of Veteran Affairs than it once was. Consequently, the costs of misdiagnosing PTSD because malingering is overlooked are probably substantially greater than they once were. These costs not only include disability compensation being erroneously awarded to malingers but also include the costs of utilizing scarce clinical resources to treat malingers that could be better utilized if these resources were devoted to treating those in greater clinical need.

Malingering (Factitious Disorder) Red Flags

1. Criminal proceedings

Malingering should always be suspected when a diagnosis of PTSD is likely to mitigate an individual's criminal culpability.

2. Disability proceedings

Malingering should always be suspected when a diagnosis of PTSD is likely to result in disability compensation for an individual.

3. History of disability claims

Malingering should always be suspected when an individual has a history of filing disability claims.

4. Antisocial personality disorder

Malingering should always be suspected when an individual has an antisocial personality disorder or antisocial personality traits as evidenced by a long history of significant legal infractions and/or social irresponsibility.

5. Poor work history

Malingering should be suspected when an individual is functioning as a marginal member of society as manifested by a poor work history, no permanent address, a vagabond lifestyle, etc. Severe PTSD or PTSD complicated by severe comorbid disorders can result in a poor work history so it is important to examine an individual's work history prior to the trauma as well as after.

6. Substance abuse disorder

Malingering should be suspected when an individual presents with a substance abuse disorder. Substance abuse disorders sometimes do evolve as a consequence of PTSD so it is important to examine the individual's substance usage before the trauma as well as after.

7. Marked disparities in psychosocial functioning

Malingering should be suspected when an individual claims substantial vocational impairment subsequent to PTSD yet retains the capacity to successfully engage in social and/or recreational activities.

8. Atypical presentational styles

Malingering should be suspected if an individual presents with extreme emotional displays and/or bizarre symptoms when discussing their trauma. At the other extreme, malingering should also be suspected if an individual presents in a bland, matter-of-fact manner when discussing their trauma. Almost all PTSD-afflicted individuals will have some emotional distress and difficulty in discussing their trauma, but it will not be so severe as to disrupt the assessment process nor will it have a histrionic quality to it. Malingerers tend to present themselves as victims and tend to externalize, condemn, and blame others for their misfortune with accompanying anger, whereas individuals with PTSD tend to internalize and perceive themselves as being primarily responsible for their misfortune with accompanying guilt and shame. Malingering should also be suspected when an individual idealizes their life and work prior to the trauma while simultaneously attributing any and all shortcomings they currently have to the trauma and/or PTSD. Malingering should also be suspected when an individual behaves in an evasive, noncooperative, or hostile manner during the assessment. Such presentational styles are atypical of PTSD-afflicted individuals in most assessment settings.

9. Atypical trauma

Malingering should be suspected when traumatic events cannot be independently verified. Malingering should also be suspected when the traumatic events contain one or more implausible elements or when there are significant inconsistencies noted from one retelling of the trauma story to the next. Malingering should also be suspected when severe PTSD is claimed, the individual has no

pre-existing psychopathology, and the trauma is a single, brief, and not a particularly gruesome tragedy.

10. Atypical PTSD symptoms

Malingering should be suspected when an individual reports a number of atypical symptoms or symptom patterns to include: substantial time delays between traumatic events and the initial onset of the PTSD symptom triad, the complete cessation of the PTSD symptoms for substantial periods of time owing to the heavy use of substances, PTSD symptoms that fail to vary in frequency and severity in concert with situational stressors, the presence of rare PTSD symptoms such as flashbacks occurring in the absence of high stress and substance abuse and a history of severe PTSD symptoms, nightmares that contain substantial fantasy and little trauma content, little in the way of avoidance of situational stimuli associated with the traumatic events, the endorsement of obvious PTSD symptoms but not subtle PTSD symptoms on psychological tests as well as overall fake-bad test profiles.

Treatment

Treatment for individuals with PTSD takes a variety of forms depending on the severity and chronicity of the PTSD symptoms, the severity and type of any comorbid disorders that might be present, the characteristics of the community and prevailing mental health service delivery system, and the characteristics of the individuals themselves, e.g., motivation, secondary gain, age, ethnicity, and gender [42, 43]. PTSD that is of recent onset and is uncomplicated by other mental health disorders or problematic environmental circumstances (e.g., homelessness or dangerous environments) generally can be effectively treated on an outpatient basis with antidepressant medications [42, 43] and exposure-based cognitive-behavior therapy [42, 43]. Exposure-based CBT safely exposes PTSD-afflicted individuals to trauma-related stimuli in imagination and/or *in vivo* while simultaneously facilitating the assimilation of their traumatic events into healthy beliefs or cognitive schema regarding themselves and their world [42, 43]. It is also often beneficial to treat PTSD-afflicted individuals' co-occurring situational problems by way of supportive problem-solving while simultaneously treating their uncomplicated, recent onset PTSD way of antidepressants and CBT – exposure. This is particularly true in the case of soldiers recently returning from a war zone. Nearly all returning soldiers will be struggling with the task of transitioning from the military back into civilian life, with all of its attendant housing, job, education, family, and social support stressors; and some of the soldiers will be struggling with recent onset PTSD symptoms as well. In most cases, the stress of their readjustment issues will aggravate and prolong the PTSD symptoms of those who have them. By reducing the readjustment-related stress, the PTSD symptoms are likely to be lessened and the spontaneous remission process is likely to be strengthened.

Hospitalization for the treatment of PTSD is seldom necessary. With the possible exception of one study [44], most of the evidence suggests that there is little sustained therapeutic benefit from treating chronic PTSD in specialized inpatient PTSD units [45–49]; and such hospitalizations appear to have iatrogenic effects for a significant minority of those who undergo such treatment [44–49]. Treatment of PTSD complicated by severe comorbid disorders is usually dictated by the nature of the comorbid disorders rather than the PTSD *per se* [42, 43]. For example, those with PTSD accompanied by severe depression and significant suicidal risk usually require hospitalization to treat the depression and suicidal threat before beginning treatment for the PTSD. In other cases of chronic, severe, and highly complicated cases of PTSD, it is sometimes best to approach treatment as one would approach an incurable and chronic medical illness. That is, the treatment should focus on palliative care and try to help the individual manage his or her psychiatric symptoms rather than directly focus on the traumatic events and PTSD symptoms in an effort to eliminate them, as would be the case with exposure-based CBT [42, 43].

Summary

In summary, approximately 75% of all adults will be exposed to one or more traumatic events during the course of their lives. About 10% of those exposed to trauma will develop PTSD subsequent to the trauma, and about 50% of those who do develop PTSD will spontaneously remit within two

years posttrauma. Those who do not remit are at increased risk to develop additional disorders such as mood disorders and substance abuse disorders. Some individuals are at greater risk to develop PTSD than the others, particularly those with pre-existing psychopathology. Multiple trauma that is gruesome, prolonged, and man-made is more pathogenic than is less repetitive and less gruesome forms of trauma. The psychosocial dysfunction stemming from PTSD varies greatly from person to person depending on the severity of the trauma, the severity of the PTSD symptoms, and the type and severity of the comorbid disorders that are often present. Recent onset PTSD can be effectively treated by way of CBT exposure-based psychotherapy and antidepressant medications on an outpatient basis. The treatment of chronic PTSD in specialized PTSD inpatient units appears to be largely ineffective and possibly harmful for a significant minority of those who undergo it. PTSD appears to be frequently misdiagnosed in the form of false positives today. Malingering should always be suspected in forensic settings. Malingering should also be suspected in clinical settings when a significant number of malingering red flags are present. Collaborating clients' self-reports of trauma, PTSD symptoms, and psychosocial dysfunction are usually required to rule out malingering.

PowerPlex

Introduction

The ability of polymerase chain reaction (PCR)-based short tandem repeat (STR) multiplexes to successfully analyze human DNA from a diverse range of circumstances is at the cornerstone of forensic DNA science. A contemporary version of these sophisticated systems has been the GenePrint PowerPlex range of multiplex STR systems (Promega Corporation, Madison, WI; Table 1).

These systems originally emerged in 1997 with PowerPlex 1.1 and progressed iteratively towards the current 16-locus PowerPlex®16 autosomal STR multiplex PCR system. The PowerPlex®16 offers extremely high discriminating power due to the combination of 15 STR loci plus the sex marker amelogenin [1, 2]. There is also the PowerPlex Y male-specific STR multiplex [3], which has specific advantages for the analysis of sex-assault cases and population genetic testing. The PowerPlex range of tests has shown its applicability to all forms of human identification casework, including kinship and disaster victim identification cases.

premenstrual syndrome (PMS). After all, it seemed so logical. Despite these efforts, medical science was never able to make the connection work. Attempts to treat PMS with hormonal treatments continuously failed. Hysterectomy and oopherectomy rarely afforded significant relief.

The breakthrough came with the discovery of serotonin, a ubiquitous neurotransmitter, now well established to underlie moodiness, anxiety, irritability, and hostility – symptoms commonly seen in PMS. Consequently, on 6 July 2000, fluoxetine became the first food and drug administration (FDA) recognized and approved treatment for the severe form of PMS, known as *premenstrual dysphoric disorder* (PMDD).[a]

So, the answer was not hormones – it was serotonin. Despite an understanding of the chemical etiology, PMS itself is a remarkably common experience and cannot itself be considered abnormal or pathological. Most women who experience PMS have mild or moderate symptoms and are not socially or occupationally impaired by them. However, a small subset of women experience significant impairment and disability in the premenstrual phase. Psychiatry has chosen to define the women suffering from this severe form of PMS as having PMDD. While deemed as an area of interest and research, PMDD is not considered to be a mental illness. It can be classified alternatively as a depressive disorder, not otherwise specified (coded 311); this category includes disorders with depressive features that do not meet the criteria for major depressive disorder. The sensitivity of the political correctness of this issue is obvious. The american psychiatric association (APA) has established diagnostic criteria, which are provided in the box below.

Legal Usage

In the 1980s, two British cases raised PMS as the basis for a diminished capacity defense reducing the quantum of guilt assessed against the accused.[b] First, in November, 1981, Sandie Smith was put on three years' probation after conviction of threatening to kill a police officer and for carrying a knife. She suffered from PMS and had committed almost 30 crimes, including arson, assault, and manslaughter, during the premenstrual period. Smith responded to progesterone therapy, advocated by English gynecologist Dr Katharine Dalton, to curb PMS. Dalton was a pioneer researcher who used her patients as a source of information for formulating what she and Dr Peter Green, a fellow researcher, named "premenstrual syndrome" in 1953.

Then, that same month Christine English pleaded guilty to manslaughter by reason of diminished responsibility. She drove her car into her lover after an argument that occurred while she was suffering from severe PMS [1]. She was conditionally discharged for 12 months.

One court martial case and an unreported US decision admitted PMS evidence as grounds for a defense. In *United States v. Morton*, the accused was charged with assault with a dangerous weapon, communicating a threat, and unlawfully carrying a concealed weapon. She pled not guilty by reason of insanity due to PMS. Morton had to establish by clear and convincing evidence that her PMS was so severe that she was unable to know and appreciate the consequences of her conduct [2]. The court held that she failed to establish insanity. It is unlikely that any US jurisdiction would allow PMS as an insanity defense.

In *People v. Santos* [3], the defendant testified in a preliminary hearing that she beat her child while in a "blackout" induced by PMS [4]. She was able to get a favorable plea bargain based on diminished capacity. Diminished capacity is an excuse defense that shifts the burden to the prosecution to disprove the excuse beyond a reasonable doubt once evidence of the excuse is admitted.[c] American states that recognize a diminished capacity defense might permit evidence of PMS to be admitted to show diminished capacity [5]. However, several states have abolished the diminished capacity defense.[d] Some states permit a diminished capacity defense murder prosecutions [6], following *United States v. Brawner* [7]. Other states permit a diminished capacity defense when the accused is charged with any crime of specific intent [8]. Federal practice under the 1983 Insanity Defense Reform Act [9] permits expert evidence on diminished capacity. Alaska allows expert testimony on diminished capacity that would permit PMS evidence during the guilt phase of trial.[e]

Diminished capacity must be established by expert opinion evidence that shows that the defendant both suffers from PMS and committed the crime charged while under the influence of PMS. Half

the states[f] and the Federal courts follow *Daubert v. Merrell Dow Pharmaceuticals Inc*. [10] and exclude expert opinion evidence if the expert's underlying scientific principles fail to meet a four-part test [11]:

1. Has the theory been tested by other researchers?
2. Has the theory been published?
3. What is the error rate?
4. Is the process generally accepted?

An expert in a *Daubert* jurisdiction must testify that PMS is a mental illness as diagnosed using diagnostic and statistical manuel of mental disorders, fourth edition, Text Revised (DSM-IV and DSM-IV(TR)) and explain the DSM-IV(TR) criteria for PMS (see Box). The expert must state that the diagnosis and criteria for PMS have been published and subject to peer review. She/he must assert the error rate for making the diagnosis of PMS. Finally, the expert should state that the criteria for diagnosing PMS and diminished responsibility are generally accepted (*see* **Expert Opinion: United Kingdom, Canada, and Australia**).

Some states follow the *Frye* rule (*see* ***Frye v. United States***) that requires the underlying scientific principles be "generally accepted" before an expert gives an opinion based on those principles [12]. Others have adopted a modified *Frye* rule with modifications using some or all of the *Daubert* factors [13]. In the *Frye* states and mixed states, the expert must testify that psychotherapists generally accept that PMS causes the sufferer to be unaware of the consequences of her action or to distinguish right from wrong.

Expert opinion evidence on PMS should be freely allowed during the sentencing phase of any trial. According to ¶ Section 5K2 of the Federal Sentencing Guidelines, the court may make a downward departure from the statutory maximum sentence for a convicted defendant on the ground of diminished capacity.[g]

Concerns about the use of PMS in the Courtroom

The forensic use of PMS has generated global controversy. Some of the principle arguments are as follows.

- **PMS is yet another sexist "woman as mad" explanation for female criminality**

Historically, deviant women have often been characterized as either "bad" or "mad" since their antisocial behavior conflicted with certain socially defined and desirable female personality traits and roles. Medical theory, from at least the mid 1800s, espoused that women's reproductive organs controlled their minds, bodies, and personalities. Such biological determinism was strongly endorsed and promulgated by psychiatry: in Freud's model of psychoanalysis, sexual temperament was conceived as a function of biology [14].

Accordingly, the nineteenth century doctors and lawyers agreed that menstruation and uterine malfunction could lead a woman to insanity or criminality. As an example, in the 1867 case *United States v. Harris*, attorneys called a psychiatrist and six other physicians who testified that the defendant was "morally insane" at the time of the homicide due to painful dysmenorrhea that led to mental derangement and hysteria. After a brief deliberation, the jury returned a verdict of not guilty by reason of insanity.[h] English courts also recognized some form of mental derangement related to the menstrual cycle as an excuse for criminality before *Harris* [15, 16]. One woman was acquitted of shoplifting in 1845 while two others were acquitted of murder in 1851. All three were found to have acted with temporary insanity due to "suppression of menstruation" [17]. One of these women had murdered her lover who had rejected her. A doctor testified that her wild eyes indicated problems with her uterus [18].

The specifics of the sociomedical theoretical explanations for female deviance shifted with time as the understanding of the female reproductive system evolved from the uterus to ovaries and then to hormones in the 1920s. With the UK cases of Smith and English discussed above, the focus in the early 1980s became PMS and its relationship to female criminality. In part, this undoubtedly reflected the growing interest in studying the female offender and etiology since statistics during the 1970s were reflecting an increasing number of crimes committed by women or, at the least, a higher number of arrests or prosecutions [19].

To some of its detractors, PMS is therefore the latest in a long line of anatomical deterministic theories of female criminality that have prevailed as

a substitute for looking at how entrenched gender inequality might contribute to crime. Instead, women's deviance has been linked with the anatomical parts that differentiate them from males and which allow them to fulfill their primary gender role of reproduction.

- **Its usage in court could stigmatize women as a whole and/or affect their equal participation in the public sphere**

There is concern that if PMS is raised as exculpatory grounds, people might generalize from the few and negatively stereotype all women or at the least those who experience any premenstrual symptoms [20]. Sensationalist captions such as "raging hormones", "premenstrual frenzy", and "Dr Jekyll and Ms Hyde" that appeared in British newspapers during the *English* and *Smith* cases can fuel imagery of women as periodically unstable and therefore unsuitable for some employment positions and/or responsibilities.

As with all medical disorders, a whole class of people with similar maladies could be stigmatized. As discussed earlier, the syndrome is fairly common, although only a minute percent manifest the symptoms that can substantially impact on their actions.

- **Its use relies upon acceptance of the legitimacy of PMS and PMDD and advocates/specialists**

All medical practitioners do not share in Dalton's belief in temporary psychosis as a symptom of the most severe PMS cases [21, 22]. The medical literature is confusing in its diversity of opinion concerning the possible connection of PMS to criminal behavior with no universally accepted medical consensus about the correlation of the severe variant with antisocial behavior.

In some countries like Australia where PMS is not raised except very infrequently in sentencing mitigation,[i] it continues to be referred to as *premenstrual tension* (PMT) and lacks acknowledgment as a legitimate medical condition. This is illustrated in a popular news feature story on PMS:

> Despite the popular belief that "it is all in the hormones", there is no convincing evidence that women with severe PMS have different hormonal fluctuations than other women . . . cause of PMS are still unknown . . . [23].

A number of female medical practitioners are quoted in the article articulating the view that women who think they have PMS may actually have clinical depression.

Yet to use it successfully a forensic expert is required. With insanity the defense must show that PMS is a disease of the mind and that the sufferer did not know the nature or quality of the act or that it was wrong (McNaughton Rule). Doing so with PMS can be highly problematic.

To raise automatism (a state in which the mind or the will does not accompany physical acts) by arguing that certain women with PMS who go hours without eating produce an excess amount of adrenalin that causes a hypoglycemic state of impaired consciousness requires an expert like Dalton to testify that hypoglycemia can be a symptom of PMS and that the defendant possessed that abnormality.

The defense with diminished responsibility or capacity must show that PMS prevented the accused from having the specific intent (*mens rea*) with hazy thinking, and impairment of self-control, judgment and willpower. Again, proof is problematic. Plus, there are several legal issues since the defense has to show that PMS is an abnormality of the mind (which is difficult since the symptoms of PMS are not even universally accepted), that it arose from an inherent cause, and that it substantially impaired the defendant's mental responsibility [24]. With potentially lengthy sentences, the convicted has the added stigma of mental illness [25].

- **It could be misused and or abused by defendants**

There is concern that PMS might be used as grounds for a defense by *non-bona fide* sufferers – either charlatans and/or women who experience some of the more mild PMS symptoms.

However, the diagnosis of PMDD can be substantiated by a heavy burden of proof, with medical evidence showing a clinically demonstrable physical disorder. A causal connection must be shown between the premenstrual symptom(s) and the criminal act. Additional evidence could include personal diaries, medical records, prior arrest record that could illustrate deviant activity correlation with the individual's premenstrual time of her cycle, and evidence by family and friends of marked premenstrual behavioral changes.

PMDD
APA Diagnostic Criteria [26]
In most menstrual cycles during the past year, symptoms (e.g., markedly depressed mood, marked anxiety, marked affective lability, decreased interest in activities) regularly occurred during the last week of the luteal phase (and remitted within a few days of the onset of menses). These symptoms must be severe enough to markedly interfere with work, school, or usual activities and be entirely absent for at least 1 week post menses.
The essential features are symptoms such as markedly depressed mood, marked anxiety, marked affective lability, and decreased interest in activities. These symptoms have regularly occurred during the last week of the luteal phase in most menstrual cycles during the past year. The symptoms begin to remit within a few days of the onset of menses (the follicular phase) and are always absent in the week following menses.
Five (or more) of the following symptoms must have been present most of the time during the last week of the luteal phase, with at least one of the symptoms being one of the first four:

1) feeling sad, hopeless, or self-deprecating;
2) feeling tense, anxious *or* "on edge";
3) marked lability of mood interspersed with frequent tearfulness;
4) persistent irritability, anger, and increased interpersonal conflicts;
5) decreased interest in usual activities, which may be associated with withdrawal from social relationships;
6) difficulty concentrating;
7) feeling fatigued, lethargic, or lacking in energy;
8) marked changes in appetite, which may be associated with binge eating or craving certain foods;
9) hypersomnia or insomnia;
10) a subjective feeling of being overwhelmed or out of control; and
11) physical symptoms such as breast tenderness or swelling, headaches, or sensations of "bloating" or weight gain, with tightness of fit of clothing, shoes, or rings. There may also be joint or muscle pain. The symptoms may be accompanied by suicidal thoughts.

This pattern of symptoms must have occurred most months for the previous 12 months. The symptoms disappear completely shortly after the onset of menstruation. The most typical pattern seems to be that of dysfunction during the week prior to menses that ends mid-menses. Atypically, some females also have symptoms for a few days around ovulation; a few females with short cycles might, therefore, be symptom free for only 1 *week per cycle.*
Typically, the symptoms are of comparable severity (but not duration) to those of a Major Depressive Episode and must cause an obvious and marked impairment in the ability to function socially or occupationally in the week prior to menses. Impairment in social functioning may be manifested by marital discord and problems with friends and family. It is very important not to confuse long-standing marital or job problems with the dysfunction that occurs only premenstrually. There is a great contrast between the woman's depressed feelings and difficulty in functioning during these days and her mood and capabilities the rest of the month. These symptoms may be superimposed on another disorder but are not merely an exacerbation of the symptoms of another disorder, such as Major Depressive, Panic, or Dysthymic Disorder, or a Personality Disorder. The presence of the cyclical pattern of symptoms must be confirmed by at least 2 consecutive months of prospective daily symptom ratings. Daily symptom ratings must be done by the woman and can also be done by someone with whom she lives. It is important that these diaries be kept on a daily basis rather than composed retrospectively from memory.
Delusions and hallucinations have been described in the late luteal phase of the menstrual cycle but are very rare. Although females with the combination of dysmenorrhea (painful menses) and premenstrual

dysphoric disorder are somewhat more likely to seek treatment than females with only one of these conditions, most females with either of the conditions do not have the other condition. A wide range of general medical conditions may worsen in the premenstrual or luteal phase (e.g., migraine, asthma, allergies, and seizure disorders). There are no specific laboratory tests that are diagnostic of the disturbance. However, in several small preliminary studies, certain laboratory findings (e.g., serotonin or melatonin secretion patterns, sleep EEG findings) have been noted to be abnormal in groups of females with this proposed disorder relative t o control subjects.

It is estimated that at least 75% of women report minor or isolated premenstrual changes. Limited studies suggest an occurrence of "premenstrual syndrome" (variably defined) of 20%–50%, and that 3%–5% of women experience symptoms that may meet the criteria for this proposed disorder. There has been very little systematic study on the course and stability of this condition. Premenstrual symptoms can begin at any age after menarche, with the onset most commonly occurring during the teens to late 20s. Those who seek treatment are usually in their 30s. Symptoms usually remit with menopause. Although symptoms do not necessarily occur every cycle, they are present for the majority of the cycles. Some months the symptoms may be worse than others. Women commonly report that their symptoms worsen with age until relieved by the onset of menopause.

Research criteria for premenstrual dysphoric disorder

A. In most menstrual cycles during the past year, five (or more) of the following symptoms were present for most of the time during the last week of the luteal phase, began to remit within a few days after the onset of the follicular phase, and were absent in the week postmenses, with at least one of the symptoms being either (1), (2), (3), or (4):
   (1) markedly depressed mood, feelings of hopelessness, or self-deprecating thoughts
   (2) marked anxiety, tension, feelings of being "keyed up", or "on edge"
   (3) marked affective lability (e.g., feeling suddenly sad or tearful or increasedsensitivity to rejection)
   (4) persistent and marked anger or irritability or increased interpersonal conflicts
   (5) decreased interest in usual activities (e.g., work, school, friends, hobbies)
   (6) subjective sense of difficulty in concentrating
   (7) lethargy, easy fatigability, or marked lack of energy
   (8) marked change in appetite, overeating, or specific food cravings
   (9) hypersomnia or insomnia
   (10) a subjective sense of being overwhelmed or out of control
   (11) other physical symptoms, such as breast tenderness or swelling, headaches, joint or muscle pain, a sensation of "bloating", weight gain.

   Note: In menstruating females, the luteal phase corresponds to the period between ovulation and the onset of menses, and the follicular phase begins with menses. In nonmenstruating females (e.g., those who have had a hysterectomy), the timing of luteal and follicular phases may require measurement of circulating reproductive hormones.

B. The disturbance markedly interferes with work or school or with usual social activities and relationships with others (e.g., avoidance of social activities, decreased productivity and efficiency at work or school).

C. The disturbance is not merely an exacerbation of the symptoms of another disorder, such as Major Depressive Disorder, Panic Disorder, Dysthymic Disorder, or a Personality Disorder (although it may be superimposed on any of these disorders).

Criteria A, B, and C must be confirmed by prospective daily ratings during at least two consecutive symptomatic cycles. (The diagnosis may be made provisionally prior to this confirmation.)

End Notes

[a.] The Massachusetts Institute of Technology holds the patent for this treatment.

[b.] The English Homicide Act of 1957 provides that "Where a person kills or is a party to the killing of another, he shall not be convicted of murder if he was suffering from such abnormality of mind ... as substantially impaired the mental responsibility for acts and omissions in doing or being a party to the killing." 5 and 6 Eliz. 2, ch. 2, § 2[1], 1957.

[c.] *LaFave* § 9.8(f)(4).

[d.] Arizona, California, Florida, Georgia, Maryland, Ohio, Oklahoma, Rhode Island, and South Carolina have abolished diminished capacity. See, e.g., *State v. Doss*, 568 P.2d 1054 (Ariz. 1977) (en banc) Cal. Penal Code § 25. Section 2.02 of the Model Penal Code abolished specific intent and diminished capacity.

Profiles: Psychological and Behavioral

Profiles are most closely associated with psychological models developed by the Federal Bureau of Investigation (FBI) in their early searches for serial murderers [1] (*See* **Serial Homicide**). The term has since been applied to a great many diverse compilations of information, as well as to what are little more than stereotypes. Over the past decade or so, "profilers" have been a favorite topic of crime dramas and novels and in the process have been glamorized and misrepresented to the point where the facts have often been obscured. Of particular concern for the justice

system, however, has been the introduction of "profiles" as a component of psychological syndromes that have suggested new categories of "victims" and alleged profiles of the perpetrators responsible for their victimization (*see* **Syndromes: Psychological**; **Deception: Truth Serum**).

Profiles as an Aid in Law Enforcement

In 1987, Judge Charles Becton published a law review article that drew attention to a seemingly chameleon-like way in which drug courier profiles adapted to any particular set of observations [2]. Within months, the Court of Appeals for the Ninth Circuit incorporate Judge Becton's arguments into *United States v. Sokolow* [3]; a case which it had debated for over 2 years. By the late 1980s, however, criminal profiles had become a staple of law enforcement. Even the US Supreme Court could not stand by and watch them wiped out in a single sweep of a judicial pen.

The High Court went back to basics, and they found their foundation in *Terry v. Ohio* [4]. Officer McFadden, and his detention of two men casing Zucker's clothing store on an Ohio day in 1963, had given rise to the Terry Stop "stop and frisk" exception to the Fourth Amendment and the reasonable suspicion test, which provided justification, short of probable cause, under which police officers could initiate limited investigatory action. The Supreme Court knew that it could not allow any decision that it could make in *Sokolow* to turn profiles into unrestricted hunting licenses for overenthusiastic enforcement officials, nor was it willing to set up an entirely new bureaucracy to review the constitutionality of each and every profile. The Court also recognized that profiles changed over time, and that their effectiveness would evaporate if they became frozen and subject to public scrutiny.

This solution requires that every law enforcement intervention, regardless of whether or not it was set in motion by a profile, must be justifiable through the same articulation of facts – the "totality of the circumstances" – required for a *Terry* stop. Searches made under *Sokolow* are reviewed on a case-by-case basis and have been overturned if they fail to meet appropriate standards [5]. In this single decision, the Court recognized the validity of the probabilistic assumptions underlying the application of behavioral science techniques in justice administration, yet made it impossible to elevate criminal profiles into a license for Fourth Amendment abuse.

Criminal profiles continue to serve as a tool in law enforcement, but more importantly, profiles are a means of leveraging investigative expertise, training investigative and enforcement officials, and applying systematic methodologies to the fast-changing and highly mobile environment that characterizes contemporary criminal operations. Once the intervention has been initiated, however, the profile is of no further probative relevance. Arrest and even the issuance of a search warrant require probable cause, and prosecution of any resulting charges must be based upon substantive evidence of guilt. The original profile is inadmissible in support of guilt, and is presumed to be inherently prejudicial [6].

The temptation to push these limits was brought home to the British public in a highly publicized 1995 case. Three years earlier, 23-year-old Rachel Nickell took her 2-year-old son and dog for a walk. She selected Wimbledon Common as her south London destination because of its reputation for safety, but, less than an hour later, she was found soaked in the blood of some 49 stab wounds, her child clinging to her lifeless body crying "get up mummy". Police responded with the biggest murder investigation in London history – and one of the nation's early attempts at using the new science of psychological profiling.

England's first encounter with the behavioral sciences in criminal investigation came in the 1985 "Railway Rapist" case. Although profiling had become well established in the United States through the work of the FBI Behavioral Science Unit, both serial killers and the methods for catching them were only just then taking hold in Britain. David Canter, professor of investigative psychology at Liverpool University, had a background in the psychology of building design, human behavior during fires, and the psycholinguistics of hoax fire calls; but the rigor of his science prepared him well to become that nation's leading criminal profiler. His methodical work led to the conviction of John Duffy, and inspired the Robbie Coltrane character in the hit television detective series *Cracker* [7].

By the time of the Nickell murder, however, the publicity surrounding criminal profiling had attracted

a host of psychologists who had been bitten by the detective bug. It was one of these who claimed the case, produced a profile, and eventually took over much of the day-to-day police operations directed toward conviction of the suspect, Colin Stagg, targeted by the profile. Through an attractive blond undercover policewoman, the psychologist initiated an 8-month liaison with the 31-year-old Stagg in which she shared violent sexual fantasies, confessed to the ritual sexual murder of a baby and a young woman, and egged him on to match her stories; even telling him that she wished he were Nickell's murderer because "That's the kind of man I want."

Stagg never claimed credit for the killing, but from 700 pages of letters and transcribed telephone conversations and public meetings, the psychologist concluded that Stagg's fantasies, modeled upon information fed to him by those familiar with the details of the crime, revealed unique knowledge of the crime scene that could be known only by the murderer. Dragged before a judge in open court at the Old Bailey, defense quickly pointed out that Stagg had not even made good guesses – he did not know the location of the crime and had wrongly asserted that the victim had been raped.

Up until that point, Great Britain had never felt the need for an entrapment statute, but the judge recognized a "honey trap" when he saw one. Clearing the accused and acknowledging the understandable pressure on the police, the judge was, nevertheless, forced to conclude that the operation betrayed "not merely an excess of zeal, but a blatant attempt to incriminate a suspect by positive and deceptive conduct of the grossest kind". Stagg left the chaotic courtroom vowing to sue everyone involved, the police were the butt of press ridicule, and David Canter observed with typical English understatement that pulling in some "media recognized expert" can undermine "more effective, longer term development of a professional discipline" [8].

It is not just the newcomers who can make mistakes. The 1996 Summer Olympics began in the wake of the first case of suspected air terrorism on American soil, and as the investigation of the TWA flight 800 crash off New York moved ahead with commendable precision, a bomb blast rocked the Olympic festivities in Atlanta. Unwilling to stand by in the face of two national assaults, an inexperienced FBI agent allowed the press to get word that a psychological profile had identified the private security guard who first spotted the bomb as the likely perpetrator. In moments, Richard Jewell went from hero to the object of media scrutiny and scorn.

After a week of publicized investigation, in which the entire world got to see Jewell live on CNN sitting forlorn on his own front steps as the FBI picked through his apartment, the investigation yielded nothing more than a few pathetic souvenirs of a man's only moment of glory. Pressed for an explanation, an FBI spokesperson on the scene curtly informed the press that "We don't make apologies". FBI director Louis Freeh, called before a congressional investigating committee, tried to put a better face on the public relations disaster but confided privately that "We wish we never heard of Richard Jewell". [9, 10].

This is not to say that mention of a profile, or court testimony that overlaps in any way with a profile, is necessarily prohibited. Testimony can mention a profile in the context of background as to how and why a defendant was stopped and searched, if such testimony is confined to the preliminary stop and not the actual investigation, and the fact that the individual satisfied the profile is not used to impugn the defendant [11]. Moreover, the expertise reflected in profiles *can* be the subject of expert testimony to refute assertions by the defendant [12], to supply factual information helpful to the trier of fact in placing the case in context [13], or to establish motive, intent, absence of mistake or accident, or identity of a common scheme or plan [14].

Profiles as Evidence at Trial

By their tentative and proximal nature, profiles pose serious issues of both scientific and probabilistic validity [15]. Their use, and the term itself, are therefore most appropriately restricted to investigative tools. As evidence, profiles easily become little more than a means to either link a defendant to undesirable traits or stereotypes; or for the defense to attribute by association positive or sympathetic attributes to a defendant.

Behavioral science is relevant to justice because it can assist the trier of fact to understand a party in litigation as an individual (*see* **Risk Assessment**),

while profiles are a tactic to attribute the qualities of a grouping to an individual. There are circumstances in which this tactic can be attractive to either side of a case, and the law has established guidelines to restrict potential abuse.

Entrapment, the affirmative defense that alleged crimes were in reality induced by government persuasion or trickery, is a good example. An entrapment defense, as with defenses to most serious criminal charges, turns on the defendant's mental state: was the defendant an active participant or simply a passive bystander to conduct actually carried out by a government operative? Although early cases tended to hold that a defendant asserting the affirmative defense of entrapment could not establish their state of mind through expert testimony, the courts now generally consider such testimony an appropriate aid to the triers of fact [16, 17].

Most other attempts to enlist expert testimony regarding a defendant's personality profile to help disprove a criminal charge have been less successful. Introduction of psychiatric testimony regarding the "dependent personality disorder" of a defendant was excluded, for example, as support of her assertion that she was unaware that computer equipment that she sold was, in fact, stolen. Here, the court felt that imprimatur of such an official-sounding label was neither necessary nor helpful to the jury in making its assessment of the defendant's mental state [18].

Similarly, the psychological profile of a murder and robbery defendant was excluded as possible support that his crime could not have been deliberate and premeditated, holding that the profile appeared to be simply a narration of the defendant's social history with little or no rational bearing on issues of premeditation and intent [19]. Such personality testimony has also been excluded as a defense to armed robbery and assault [20], and manslaughter [21], where the defendants sought to establish that they were simply not the "type" to use a weapon.

In many instances, the testimony is simply a way in which to introduce character evidence. Testimony in support of good character is generally permissible [22], but the courts are leery of according it scientific stature [23]. Nevertheless, in two controversial decisions, lay character witness testimony has been upheld in a child molestation case [24], and a psychologist's opinion was upheld as appropriate testimony concerning a defendant charged with lewd and lascivious acts upon a child, noting that the testimony was based, at least in part, upon standardized testing [25].

Most frequently, however, courts have excluded expert testimony aimed simply at ruling out a defendant as the guilty party. This has been the case in proposed testimony as to "peaceableness" [26], psychiatrist testimony as to lack of characteristics "likely to result in abuse of infant victim" [27], psychiatrist testimony that defendant had made previous false confessions and may therefore be mentally ill and his confession untrustworthy [28], expert testimony as to defendant's remorse or lack of remorse [29], and that the defendant had undergone a religious conversion and therefore could be rehabilitated [30]. Expert testimony is also typically not allowed as to mitigation of an offense [31]. Often, such expert testimony is proffered in place of the defendant taking the stand on his or her own behalf, thus becoming subject to cross-examination. The jury system quite correctly assumes that a defendant is his own most revealing character witness, and that if character is to be made an issue it is best presented by the defendant himself [32].

Expert behavioral testimony on behalf of a defendant can also end up working against that defendant. For example, in *State v. Hunt* [33], the defendant claimed that a borderline personality prevented him from being able to form the necessary intent to be guilty of a shooting charge. The court ruled that this assertion opened the door for broad inquiry into his mental condition, and allowed the prosecution to counter the claim with expert testimony that the defendant was actually suffering from nothing more than "antisocial personality disorder". To explain how this conclusion was reached, the expert was further permitted to recount for the jury defendant's difficulties in interpersonal relationships, including his prior "bad acts".

If profile evidence has had little impact upon the ability of the accused to fashion a defense, it *has* provided a potentially devastating weapon in the hands of the prosecution. The case of Sgt. Russell Banks illustrates just how powerful and insidious prosecution profile testimony can become, even when the "expert" does not testify as to a personal conclusion about the guilt or innocence of the defendant. In this instance, a pinpoint profile that could only describe the defendant – a stepfather living with his wife

and her young daughter – combined with the known limitations of a child witness, and an aggressive child "therapist" able to lead that witness and allowed to testify as to her own conclusions, created a direct path to the defendant, which a jury would be hard pressed to ignore.

In its *Banks* holding [34], the Court of Military Appeals noted that its reversal of Sgt. Banks conviction for child rape and sodomy was consistent with the case law in both federal and state courts that has severely criticized attempts to introduce "profile" evidence to establish either guilt or innocence. As the Supreme Court of Kansas noted in the 1989 case of *State v. Clements*, "Evidence which only describes the characteristics of a typical offender has no relevance in determining whether the defendant committed a crime in question, and the only inference which can be drawn from such evidence, namely that the defendant who matches the profile must be guilty, is an impermissible one" [35]. This conclusion has been reached in cases as diverse as child molestation [36], child abuse [37], murder [38], rape [39], and shoplifting [40].

This is not to say that expert profile testimony may never be used by the prosecution. If the defendant places his own personality and character at issue, the prosecution can call experts to help rebut defense assertions [41]. In a Washington state case, a defendant who stuttered pointed to the fact that the person he allegedly assaulted was unable to identify his assailant as a stutterer. The prosecution was permitted to introduce to the jury expert scientific testimony as to the statistical percentage of probability that a stutterer would not exhibit that particular speech anomaly in certain situations [42].

Expert profile testimony as to a lack of profile can also be admissible when a defendant deviates significantly from the expectation that a lay jury may hold about people who commit particular types of crimes [24]. Finally, background testimony that does not specifically address guilt or innocence of a defendant but instead enables the jury to understand evidence that does go to guilt or innocence has been held to be permissible profile evidence.

Conclusions

The often misused term *profile* is best restricted to investigative tools used to narrow down likely suspects and establish reasonable suspicion necessary to justify an action in the field. Reasonable suspicion is reviewed on a case-by-case basis to assure protection of suspect rights. As evidence at trial, profiles easily become little more than a means to either link a defendant to undesirable traits or stereotypes; or for the defense to attribute by association positive or sympathetic attributes to a defendant. Although behavioral science evidence may be proffered for use at trial, including statistical compilations, such evidence should have relevance to the applicable party as an individual, and the term *profile* avoided when possible.

Expert testimony concerning a trait of an accused may only be used as evidence that the accused possesses such a trait. It must be left to the jury to determine whether and how such a trait may influence the facts of the case [43]. While the term *profile* may appear to give behavioral evidence an aura of scientific respectability, such labels themselves do nothing to enhance the stature of the substantive underlying observations. In fact, if anything, good science and credible observation are more readily accepted without them [44].

Psychological Autopsy

Origins

The psychological autopsy originated in approximately 1958 as a result of the Los Angeles County Medical Examiner's Office consulting the Los Angeles Suicide Prevention Center for assistance in distinguishing drug-related accidental overdoses from suicides [1]. This collaboration laid down the basic principles of the psychological autopsy procedure. Edwin Schneidman, a director of the LA Suicide

Table 1 Commonalities of suicide

- Purpose: seek a solution
- Stimulus: unbearable psychological pain
- Stressor: frustrated needs
- Emotion: hopelessness, helplessness
- Cognition: ambivalence
- Perception: constriction

Adapted from Schneidman, 1996

Prevention Center, is credited with coining the term *psychological autopsy*. Schneidman's initial definition of the psychological autopsy was "a thorough retrospective investigation of the intention of the decedent" [2]. The process was partially based on his observations that many suicides shared certain common characteristics that could help identify a suicidal individual. Table 1 lists some of Schneidman's "commonalities of suicide".

Over the past 50 years, the procedure has become familiar to most suicidologists, suicide researchers and major city homicide investigators. However, a single standard definition has yet to be formally agreed upon. This article uses the following definition for the psychological autopsy: "A postmortem investigative procedure requiring the identification and assessment of suicide risk factors present at the time of death, with the goal of enabling a determination of the manner of death to as high a degree of certainty as possible".

Thus, the psychological autopsy can be conceptualized as synonymous with a postmortem suicide risk assessment. The strength of framing the psychological autopsy in this manner lies in the fact that performing formal suicide risk assessments on patients who are at risk for suicide is endorsed by overwhelming clinical consensus [3], and will be further clarified below in the section on current controversies. Regardless of the definition or method used, the quality of the assessment will depend heavily on the training, knowledge, experience and clinical judgment of the investigator.

In the push toward standardization, the psychiatric autopsy has evolved through a number of iterations. Initially, Schneidman developed a list of 14 areas of inquiry to guide the investigator when conducting a psychological autopsy [2]. In the late 1980s, the Centers for Disease Control established a list of 22 criteria to assist forensic investigators, called the Operational Criteria for the Determination of Suicide (OCDS) [4]. Shortly afterwards, suicide researchers developed the Empirical Criteria for the Determination of Suicide (ECDS). This instrument subsumed the OCDS, as well as other important criteria from the research literature [5].

While the Department of Defense had long employed the psychological autopsy method, in 2002 it published a sample model curriculum for conducting them, along with recommendations for training and peer review [6]. Finally, in 2006, leading suicidology experts and researchers proposed an initial standard protocol for lines of inquiry to improve reliability and validity [7]. This protocol, which has been further amended with the assistance of an expert from this research group (Berman, A. *Personal communication*, 2007), is presented toward the end of this article.

Despite progress in psychological autopsy research, some deaths (i.e., drug-related fatalities [8, 9]) continue to frustrate medical examiners (MEs). Thus, the psychological autopsy methods and protocol must continue to be vigorously pursued and tested.

Purpose

Psychological autopsies are an invaluable tool for assessing equivocal deaths. An "equivocal death" may be one in which the manner of death is questionable, or the circumstances surrounding the death are otherwise unclear [7]. Typical equivocal death scenarios are listed in Table 2.

When MEs perform autopsies, they attempt to classify the death into one of four categories or "modes": natural, accidental, suicide, or homicide (NASH) [10]. When a death cannot be immediately classified, it is often officially referred to as *undetermined*. Table 3 lists the basic elements of death classification.

Table 2 Typical equivocal death scenarios

- Drug-related deaths
- Autoerotic asphyxia
- Self-induced asphyxia (e.g., the "choking game")
- Drownings
- Vehicular deaths
- "Russian Roulette"
- "Suicide by cop"
- Staged death scenes

Table 3 Death classification

1. Cause: gunshot, poisoning, etc.
2. Mode: circumstances leading to cause
   a) Natural
   b) Accidental
   c) Suicide
   d) Homicide
3. Motive: reasons for the action
4. Lethality: probability of death as a result of method and circumstances chosen (low, medium, and high)
5. Intent: what the decedent wanted to happen at the time

The goals of the psychological autopsy include obtaining an in-depth understanding of the decedent's personality, behavior patterns, and possible motives for suicide. The investigator strives to obtain an objective analysis of the decedent's suicide risk enhancing and protective factors. In certain cases, an experienced investigator can use the method to help sort out the degree of risk, intent and causal factors at the time of death [3]. Ultimately, this should allow for a well informed assessment of whether or not the deceased was a likely candidate for suicide. Table 4 lists some of the more important goals of the psychological autopsy.

The psychological autopsy has utility in a variety of settings. Table 5 gives a list of some of its more common uses. As noted, it can be an extremely helpful tool for assisting MEs and homicide investigators. It has been shown to have a significant impact on MEs determination in equivocal cases [11]. It has been used for several decades to collect valuable research data about suicide that ultimately informs prevention efforts [12–14]. The vast majority of these studies suggest that mental disorder is present in a preponderance of suicides. The first generation of research driven by psychological autopsies found that more than 90% of completed suicides suffered from mental disorders, mostly mood disorders and substance use disorders [3, 15]. The second generation of psychological autopsy research has employed case-control designs, resulting in better estimations of the role of various risk factors for suicide [16].

Table 4 Psychological autopsy goals

- Identify behavior patterns – stress reactions, adaptability, habit, or routine changes
- Establish presence or absence of mental illness
- Identify possible precipitants
- Determine presence or absence of motives
- Determine presence or absence of suicidal intent
- Determine suicide risk factors – both mitigating and aggravating
- Perform a postmortem suicide risk assessment
- Establish whether or not the deceased was a likely candidate for suicide

Table 5 Psychological autopsy uses

- Assist medical examiners with "equivocal" deaths
- Research on suicide
- Insurance claims
- Criminal cases
- Estate issues, contested wills
- Malpractice claims
- Worker's compensation cases
- Product liability cases
- Organizational suicide prevention efforts

The psychological autopsy method has also been used in a forensic context in both criminal and civil courts. While courts have admitted testimony based on psychological autopsies in many civil cases, criminal courts have been more hesitant [17]. The issue of the psychological autopsy's legal admissibility will be further discussed below. In criminal cases, the psychological autopsy may be used to establish whether a decedent was likely to have committed suicide, or whether the matter should be viewed as a homicide. In some criminal cases, most notably *Jackson v. State* (Fla. 4th DCA 1989), the psychological autopsy has been used to help analyze whether an abusive relationship played a role in a suicide [18]. In the criminal case *U.S. v. St. Jean* (US Ct. of Appeals for Armed Forces, 1996), the psychological autopsy was used by the prosecution to assist in determining whether or not a suspected homicide victim had been a likely candidate for suicide.

In civil cases, the psychological autopsy has been used to help determine whether benefits are owed to the decedent's beneficiaries [10]. This often involves life insurance payments, where many policies hold that a suicide precludes benefits. However, some policies permit payment if it can be proven that the decedent's death was an "insane suicide". "Insane suicide" is a legal term that was defined by the US Supreme Court in the case of *Mutual Life Insurance Company v. Terry* (US 1872; 82: 580). The Court held that a suicide was "sane" when the "assured, being in the possession of his ordinary reasoning faculties,

from anger, pride, jealousy, or a desire to escape from the ills of life, intentionally takes his own life."

In contrast, an "insane" suicide was defined as "when his reasoning faculties are so far impaired that he is not able to understand the moral character, the general nature, consequences, and effect of the act he is about to commit, or when he is impelled thereto by an insane impulse, which he has not the power to resist . . ." Thus, a sane suicide implies the decedent had a rational understanding that his acts would result in his death, whereas an insane suicide implies the decedent was so emotionally disturbed that he did not have a rational appreciation of his actions [10].

Worker's compensation cases generally involve allegations that the decedent's employer was somehow legally responsible for his suicide. Similarly, product liability cases allege that the decedent's use of a particular product (e.g., medication) caused him to commit suicide. In psychiatric malpractice cases involving suicide, the plaintiff must prove that the doctor's negligence was a proximate cause of the decedent's suicide [19]. In addition to determinations regarding the standard of care, a postmortem suicide risk assessment must be conducted to determine the decedent's overall suicide risk and the foreseeability of the suicide.

Another potential use for the psychological autopsy may be its clinical utility in helping surviving family members better understand the tragedy and begin the grieving process [20]. The psychological autopsy may be used for other clinical purposes, such as informing an institution's morbidity and mortality conference after a client's suicide. For historical purposes and interest, psychological autopsies have been conducted on numerous public figures such as Ernest Hemingway [21], Vince Foster, (Berman, A. *Personal communication*, 2007), Howard Hughes and Marilyn Monroe.

Methods

The psychological autopsy method involves collecting and analyzing all relevant information on the deceased. This means that all applicable records are reviewed, including medical records, psychiatric records, police records, and autopsy findings. A visual inspection of the death scene via photographs is necessary, and occasionally a visit to the scene will be required. A thorough review of the decedent's writings in the form of diaries, journals, e-mails and internet correspondence is vital. The suggested protocol at the end of this article provides a list of other important sources of data. In addition to reviewing records, structured interviews of family members, relatives or friends are necessary. Thus, a psychological autopsy synthesizes data from multiple informants and records. When performed in a comprehensive manner, the method may take anywhere from 20 to 50 or more hours to complete. The overriding principle is that the greater the amount of relevant data analyzed, the more accurate the investigator's conclusions are likely to be.

Suicide risk factors vary among different populations [22]. The investigator should consider any special nuances of the deceased, such as age group [23], mental health diagnosis, gender [24] and other factors that may allow for a more precise consideration of risk factors associated with that group. This requires keeping up to date with the evolving psychiatric and suicidology literature, which is steadily becoming more detailed about risk factors in distinct diagnostic categories such as depression [25], bipolar disorder [26], and persons who are outside the care of mental health services [27]. Some individuals may display unique, individualized behaviors suggestive of increased or decreased suicide risk that will be known only by close social contacts or treating mental health professionals [22]. Thus, an understanding of the decedent's individualized risk factors and past stress reaction patterns becomes important.

Suicide Notes

There is a considerable literature on suicide notes. Research suggests that suicide notes are left only by a minority, approximately 10–33% of all suicides [15]. Regarding persons who do leave notes, available research has not found any significant differences when compared to suicides who do not leave notes. A few studies have suggested that whites and women are slightly more likely to leave suicide notes. At least one study has suggested there are no significant differences in the themes of notes between male and female suicides [28]. Themes of love and relationships were found to be more common than achievement themes in both men and women [29]. Another study found that suicide notes written by young people were longer and rich in emotions, whereas notes

written by the elderly were shorter, contained specific instructions, and were less emotional [30].

In a study of 42 suicide notes, the most common themes were: "apology/shame" (74%), "love for those left behind" (60%), "life too much to bear" (48%), "instructions regarding practical affairs postmortem" (36%), "hopelessness/nothing to live for" (21%), and "advice for those left behind" (21%) [31]. The common usage of computers, the Internet [32] and various electronic types of messaging have introduced another important source of data for the psychological autopsy. The investigator should not fail to inquire about these potential sources of information, as they may provide critical insight into the decedent's state of mind and intentions.

One important caveat regarding suicide notes is the possibility that they have been fraudulently prepared and left by another person attempting to disguise a homicide. While there has been some attempt to develop a method for distinguishing genuine from simulated suicide notes [33], more research in this area is required. In such cases, collaboration with a forensic handwriting analysis expert might be considered. Another important consideration for the investigator is the possibility that family members or others who find a suicide note may destroy it or remove it from the death scene for various motives.

Collateral Interviews

The importance of collateral interviews as part of the psychological autopsy method cannot be overstated. Careful interviews of the decedent's family members and other relevant social contacts distinguish a proper psychological autopsy from a mere analysis of demographic data and police reports. Most experts recommend a structured or semistructured approach to collateral interviews. At least one study has developed a semistructured interview for the psychological autopsy which has demonstrated inter-rater reliability [34]. For research purposes, there has been a trend toward using modified instruments such as the Structured Clinical Interview for Diagnostic and Statistical Manual of Mental Disorders, 4th ed.-Text Revision Disorders (SCID), as well as a life events calendar method, which helps identify and quantify the burden of events that may be associated with suicide [35].

Regardless of method used, collateral interviews often reveal critical information about the decedent that cannot be obtained elsewhere. Recent theories about suicide have stressed that psychiatric illness alone is not enough to fully explain an individual suicide. Rather, a stress-diathesis model has been proposed, in which the risk for suicidal acts is determined by the interplay of biopsychosocial factors and situational variables [36]. According to this model, a diathesis may be reflected in an individual's tendency to have maladaptive responses to stressors, such as acting impulsively. Such information is most likely to be obtained via collateral interviews.

Ethics and Sensitivity. An important ethical and practical consideration related to gathering collateral data is the manner in which collateral sources should be contacted and interviewed. Interviewing surviving family and friends is a very sensitive matter that must consider the survivor's reactions. Ideally, the investigator should have adequate clinical experience in order to handle survivors' reactions with appropriate sensitivity [37]. For "research purposes", it has been recommended that a two to six-month time interval between the suicide and interview be used [37]. There does not appear to be a significant relationship between the timing of the interview and the quality of information obtained when this time frame is used [38].

While a concern about untoward emotional reactions to the interview is an obvious concern, some have noted that survivors appeared to have benefited from the interview experience in terms of being able to express their feelings and receive a mental health referral if needed [37]. Presently, there is no clearly agreed upon method for initiating contact with survivors. Investigators performing a psychological autopsy for forensic legal purposes will likely be supplied with relevant phone numbers and/or addresses of potential interviewees. Often, attorneys will have previously informed the interviewees that an investigator will be contacting them. Investigators seeking interviews for research purposes may consider a letter followed by a phone call, or vice versa [10].

Postmortem Suicide Risk Assessment

A comprehensive postmortem suicide risk assessment is necessary because of the fact that there is no single pathognomonic risk factor for suicide [22]. Single risk factors do not have adequate statistical power on which to base conclusions. Particularly in the context

of forensic expert testimony, the postmortem suicide risk assessment approach is recommended [3]. This involves a careful identification and assessment of suicide risk factors present at the time of death.

Risk enhancing factors (both proximal and distal) should be carefully weighed along with risk reducing factors. When thoughtfully analyzed in the context of the totality of the decedent's circumstances, the investigator should be able to arrive at conclusion about the decedent's overall risk of suicide near the time of death. This ultimately informs the investigator's opinion about whether or not the decedent was a likely candidate to commit suicide at the time in question.

Testimony that focuses on whether the psychological autopsy yielded results consistent with an individual who committed suicide is more likely to be found admissible in court. In contrast, overreaching opinions that conclude the decedent did or did not commit suicide are more likely to be found inadmissible. For example, in the case of *State v. Guthrie* (2001 SD 61, 627 N.W. 2d 401), the court found that the expert's testimony became inadmissible when it "shifted from discussing typical suicide characteristics", to a "bold declaration" that the decedent did not die by suicide [39].

Limitations and Controversies

In both research and forensic legal settings, mental health professionals are legally and ethically obligated to note the limitations of their methods. In the case of the psychological autopsy, controversy over its limitations has existed for as long they have been performed [40]. Commonly cited controversies involving the psychological autopsy are listed in Table 6. The limitations largely involve the fact that there is no unanimously accepted standardized protocol for conducting a psychological autopsy. However, dedicated efforts are currently underway to resolve this issue [7]. Progress in this area may be somewhat dependent on the field of suicidology developing a standard, comprehensive nomenclature. For example, even the basic term *suicide attempt* may have different meanings to different investigators [41].

Table 6 Current controversies [42]

- Lack of standardized protocol
- Lack of standardized suicidology nomenclature
- Methodological problems
- Reliability of assessment instruments
- Lack of homogeneity among studies
- Bias among collateral informants

Controversy surrounding admissibility and meeting Daubert standards may be best resolved by adopting the postmortem suicide risk assessment approach. The reasoning for this is as follows: (i) in clinical practice, the standard of care requires the clinician to gather relevant information and assess the patient's level of suicide risk; (ii) performing such suicide risk assessments on patients considered to be at risk for suicide is endorsed by overwhelming clinical consensus (i.e., it is "generally accepted"); and (iii) the psychological autopsy is similar in that it is the assessment of suicide risk factors present in the decedent near the time of death [3].

This approach to the psychological autopsy should meet the process-driven Daubert criteria, particularly where *Kumho Tire Co. v. Carmichael* (1999 536 U.S. 137, 141) has held that Daubert standards are not limited only to scientific evidence, but may include "technical, or other specialized knowledge" [43]. In the event that a court found that the postmortem suicide risk assessment did not meet Daubert criteria, it should at least meet the *Frye v. U.S.* (DC COA, 1923) criteria of "general acceptance" among mental health professionals. This line of reasoning was adopted by a Louisiana appeals court when it found the psychological autopsy admissible under Daubert. The case, *In re Succession of Pardue* (La Ct. App. 2005 915 So. 2d 415), involved estate issues and testamentary capacity. The court held that the methodology used in the psychological autopsy was sufficiently reliable and generally accepted in psychiatry.

In federal court where expert testimony is governed by the Federal Rules, opinions on the basis of the postmortem suicide risk assessment method would appear to comply with Federal Rules 703 and 702, which allows expert opinions if they are "of a type reasonably relied upon by experts in the particular field", and if the testimony is "the product of reliable principles and methods" [44].

An obvious criticism of the psychological autopsy is the problem of not being able to interview the decedent so as to more accurately determine intent. One response to this issue is that the comprehensive nature of the psychological autopsy, with its

wide net of collateral data, may ultimately allow a reasonable approximation or inference of intent. Additionally, it has been argued that having no prior contact with the decedent removes the vagueness and subjectivity inherent in an interpersonal relationship with the decedent [18]. Therefore, one might argue that psychological autopsies may be more objective and less controversial than the analysis of living patients.

To date, only a restricted number of research studies have relied on standardized instruments, making the comparison of findings problematic [42]. Current studies are increasingly using the SCID, but this approach has yet to be conclusively validated for administration to proxies. However, at least two studies (of psychiatric inpatients admitted following a suicide attempt) have suggested that proxies are good judges of past history of suicide attempts, level of suicidal intent and data leading to a psychiatric diagnosis [45, 46].

The issue of bias in collateral informants requires a cautious approach by investigators. Informants' reports may be biased by many factors such as their own personal attitudes toward suicide and their emotional state at the time of the interview. Further, their recollection of circumstances may be impacted by the emotional trauma of the death of their loved one [42]. The demeanor and interpersonal style of the investigator may also become a factor. It is possible that informants may react to the investigator's personal characteristics, which may then influence the amount and type of information they are willing to divulge.

In summary, there is a considerable need for further research efforts aimed at improving the validity and reliability of the psychological autopsy [17]. There is concern that testimony based on a faulty or inadequate psychological autopsy may result in a "miscarriage of justice" [47]. Forensic experts who give testimony in court on the basis of psychological autopsy findings must be prepared to concede any relevant limitations.

Toward a Standard Protocol

In the interest of improving validity and reliability, forensic suicidology must continue to work toward an accepted, standardized protocol for the psychological autopsy [7]. Below is a recommended template that was developed by expert consensus [7], (Berman, A. *Personal communication*, 2007) and further enhanced according to relevant research and clinical findings [5–7, 10, 20, 48–50]. The protocol may be used to guide areas of investigation and lines of inquiry for collateral interviews. Use of a standardized protocol can serve as a framework for conducting a psychological autopsy. Ultimately, a standard protocol will enhance admissibility, and aid in the testability of the method [7].

The psychological autopsy method allows for a "polyperspective" that can help illuminate key aspects of an equivocal death [51]. However, the light that it shines may also be distorted by the perspective of the investigator. Therefore, it is critical that the individual performing the psychological autopsy possess adequate training. This includes having sufficient knowledge in the fields of suicidology, related mental health concepts, and basic death scene investigation. Data obtained from the death scene and physical autopsy are often highly determinative, and meticulous inspection of the death scene and related items may be necessary in certain forensic legal cases. For example, in cases of suspected "simulated suicidal hanging", there may be important evidence suggesting a homicide that was staged to appear as though it was a suicide [52]. Detailed investigation of body position, ligature placement and knot formation may be required to distinguish a suicide from a homicidal hanging [53]. Further, in cases of suspected autoerotic asphyxiation, researchers have noted characteristic death scene findings (see Appendix 1) [54].

Finally, the problems inherent in assessments of suicidal intention require that the investigator be cognizant of the limits of the data and corresponding conclusions. This is primarily because of clinical observations that suicidal individuals are often ambivalent, and may even have multiple intentions at the same time [55]. In certain cases, the presence and degree of suicidal intent may be difficult to determine because of ambivalence, denial, minimization or confusion. In contrast, the nuances of other cases may present a rather straightforward inference that the decedent's intent was to die. In difficult cases, the investigator may choose to simply report on the results of the postmortem suicide risk assessment, or provide reliable evidence that "Natural", "Accidental" and "Homicidal" causes of death can be excluded [56].

Psychological Autopsy Protocol

Records and documents

- Medical records
- Mental health records
- Police records and related witness statements
- Legal records
- Criminal records
- School records
- Financial records
- Military records
- Suicide note(s), communication or video
- Decedent's journals, diary
- Electronic data: E-mails, text messages, instant messages, and websites
- Forensic computer analysis report if available
- Autopsy report
- Toxicology report

Death scene

- Photos of death scene and site visit if necessary
- Presence of atypical wounds (see Appendix 1)
- Decedent's relationship to site
- Evidence of rescuability versus precautions taken against
- Evidence of planning and/or rehearsal
- Evidence of staged manner of death (see Appendix 1)

Demographics

- Socioeconomic status
- Employment status
- Financial status
- Age/gender/race/height/weight
- Marital status
- Educational status
- Religion and religiosity
- Adopted vs. biological family status
- Immigrant status – acculturation issues
- Residence relative to recent mobility

Recent symptoms and behaviors

- Appeared depressed, sad, tearful, or moody
- High risk depressive symptoms [25]
  - Insomnia
  - Appetite loss
  - Weight loss
  - Feelings of worthlessness and/or inappropriate guilt
  - Physical agitation
  - Depression comorbid with anxiety
- Expressed suicidal ideation or preoccupation with death
- Appeared to have made a change for the better
- Appeared anxious, or complained recently of anxiety or panic attacks
- Appeared agitated
- Behaved in an impulsive manner
- Displayed uncontrolled rage or aggressive behavior
- Demonstrated constricted thinking or "tunnel vision"
- Disclosed feelings of guilt or shame
- Appeared confused, disoriented or psychotic
- Expressed feelings of hopelessness, helplessness or worthlessness
- Engaged in excessive risk-taking behaviors
- Mental Status evidence of:
  - Impaired memory
  - Poor comprehension
  - Poor judgment
  - Hallucinations or delusions
  - Inflated sense of self or signs of magical thinking

Precipitants

- Significant losses (relationships, job, finances, prestige, self-concept, family member, moving, or anything of importance)
- Significant (or perceived) disruption of a primary relationship
- Legal troubles or difficulties with police
- Traumatic events
- Significant life changes (negative or positive, birth of child, promotion, etc.)
- Completed or attempted suicide by a family member or loved one
- Anniversary of important death, loss, etc.
- Exposure to suicide of another via media or personal acquaintance
- Preparations for death (e.g., gave away prized items, settled personal accounts, updated will, and said "goodbye" to loved ones)
- Expression of wish to reunite with a deceased loved one, or to be "reborn"

Psychiatric history

- Prior suicidal behaviors

  - Total number of past attempts
  - Dates
  - Precipitants
  - Method, lethality
  - What stopped event, if anything? How found
  - Attitude and behavior after found
- Prescribed psychotropic medications
- Observed adverse reactions to psychotropic medications
- Lack of compliance with psychotropic medications
- Efficacy of treatment (e.g., subtherapeutic doses, poor or incorrect agent choice, inadequate blood level, etc.)
- Psychiatric hospitalization (reasons, dates, diagnoses, and treatment)
- Outpatient treatment (psychiatrist, psychologist, therapist, and Primary Care Physician PCP)
- Psychotherapy at time of death (duration, quality of alliance, compliance, and diagnosis)
- Expressing concerns about "going crazy" or losing cognitive function

Physical health

- Recent visit to physician (reasons)
- Chronic pain
- Chronic, fatal or debilitating disease
- Recent reduction in physical/functional capabilities
- Current medications (compliance or recent changes)

Substance abuse

- History and pattern of alcohol, drug abuse
- Recent attempts to discontinue use
- Recent increase in pattern of use
- Degree of use at time of death (binge drinking, etc.)
- History of "accidental overdose" (when and type of drug)

Family history

- Suicide or attempted suicide
- Nonnatural deaths
- Level of support or observed closeness in nuclear and extended families
- Physical, sexual, or emotional abuse
- Substance abuse
- Violent behavior
- Affective or other psychiatric disorders

Firearm history (if relevant)

- Ownership
- Recent purchasing or obtaining (stated purpose?)
- Recent movement of gun (from where to where?)
- Pattern of weapon care and cleaning
- Pattern of storage and use
- Accidental discharges

Social Supports and Attachments

- Ability to create and maintain close personal relationships
- Ability to express feelings as needed in relationships
- Recent talk about feeling unsupported, uncared for, unimportant
- Relative success in personal relationships
- Relative success in work
- Attachment to hobbies, interests, religion, etc.
- Recent change in any of the above attachments/supports

Emotional reactivity

- History of violence toward others
- Impulsive behaviors
- Excessive rage or aggression

Lifestyle/character

- Typical coping patterns, pattern of reaction to stress
- Perfectionism
- Self-destructive behaviors (self-mutilation, deliberate self-harm, driving while intoxicated, etc.)
- Frequent crises
- Victimization behaviors (bullied or abused)
- Tendency to dissembling (hiding emotions or stoicism)

Access to care

- History of help-seeking behaviors
- Barriers to healthcare (no insurance or no accessible caregiver)

Other areas of inquiry

- Occupational history
- Personal interests, hobbies
- Gambling history
- Degree and type of religiosity
- Description of activities/behaviors in last days before death

Factors associated with suicide risk reduction

- Evidence of future-oriented thinking or behaviors (doctor's appointments, job interviews, etc.)
- Responsibility for a child under 18 (stronger for women vs. men)
- Absence of suicidal ideas or intent
- Hopefulness
- Willingness to accept help and/or treatment for psychiatric conditions
- Low symptom severity
- Good therapeutic alliance with mental health professional
- Stable, supportive marriage or spouse
- Religious prohibition

Collateral interviews

For each interview, note the following:

- Relationship to deceased
- Time interval between death and interview
- Reactions to the death (surprise, acceptance, and beliefs)
- Attitudes about suicide
- Potential biases (pending lawsuits, insurance claims, denial, etc.)
- Assessment instruments used

Appendix 1

Evidence of Alternative or Staged Manner of Death

- **Presence of Autoerotic Characteristics** [57]
  - Body partially supported by ground
  - Ligature with self-rescue mechanism (slip knot, etc.)
  - Bondage items and/or sexual masochistic behavior (genitals, nipples, etc.)
  - Male wearing female attire
  - Protective padding between ligature and body
  - Sexual paraphernalia (vibrator, pornography, and mirrors)
  - Evidence of previous autoerotic practices
- **Presence of Atypical Self-Inflicted Gunshot Wounds** [58]
  - More than one gunshot injury
  - Gunshot injury without contact or near contact
  - Uncommon entrance wound sites (back of neck or head, ear, and eye)
  - Uncommon bullet paths (downward and back to front)

Acknowledgment

The authors would like to acknowledge Alan L. Berman, PhD for his expertise and assistance, particularly with the Psychological Autopsy Protocol.

Psychological Testing

Introduction

Psychological testing is best understood within the larger context of psychological evaluation or assessment that, in turn, is seen as one discipline's approach to a more general and shared task of information collection. The *APA Dictionary of Psychology* [1] defines psychological assessment as "the gathering and integration of data in order to make a psychological evaluation, decision, or recommendation" (p. 751). Multiple tools of assessment are listed including interview, behavioral observations, tests, and other specialized instruments. A psychological test is a "standardized instrument (i.e., a test, inventory, or scale)" used for the purpose of measuring any of a variety of abilities, aptitudes, or attributes (p. 753).

This article includes discussion of psychological testing and differentiates it from other types of assessment and focuses on one area of personality testing (*see*, in contrast, **Neuropsychological Assessment**; **Neuropsychological Assessment: Child**; **Head Injury: Neuropsychological Assessment**). While general information is applicable to examinees of all ages, most of the tests that are discussed here were developed for use with adults.

Clinical Assessment and Formal Testing

Evaluation or assessment is used in all clinical disciplines and may involve elaborate, sophisticated technology, such as magnetic resonance imagery (MRI) to look for the presence of a brain lesion, or may depend on more informal, intuitive ways of combining personal observations to form hypotheses or conclusions, such as surmising a person acts depressed. Different clinicians within mental health "work up" a client or patient using common as well as unique tools and methods associated with the specialized training and expertise of the particular discipline. For example, almost all mental health clinicians assessing someone not only interview the person by asking common questions about mood, sleep, appetite, and daily functioning but also probe other areas more selectively.

Psychiatrists are more likely to consider medical or biological factors potentially contributing to emotional problems, whereas social workers may spend

more time exploring the person's interchanges with social systems. Family therapists may look more acutely at the history of family relationships and alliances, and psychologists are more likely to use inventories and psychological testing. Each discipline's approach is a blend of commonly shared tools, literature, and research arising from several disciplines as well as unique resources based on clinical specialization and scope of practice for that particular discipline.

Differences between Psychiatric and Psychological Testing

Clinical psychologists and psychiatrists both provide assessment and treatment services in the field of mental health, but the differing educational and clinical training routes shape distinct elements that each group uses for these services (*see* **Behavioral Science Evidence**). Psychiatrists, like other physicians, attend medical school for four years during which time they focus on studying chemistry, anatomy, and physiology as well as work in a wide variety of medical speciality placements before getting the MD (medical doctor) degree. They also may take courses in research, statistics, and learning theories. During psychiatric rotations in medical school and later in residency specialization (3 or 4 years), they learn about medical tests and clinical diagnostic techniques for mental health problems, study personality theories and human development, and acquire skills for treating mental illness.

For most psychiatrists, treatment is heavily based on biological and chemical factors that medicines affect (*see* **Psychopharmacology**; **Psychopharmacology: Child and Adolescent**). Assessment is therefore oriented toward finding biological factors or markers for which medical or somatic intervention is well matched. Psychiatric assessment relies heavily on clinical observation (something physicians are well trained to do) and the use of mental status evaluation (*see* **Mental Status: Examination**). A mental status evaluation involves assessing a person's orientation (knowledge of place, time, and self); ability to attend to environment and to communicate; mood and expression of feelings; and congruence or incongruence within the situation (appearing to hallucinate or act delirious). Depending on the nature of the hypothesized mental health problem, the psychiatrist may use brief tests or inventories to support or exclude certain diagnoses. These instruments may include behavioral inventories designed to collect information about classroom behavior of children; self-reported symptoms on a depression checklist; or a brief cognitive status exam looking for signs of dementia. More elaborate psychiatric testing is usually medically or biologically oriented as the psychiatrist reaches into his/her medical training to refine diagnosis (e.g., radiological tests looking for brain tumor; electroencephalogram (EEG) to document seizures or to find unusual electrical patterns in the brain; and blood tests to measure hormone levels or to check for problems such as anemia).

Psychologists, on the other hand, begin their training by attending a university graduate school for four or more years taking courses in personality theory and human development, measurement theory and test development, research statistics, learning theories, methods of mental health interventions, and principles of social contexts and human interactions. To a lesser degree, course work includes anatomy and physiology of the nervous system, human biochemistry, and genetics. Students in a psychology Ph.D. (doctor of philosophy) program complete both a masters level research project and a doctoral dissertation.

Clinical training involves multiple placements in clinical sites during graduate school followed by a 12-month internship in a mental health setting prior to graduation. Some states require an additional year of postgraduate supervised clinical work before licensure, and several areas of professional specialization offer residency training for one or two years. Some areas of specialization are clinical psychology (dealing with application of psychological knowledge and principles to address mental health problems), neuropsychology (study of brain–behavior relationships), experimental psychology (basic physiological or social factor research), and forensic psychology (application of psychological knowledge and principles to address legal issues). Each of these areas makes heavy use of assessment and testing.

When psychologists conduct an evaluation, they also rely on the common tools of observation and interview with the person and collateral sources (family members, teachers, institutional staff who have information about the person's behavior). As do psychiatrists, they conduct mental status evaluations and may also use brief inventories, checklists, or simple tests to support or dismiss diagnostic hunches. However, when psychologists proceed to more elaborate

testing, they rely most heavily upon the tools their discipline has developed. For the most part, these tests involve either measurement of cognitive abilities (e.g., intelligence, memory, and academic skills) or personality factors (e.g., traits and emotional states).

Cognitive Testing. Cognitive testing may be thought of as a way to measure how well the brain is functioning. Neuropsychology, a specialty with its own postgraduate training and certification, has developed a vast array of tests that measure not only basic intelligence but also learning and memory, sensory perception and sensory-muscle integration, reasoning and problem solving skills, language and communication abilities, and basic academic skills such as reading (*see* **Neuropsychological Assessment**; **Neuropsychological Assessment: Child**). Cognitive testing is able to identify and to document the level of skill or the degree of impaired functioning of a person. It is often used in conjunction with neurological or radiological testing that documents impaired structure of the brain or nervous system. Findings from cognitive testing may be used for such tasks as assisting with decisions about academic placement or need for special education resources (*see* **Mental Retardation**); rehabilitation treatment planning after head injury or neurosurgery (*see* **Head Injury: Neuropsychological Assessment**); diagnosis of conditions having subtle onset such as early stage dementia; measurement of progress or lack of response to remediation efforts after head injury or stroke; or documentation of progression of effects of diseases such as Parkinson's or Multiple Sclerosis. Neuropsychologists are often called upon in forensic cases involving head injury, toxic exposure, or questions of competency or capacity (*see* **Capacity to Stand Trial**; **Capacity Assessment**; **Guardianships of Adults**).

Personality Testing. If cognitive testing is thought of as a way to measure the brain's work, personality testing may be thought of as a way to assess the mind of the person. Whereas one deals with neurophysiology and often uses physical measures, the other deals with psyche and uses measures of emotion, attitude, and traits. Personality testing explores intrapsychic (internal aspects of self, value conflicts and ambivalence, moods, motivation) and interpersonal issues (social behavioral clusters, styles of interaction, orientation toward others).

Personality testing is often used to gather information to allow psychologists to describe what a person is like; how a person is different from others and to what degree; how the person functions or is likely to function with others; whether there is significant psychopathology; extent to which a person is open and transparent in self-presentation or guarded or even deceptive (*see* **Deception: Detection of and Brain Imaging**; **Deception: Detection of**); **Malingering: Forensic Evaluations**) and prognosis for improvement with treatment for mental health problems. Psychologists are often called upon in forensic cases to use personality testing to address questions involving risk assessment (*see* **Dangerousness: Risk of**); mental illness diagnosis and treatment recommendations; competency and capacity; tort cases where emotional distress claims are made (*see* **Posttraumatic Stress Disorder**); and criminal cases where mental illness factors are being presented (*see* for example **Insanity: Defense**; **Temporary Insanity**).

Properties of Formal Testing

Testing, which is a relatively circumscribed activity involving use of tests to obtain specific scores, is one part of an overall assessment that collects information from multiple sources using multiple methods. Information usually includes records that place a person's current performance in historical context, referral information that places a person in a situational context, behavioral observations, interviews, and consideration of the person's test taking attitudinal factors (fatigue, rapport, motivation, exaggeration, or defensiveness). The person–context information can be as important as the test result information, for instance when the person is observed to be disengaged from the task or hostile toward the examiner. As a result of such situational data, the psychologist interprets data cautiously or may even disregard the scores as being invalid measures. This person–situation information, whether obtained from direct observation or from validity scales embedded within tests, helps determine if test results are considered valid for interpretation.

Together with information from these other sources, test results are then used to assist in diagnosis, to identify areas for intervention, or to provide information about current functioning.

These results are integrated into a cohesive and comprehensive understanding of the person to communicate it to others including the person being tested. Indeed, providing feedback to the person often serves as an intervention itself and can be a very important part of treatment.

Formal testing refers to an assessment process using standardized instruments that have rules for administration and for scoring responses, normative information for comparing scores, and guidelines for interpretation of results. Holding these test factors constant means there should be minimal "noise" produced so that it may be logically assumed that most of the variability of scores between examinees is a result of something associated with differences between the individual test takers. Just as the use of an accurately calibrated thermometer allows a physician to verify or rule out the presence of fever to help refine diagnostic hunches, the use of psychological testing allows psychologist to verify or rule out abnormalities and to refine diagnostic hunches on the basis of test score patterns and known psychological conditions.

Reliability

Reliability is the term used to indicate the concept of score consistency on a test. It is a measure of how closely clustered or how far apart a person's scores would be with repeated administrations of the same test or with alternate versions of the test. Reliability is a measure of how much error (or "noise" as compared to "signal") is present in test scores [2, 3].

Validity

Validity is the term used to designate the concept of score accuracy of a test. It tells how well a test works in measuring what it purports to assess. Validity may be determined by comparing a test with a "gold standard" in the field, by seeing how well test scores discriminate between known groups on a particular factor, or by how well a test covers relevant aspects of a construct but avoids tapping other constructs. Just as a rifle must shoot true before a marksman can attain target accuracy, a test must have reliability (consistency of measured scores) before its validity (accuracy of measured scores) can be established [2, 3].

Standardization

Standardization refers to the process whereby a test and its components are made standard or routine in details of administration. Test items, the order of administration of items, ways of recording and scoring responses, and ways of instructing examinees about how to take the test must become standard or fixed. Standardization and adherence to instructions regarding the test should decrease the "noise" associated with a person's scores so that differences between examinees (or the same person tested at different times) should be related to actual differences rather than to errors involved in the process of obtaining the scores [2, 3].

Norms

Norms refer to the collection of scores that represent a sample group's responses on a test. Norms can be obtained when many people take the test under the same standard conditions. The mean (average) and standard deviation (SD) (measure of variability of scores) can be calculated and used to evaluate a particular person's obtained score in relation to the cluster and range of scores produced by the norm group. Raw scores are often transformed to standard scores (mean $= 100$, SD $= 15$), T-scores (mean $=$ 50, SD $= 10$), or scale scores (mean $= 10$, SD $= 3$) to create a shorthand way of conveying a person's score in relation to the sample group's norms. A well-developed test has a heterogeneous (mixed gender, ethnicity, and socioeconomic status) group of individuals whose scores are used to calculate the norms. As a result, the sample group norms should be more representative of the entire population of interest than if only a homogenous group was tested and scores calculated.

By having good normative data, it is possible to determine to what degree the examinee is similar to or different from the average person taking the test. By having test data from differing groups of people with a known condition or factor, it is possible to use a person's test results to refine diagnostic hypotheses about the examinee. By using information about a person's score in relation to the norms, the psychologist can then analyze and interpret test score data. Analysis of test data can occur at three levels: specific details about skills, deficits, or symptoms based on actual scores; level of performance or

information about severity of problem or level of skill based on relationship of score to group norms; and syndrome or pattern of scores, which generalizes to life context, based on research literature and clinical knowledge [3, 4].

Testing offers advantages over interview or observation alone by providing empirically quantified information that is usually more precise than interview impressions. Testing may cover a variety of constructs, and, in the case of personality testing, it covers a large array of traits in an efficient manner. Standardized administration and scoring means a common yardstick is used for measuring a person, and behavior is observed in a uniform context. Test norms allow scores to be compared to known groups, and research with such known groups provides the psychologist with a stimulating backdrop from which to generate and evaluate hypotheses related to test scores [5].

History of Psychological Testing

A brief history of psychological testing can provide a useful context for understanding its current state. A very influential English figure was Sir Francis Galton who in 1869 published "Classification of Men According to Their Natural Gifts" [6]. Galton pioneered use of questionnaires and rating scales, developed statistical methods for analysis of individual differences, and popularized forms of psychological testing. At the International Health Exhibition in London (1884), he and his assistants tested individuals willing to pay to learn about their vision and hearing sensitivity, muscle strength, reaction time, and memory. This focus of attention on individual abilities was in contrast to the emphasis on group data being collected by others. Wilhelm Wundt, a German psychologist who had established the first psychology lab in Leipzig five years before, considered individual differences to be errors and was far more interested in measures of perception that portrayed information about the species as a whole [7].

In the same tradition as Galton, James M. Cattell established a testing lab at the University of Pennsylvania (1888) and used tests to measure sensitivity to pain, perceptual discrimination, memory, and other cognitive skills as ways to study individual differences in intelligence. Cattell was the first to use the term *mental test* to describe his techniques [7]. In general, testing in clinical psychology testing has continued to focus more on individual distinctives, whereas measurement in physiological or experimental psychology has focused more on data that add to knowledge about collective or group characteristics of humans and other animals.

Psychological testing took a major leap forward in 1905 when Alfred Binet, a French psychologist, and Theodore Simon, a psychiatrist, collected 30 brief cognitive tests to use as an intelligence scale for the purpose of determining school entry for Parisian children. They later revised their collection of tests and developed the concept of mental age (the age at which an average child could pass a particular test). In the United States, Lewis Terman added some other tasks and developed the concept of intelligence quotient (IQ) that was found by dividing the attained mental age by the person's chronological age. Eventually, IQ came to be calculated in a different manner on the basis of comparison to group information and how far from the group mean a person's scores were [8].

Another major advancement in psychological testing occurred in 1917 when the US Army had to classify World War I (WWI) recruits for their suitability for military service as well as for possible officer training. In a period of two years, 1.7 million inductees were given group administered intelligence tests based on alterations of the Binet and Terman tests. For those literate in English, the Alpha version (verbal tests) was used; for illiterate or non-English speaking recruits, the Beta version (nonverbal tests) was used. Nonverbal or language free tests had been used in the United States at Ellis Island for screening immigrants for mental defects and had also been used in Chicago with unschooled juvenile delinquents.

David Wechsler, a psychology graduate student, enlisted in the Army and was trained to conduct individual intelligence tests for the 5% of recruits who failed one of the group-administered versions. Many years later as psychologist at Bellevue Psychiatric Hospital in New York City, he developed a different approach to intelligence testing that combined verbal and nonverbal tasks to result in a single score. He also collected normative data on a large group from the general population and compared each person's score to the group average (mean). This deviation derived IQ score (relationship of person's score to group average) provided information about how far a person's score was above or below the mean score for

the group. In 1939, he contracted with Psychological Corporation for production and sale of his test [8].

Psychological Corporation, formed in 1921, had already been marketing intelligence tests (termed *scholastic aptitude tests*) and other specialized aptitude tests to schools and industries after the war, but the number of psychological tests had been rather limited until the mid-1930s.

Oscar Buros' first edition of *Educational, Psychological, and Personality Tests of 1933 & 1934* had been only 44 pages, but his 1938 edition of what became *Mental Measurements Yearbook* was more than 400 pages long and covered 4000 tests. The current edition is multivolume and covers thousands of tests [9]. The entry of the US military into World War II brought with it the need for testing four million recruits for military assignments. Once again, a national crisis produced a surge of testing emphasis which propelled psychological testing from academic or clinical environments into the larger culture. A similar peacetime surge occurred in the Cold War with a strong focus on achievement and aptitude testing when the space race was initiated with the launch of the Russian satellite Sputnik. These intelligence, aptitude, and achievement tests fall into the general category of cognitive testing [10].

Objective Tests

In a different line of development, another contribution out of the WWI era was the self-report inventory that formed the basis for objective personality testing. Robert Woodworth's personal data sheet was developed too late for military use in the war but was used afterwards in civilian life to screen for seriously disturbed individuals. The inventory was basically a self-report of recognized symptoms associated with psychiatric problems. This approach culminated in the 1943 publication of the Minnesota Multiphasic Personality Inventory (MMPI). Starke Hathaway, a psychologist, and Charnley McKinley, a psychiatrist, had developed the set of test items empirically by selecting those items that successfully differentiated known patient groups from a general population sample (both genders but all Caucasian samples comprised mostly of hospital visitors, some airline workers, and civilian conservation corps workers in Minnesota). The inventory was remarkable for this use of empirical research that served as a basis for item selection and for its use of three validity scales designed to measure test taking attitude (defensiveness, exaggeration of symptoms, and subtle defensiveness) [7, 11].

From this line of development has come a wide range of objective tests that provide information about personality traits (e.g., introversion, dominance, and self-constraint); emotional states (anger, anxiety, and depression); behaviors (substance abuse, risk-taking, and antisocial acts); and interpersonal orientation (psychopathy, altruism, and cooperativeness). Often these tests are pencil and paper or computer administered self-report measures that have validity scales to assess manner of self-presentation. As the tests are usually in written form, it is important to assess the examinee's reading level to assure it is sufficient for the task. The results of the tests are thought to be explicit self-representations of the test taker. Test items are seen as stimuli, and self-report statements of endorsement or denial of particular items are seen as responses that define and describe the person. Some tests are also designed to be completed by collateral sources who know the person, and this information can be quite useful in assessment of children or when the examiner wants to know how others perceive the person [3].

Projective Tests

A different approach to personality assessment is the use of projective tests, best typified by the inkblots used by Hermann Rorschach, a Swiss psychiatrist. Others had previously used vague or ambiguous stimuli to elicit a person's responses, which then were interpreted on the basis of the assumption that the subject's internal struggles, fantasies, and needs were being projected onto this ambiguous but neutral stimulus material. Rorschach began experimenting with inkblots around 1910 and established a system for eliciting and scoring responses, which he published along with 10 inkblots in *Psychodiagnostik* (1921).

This line of assessment was further elaborated by the work of Henry Murray in the development of the Thematic Apperception Test (TAT) (picture cards used to elicit short stories from the subject), Goodenough's draw a person test (originally used as an intelligence measure), and various sentence completion or word association tests. Often projective tests are administered directly by the examiner who records responses of the examinee, but some projective tests are also self-administered

(house–tree–person drawings and sentence completion tasks). Regardless of the manner of administration, the stimuli are used to evoke behavior that is thought to contain implicit information that must be discovered and interpreted by the trained examiner [12].

Personality Testing

The study of the nature of personality has a long lineage dating back at least to early Greek philosophers and playwrights. In the mid-nineteenth and early twentieth centuries, scientists such as Galton, Wundt, and James moved psychology away from being a philosophical exercise to the study of actual human behavior, many times trading erudite speculation for humble inquiry. Much of the physiological and cognitive research work of the European psychologists was laboratory based study of normal behavior but lacked a theory of person. In contrast was the work of Freud, a psychiatrist who was a seminal figure in the history of personality theory who worked with disturbed patients and searched for a model of the psyche combining understanding of normal and abnormal personality that would fit neurological evolution. His treatment approach and psychoanalytic theory came from his clinical model of inquiry and observation, and his major contributions were related to abnormal personality.

Issues in Personality Test Theory

There remains a basic division in personality research regarding whether personality is known by studying normal or abnormal behavior. In the United States, Gordon Allport studied the individual and the unique combination of the individual's normal traits. Henry Murray (who developed the TAT) studied individual differences seen in normal drives or traits and how they were integrated in the person. Both assumed personality is defined by traits that are independent of psychopathology, but both taught that the individual cannot be understood by fragmenting these traits. Eysenck, who proposed a two factor theory of neuroticism/emotional stability and extroversion/introversion, and Cattell, who developed the 16 Personality Factor (16 PF) test, carried on this line of work that now has given rise to the five factor model of Costa and McCrae [13]. This model is the basis for the NEO-Personality Inventory (NEO-PI) [14]. In contrast, developers of inventories such as the MMPI [11] or the Personality Assessment Inventory (PAI) [15] have paid more attention to clinical groups and abnormal personality.

Those who attempt to reconcile normal and abnormal personality research must address the question articulated by Paul Meehl as to whether personality traits (enduring characteristics in contrast to temporary states) occur in a dimensional spectrum that ranges from normal to abnormal extremes or occur in categorical divisions (taxons or uniquely different groups). The thinking behind the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) approach to diagnosis assumes distinct categorization. Some trait theorists such as Millon posit a dimensional approach where either extreme of a trait may be pathological [16, 17].

Those who study personality are also divided as to whether traits actually exist independent of models of thought (constructive-realist) and are largely determined by physiology or whether traits are only psychological explanations of behavior, actually determined by social domains affecting expression of biological needs (socioanalytic). The debate comes out in discussion about nature versus nurture causing behavior but goes beyond to attempt to answer whether there are really inherent basic trait domains (such as hardwired extroversion/introversion or even psychopathy) or only differences evident in the way people respond to or cope with biological needs based on social factors [18].

Atheoretical Approaches to Personality Testing

In addition to the trait research, other American work has significantly influenced personality testing from an atheoretical model. Coming out of the medical exam/psychiatric interview methodology, Hathaway (psychologist) and McKinley (psychiatrist) in the 1930s and early 1940s developed the MMPI in an attempt to find an empirically derived test that would differentiate medical patients with psychopathology from normal individuals. Even though self-report methodology, which had been developed by Woodworth in World War I with the Personal Data Sheet, had come to be criticized as too easily manipulated, Hathaway and McKinley used the technique anyway. They collected a large pool of items that were associated with psychiatric and medical symptoms

and asked individuals to respond to each by endorsing or denying its occurrence in their own lives. The MMPI authors, aware that responses might be affected by efforts to distort self-presentation, created validity scales to be used in interpretation of scores. They disregarded theoretical constructs and attempted to use only empirical means to identify those particular items that produced scores able to distinguish between specific diagnostic groups of patients and nonpatients. The original hope and early emphasis with the work at the University of Minnesota and later at Menniger Clinic in Kansas was to develop a tool capable of providing psychiatric diagnosis using a practical, empirically derived approach [19, 20].

The work on the MMPI was part of a post-World War II interest in testing. Similar to the demands of WWI, the military during wartime had responded to the task of classifying millions of recruits. After the war, in the United States there was a large number of nonmedically trained mental health providers, mainly clinical psychologists, who were equipped and ready to apply science, which had been optimistically embraced by the nation, to the study and treatment of mental health problems. Testing was valued in clinical, educational, industrial, and correctional settings and was seen as a way to bring efficiency, empiricism, and objectivity to tasks in these fields.

During the rise and reign of behaviorism (1960s and early 1970s), there was strong challenge to the concept of "personality", something that was intangible and considered an unnecessary and useless myth in explaining behavior. There was no need for the concept of "self" as there was exclusive focus on what an organism did in response to particular stimuli. Testing did not go away, but there was a much stronger emphasis on behavioral assessment – identifying particular behaviors of interest and recording the circumstances and frequency of their occurrence. In the past few decades, there has been modification of this model that now includes cognitive as well as behavioral aspects of assessment and treatment [21]. With this cognitive-behavioral approach there is focus on specific assessment using specialized instruments (Beck Depression Inventory and Beck Anxiety Inventory) that make no effort to describe the person as an integrated personality or even to provide a comprehensive clinical picture. Some have suggested that these brief rating scales and inventories, which are limited in scope, represent a third type of personality assessment: rapid personality assessment instruments [3].

Currently, in many settings outside the teaching or research environments, comprehensive personality assessment is often not seen as important or is not viewed as essential even if important. In addition, managed care of mental health services has often taken a restrictive stance toward more comprehensive testing. A survey of psychologists assumed to be in private practice found that 25% did not do personality testing at all. Of the ones who did such testing at least sometimes, about half used one or both of the two widely recognized tests (MMPI and Rorschach Inkblots) although the most utilized personality test reported was sentence completion [21].

Current Psychological Test Usage

Other surveys of psychologists have likewise documented a decided trend toward less testing in recent years. Psychologists in 1959 said 44% of their time was spent in assessment, but that figure was down to 22% in 1982. In 1971, 5 of the top 10 most often used psychological tests were projective personality tests; 1 was an objective personality test (MMPI), and 3 others were IQ tests. The core of the most popular tests remained stable through the early 1990s, but the amount of time devoted to assessment declined markedly. By the end of the decade, a study on test usage conducted for the American Psychological Association (APA) found fewer than 20% of clinical psychologists spent as much as 5 hours a week doing testing although about three-quarters of neuropsychologists spent at least that much time testing. Of those clinical psychologists with at least 5 hours a week devoted to testing, approximately 40% of their service was devoted to IQ or achievement testing and one-third to personality testing.

Neuropsychological testing was the next highest category of time spent (about 20%) but was (as expected) the major use of time for neuropsychologists who also spent about 20% of their time doing personality assessment. The MMPI/MMPI-2 was the most widely used test in the combined two groups with an IQ test (Wechsler Adult Intelligence Scale-Revised (WAIS-R)) placing second overall. Clinical psychologists also tended to use the Rorschach Inkblots (ranked fourth), but neuropsychologists did not (ranked eighteenth). No other personality tests

were popular with neuropsychologists, but at least half of clinical psychologists in the survey used the TAT (ranked sixth in frequency of use) [22].

Psychological Testing in Forensic Context

In addition to neuropsychology, another area of psychology that relies heavily on assessment and testing is forensic psychology. A survey of state directors of mental health resulted in information for 41 state corrections departments. Of those responding, 40 used testing at intake while 25 used it also for pre-parole work-ups. Of those testing at intake, 26 (65%) used MMPI/MMPI-2, 18 (45%) used intelligence tests, and five (12.5%) used Rorschach Inkblots in their department protocols. Of the 25 using testing for preparole evaluations, 24 (96%) used MMPI/MMPI-2, eight (32%) used intelligence tests, and nine (36%) used Rorschach Inkblots [23].

Results of a survey of 152 forensic psychologists who were members of American Psychology-Law Society (AP-LS) or diplomates of the American Board of Forensic Psychology (ABFP) indicated they averaged 56% of their time doing forensic work, presumably largely assessment, with almost a third (29%) being spent in actual testing. When asked about most frequently used tests in particular types of adult assessments, the top five in order of weighted frequency of usage across referral questions were: MMPI-2, one of the Wechsler intelligence or memory, one of the Hare Psychopathy Checklist versions (*see* **Psychopathy Checklists**) Structured Interview of Reported Symptoms (SIRS), and PAI [24].

Another survey of 64 diplomates of ABFP asked which tests were considered acceptable for use in six areas of forensic assessment. Across areas, both the MMPI-2 and the Wechsler Adult Intelligence Scale, Third Edition (WAIS III) showed strong acceptance as did the PAI to a lesser but still major degree. The Millon Clinical Multiaxial Inventory, Third Edition (MCMI-III) was rated as acceptable in only one area (mental status at time of offense). The Rorschach *inkblots* was rated as unacceptable by the majority (52–60%) of the respondents in five of the six areas (equivocal for use in exploration of mental status at time of offense) while other projective tests were deemed unacceptable in all areas by a significant majority (60–95%). Two neuropsychological batteries (Halstead-Reitan and Luria-Nebraska) were reported to be acceptable in half of the areas as was another IQ test (Standford-Binet) [25].

Forensic Assessment: Psychology and Law

Historical Developments

Hugo Munsterberg, considered the founder of applied psychology, was the first director of the psychology lab at Harvard after leaving the University of Leipzig where he had been a student of Wilhelm Wundt. He was an early pioneer of the study of eyewitness testimony and a strong advocate of application of psychology to law. In his book *On the Witness Stand* (1908), he chastised attorneys and judges for not embracing the research findings of psychology and using them in the courtroom. He was strongly criticized and his ideas mocked, but in the 1920s law schools began hiring psychologists to teach courses. Psychology was involved in courts largely in relation to treatment and disposition of children, and psychiatrists were more involved with competency and sanity questions. But psychologists and other social scientists were involved in Brandeis briefs, the most famous being the work of Kenneth Clark and colleagues in *Brown v. Board of Education* (1954) [26]. Only after *Jenkins v. United States* (1962) [27] was the way open for psychologists to provide expert testimony on mental health issues.

Other more recent legal rulings that have significantly impacted the practice of forensic psychology have been *Daubert v. Merrell Dow Pharmaceuticals, Inc*. (1993) [28], which replaced *Frye* (1923) criteria and defined the standards for consideration of scientific expert testimony; *General Electric v. Joiner* (1997) [29], which established the authority for the trial judge to determine what proffered testimony met *Daubert* standards; and *Kumho Tire Co., LTD v. Carmichael* (1999) [30], which expanded *Daubert* criteria to other fields of technical and specialized knowledge. Although these rulings only apply to federal courts, states have their own case law decisions in these areas [31].

Prevalence of Forensic Psychological Assessment

No data were found that indicate the current extent of psychological assessment utilization by US courts, but a conservative estimate of Competency to Stand

Trial evaluations in 1993 was 50 000 [32]. A more recent work cited research indicating 4–7% of criminal cases involved referral for these competency evaluations, the most prevalent mental health evaluation for criminal courts [33]. Civil courts often refer custody case participants for psychological evaluations, and personal injury cases frequently involve mental health expert testimony. Although the data are not available, it is obvious that a significant number of legal cases involve psychological or other mental health assessment. This reliance on psychology appears to be growing as evident with the publication of this volume that verifies Munsterberg's foresight.

The practice of forensic psychology, which is heavily dependent on psychological research and assessment tools, is one of the speciality areas in which the American Board of Professional Psychology (ABPP) offers board certification or diplomate status. The APA Division 41 (AP-LS) is devoted to exploration of the interface of psychology and law. Several well respected, refereed journals (including *Law and Human Behavior; Behavioral Sciences and the Law; Psychology, Public Policy, and Law*) are devoted exclusively to publication of research in this area of disciplinary overlap.

Tensions between Clinical and Forensic Assessment Perspectives

Forensic assessment in some important ways differs from traditional clinical assessment as discussed by Melton *et al.* [34], Heilbrun [35], and Archer *et al.* [31]. Some of the major ways include purpose, scope, and understanding of who is being served (broad understanding of purpose and scope in mental health evaluation where examinee is also the client being served versus forensic assessment addressing specific legal or quasilegal question(s) regarding the examinee to assist the decision maker who is considered the client). In addition, forensic examinees are frequently mandated for an evaluation and often assumed to have significant reasons to be purposefully selective in self-disclosure so that a much stronger focus must be placed on examiner objectivity and assessment of examinee's response style (pattern of self-presentation). Because of the threats of conscious deception or selective self-presentation in forensic evaluations, there is more emphasis on use of multiple sources of data to create hypotheses or to verify information as well as strong reliance on external sources (collateral observations, historical records, and reports of others) apart from the formal assessment interactions with the examinee.

While there are some instruments specifically developed for forensic use, these tend to be structured interviews, rating scales, or tests designed for use with a particular legal application in mind (e.g., Competence Assessment Instrument for Standing Trial (CAI), Psychopathy Checklist-Revised (PCL-R), and Competence Assessment for Standing Trial for Defendants with Mental Retardation (CAST/MR)). Quite frequently other instruments, developed for nonforensic purposes, are used in a forensic assessment because of the vast research on the instruments, validity indicators built into some of the instruments, or ability for these tests to contribute to a broad understanding of the person to develop hypotheses related to factors bearing on the legal question(s). Obvious examples would include well researched personality tests, tests of malingering, and cognitive tests including IQ measures. When any test is considered for forensic evaluation, these factors are important to consider: sufficient research and norms with a population similar to that of the examinee, adequate test development and psychometric properties, and ability to link test results to conclusions regarding the referral question [35].

A major risk inherent with use of clinical tests is overinterpretation of results where adequate validity research (relating test scores to real world conditions or outcomes) does not demonstrate clear connections between the test data and specific legal question(s) [34]. This problem was pointed out in a marked way by Jay Ziskin and David Faust, two psychologists, in the 1970s and 1980s (*Coping with Psychiatric and Psychological Testimony; The Limits of Scientific Reasoning*). They criticized mental health providers for going beyond the data and research by offering forensic opinions based on personal impressions rather than scientific conclusions. As a more recent writer noted, the task should be to provide "the best that psychology has to offer but also to be candid about the limits of our science and our expertise" (p. 131) [36].

Tensions between Psychological and Legal Perspectives

Even though psychologists are often used to conduct assessments and to provide relevant information

to the courts about psychological factors having a bearing on legal issues, there remains basic tension between psychology (which is experimental, descriptive, and probabilistic in its orientation to pursue scientific truth) and law (which is adversarial, prescriptive, and decisive in its orientation to pursue social and individual justice) [34, 37]. Psychology operates from a perspective of determinism (i.e., behavior can be predicted by some combination of genetic, biological, social, interpersonal, and environmental factors) whereas law operates on an assumption of free will (i.e., behavior is the result of personal choice and responsibility as each person is a free moral agent).

Other differences are evident as law applies broad terminology to specific cases, and psychology seeks to define and operationalize terminology into quantifiable form. Questions arise about legal terms for which there are no operational definitions either in law or psychology (e.g., reasonable degree of certainty pertaining to professional opinions, best interest of the child, reasonable degree of rational understanding for competency, unable to appreciate the nature and quality or wrongfulness of acts for criminal responsibility) or where the meaning of words or use of concepts differ (insanity as a legal construct and psychosis as a mental health concept). Despite the sometimes ill-fit of the two systems of thought, courts continue to rely on psychologists for help; and psychologists continue to explore better ways to respond to the task by developing methods to tie psychological data to legal constructs in a rational manner that can be logically followed [38].

Brief Overview of Major Personality Tests

Minnesota Multiphasic Personality Inventory (MMPI and MMPI-2)

The original 550 items and norms were developed by Hathaway and McKinley in the 1930s, mostly with patients and visitors at the University of Minnesota Hospital. The instrument was developed to aid in psychiatric and medical screening [7]. A revision (MMPI-2) was published in 1989 with updated items (66 modified, 90 omitted, and 107 newly created) and contemporary norms (2600 subjects of which 5% were current psychiatric patients). Individuals in the new norm group were from seven states representing a geographic diversity and were roughly balanced for gender (56% female).

Although ethnic and socioeconomic diversity was sought, Hispanic and Asian American groups are underrepresented in the norms. The normative sample is also skewed with college graduates comprising a larger percentage than is present in the US population [20]. The current 567 item true/false inventory requires an eighth grade reading level according to the 1989 version of the manual or a sixth grade reading level according to the revised edition of the test manual published in 2001 [11]. In addition to the original three validity scales (L, F, K), there are now several others measuring tendency to acquiesce, marking responses randomly, or subtly presenting self in a consciously distorted manner. Although well respected and popularly used, the inventory is criticized for its scales being too highly intercorrelated and therefore not distinct because many items are used simultaneously for scoring on different scales.

The MMPI was originally constructed for diagnostic classification purposes, but it proved to be disappointing in that regard when used in replication studies. Meehl was influential in adapting interpretation to a larger context by focusing on patterns of scores (profiles) and code types (based on scores of highest scales in a person's profile). These profiles and code types were researched to provide psychiatric descriptions for the major groups. While code type or group profile descriptions came to be widely used, research revealed problems with temporal instability of the code types when individuals were retested [19].

Another way of using test results from the MMPI has grown through the development and use of content scales, which are comprised of items that seem to be consistently related to a similar construct. This approach led to content scales providing descriptive rather than diagnostic information about a person and has more recently led to innovations such as Restructured Clinical (RC) scales (basic clinical scales with a general demoralization factor removed) and Restructured Form (MMPI-2-RF) with RC scales and newly developed specific problem (content) scales in a shorter version. These innovations also removed the use of K-corrections in calculating scores and removed item overlap within the basic scales [19].

Personality Assessment Inventory (PAI)

The PAI, a self-report inventory comprised of 344 items to which a person marks one of four choices

about how well each item applies to self, produces scores on 22 scales and 31 conceptually derived subscales. Scales were devised based on content and internal consistency and no item is scored on more than one major scale. Raw scores are transformed to T-scores using norms from a group of 1000 community dwelling subjects matching 1995 US census projections. Comparison clinical norms are also available based on a group of 1246 patients. Construction of the PAI was based on the assumption that normal personality constructs are distributed for both patients and nonpatients according to a bell-shaped (normal) curve. However, abnormal symptoms and constructs differ markedly within the two populations and occur very infrequently in the general population. The PAI requires a fourth grade reading level. It has four validity scales measuring positive and negative self-presentation, random responding, and overendorsement of unusual items [15, 39].

NEO-Personality Inventory-Revised (NEO-PI-R)

A third objective personality measure is the NEO-Personality Inventory-Revised (NEO-PI-R) that measures five basic stable dimensions of personality based on the work of Tupes and Christal who analyzed data that had been collected by Cattell in his work on normal personality traits. These personality domains are neuroticism, extroversion, openness to ideas, agreeableness, and conscientiousness. These five scales each have six subscales that have been developed by logical and factor analytic strategies utilizing known research on normal personality traits. This inventory is comprised of 240 items marked with one of five possible responses (strongly disagree to strongly agree). It contains no validity scales. Norms were developed using 500 males and 500 females selected to match 1995 US census projections. Forms are available for both self-rating and ratings by collateral persons who know the examinee [13, 14].

Rorschach Inkblots

This projective test, a standard set of 10 inkblots, was published by Swiss psychiatrist Hermann Rorschach in 1921 and is based on the assumption that personality can best be assessed through analysis of responses to ambiguous stimuli. Such implicit knowledge is less confounded by conscious distortion than is explicit information obtained by self-report. The assumption is that self-report only describes behavior, but this projective task actually produces behavior that can be observed, recorded, scored, and analyzed. Over the next five decades after Rorschach's publication, several different systems for scoring and interpretation emerged in both Europe and the United States. John Exner, influenced by Meehl's writings about actuarial rather than intuitive approaches to test interpretation, set out to standardize rules for scoring responses so that empirical data could be developed and used in interpretation. His comprehensive system of coding caught on and has largely shaped the use of this instrument since its introduction in the mid-1970s. Use of Exner's system [40] leads to specific data that can be related to norms and empirical research to provide information about a person's ability to control stress; ways to process information or make sense of the world; patterns of thinking about self and the world; emotional state; and ways of perceiving events and relationships.

Despite criticisms and disfavor of projective tests in general, the Rorschach Inkblots, especially when scored and interpreted using the Exner system, has remained a respected instrument for personality assessment and has passed *Daubert* scrutiny enabling expert testimony based on its findings. It provides limited information about diagnosis with the notable exception of thought disorder but provides a wealth of information to enable an understanding a person as an individual [41].

Other Resources

Clinical and forensic uses of these and other personality tests are discussed at length in Butcher [42, 43], Goldstein [44], Meyer and Deitsch [45], Maruish [46], Strack [47], and Archer [48].

Psychopathology: Terms and Trends

Introductoin

Society cannot exist without norms, and yet the definition of what is normal proves to be a thorny task for both social science and the field of mental health. In particular, at the interface of behavioral sciences and the law, forensic assessment requires clarity regarding threshold issues in the determination of the presence or absence of pathology and psychical suffering. Whether societal norms are identical to norms of psychical functioning or whether these two norms diverge from one another in specific and definable ways, the line between mental health and mental illness always necessarily implies an appreciation of the individual's ability to function effectively within his environment.

This environment, however, is not a biological one but rather is societal. An individual's ability to function in the social environment is mediated through his subjective interpretation of its laws and imposed constraints, that is, his perception of and ability to integrate norms. A forensic evaluator's role is precisely to introduce and assess this subjective point of view within the parameters of legal proceedings; parameters are designed to apply to all cases equally while providing for individual differences.

Norms and Normality

Psychopathology refers to the description, explanation, and logical formulation of the individual's mental state and mental processes, with the aim of characterizing abnormalities or guiding interventions in the context of treatment. Psychoanalysis has traditionally played an important role in psychopathology, along with cognitive science, neurobiology, and epidemiology (the study of diseases within populations). The overarching aim of psychopathology is the task of demarcating mental health and mental illness, two concepts whose meanings are inextricably bound up with one another, in reference to a norm.

In an article in the September 1967 issue of *Archives of General Psychiatry*, Sabshin outlines four perspectives on normality: (i) normality as health

or adequate functioning; (ii) normality as utopia or optimal functioning; (iii) normality as average or statistically common behavior; and (iv) normality as process or constant redefinition of the human condition relative to advances in civilization [1]. Canguilhem offers an additional viewpoint, defining normality as the individual's capacity to adjust his relationship to the environment toward the restitution of a norm, when confronted with "error" or deviation due to an anomaly or defect [2].

As cited by Sabshin, Freud's work, *Civilization and its Discontents* [3], describes civilization's impact on human nature as an intrinsic potential source of pathology. The imposition of culture upon the biological organism necessarily induces discomfort, though not always illness. To the extent that society's norms are evolving and imperfect, absolute conformity to such norms would entirely efface the individual's initiative. Normality, thus involves the negotiation of desires within social parameters and the law.

Values, Theory, and the Problem of Stigma

In the previously cited issue of *Archives of General Psychiatry*, medical sociologist Strauss argued that deviant behavior becomes pathological through "visibility," through public attention [4]. Deviant behavior is assigned significance through societal attribution of harm or potential harm – a judgment of value. The process of distinguishing between deviant behaviors that are due to mental health problems and behaviors that are not due to mental pathology has been subject to complex debate.

Wakefield [5, 6] is a key contemporary author in this debate, who introduced the concept of *harmful dysfunction* as a criterion for disorder. Although a detailed summary of the debate is beyond the scope of this article, the concept of harmful dysfunction has gained credence and acceptance and requires elaboration. Among other topics, Wakefield has addressed the advantages of an approach to diagnosis that emphasizes the development of a common vocabulary for improved communication between clinicians and for research purposes, and which thereby allows for the clarification of causation of symptoms using multiple explanatory theories.

Wakefield developed the concept of harmful dysfunction in response to a lack of clarity regarding the definition of a "disorder." Although clinicians utilize the concept of disorder and are able to reach a consensus about what is and is not a disorder, the formulation of an operational definition of disorder remains problematic. The concept of harmful dysfunction involves two separate elements, both of which must be present in order for there to be a mental disorder. First, there must be *harm* of some kind to the individual or others. This is a value judgment, in reference to societal norms. However, harm alone would not define a mental disorder, since many forms of harmful behavior are simply social evaluative judgments. The second element *dysfunction* implies a cause that is in some way internal to the functioning of the individual – in other words, a disturbance of an evolutionary capacity from which the resulting harmful behavior flows. If there is dysfunction but no harm, then there is no disorder. Similarly, if there is harm but no dysfunction, there is no mental disorder.

Klein agrees with Wakefield and adds the "involuntary" nature of the dysfunction [7]. In a disorder, harm arises from a process that occurs without the individual choosing it. Spitzer remarks that the current diagnostic criteria may be overly inclusive of nonpathological syndromes, and that the testing of diagnostic criteria according to the harmful dysfunction analysis would result in more precise definitions of disorders. With regards to adjustment disorder (symptoms which arise in the context of life stressors) he writes, "the degree of distress ... is a poor marker for discriminating disorder from nondisorder. What would be more helpful would be the issue of whether the individual's response to the stressor helped or hindered the individual in dealing with the stressor. ... If the reaction, even if associated with marked distress, facilitated dealing appropriately with the stressor, then a judgment of nondisorder would be appropriate." [8].

Separation of harm from dysfunction as components of mental disorder allows for clarification of the nature of psychopathology, as defined by norms that are not entirely determined by judgments of social value. The definition of disorder as a combination of harmful manifestations and underlying dysfunction may reduce the tendency toward stigmatization of the mentally disordered person, since disorder is, thus, attributed neither to social norms nor to causes that are beyond the individual's control [9].

Diagnostic and Statistical Manual of Mental Disorders, 4th Edition, Text Revision (DSM-IV-TR)

In the United States, there is consensus by mental health forensic experts on the use of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM) for attribution of diagnoses in legal proceedings, despite the fact that the DSM explicitly indicates that it is not designed for this purpose [10]. The first edition was issued in 1952, and involved narrative, descriptive paragraphs according to categories from the psychoanalytic orientation of psychopathology at that time. The second edition, with some revisions, was issued in 1968 and continued the previous edition's characterization of disorders through narrative paragraphs. A major conceptual shift occurred in 1980 with the release of the third edition, shaped in parallel with the research diagnostic criteria (RDC), which identified disorders according to specific criteria, which were required in order to assign the diagnosis. This was a significant step in the international standardization of diagnosis for the purposes of biomedical research, and the DSM was also applied in clinical and public mental health settings [11]. The strict set of criteria present for establishing a diagnosis were designed to focus on the phenomenology, or symptom description, rather than the underlying theory or causal explanation of the symptoms.

The same conceptual basis was retained in subsequent revisions, the DSM-III-R (R for revised), the DSM-IV and the DSM-IV-TR (TR for text revision, indicating that the accompanying text was updated without changing the criteria). However, the two editions of the DSM-IV emphasized empirical evidence, including field trials of the diagnostic criteria and classification, as well as data from published research [12]. A dramatically different system of classification, with a new conceptual basis, is likely in the forthcoming fifth edition of the DSM (see below).

The DSM-IV-TR divides mental disorders into broad categories and defines within each grouping a set of specific disorders with symptom lists and other criteria that must be met in order to assign the diagnosis. While some diagnoses are excluded or superseded by the presence of symptoms meeting criteria for another disorder, other diagnoses allow for the presence of multiple other disorders, sometimes with overlapping symptoms. Although the definitions require clinical judgment in assigning diagnosis, the method of arriving at a diagnosis specifies that if the clinical manifestations do not meet all of the necessary criteria for a given diagnosis, the diagnosis cannot be assigned.

For this reason, many clinically significant syndromes do not fit into specific DSM disorders, and the DSM provides for these through "not otherwise specified" diagnoses within each large category. The "not otherwise specified" diagnoses generally focus on a predominant symptom, such as anxiety or depressed mood, and indicate that such symptoms are present, without the individual meeting full criteria for a specific disorder. Diagnoses with the suffix "not otherwise specified" should not be taken to be less meaningful than specific diagnoses, since the individual's level of impairment may be as significant as that of a person who meets the criteria for a specific diagnosis. The reality of clinical practice suggests that disorders arise on a continuum with gradations from subtle to more severe and marked manifestations; the existence of "not otherwise specified" diagnoses reflects the reality that some symptomatic individuals with clinically significant distress or impairment do not fit neatly into the criteria which define research categories, but nevertheless closely resemble them.

The International Classification of Diseases, 10th Edition (ICD-10)

The International Classification of Diseases (ICD) includes diagnostic codes and criteria for all medical disorders, including mental health disorders [13]. The ninth version of the ICD was finalized 1 year after the task force for DSM-III was formed, without coordination of the criteria or nomenclature [14]. The preparation for a 10th edition of the ICD began well in advance of the work of the DSM-IV task force, making it impossible for the two systems to become identical [15]. During the subsequent development of the ICD-10 and the DSM-IV, international groups worked to improve the concordance between the two [15]. When both systems of classification are present in legal proceedings (e.g., where expert opinions are expressed in terms of DSM-IV-TR criteria and medical records contain ICD-10 coding), possible differences in specific criteria used to assign diagnoses should be clarified.

Beyond the Clinical Interview

Although the clinical interview and the mental status examination (*see* **Mental Status: Examination**) form the basis of diagnostic assessment, the examiner often has recourse to additional information, including documents, such as prior hospital records. Some of the criteria required for assigning a DSM diagnosis are difficult to confirm or disaffirm through the evaluee's self-report of symptoms or past behavior alone.

Parallel History

Some disorders are characterized by a lack of awareness of symptoms. Individuals with disorders such as schizophrenia or a personality disorder often manifest symptoms that they themselves are unable to perceive. Their symptoms are more readily perceived by others in their entourage. For this reason, information obtained from sources other than the evaluee (family members, employers, or the individual's treating physician) may be of value in determining the nature of the psychopathology. In addition, diagnostic criteria for some disorders include the time course of symptoms, and parallel history obtained from family members or others may be useful, for example, in confirming whether or not the symptoms of schizophrenia have been present for six months or longer, or whether elements suggestive of a personality disorder do in fact represent a life-long pattern, present from the time of childhood or adolescence.

Psychometric Validation

Although a large number of rating scales and standardized diagnostic instruments are available for the assessment of psychopathology (*see* **Psychological Testing**), the use of such techniques is not obligatory in forensic clinical practice for the determination of the presence of a mental disorder. Some examiners routinely administer psychometric tests, whereas others have recourse to them only in cases where there is ambiguity in the examination or where findings in the clinical interview suggest the presence of malingering (*see* **Malingering: Forensic Evaluations**). Caution must be exercised in relying too heavily upon the results of standardized testing, because the results are calibrated upon findings within a defined population as statistical probabilities and not as probabilities in an individual case. Even reporting of a highly validated and reliable examination such as the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) is usually expressed in terms such as "Individuals with this profile tend to . . ., " suggesting that the result indicates a trend that is relevant to the particular case only after appreciation in the context of findings upon clinical examination.

However, the diagnosis of a mental defect (*see* **Mental Retardation**) such as mental retardation or dementia (disturbance of memory and either language, motor activity, or complex task completion) (*see* **Neuropsychological Assessment**) does require testing beyond the clinical examination. By definition, these mental defects involve deficits in cognitive function that are sometimes subtle and require detailed evaluation with psychometrically validated techniques. In some cases, dementia may be so evident upon clinical examination that confirmation through specialized testing is unnecessary.

Genetics

Efforts in the field of neurobiology to determine the genetic basis of mental disease (*see* **Genomics and Behavioral Evidence**) have yielded results that are as yet unreliable, though some researchers propose classification of psychopathology on a genetic basis in the future [16–18]. Owing to variability in the expression of genes and environmental factors in disease causation, it appears unlikely that genetic typing will supplant clinical examination as a basis for diagnosis at any time in the near future. Even a disease with strong genetic underpinnings such as schizophrenia is present in both identical twins only approximately 50% of the time [19, 20]. Should genetic evidence in support of a diagnosis become admissible in courts, it will likely have a status similar to that of psychological testing, as data that supplements the clinical impression and not as definitive proof of diagnosis.

Neuroimaging

Recent developments in structural and functional magnetic resonance imaging (MRI) have led some jurisdictions to permit testimony from experts in brain imaging (*see* **Deception: Detection of and Brain Imaging**) as an aid in the assessment of psychopathology, though the future use of such

techniques in legal proceedings remains uncertain at the time of writing of this article.

Structural Approaches

The concept of *structure* refers to the underlying organization of internal psychical functioning, at a level beyond what is manifest. Structure is interpreted in different ways by various schools of thought, particularly within psychodynamic psychiatry and psychoanalysis. The notion refers, in general, to latent relationships between different elements of the psyche, viewed as a set [21]. Recent articles utilize the concept of structure to describe the underlying organization of psychopathology, including the integration of temperament, personality, and symptoms [22–24].

Although the various conceptualizations of structure are valuable in clinical practice, they pertain to enduring patterns relating to personality diagnosis and are seldom relevant to specific legal adjudications such as insanity at the time of the criminal act. Structural assessment of a forensic evaluee is challenging under evaluation conditions, since accurate formulation may require serial interviews over a significant period of time. Hypotheses regarding structural diagnosis may lead the forensic examiner to identify traits or historical features that he may then integrate into formulations that are pertinent to criminal mitigation or the assessment of civil damages. In addition, preliminary hypotheses regarding structural diagnosis may lead to further exploration of an individual's points of vulnerability in the setting of assesment of fitness for duty or of risk for future violence.

Psychodynamic Diagnostic Manual (PDM)

In 2006, a task force representing six psychoanalytic organizations published the result of their collaborative effort to develop a system of diagnostic classification to "complement the DSM and ICD efforts of the past 30 years in cataloguing symptoms by explicating the broad range of mental functioning," and with a wider appreciation of the patient as a "whole person" with a complex and rich life history [25]. Prior to the Psychodynamic Diagnostic Manual (PDM), some authors provided cogent psychoanalytic perspectives on DSM-IV diagnoses, reflecting the perceived need for enhanced formulations of the processes underlying descriptive diagnostic categories [26, 27]. Although the PDM includes syndromes that are recognizable to readers of the DSM-IV, it also describes other syndromes and classifies them in a manner that allows the clinician to find a basis to link diagnoses that are commonly co-occurring. In other words, in the PDM disorders are not considered as separate categories but as identifiable manifestations of the individual's underlying internal functioning.

The PDM is likely to be useful to treating clinicians, but is unlikely to supplant the DSM as a basis for expert opinion, a use for which it is not explicitly intended. The authors state quite clearly that it is not their intention to displace the DSM as a scientific classification necessary for research studies. Only time will determine whether forensic experts will refer to the PDM in supplementing their case formulations when arriving at an opinion or testifying in court. The PDM represents a consensus statement that supports what careful forensic mental health professionals already do – that is to say, to seek in detail the case-specific factors that are at issue in explaining past behavior and the likely future evolution of an individual within his personal history and in terms of idiosyncratic subjective experience.

Dimensional Approaches: the DSM-V and Beyond

Planning for the DSM-V began in 1999 and resulted in the publication in 2002 of *A Research Agenda for DSM-V* [28]. After a review of the existing literature, DSM-V workgroups were formed in 2007, with an aim to publish DSM-V by as early as 2011 [29]. A major conceptual revision of the DSM is anticipated, in light of numerous observations regarding the DSM-IV, which utilizes a *categorical* system of classification of disorders, in which the particular disorder is either present or absent. Clinicians have noted that disorders do not easily conform to such a system, since symptoms that partly meet criteria may result in significant impairments that are susceptible to treatment. Researchers have noted that categorical diagnosis may exclude individuals from studies, resulting in a skewed picture of underlying pathological processes [30].

In order to remedy such difficulties, the DSM-V workgroups began to consider the feasibility of a *dimensional* approach to diagnosis, which would

retain the categorical diagnoses currently in use, with modifiers to indicate the milder versions or partial syndromes, which are nonetheless related to the primary diagnosis. This approach is based on the assumption that psychopathology exists on a continuum, although there are characteristics which define a "prototype" of the disorder [31, 32]. Previously, the terms "categorical" and "dimensional" were most widely used in the diagnosis of personality disorders, where a wide range of assessment instruments were developed, alternately defining disorders using strict criteria for determining the presence or absence of a specific entity ("borderline personality disorder" or "antisocial personality disorder") *versus* defining disorder according to the predominance of traits that were deemed to be more or less characteristic of the individual's life pattern. The clarification of relevant dimensions in disorders other than personality disorders is likely to require the development of consensus through empirical study of the types of dimensions most characteristic of the "prototype" for each specific disorder [33, 34].

The DSM-V may also include a reorganization of disorders into *spectra*, of related disorders. Beyond the identification of relevant dimensions for specific disorders, the spectrum approach seeks to group together disorders that share similar underlying processes [35, 36]. For example, pathological gambling, eating disorders, and substance abuse could be conceptualized as disturbances arising from an underlying process of compulsion (*see* **Compulsion**), and these might therefore be more likely to occur together in the same individual.

Although the process of DSM revision is lengthy and careful, including field testing of the criteria prior to finalization, commentators observe that the major conceptual change will likely require further refinement after the DSM-V is published [12, 37]. After extensive discussion, the final published criteria for DSM disorders summarize only the essential findings of the committees. For this reason, the *DSM-IV Sourcebook* [38] – a summary of debates prior to arriving at final criteria – is a useful reference when clarification is needed, and provides further information for assessment of the intended meaning of DSM diagnoses. Hopefully, the DSM-V will also be accompanied by such a companion sourcebook to aid the reader.

Relevance to Legal Proceedings

At first blush, a dimensional approach to the diagnosis of mental disease would appear to be contraindicated in the context of legal proceedings. Case law has defined, for example, what diagnoses are eligible for consideration as a "severe mental disease" leading to criminal nonresponsibility, implying that adjudications require clear thresholds provided by categorical diagnosis. However, closer scrutiny reveals that a dimensional approach is compatible with the process of expert evaluation in cases involving mental disorders, to the extent that forensic opinions do not rely solely upon diagnosis, but rather present the relationship between particular symptoms and specific behavior or distress, along a continuum of severity. A term such as "severe mental disease" is, thus, a legal term of art that can accommodate evolution in the professional standards regarding mental pathology, in accordance with contemporary scientific definitions.

Conclusion

Psychopathology is a complex and evolving field of study, with a long historical tradition that merits a closer examination than is possible in this article. Systems of classification of mental disorders have been constructed in accordance with changing needs and new findings in research. Although manuals such as the DSM and the PDM are commercially available for purchase, works such as these should be viewed as guides for use by mental health professionals in light of their education, experience, and intuition based on clinical reasoning and the specifics of each case. Through research and consensus, it has been possible to define categories of psychopathology using standardized criteria that serve as a common language, across theoretical orientations. However, debate continues as to the adequacy of these categories, particularly given the wide variety of clinical manifestations and underlying mental processes involved in the experience of each person, and efforts are under way to revise the existing classifications in light of new findings.

SUZANNE YANG AND FRANÇOIS SAUVAGNAT

Psychopathy

Psychopathy or psychopathic personality disorder is referred to as *antisocial personality disorder* in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* or *DSM-IV* [1] and as dissocial personality disorder in the tenth edition of the *International Statistical Classification of Diseases and Related Health Problems* or *ICD-10* [2]. Previously, it was referred to as *sociopathy* or *sociopathic personality disorder*.

Clinical Description

According to clinical descriptions over the past 200 years [3, 4], psychopathy is characterized by a broad range of symptoms in several major domains of personality functioning. In the domain of *behavioral organization*, they include lack of perseverance, unreliability, recklessness, restlessness, disruptiveness, and aggressiveness. The *emotionality* domain includes lack of anxiety, lack of remorse, lack of emotional depth, and lack of emotional stability. The domain of *interpersonal attachment* includes detachment, lack of commitment, and lack of empathy or concern for others. The domain *interpersonal dominance* includes antagonism, arrogance, deceitfulness, manipulativeness, insincerity, and glibness or garrulousness. The *cognitive* domain includes suspiciousness, inflexibility, intolerance, lack of planfulness, and lack of concentration. Finally, the *self* domain includes self-centeredness, self-aggrandizement, self-justification, and a sense of entitlement, uniqueness, and invulnerability.

Assessment and Diagnosis

In the *DSM-IV* and *ICD-10*, the diagnostic criteria for psychopathy focus primarily on symptoms from the behavioral organization domain, especially those related to violation of explicit social norms. In many civil psychiatric settings, these diagnostic criteria have adequate reliability (e.g., stability or consistency across evaluators and time) and validity (e.g., prognostic value with respect to poor treatment response, institutional misbehavior, or community violence) [1, 5]. In forensic settings, however, the *DSM-IV* and *ICD-10* criteria are less useful. Their heavy focus on criminality leads to extremely high prevalence rate – typically 50–75% or higher – in correctional offenders and forensic psychiatric patients [1, 5]. For this reason, many forensic mental health professionals prefer more comprehensive diagnostic criteria, such as the *Hare Psychopathy Checklist Revised* or *PCL-R* [6] and its progeny, such as the *Screening Version* or *PCL:SV* [7] and the *Youth Version* or *PCL:YV* [8]. These latter tests yield a lifetime prevalence rates of ~15 to 25% – about one-third the rate observed using the *DSM* criteria for antisocial personality disorder [5, 6] – and also have superior reliability and validity (*see* **Psychopathy Checklists**).

Course

Symptoms of psychopathy may emerge as early as age 6–10 [9], and it is common for adults with psychopathy to have been diagnosed in childhood or adolescence as suffering from one of the disruptive behavior disorders. Indeed, the *DSM-IV* diagnostic criteria for antisocial personality disorder require that the person met the criteria for a conduct disorder before age 15 [1]. Unfortunately, the majority of children or adolescents so diagnosed – 50 to 75% or more – spontaneously desist antisocial behavior and do not go on to develop psychopathy as adults [9, 10]. Consequently, it is recommended not to diagnose psychopathy before the beginning of early adulthood, at least 18 years old or possibly even 25 years old [1, 2].

The course of the disorder during adulthood is characterized by relative stability. For example, there is evidence of moderate diagnostic stability across periods of several months to several years [6], persistence of symptoms across adulthood [11, 12], and long-term risk for negative health outcomes

such as morbidity and mortality [13]. But there is also evidence that symptom severity may fluctuate substantially over time [14].

Prevalence

Epidemiological research in the United States indicates that the lifetime prevalence of psychopathy in the general population, according to *DSM-IV* or similar criteria, is ~1.5 to 3.5% [15, 16]; in correctional offenders, the rate is 50–75% [6].

When more comprehensive diagnostic criteria are used, the prevalence rate is considerably lower. For example, research using the *PCL-R* with correctional offenders and forensic psychiatric patients in the United States has reported lifetime prevalence rates of ~15 to 25% – about one-third the rate observed using the *DSM* criteria [6].

Gender, Age, and Sociocultural Factors

Lifetime prevalence rates of psychopathy vary across three major group factors: gender, age, and culture. First, with respect to gender, the male : female sex ratio in diagnosis is typically about 3 : 1 [15, 16]. This gender difference is not limited to a few clinical features, but is evident across the full range of symptomatology. Second, with respect to age, some epidemiological research in the United States using *DSM-III* and *DSM-III-R* criteria has reported a cohort effect, with higher lifetime prevalence rates in younger generations than in older generations [17]. Third, with respect to culture, anthropological and epidemiological research indicates that psychopathy is found across cultures [18], but there is evidence of cross-cultural differences in prevalence. For example, according to general population studies, the lifetime prevalence of psychopathy in Taiwan is much lower than that reported in the United States [19], and according to studies of correctional offenders and forensic psychiatric patients, the prevalence of psychopathy is higher in the United States than in Europe [20.]

These group differences may be due to *cultural facilitation* [20, 21]. In highly individualistic cultures such as the United States, norms and values that emphasize the importance of distinctiveness, status, self-confidence, honor, competition, and freedom from obligations to others may also foster the development of extreme manifestations of the same characteristics – for example, conceit, manipulativeness, irresponsibility, pathological dominance, and aggressiveness. Similarly, within a dominant culture, the expression of symptoms of psychopathy may be facilitated in certain subgroups, such as males or younger generations, that subscribe to more individualistic norms and values.

The group differences may also be due to inadequacies in diagnostic criteria. The current diagnostic criteria for psychopathy may be biased to reflect its prototypical manifestation in young males from individualistic cultures; if this is true, any differences due to gender, age, and culture may be smaller than suggested by research to date [20].

Comorbidity

Psychopathy has a high rate of comorbidity with substance use disorders [15, 22, 23]. This comorbidity may reflect a common etiological mechanism, or it may be that in some cases substance use disorders are a consequence or complication of psychopathy.

Psychopathy also has a high rate of comorbidity with other personality disorders, specifically, borderline, the Cluster B narcissistic, and histrionic personality disorders in *DSM-IV* or emotionally unstable and histrionic personality disorders in *ICD-10* [24, 25]. The high rate of comorbidity among them almost certainly reflects inadequacies in their diagnostic criteria (i.e., a failure to "carve nature at its joints"), as well as common etiological factors.

Low rates of comorbidity are observed between psychopathy and certain other personality disorders, specifically the Cluster C avoidant, dependent, and obsessive–compulsive personality disorders or anxious/avoidant, dependent, and anankastic personality disorder in *ICD-10* [24, 25]. The low rates of comorbidity among the disorders suggest they have independent or even competing etiologies.

The rates of comorbidity between psychopathy and most other disorders are inconsistent, unclear, or unremarkable [15, 24, 25].

Etiology

The etiology of psychopathy is unknown. Theoretical models of etiology can be divided into two main categories based on whether they view psychopathy

as a true disorder, that is, a *bona fide* form of mental abnormality.

Theoretical models of psychopathy as mental abnormality have focused on the potential causal influence of social and biological factors. Overall, the research literature supports the relative importance of biological over social factors. With respect to social factors, there are no child-rearing experiences, familial dysfunctions, or adverse life experiences that are found both frequently and specifically in people with psychopathy compared with people with other personality disorders. As noted previously, however, sociocultural factors certainly appear to play a role in the expression of the disorder [20, 21]. With respect to biological factors, researchers have reported elevated rates of prenatal trauma, neurotransmitter abnormalities, and structural abnormalities of the brain associated with symptoms of psychopathy [26–28], but none of these factors is clearly pathognomonic. Also, some adoption research has reported that the heritability of psychopathy is substantial [11, 29], but molecular genetic research has not identified genetic markers. A common theme underlying many etiological theories that focus on biological factors is that psychopathy is associated with impaired ability to experience emotions and integrate them in executive functions; this core emotional deficit results in a failure of attachment to others, inattention to cues of impending punishment, and insensitivity to reward or punishment.

Other theoretical models reject the notion that psychopathy is a mental abnormality at all. First, some interpersonal and behavioral genetic theories view psychopathy as an extreme variant of the same personality traits found in all people [30, 31]. According to these theories, psychopathy is not associated with any unique or specific causal influences and any differences between people with *versus* without the disorder are quantitative rather than qualitative in nature – that is, the differences are a matter of degree rather than of kind. Second, some sociobiological and evolutionary theories view psychopathy as an adaptation [32]. According to these theories, the human species has the genetic capacity to express traits associated with psychopathy. In sociobiological theories, the genetic capacity exists in only a minority of humans and its manifestation is only partially dependent on environmental circumstances; in evolutionary theories, the genetic capacity exists in all humans, but is manifested in only a minority of humans who are exposed to specific environmental circumstances. In both the theories, people with psychopathy have an evolutionary advantage in terms of an increased likelihood of producing offspring.

Treatment

There is no methodologically sound research on the treatment of psychopathy, and so there no good evidence that it can be successfully treated [33]. Notwithstanding methodological limitations, there is evidence that psychopathy is associated with increased risk for disruptive behavior during treatment, treatment dropout, and posttreatment recidivism [34].

Forensic Relevance

Psychopathy does not appear to impair cognitive abilities to the extent that it is relevant in the assessment of psycholegal competencies or capacities. With respect to civil-forensic evaluations, psychopathy generally is not considered by either research or law to be relevant to issues such as competence to consent to treatment, enter into contracts, or testify. With respect to criminal forensic evaluations, it is generally not considered relevant to issues such as competence to confess or stand trial, or to ability to form criminal intent.

In contrast, psychopathy does appear to impair volitional abilities to the extent that it is relevant to the assessment of risk for serious crime, and, in particular, for violence. A large body of research indicates that psychopathy is a major risk factor for disruptive behavior while institutionalized and for recidivism upon release to or while under supervision in the community [35, 36]. Explanations include the following [35]:

1. Psychopathy increases the perceived benefits of serious crime. For example, interpersonal symptoms may make demeaning, controlling, and hurting other people rewarding; and behavioral symptoms may make exciting, risk activities rewarding.
2. Psychopathy decreases the perceived costs of serious crime. For example, attachment symptoms, emotional deficit, and self symptoms may

result in failure to be deterred by anxiety, empathy, remorse, or self-punishment.
3. Psychopathy destabilizes general psychosocial adjustment. For example, all symptoms of psychopathy may increase problems in daily living, decrease social integration or cohesion, or otherwise increase interpersonal conflict.

Given the association between psychopathy and serious crime, as well as the lack of demonstrably effective treatment for psychopathy, it is understandable that psychopathy is potentially relevant in a wide range of psycholegal evaluations involving risk for serious crime. With respect to civil-forensic evaluations, psychopathy is relevant to issues such as parental capacity (i.e., risk for child abuse), employee discipline and dismissal (i.e., risk for workplace violence), and civil commitment as a sexually violent predator (i.e., risk for sexual violence). With respect to criminal forensic evaluations, it is relevant to issues such as pretrial release, sentencing, correctional classification, and community registration, notification, and supervision.

Psychopathy Checklists

Psychopathy is a specific form of personality disorder (*see* **Psychopathy**). The *Hare Psychopathy Checklist-Revised* (*PCL-R*) [1, 2] and the *Screening Version of the Hare Psychopathy Checklist-Revised* (*PCL:SV*) [3] are standardized psychological tests of lifetime psychopathic symptoms in adults. They have proven to be particularly useful forensic mental health evaluations and are in wide use, both in the original English and in numerous foreign language translations.

History

In the mid-1970s, Robert Hare was dissatisfied with the assessment procedures for psychopathy then in use, as they focused primarily on impulsive, irresponsible, and antisocial behavior and had only low-to-moderate correlations with each other [4]. Hare began work on the development of measures that were more comprehensive and reliable. His first attempt, the *Psychopathy Checklist* (PCL), was distributed informally starting in about 1980 [5] and stimulated considerable interest among researchers and forensic mental health professionals. The manual for the revised PCL, or PCL-R, was published in 1991 [1] and updated in 2004 [2].

Several derivations of PCL-R were developed by Hare and colleagues. One of these was PCL:SV, which is shorter and easier to administer than PCL-R, as well as being appropriate for use in general community and civil psychiatric settings [3]. Development of PCL:SV began in the mid-1980s, concurrent with the revision of the PCL, and a test manual was published in 1995.

Format

PCL-R and PCL:SV are multi-item observer rating scales designed to assess the lifetime presence and severity of psychopathic symptoms. Ratings are based on personal interviews and third-party information (e.g., collateral interviews and official records). Each item reflects a different symptom or characteristic of psychopathy, defined in the test manual, and is rated on a 3-point scale (0 = absent, 1 = present to a limited extent, 2 = present and severe). A small number of items can be omitted if insufficient information is available to rate them. Items are summed (and prorated, if necessary) to yield total scores. Total scores can be interpreted dimensionally, relative to norms from various comparison groups, or cut-off scores can be used to make categorical diagnoses. Items can also be summed to yield factor scores, although these are used primarily for research purposes.

PCL-R is intended for use with adult correctional offenders and forensic psychiatric patients, male or female. It comprises 20 items, some of which reflect pathological personality traits and others that reflect specific forms of antisocial conduct. Item definitions average about 200 words or so in length. Total scores range from 0 to 40; a cut-off score of 30 and higher is used to diagnose psychopathy. Norms are available for a variety of reference groups. Scores can be calculated for two superordinate factors or four subordinate factors.

PCL : SV is intended for use with adults in general community and civil psychiatric settings, in addition to adult correctional offenders and forensic psychiatric patients, male or female. It comprises 12 items, all of which tap relatively broad pathological personality traits. Each item is either a simplified version of a PCL-R item or a combination and simplification of two PCL-R items. Item definitions are shorter than in PCL-R, averaging about 50 words. Total scores range from 0 to 24, with scores of 18 and higher used to diagnose psychopathy. Norms are available for reference groups of male or female correctional offenders, forensic psychiatric patients, civil psychiatric patients, and community residents. Scores can be calculated for two factors, isomorphic to the superordinate factors of PCL-R.

In forensic settings, PCL:SV can be used in conjunction with PCL-R as a screening test for psychopathy; most evaluators, however, tend to use PCL-R if the person being evaluated has a history of serious criminality (e.g., chronic or long-sentence offenders), and PCL:SV when the person does not (e.g., first-time, short-sentence, or less serious offenders; mentally disordered offenders; and forensic psychiatric patients).

Administration

PCL-R and PCL:SV are usually administered as part of a comprehensive psychodiagnostic evaluation. It takes about 20–30 min to score and interpret PCL-R, and about 10–15 min to score and interpret PCL:SV in these circumstances. Single-use assessment guides are available for both PCL-R and PCL:SV, which include a semistructured interview and space for recording relevant third-party information.

It is possible to administer the tests solely on the basis of third-party information if a person refuses or is otherwise unable to be interviewed, provided the quantity and quality of this information is sufficient. This procedure may, however, result in a score that is substantially lower than would have been obtained if the person had been interviewed.

It is not possible to administer PCL-R or PCL:SV without access to third-party information, except for certain research purposes.

Test User Qualifications

PCL-R and PCL : SV are controlled psychological tests. Independent use of the tests for clinical purposes is limited to people who are legally entitled to use psychological tests to assess and diagnose mental disorder. Test users also should have advanced education and training in individual assessment and psychological testing that would qualify them to practice as a mental health professional (e.g., graduate or medical degree). PCL-R manual also recommends

that test users should have at least 2 years experience working in forensic settings. Completion of training workshops and supervised practice in the use of PCL-R and PCL:SV is recommended, but not required. Similarly, the manuals recommend completion of 5–10 practice cases prior to clinical use of the tests.

Psychometric Properties

The psychometric properties of PCL-R and PCL:SV have been evaluated extensively within the framework of classical test theory [2, 3, 6]. The most relevant forms of reliability for the tests are structural, inter-rater, and test–retest reliabilities. Structural reliabilities are good to excellent: Item adequacy, as indexed by corrected item-total correlation, is typically 0.40–0.50; item homogeneity, as indexed by mean inter-item correlation, is typically 0.20–0.30; and internal consistency, as indexed by Cronbach's α, is typically 0.85–0.90. Inter-rater reliabilities also are good to excellent: For items, the intraclass correlation coefficient (ICC1) is typically between 0.60 and 0.80; for total scores, ICC1 is typically 0.80–0.90; and for categorical diagnoses, inter-rater agreement, as indexed by κ, is typically 0.50–0.75. Test–retest reliability of total scores and diagnoses has been examined infrequently, but appears to be good to excellent over periods of 1 week to 1 month and at least fair over periods of 6 months to 2 years.

More recently, the tests have been evaluated within the framework of item response theory (IRT) by Cooke, Hare, and colleagues [2, 7, 8]. The interpersonal, affective, and behavioral symptoms have good discriminating power; in contrast, the discriminating power of antisocial behavioral items is weaker. The interpersonal symptoms discriminate the latent trait at high levels (i.e., psychopathy), affective symptoms at moderate levels, and behavioral symptoms, at low levels.

IRT is also being used to examine potential metric bias in PCL-R and PCL : SV scores. Some researchers have reported evidence of a small but statistically significant metric bias across dominant cultures, with offenders and patients in the United Kingdom and other European countries scoring lower on PCL-R than those in Canada and the United States, given equivalent standing on the latent trait [9, 10]. This may be due to the effects of cultural facilitation, with symptoms of psychopathy being expressed more often in highly individualistic societies. There is no evidence, however, of metric bias between ethnic majority versus minority groups within a dominant culture [11]. Only recently have researchers started to investigate metric bias across gender and age.

Association Between PCL-R and PCL:SV

Cooke and colleagues have evaluated the derivation of PCL:SV using IRT methods [8]. They found a strong association between corresponding PCL-R and PCL:SV items or item pairs. They also found that PCL:SV items had a discriminating power as good as or better than the corresponding PCL-R items or item pairs.

Total scores on PCL-R and PCL:SV are also strongly associated. Cooke and colleagues [8] reported a high correlation ($r = 0.94$) between scores on the latent trait underlying both tests according to IRT analyses, and Guy and Douglas [6] reported similar high correlations ($r = 0.94–0.95$) between (raw) total scores on the tests in forensic samples. Guy and Douglas [6] also found that PCL:SV had good validity as a screening test for high-PCL-R scores in the same two forensic samples, with large areas under the curve (AUC = 0.98) according to receiver operating characteristic (ROC) analyses.

Factor Structure

Initial investigations of the dimensionality of PCL-R and PCL:SV used exploratory factor analysis (EFA) methods. The only consistent finding was the absence of a simple, unidimensional latent variable underlying the tests. Hare and colleagues proposed a structure comprising two orthogonal (i.e., correlated) factors: one reflecting interpersonal and affective symptoms, and the other reflecting behavioral symptoms and antisocial conduct [1].

Cooke and Michie [12] overcame the limitations of EFA by using confirmatory factor analysis (CFA) methods. After omitting PCL-R and PCL:SV items tapping antisocial conduct, they found strong evidence of a hierarchical three-factor structure, comprising a superordinate general factor (psychopathy) underpinned by three correlated subordinate factors (interpersonal, affective, and behavioral symptoms).

The hierarchical three-factor structure was replicable across diverse samples of offenders and forensic psychiatric patients from different nations. Importantly, it was even found when factor-analyzing diagnostic criteria for psychopathy other than PCL-R and PCL:SV.

Subsequent to Cooke and Michie's article, several researches have found support for the three-factor hierarchical structure. But others, including Hare and his colleagues, have argued that the entire item pools of PCL-R and PCL:SV should be included in factor analyses, which they say results in the addition of a fourth subordinate factor, reflecting antisocial conduct; this view was reflected in the updated PCL-R test manual [3]. Debate continues on whether antisocial conduct should be considered a primary symptom of psychopathy versus a secondary symptom, sequela, or consequence of the disorder [13].

Validity

As PCL-R and PCL:SV have been used in virtually hundreds of published studies, only a general review of research is presented here; and as the tests are strongly associated, they are reviewed together.

One important line of research has evaluated the *concurrent validity* of PCL-R and PCL:SV, that is, their association with other procedures for assessing psychopathy. Total scores on the tests have moderate to large correlations with clinical diagnoses made using other criteria, and moderate correlations with self-report measures of psychopathy [2, 3]. Both clinical diagnoses made using other criteria and self-report measures tend to correlate more highly with PCL-R and PCL:SV items reflecting behavioral symptoms and antisocial conduct than with items reflecting the interpersonal and affective features [2, 3].

With respect to *predictive validity*, total scores on PCL-R and PCL:SV are reliably associated with serious antisocial behavior, including violence, in both institutional and community settings. Summarizing a number of reviews in recent years [14, 15], several general conclusions may be drawn. First, the predictive validity of PCL-R or PCL:SV with respect to serious antisocial behavior is typically moderate in magnitude, $r = 0.20–0.30$. Second, the predictive validity tends to be larger in community settings than institutional settings. Third, the predictive validity tends to be larger when the outcome reflects general but serious antisocial conduct (e.g., "any violence"), rather than more specific or less serious antisocial conduct (e.g., "sexual violence" or "any misconduct"). Fourth, the predictive validity of psychopathy, as measured by PCL-R and PCL:SV, typically is higher than that of other established demographic, criminal history, and clinical risk factors (e.g., age, prior antisocial conduct, substance use); indeed, PCL-R and PCL:SV predict antisocial conduct about as well as do multifactor risk assessment procedures constructed theoretically or statistically. Fifth, the predictive validity of PCL-R and PCL:SV is not attributable solely or even primarily to the inclusion of items reflecting past antisocial conduct.

With respect to other aspects of *construct validity*, PCL-R and PCL:SV have been used to study the course, comorbidity, etiology, and treatment of psychopathy [16]. (*See also* **Psychopathy**.)

Forensic Applications

In the practice of forensic mental health, PCL-R and PCL:SV are used most often as part of comprehensive assessments of risk and treatability for sentencing, civil commitment, institutional classification, and release decision making. This application is supported by research on the prediction of serious antisocial conduct and on treatment response. Indeed, PCL-R and PCL:SV are incorporated explicitly into several procedures for assessing violence risk (*see* **Dangerousness: Risk of** and **Risk Assessment: Patient and Detainee**).

Forensic mental health professionals should be aware of some important limitations of PCL-R and PCL:SV [17, 18]. First, as observer ratings scales, the tests may be susceptible to distortion – unconscious or deliberate – by evaluators. To safeguard against this, evaluators should closely follow the administration instructions in the test manuals; training and supervised practice in the use of the tests may also be helpful. Second, although the tests have good psychometric properties in adult male offenders and forensic psychiatric patients in the United States and Canada, the possibility of bias due to culture and gender has not yet been ruled out. Third, the tests reflect the lifetime presence of psychopathic symptoms; this means they cannot be used to measure changes in the presence or severity of symptoms over time, or used to determine whether the person currently suffers

from psychopathy. Fourth, although comprehensive, PCL-R and PCL:SV are not exhaustive in content and relatively heavily saturated with items reflecting antisocial conduct. Evaluators should consider using PCL:SV instead of PCL-R in cases where the person being assessed does not have a serious history of criminality. Fifth, although psychopathy is a robust risk factor for antisocial behavior, PCL-R and PCL:SV scores cannot be used – either on their own or in combination with other factors – to estimate the specific probability or absolute likelihood that a given person will commit a criminal or violent act with any reasonable degree of scientific certainty.

Psychopharmacology

Psychopharmacology is the study of the effects of drugs on psychological function. It is a branch of pharmacology, which focuses on the nervous system. Clinical psychopharmacology is the portion of psychiatric practice, which pertains to the use of medication as a tool to treat mental disorders [1, 2].

Clinical psychopharmacology involves an assessment process, development of a treatment plan, and subsequent assessment of the effects of treatment [3].

Psychopharmacologic testimony is often relevant in both civil and criminal cases. Establishing standard of care, and causation of damages in cases alleging negligent prescription, evaluating complex disability claims, and testamentary competency are some areas for psychopharmacological consultation. Cases of suspected poisoning or suicide may also warrant psychopharmacological consultation.

Since many crimes are committed under the influence of substances (*see* **Substance Abuse**), the effect of those substances on the defendant's mental state may be relevant (*see* **Insanity: Defense**; **Temporary Insanity**; **Mitigation Testimony**). Even though voluntary intoxication may not negate a mental state in many jurisdictions, the distinction between intoxication, mental illness, and "settled insanity" [4] requires psychiatric evaluation.

Defendants who are incompetent as a result of mental disorder (*see* **Capacity to Stand Trial**) may often be restored to competence through treatment. If the defendant refuses treatment, psychopharmacological evaluation is necessary to inform the court that medication is substantially likely to render the defendant competent to stand trial and substantially unlikely to have side effects that will interfere significantly with the defendant's ability to assist counsel in conducting a defense [5].

Basic principles of psychopharmacology are outlined in this article, along with an overview of psychotherapeutic agents, and some clinical and medical legal issues related to them. Substance abuse and dependence are reviewed in **Substance Abuse**; **Addictions**.

The study of pharmacology includes an understanding of pharmacokinetics, pharmacodynamics, and drug mechanisms. Pharmacokinetics describes what happens to a drug when it enters the body. How a drug is absorbed, metabolized, activated or inactivated, and excreted, influences how much of a drug is available at the site of action. Pharmacodynamics explains the effect of drugs on the sites of action [6].

Drug effects may vary as a result of the route of administration. For example, intravenous benzodiazepines can reliably cause short-term amnesia, which is useful to anesthesiologists. The same dose of drug ingested orally will usually not have the same effect.

Once a drug is absorbed, it enters the bloodstream to be carried through the body. Most psychoactive drugs are lipid (fat) soluble. They do not dissolve well in water. Thus, they are carried through the bloodstream bound to protein.

Many drugs are metabolized through interactions with enzymes in the liver (many are metabolized throughout the body). When a drug is metabolized, it is altered, often to an inactive or water soluble form. Sometimes the metabolites are themselves active drugs. If the drug is ingested by mouth, after it is absorbed in the intestines, it goes through the portal system to the liver for first pass metabolism, and then to the general circulation, where it can effect other organs.

Drugs that are inactivated to an efficient degree by the liver are not effective when administered orally. First pass inactivation can be bypassed through alternative routes of administration: intravenous, sublingual, or intranasal.

Drugs and their metabolites are excreted through urine, feces, and perspiration. The time required for the plasma concentration of a drug to fall by one half is the half-life of the drug ($t_{1/2}$). When the amount of drug administered in a given time equals the amount eliminated, the drug has reached steady state.

In order for a drug to act on the brain, it must cross the blood–brain barrier. Factors that affect a drug's ability to enter the brain include size and charge of the drug molecule, and its lipid solubility. For example, L-Dopa will cross the blood–brain barrier, while Dopamine (DA) will not.

A drug may have a nonspecific effect on the nervous system when it affects energy metabolism, or membrane stability. Specific drug effects arise from interaction with identifiable molecular mechanisms unique to target cells, which bear receptors for that drug. Sometimes a drug with specific effects at a low dose has general effects at a higher dose. Alcohol and general anesthetics are general depressants of the central nervous system, while drugs such as caffeine can be general stimulants [6].

Psychoactive drugs generally affect psychological function through interaction with the normal function of the nervous system [1, 6–8]. The brain contains billions of neurons supported by glia. Glia are considered supporting tissue for the nerve cells. Some form myelin, which facilitates axon function. Others are involved in metabolic activity, and the formation of the blood-brain barrier. Ongoing research suggests

that glia may, in fact, serve a more active role in brain function than previously believed [3].

The cell body contains the nucleus of the neuron. It is the center of metabolic activity. Dendrites extend and branch from it, and connect to the terminal processes of other neurons to form synapses. The axon is a single, often long, process, which arises out of the cell body to connect to other neurons.

The concentration of ions, like potassium, sodium, chloride, and calcium within the cell is not equal to the concentration outside the cell. As a result, the cell membrane carries a charge across it, like a microscopic battery. When a nerve fires, the membrane allows ions to cross, depolarizing it briefly. The depolarization travels down the length of the axon (an action potential). At the terminal process, packets of chemicals – neurotransmitters – are released across the membrane into the synapse, where the terminal process connects to the dendrite of another neuron.

The surface of the dendrite contains special proteins called a *postsynaptic receptor*. The axon may contain presynaptic receptors as well. Each receptor is specialized to react to a specific neurotransmitter. The effect may be to excite the neuron or to make excitation more difficult – to inhibit it (depending on the neurotransmitter and receptor). When the sum of excitatory minus inhibitory stimulation exceeds a threshold, the nerve will fire.

The system is regulated through feedback mechanisms mediated by (presynaptic) autoreceptors and secondary messengers. When stimulated, autoreceptors on the presynaptic neuron signal the cell to stop release of neurotransmitter. Secondary messengers within the postsynaptic neuron modulate metabolic processes in the cell, including protein production. This controls neural plasticity, including long-term potentiation, long-term depression, down regulation and up regulation of receptors.

Neurotransmitter molecules are removed from the synapse by the presynaptic neuron (which released them) through a reuptake process. Once removed, the neurotransmitter does not interact with the receptor, until it is released again. Some neurotransmitter is inactivated through enzyme-assisted metabolic degradation.

The synapse is the site of action of most psychoactive drugs.

Neurons are organized in circuits, with specialized function. The systems that are most interesting to the psychiatrist are the limbic system, the basal ganglia, and the thalamocortical system.

The limbic system is involved with the experience and expression of emotion. Basal ganglia are involved in both motor and cognitive function. The thalamocortical system is involved in sensation, movement, and cognition.

Drugs of abuse affect DA circuits in the nucleus acumbens, an area of the brain involved in learning and motivation. The reinforcing effect of such stimulation is difficult to overcome, as reflected in the rates of lapses and relapses in recovering addicts (*see* **Addictions**).

A non-comprehensive list of neurotransmitters follows:

- Dopamine (DA);
- serotonin (5-HT);
- acetylcholine (ACh);
- norepinephrine (NE);
- gamma aminobutyric acid (GABA);
- glutamate (Glu);
- endorphins;
- enkephalins;
- histamine; and
- aspartate.

Therapeutic Classes of Drugs

Drugs are often classified in terms that identify the target syndrome or symptoms for which the particular drug was first marketed. Thus, we have antipsychotic drugs, antidepressants, sedative hypnotics, stimulants, mood stabilizers, and cognitive enhancers. Over the course of time, however, drugs are often used effectively for purposes other than those for which they were initially marketed. Some antipsychotic drugs can be used for anxiety, depression, and mood stabilization. Some antidepressants are used for first line treatment of anxiety disorders. Other classification schemes based upon chemical structure or target chemical systems are sometimes employed by practitioners. Thus, various drugs may be described as benzodiazepine, or tricyclic, or selective serotonin reuptake inhibitor (SSRI).

Antipsychotic Medication

The practice of psychiatry was revolutionized in the 1950s with the introduction of chlorpromazine, the

first effective antipsychotic drug. Its use reduced the need for restraints, seclusion, and locked psychiatric facilities [6]. As the only effective treatment for psychosis at the time, it was accepted rapidly, despite its side effects.

The success of chlorpromazine stimulated the development of other phenothiazine drugs: thioridazine, fluphenazine, perphenazine, and trifluoperazine. In attempts to increase potency while reducing side effects, the pharmaceutical industry developed butyrophenones (haloperidol), thioxanthenes (thiothixene), dihydroindolones (molindone), and dibenzoxazepines (loxapine). By the 1980s, clozapine was recognized as an effective treatment for psychotic illness, which had not responded to other medications. Its significant toxicity (agranulocytosis) necessitated weekly blood counts, and precluded its use as a first line treatment in the United States. However, its atypical neurochemical profile, its lack of movement side effects, and its affect on negative symptoms of schizophrenia, suggested significant advantages over older line medications. Olanzapine, risperidone, quetiapine, ziprasidone, and aripiprazole were developed in attempts to provide clozapine's therapeutic advantages without potentiating agranulocytosis. These second-generation antipsychotics, also known as *atypical antipsychotics* are now used more frequently than neuroleptics for treatment of chronic psychosis, as their side effects are generally milder and more easily tolerated by patients.

Antipsychotic medication is indicated for treatment of schizophrenia, schizoaffective disorder, schizophreniform disorder, or psychotic symptomatology caused by medical disorders.

Symptoms of schizophrenia can be divided into positive and negative symptoms. Atypical antipsychotics are more effective than first-generation drugs for negative symptoms, which include flat or blunted affect, inactivity, diminished pleasure in activities, and poverty of thought. First-generation drugs primarily affect positive symptoms, including delusions, hallucinations, confusion, and anxiety [9–12].

Blockade of some DA receptors (D_2) is associated with both the antipsychotic effect and movement side effects of these drugs. (In fact, the first psychiatrists to use chlorpromazine did not expect to see antipsychotic effects without an extrapyramidal syndrome.) The blockade of some serotonin receptors (5-HT_2) is associated with relief of negative symptoms, as well as mitigation of movement side effects [1, 6, 7].

Side effects of antipsychotic medication include sedation, orthostatic hypotension, dry mouth, constipation, blurry vision, urinary hesitancy, extrapyramidal effects, weight gain, and metabolic effects.

First-generation antipsychotics were differentiated from each other on the basis of their side effect profiles, rather than their efficacy. These side effects, related to the drugs' effects on cholinergic, adrenergic, and histamine receptors [1] were understood in relation to differences in the structures of the side chains of these molecules.

Anticholinergic effects include dry mouth, constipation, blurry vision, confusion, and urinary hesitancy.

Adrenergic blockade may cause changes in blood pressure, and cardiac rhythm, as well as symptoms of dizziness.

Histamine blockade is associated with sedation, drowsiness, and weight gain.

Extrapyramidal side effects are caused by DA blockade. DA and ACh are neurotransmitters of the extrapyramidal motor system, involved in posture and coordinated movement. Excessive blockade of DA receptors in this system may lead to an imbalance, and one of four extrapyramidal syndromes: Akathisia, dystonia, Parkinson's syndrome, or tardive dyskinesia.

Akathisia is an uncontrolled sense of inner restlessness, which must be distinguished from anxiety. If it is mistaken for anxiety, and treated with increased dose of medication, it will be worsened.

Dystonia is spasm of the muscles, usually of the head and neck.

Parkinson's syndrome includes muscular rigidity, tremor, slowed motor responses, and diminished facial expression.

Tardive dyskinesia is an often irreversible effect of antipsychotic medication characterized by involuntary movements of the mouth and tongue, as well as of the trunk and extremities.

Akathisia, dystonia, and Parkinson's syndrome may be treated as they emerge through the use of anticholinergic agents, minor tranquilizers, or adjustment in dose of antipsychotic medication.

While various drugs have been used to diminish symptoms of tardive dyskinesia, there is no cure. Discontinuation of the antipsychotic medication will

lead to initial worsening of dyskinesia. Over time, symptoms often will remit.

Atypical antipsychotic drugs are less frequently associated with tardive dyskinesia, or other extrapyramidal side effects, than older first-generation antipsychotics.

Significant weight gain is a common problem with antipsychotic drugs, and appears to be associated with an increased risk of diabetes. Aripiprazole and ziprasidone are less likely than other agents to be implicated in weight gain.

Neuroleptic malignant syndrome is a rare complication of antipsychotic drug use. It is characterized by severe muscular rigidity, fever, increased blood pressure, increased heart and respiratory rate, and changing levels of consciousness. Laboratory testing show elevations in creatine phosphokinase (CPK), sometimes along with altered liver functions, and myoglobin (a muscle protein) in the blood or urine. Immediate treatment with supportive symptomatic measures and discontinuation of antipsychotic medication is necessary when this diagnosis is made. Treatment with DA agonists as well as benzodiazepines should be considered with high fevers.

Antidepressants

Iproniazid was an antituberculous agent developed after World War II. After its mood-elevating qualities were noticed, it was investigated, and then marketed as an antidepressant in the late 1950s. The therapeutic action was a result of inhibition of monoamine oxidase (MAO) enzymes, which break down serotonin and NE.

Iproniazid was withdrawn because of toxic effects on the liver. Other MAO Inhibitors were developed, but their use was limited because of the need for dietary restrictions to avoid potentially fatal hypertensive reactions. Recently a transdermal form of selegiline was developed, allowing fewer dietary restrictions.

Around the same time that iproniazid was developed, phenothiazine-like drugs were being tested for antipsychotic effects, with the hope that new drugs could be found without the side effects of chlorpromazine. One, imipramine, was relatively ineffective in calming psychotic patients. However, it did have a therapeutic effect on depressed patients, especially those characterized by regression and inactivity. It was marketed as the first tricyclic antidepressant.

Over the following years, several other tricyclic antidepressants were developed: desipramine, amitriptyline, nortriptyline, clomipramine, trimipramine, doxepin, protriptyline, amoxapine, and maprotiline (a tetracyclic). All block the reuptake of NE into nerve terminals. Imipramine, amitriptyline, doxepin, nortriptyline, and especially clomipramine, also block reuptake of serotonin (5-HT).

These drugs are all pharmacologically "dirty". In addition to their desired effects, they bind to a host of other receptors, with resultant unwanted side effects, including faintness, cardiac arrhythmias, constipation, dry mouth, sedation, and weight gain.

SSRIs or SRIs represent an important pharmacological advance in the treatment of depression, as pharmacologically cleaner drugs, their safety, and tolerability have led to their becoming the predominant class of prescribed antidepressants.

Venlafaxine and duloxetine, serotonin and norepinephrine reuptake inhibitors (SNRIs) may be more useful than SSRIs in treating chronic pain.

Bupropion effects DA and NE reuptake. Trazodone and nefazodone block a portion of the serotonin receptors. Mirtazapine blocks some alpha-adrenergic and serotonergic receptors. These drugs are less likely to cause sexual side effects than other antidepressants.

All antidepressants are indicated for treatment of major depression, including vegetative symptoms of appetite and sleep disturbance, fatigue, diminished sex drive, anhedonia (loss of the ability to experience pleasure), agitation, restlessness, or psychomotor retardation.

In addition, many are effective for generalized anxiety disorder, panic disorder, posttraumatic stress disorder, insomnia, and enuresis.

Tricyclic antidepressants and SNRIs are effective in chronic pain conditions. SSRIs and clomipramine are effective in obsessive compulsive disorder [13–15].

Bupropion can reduce craving for cigarettes, probably as a result of its dopaminergic effect on the nucleus accumbens.

The mechanism of action of antidepressants is not fully understood. While antidepressant drugs exert immediate effects on brain receptors, the therapeutic effect is delayed, usually 2–6 weeks. This suggests that the therapeutic effects arise from a cascade of adaptive processes to repeated administration of the drug. Increased availability of serotonin and/or NE

in the synapse evokes negative feedback mechanisms to restore homeostasis. This includes downregulation and desensitization of receptors, and alterations in tonic inhibition and stimulation mediated through secondary messengers in the neuron, which signal formation of new protein.

Newer antidepressants present fewer, less toxic side effects than older tricyclics and MAO Inhibitors. As a result, patients are more likely to comply with treatment long enough to obtain a therapeutic effect than those prescribed tricyclic antidepressants. Patient acceptability and relative safety in overdose have contributed to the popularity of these drugs.

Tricyclic antidepressants cause side effects related to their effects on the autonomic nervous system. These include dry mouth, dizziness, palpitations, blurry vision, constipation, tachycardia, orthostatic hypotension, and cardiac arrhythmias.

MAO Inhibitors may cause postural hypotension. Drug and diet interactions may precipitate hypertensive crisis or serotonin syndrome, which includes restlessness, muscle twitching, sweating, shivering, and tremor [16].

SRI and SNRI side effects include nausea, headache, delayed ejaculation, and impaired orgasm. Bupropion can cause anorexia, insomnia, and agitation. Trazodone can cause priapism. Mirtazapine is sedating and can cause weight gain.

Patients with bipolar disorder treated with antidepressants may be at risk of switching from depression to a hypomanic or manic state [17–19].

Mood Stabilizers

Cade first described the therapeutic effects of lithium on mania in 1949. It was first approved by the US FDA for treatment of acute mania in 1970s, and for prophylaxis of bipolar disorder in 1974.

While lithium is quite toxic, it is very effective for treatment of both manic and depressive phases of bipolar disorder. Several large-scale studies have demonstrated significant reduction in suicide risk associated with lithium therapy [20, 21]. There is an increase in suicide risk after discontinuation of lithium [22].

Adverse effects include acne, leucocytosis, hypothyroidism, hypoparathyroidism, nephrogenic diabetes insipidus, and kidney damage. Signs of toxicity include tremor, weakness, fatigue, nausea, vomiting, cardiac arrhythmias, hypotension, shock, stupor, coma, and even death.

Safe use of lithium requires monitoring of blood levels, since the therapeutic dose is close to the toxic dose. Evaluation of serum electrolytes, thyroid, parathyroid, renal, and hematological function is necessary at the commencement of treatment and periodically during the course of therapy.

Valproate was approved by the FDA for treatment of acute mania in 1994. It is less toxic, and easier to prescribe than lithium. It consequently has been prescribed more frequently than lithium, even though the evidence of its effectiveness for prophylaxis is not robust.

In 2003, the FDA approved the use of lamotrigine for long-term treatment of bipolar disorder. This anticonvulsant demonstrates little effect on acute mania. However, it shows antidepressant effect and prophylactic effects in bipolar patients. Other anticonvulsants, which are used as mood stabilizers, include carbamazepine, gabapentin, pregabalin, topiramate, tiagabine, oxcarbazepine, and zonisamide.

Antipsychotic drugs such as olanzapine, aripiprazole, and quetiapine are also termed *mood stabilizers* because of their demonstrated roles in treatment of bipolar disorder [23].

Anxiolytics

Chlordiazepoxide and diazepam were the first benzodiazepines, introduced in the early 1960s. They were soon widely prescribed by physicians for pathological anxiety, because they were effective and safer than meprobamate and barbiturates. Other benzodiazepines were subsequently developed and marketed, including clorazepate, alprazolam, oxazepam, and clonazepam.

All benzodiazepines exhibit anxiolytic, sedative hypnotic, muscle relaxant, and anticonvulsant effects. The primary differences among them are a result of pharmacokinetic properties, including rates of absorption and elimination.

Benzodiazepines bind to specific receptors in the brain – the GABA – BZ complex. GABA is a primary inhibitory neurotransmitter in the brain. When it is bound to its receptor, a chloride channel on the membrane is opened a little, making depolarization of the nerve more difficult. GABA works more effectively in the presence of a benzodiazepine.

Sedation and drowsiness are common side effects of benzodiazepines. Motor impairment may occur, as may memory impairment. Tolerance may occur, and physical dependence is common with prolonged treatment. Abuse and dependence (*see* **Substance Abuse**; **Addictions**), as defined by Diagnostic and Statistical Manual of Mental Disorders-IV (DSM-IV) [24], are less common, but may still be problematic.

Buspirone is a unique nonsedating nonbenzodiazepine anxiolytic drug, which appears to exert its effect through actions on a subset of serotonergic receptors (5-HT_{1A}). It is effective for generalized anxiety disorder, but not for panic attacks. Its effect builds up slowly, over several weeks. Side effects may include dizziness, headaches, and nausea.

Addition of buspirone to an antidepressant can be beneficial for patients with inadequate or poor responses to an initial trial of antidepressant treatment [25–28].

Stimulants

Amphetamines and methylphenidate stimulate the release of DA and NE at the synapse. They are useful for the treatment of attention deficit disorder [29–32] (*see* **Psychopharmacology: Child and Adolescent**), and have been used for appetite suppression, fatigue, and treatment of poststroke depression.

Side effects include nervousness, insomnia, and agitation. Arrhythmias and seizures may occur. Hallucinations and delusions are uncommon with stimulants administered orally at usually prescribed doses. They are a frequent complication of inhaled or injected amphetamines.

Stimulant psychosis, including visual hallucinations, disorientation, agitation, pacing, and thought disorder, may persist for months after cessation of amphetamine use.

Modafinil is similar to stimulants, in that it increases wakefulness. It does not increase reinforcement, like other stimulants. Thus it is, in a class by itself, a "wakefulness promoting agent". It is indicated for narcolepsy, and the fatigue associated with shift work and sleep apnea.

Drug Interactions

Concurrent use of more than one drug, or a drug with other substances, may lead to altered pharmacological effect – a drug interaction. Pharmacokinetic interactions occur when an agent alters the absorption, distribution, or metabolism of a drug. Pharmacodynamic interaction involves changes at the receptor, or the biologically active site.

The absorption of buspirone and ziprasidone are enhanced in the presence of food. Antacids may decrease absorption of some antibiotics. Drugs that are bound strongly to protein, like fluoxetine, will displace other protein-bound drugs, possibly enhancing their action or leading to toxic effects. Excretion of lithium is diminished with certain diuretic drugs, leading to increased serum concentration. Grapefruit juice may inhibit Cytochrome P450 enzymes, which break down imipramine, leading to increased serum concentration. These are all pharmacokinetic interactions.

Many drugs are metabolized by the Cytochrome P450 family of enzymes, predominantly found in the liver, the gut, and the brain. The activity of these enzymes, in turn, is enhanced or inhibited by many drugs. Many significant pharmacokinetic drug interactions are mediated by changes in these enzymes [33]. Much variability in individual sensitivity to therapeutic agents can be explained by variations in the concentrations and activities of these enzymes.

Pharmacodynamic interactions can cause increased or decreased pharmacological effect. For example, alcohol can potentiate the sedative effect of hypnotic drugs. Lithium can potentiate the effect of antidepressant drugs. MAO Inhibitors can provoke a serotonin syndrome when administered with an SSRI.

Attention to the potential for drug interactions allows a psychopharmacologist to safely and effectively provide rational treatment.

Drug Testing

For most psychotherapeutic drugs, the relationship between serum concentration and clinical effect has not been established. Lithium, valproate, carbamazepine, and nortriptyline are important exceptions. The difference between the therapeutic dose and a toxic dose of lithium is small. Periodic measurement of serum concentration is necessary to safely prescribe it. The interactions of carbamazepine and valproate with the Cytochrome P450 enzymes necessitate blood testing to establish an appropriate therapeutic dose. Sometimes physicians will check on the

concentration of other prescribed drugs when toxicity is suspected. Sometimes less expensive qualitative testing can confirm or refute suspicions of noncompliance. Generally, however, adjustment of doses of psychotropic medication is made on clinical grounds.

Qualitative testing for the presence of drugs in blood, urine, saliva, or hair samples is often part of a treatment program for patients with substance use disorders (*see* **Drug Testing: Urine**; **Amphetamine**; **Benzodiazepines**; **Cannabis**; **Cocaine**; **Opioids**). Serum concentration is often presented to the forensic psychopharmacology consultant for interpretation (**Toxicology: Forensic Applications of**).

Substances associated with dependence tend to evoke tolerance over time. Thus, without additional data, one cannot usually determine from a single sample of body fluid, the level of intoxication experienced by a user. Was the blood level the result of one use or many over time? How was the drug ingested? How long ago? Were blood levels on their way up, or down? Or was this steady state?

Concentrations of drugs obtained during necropsy are often quite different than those obtained during life (Postmortem blood has been described as a fluid resembling blood that is obtained from the vasculature after death [34]). A drug that has been concentrated in solid organs and tissues will diffuse into the blood after death, increasing its concentration. This was demonstrated in the case of a man who committed suicide by ingesting an overdose of imipramine. Concentrations of imipramine and its active metabolite, desipramine, obtained during postmortem examination 7 h after death were compared with concentrations in blood samples obtained in the emergency room 2 h prior to death. Postmortem imipramine concentrations ranged from 1.8 to 7.9 times the concentration of the emergency room sample (depending on the site in the body from which the blood was drawn), while desipramine ratios ranged from 1.6 to 6 [35].

The Volume of distribution (V_d) is a hypothetical volume of body fluid that would be necessary if the total amount of drug in the body were distributed uniformly in the same concentration as in the plasma. In general, lipophilic drugs have a high volume of distribution. Caffeine, which dissolves equally in water and in fat, has a V_d of $1\,l\,kg^{-1}$. For imipramine, it is $11–16\,l\,kg^{-1}$. For sertraline, it is in the range of 50–80. Drugs with a high volume of distribution will show the greatest change in concentration postmortem (*see* **Toxicology: Analysis**).

SAMUEL I. MILES

Psychopharmacology: Child and Adolescent

Psychopharmacology's Role in Treatment of Child and Adolescent Mental and Behavioral Disorders

Psychopharmacology is the study of drug–behavior relationships and the use of medications to influence affective and emotional states and thoughts. In children and adolescents, psychotherapeutic medications are best used in conjunction with a holistic bio-psycho-social approach to identify youth's problems and at times in combination with specific nonmedication-based therapies [1]. Transactions between individual genetics, environmental, family and social stresses, and protective factors are currently considered integral to the development of or protection from psychiatric illness. The use of psychotherapeutic medication, when based on scientific evidence, has an important role in fostering improved adaptation in the face of an individual's lowered threshold toward disease. Psychotherapeutic medications are not intended to affect a cure but rather to help by reducing problematic behaviors or relieving mentally painful symptoms.

If a biologic predisposition to a mental disorder lowers the threshold at which a disease becomes evident, then understanding the nature of the risk exposure, while not always immediately evident in the chain of causality, is important. Examples include how the toxic effects of lead and mercury on the development of human nervous system lead to disease states, learning disabilities, and behavioral disorders. Likewise, fetal alcohol effects are discussed as public policy issues, while families, pediatricians, child and adolescent psychiatrists, teachers and the juvenile, and adult justice system attempt to mitigate the damage at a more individual level.

Our knowledge of the pernicious effects of multigenerational cycles of physical and mental maltreatment in childhood, leading to states of affective dyscontrol beginning in childhood and continuing throughout the life span, has expanded to include neuroanatomical and biochemical proof of the disordered states. Addictions are diseases compounded by genetic predispositions that affect motivational circuitry in the brain. Interrupting the cascading effects of untreated disease on the individual, families, and larger society is an important goal. Medication is a component in treatment. There are multiple textbooks on this subject and this article addresses only a few of the issues [2–4].

The Prescriber, Privacy, and the Court

Subpoenas to courts do not provide the authority to release confidential health information that is protected by privacy laws. The prescriber needs to assure that the person who controls protected information has consented to its release or that there has been a judicial determination that privilege does not apply. If uncertain and questioned in court, the prescriber should indicate that the information is privileged and follow the direction of the judge.

Tort Law and the Standard of Care

The use of the word prescriber rather than physician is intended to reflect the fact that many jurisdictions allow nonphysicians such as nurse practitioners to prescribe medications. The tort of negligence has been described as "conduct that falls below the standard regarded as normal or desirable in a given community for those who are perceived to be competent in carrying out their profession within the standards of reasonable skill and proficiency" [5].

In prescribing the medications for psychiatric illness, liability for malpractice does not ensue necessarily from a bad outcome but rather from deviation from the accepted use of the medication. In most jurisdictions, the standard of care in assessing negligence is a matter of medical judgment. In making this decision, rarely does the law provide an answer but rather testimony of experts, articles in learned journals and textbooks, guidelines from professional organizations, etc. will be used to advise the decision maker.

Lawsuits against prescribers of psychotherapeutic medicine often make claims of negligence in either failing to obtain an informed consent for or in the prescribing, administering, and/or monitoring of medications.

Informed Consent for Psychotheraputic Medications in Children and Adolescents

Treatment with psychotherapeutic medication requires informed consent. Applebaum and Gautheil state "Treatment without any consent or over a patient's objections may constitute a battery, but treatment after an inadequate consent is properly considered as a form of malpractice" [6].

A free person is considered to have a right to control what happens to his or her body. Most jurisdictions give the individual patient and not the prescriber of treatment the right to balance risk *versus* benefit of the procedure and to consent to it or refuse it.

Informed consent involves two essential parts: a document and a process. It is important to document it in the medical record but it is more than a signed piece of paper. Ongoing explanations help the patient make wise decisions about whether it is essential to begin or continue taking a particular treatment or medication.

The three elements of informed consent are as follows:

1. the mental *competency* to make a rational decision;
2. the *voluntary* nature of the decision; and
3. *sufficient information* to make a decision.

In children and adolescents, the issue of competence and substitute decision making are especially involved.

Competency

Statutory rules determine when the age of competence to seek or refuse psychiatric treatment occurs. This often occurs before the age of majority. Emancipated minors have full competence. Statutes and age of consent vary from one jurisdiction to another. Informed assent of the older child or adolescent helps the therapeutic relationship and improves compliance. Research trials are governed by more stringent guidelines in this regard. In the United States, the National Commission for Protection of Human Subjects of Biomedical and Behavioral Research has established age 7 as a reasonable minimum age for children involving in some kind of assent or dissent process and "parental permission" rather than "proxy consent" is considered the norm [7].

Sometimes clarification from a court as to who has authority for decision making for a child may be necessary. Divorced or separated parents with shared decision-making powers might disagree with one another's opinion. Substitute nonparent decision makers who are actively raising the child (grandparents, foster parents, social service agency workers, etc.) may not have the medical decision-making authority to consent.

Voluntary Decision Making

Regarding the issue of substitute decision making, one should consider the agency of the prescriber. Children and adolescents rarely seek psychiatric treatment on their own and are usually dependant upon their parents who act as decision makers. Because the parents are so much a part of the child's decision to be in treatment to some extent, the prescriber should be aware when he or she is acting in their agency as well as the child's. Other situations of potential for dual agency exist when clinicians are contracted to or are employed by schools or social agencies or treatment facilities. The prescriber should assure that school authorities or others are not coercing decision maker to medicate the child.

Information to Make the Decision

To make a submissible case based on negligence in obtaining informed consent, a plaintiff must show nondisclosure, causation, and injury.[a] To show nondisclosure, a plaintiff must include evidence of the risks involved and what disclosures were made by the prescriber.[b] Some jurisdictions have a professional standard of disclosure that the sufficiency of information disclosed should be what a "reasonable clinician" would reveal to his or her patient. Expert testimony of what risks a reasonable medical practitioner would disclose under the same or similar circumstances is required.[c,d] A plaintiff must also establish causation between the inadequate disclosure

and the injury.[e] The issue is whether a reasonable person in the plaintiff's position would have consented to the procedure had the proper disclosure been made.[f] The plaintiff has the burden of producing evidence from which a jury or other decision maker could determine whether a reasonable person would have consented to the procedure.[g]

Other jurisdictions use a "reasonable person" standard. This would involve disclosing the information sufficient for a reasonable patient or legal decision maker acting on that patient's behalf to make a rational decision. In those jurisdictions, the clinician should discuss the following matters with the patient and or authorized decision makers:

1. The nature of the condition for which medication is being proposed.
2. The likely outcome of nontreatment.
3. The proposed medication treatment and how and to what extent that will benefit the patient and condition.
4. The risks and side effects associated with the medication. Risks of medications or other treatments proposed that should be disclosed should include those that a reasonable person would be likely to consider significant. The standard in malpractice case law is that the information not disclosed would have been considered substantial in evaluating the risk. Exceptions to this exist when severe harm could result if disclosure were made (principle of therapeutic privilege). Transparency in self-disclosure is important. The clinician's biases and skill level should be disclosed as that might also effect a patient's decision about the risk involved. If a clinician has never treated a certain condition before or never used a certain treatment before, it may be later be judged important to have informed the decision maker of this. Disclosure of potential conflict of interests or even the appearance of such conflict is recommended.
5. Alternative treatments available with their attendant benefits and risks.

Documentation

In the defense against a claim of negligence, legible and timely documentation of prescriptions and orders along with details of the informed consent process, and instructions given to patient and caregivers support the assertion that proper care was given. Prescriptions that are difficult to read pose a hazard to the patient. The prescriber should assure patient and caregivers understand instructions about dosages and interval between doses and potential side effects is important. Warning as to the importance of parental oversight and responsibility to safeguard potentially dangerous medicines should be given.

Documentation of all other medications the patient is currently taking and consideration of drug–drug interactions is a part of clinical care.

Refills, frequency of follow-up intervals to monitor for effectiveness, appropriate compliance with therapy and side effects is important, particularly in children and adolescents with medicines that have a potential for lethality in overdose, irreversible side effects, or abuse potential.

It is important to have permission to communicate with the other individuals involved with the child or adolescent's care about all medications that are being prescribed and about signs, symptoms of side effects, and positive responses to the medications. When a patient or their decision maker will not allow this, then the prescriber's ability to treat the patient is compromised.

Law of Agency/Vicarious Liability

Multiple professional disciplines interact with individual children and families. Pediatric psychopharmacology is practiced within this greater framework. Given the multidisciplinary nature of the treatment of a child or adolescent with interactions with family, school, and larger society, there might be tensions or disagreement at times of critical decision making regarding issues such as dangerousness to self or others, diagnostic labeling, as well as treatment choice recommendations. The prescriber often does not have input on important treatment decisions. The concept of *respondeat superior* is affected by these facts. Most others interacting with the child or adolescent are not acting as agents for the prescriber. The prescriber, even a physician, collaborating with a therapist is not responsible for the actions of that therapist unless he or she is directing these activities in a supervisory manner. The nonsupervisory nature of the relationship should be made clear so that false assumptions are not made.

Medication Practices

Psychotherapeutic medications for the treatment of mental illness are considered one of the most useful and important forms of treatment available for mental illness in both adults and youth. Millions of prescriptions are written annually. Prescribing medications has become so routine and commonplace; it is easy for prescribers and patients to lose sight of the risks involved.

Multiple factors have led to the increased recognition of mental illness in children and adolescents as well as the increase in medication use including the following:

1. The nature *versus* nurture controversy of the last century yielded an increased emphasis and understanding of the biology of mental illness. Biological psychiatry with primary emphasis on the individual's biological vulnerabilities interplaying with psychosocial stressors led to popularization of the simplistic concept of "chemical imbalance". A corollary to this concept was the idea that psychotherapeutic medications righted the imbalance. This notion was applied to youth as well as adults.
2. Large epidemiologic studies such as the 1999 Methodology for Epidemiology of Mental Disorders in Children and Adolescents (MECA) showed significant functional impairment due to mental or addictive disorders in approximately 1 in 10 of the pediatric population, for a total of four million in the United States alone [8].
4. Successful marketing by the pharmaceutical industry of psychotherapeutic medications had significant impact on both prescribers and the general public in terms of *increased expectations* of relief from distressing symptoms. Given the awareness of the availability of medications helpful in treating adults, there has been a willingness to treat youth without awaiting regulatory approvals.

Pediatric Psychohamacology in Practice

It is a statement of fact that most of the medications, psychiatric or not, used in children and adolescents, with the exception of stimulants, were not extensively studied or approved for use in this population. Manufacturers regularly put in disclaimers to that effect in their labeling. Therefore, the use of "off label" (i.e., not regulatory agency approved) prescribing remains the norm rather than the exception.

Pharmacodynamics is the branch of pharmacology that studies how medicines work. In general, psychoactive medications alter the biochemical environment in the synaptic space through either the blockade or activation and enhancement (antagonism, partial agonism, and agonism) of nerve cell membrane receptors. This in turn alters the way the nerve cells communicate.

In children and adolescents, more than in the midadult period in which most new medications are studied, the brain is developing by growing, and pairing down dopaminergic, serotononergic, and noradrenergic cell networks in areas of the brain, which are important to functions of attention, mood, anxiety, and perceptions. In adult populations these brain systems are relatively stable and the medications have been studied more extensively prior to approval and widespread use. Younger, developing brain systems may be permanently affected by mechanisms that are not well understood. Because of this, children and adolescents have differential risks when administered psychotherapeutic medicines. Examples include different risks of side effects such as extrapyramidal motor side effects and dyskinesias from antipsychotics as well as possibilities of overactivation of mood and attentional systems due to increased sensitivities to antidepressants.

Pharmacokinetics studies and informs us as to the absorption, distribution, metabolism, and excretion of medicines. It is important to understand that various people and subpopulations do this differently. In children and adolescents, the phamacokinetic properties of medicines need to be studied thoroughly for the safest administration of medicines that benefit them.

Children have a higher gastric and intestinal motility than adults thus favoring more rapid absorption. Prepubescent children and adolescents usually have fewer fat stores compared with adults, which may lead to higher plasma concentration of medicines in part distributed among fat stores. The metabolic breakdown of medications and toxins in the body differs. Excretion of medicines or the metabolites of medicines, usually by the kidneys might also be affected.

Treatment

Because standard of care is determined on all clinical data available for an individual child or adolescent, the following information is intended as informational only and not intended to imply adherence or deviance from the standard. Side effects are fairly common and so management should include regular periodic monitoring and routine reassessment as to the need to continue with the medication.

History

Review of history is very important for diagnosis and treatment planning. It is not unusual for psychiatrically ill children to have comorbid medical conditions that can influence their psychiatric symptoms. Developmental history should be reviewed with specific attention to development of gross and fine motor skills, speech and language development, affective relatedness, and attachments. A medical history (allergies, adverse drug reactions, acute and chronic illnesses, hospitalizations, injuries, loss of consciousness and traumatic brain injuries, and treatments) should be obtained. Previous laboratory findings and brain imaging if available should be reviewed.

Psychosocial history should include the family of origin, adoption, foster care, exposure to influences of alleged maltreatment, abuse, trauma, and losses.

Past psychiatric treatments and results should be reviewed.

A recent physical examination by the child or adolescent's primary care provider should be reviewed. Many psychiatric medications can be teratogenic and most teen pregnancies are unplanned. Sexually active postpubertal girls should have a pregnancy test along with counseling regarding the use of appropriate methods of birth control and methods of preventing sexually transmittable disease.

Documentation of the above and appropriate laboratory tests ordered prior to initiation of medication therapies and during ongoing monitoring is important.

Diagnosis

Accurate diagnosis in children and adolescents requires clinical assessment often using multiple sources of information including interactions with, observation of, and interview of the child or adolescent, parents, caregivers, and teachers if possible. Guidelines for assessment and treatment are available from the American Academy of Child and Adolescent Psychiatry, American Academy of Pediatrics and other organizations [9, 10].

Substance Abuse. Drug and alcohol screening with clinical questions augmented by urine toxicology for substances of abuse when indicated should be routine among adolescents and preadolescents. Substance-induced behavioral effects can mimic psychiatric illness and cause or aggravate other mental illnesses. Substance use disorders and tobacco addiction need treatment along with other mental illnesses. Making appropriate referrals for treatment of addiction and dependence and identification of patients or caregivers who might be misusing medications, altering prescriptions or getting multiple prescriptions from multiple sources (doctor shopping) is important.

Examples of Therapeutic Medications. *ADHD and the Use of Stimulants and Nonstimulants in its Treatment.* Attention deficit hyperactivity disorder (ADHD) is characterized by early childhood onset of an enduring pattern of inattention and/or hyperactivity and impulsive behavior. In total, 4–12% of children are affected by the disorder [11].

Many children can contain their behaviors during office visits and so collecting information about the child's behavior in multiple settings is most useful. Well-validated and normed behavior rating scales are available and useful in assessing and measuring treatment effects. These would include the Conners' Rating Scales-Revised; Brown Attention-Deficit Scales; and Swanson, Nolan, and Pelham (SNAP-IV) [12].

Stimulant Medications. In 1937, Bradley reported on the positive effects of amphetamine on children institutionalized for neurobehavioral reasons [13]. Since then, opposing social forces have exerted pressures for either wider acceptance of these medications or for more restrictions on their use. The existence of these pressures has led scientists to explore the issue and, for the most part, demonstrate the efficacy of these medicines [14]. Concerns regarding associations with sudden cardiac death have brought these medications into greater controversy in the recent years.

Nonstimulant Medications. Atomoxetine is a selective norepinephrine reuptake inhibitor that is superior to placebo in the treatment of ADHD at appropriate doses [15]. Although the manufacturer recommends once a day dosing, avoiding adverse effects while maintaining adequate therapeutic doses often requires twice a day dosing. Because it shares features with the antidepressants it is associated with an increased risk of suicidality.

Guanfacine and clonidine are antihypertensive medications that have found usefulness. They are generally used in children who cannot tolerate or as adjuncts to the other medications.

Antidepressant Medications, Mood Disorders, and Suicide. Major depression and bipolar mood disorders are enduring and disabling conditions. Suicide is among the most feared of outcomes in the field of mental health. Ninety percent of suicides occur in the context of psychiatric illness and mood disorders are the most likely illnesses to be associated with the act [16]. Suicide is a major cause of preventable death among youth [17].

The prevalence of mood disorders is relatively low before the onset of puberty and equally distributed among the two sexes. After puberty, however, the prevalence increases to adult levels. Various epidemiologic studies point to a prevalence of 5–10% of teens and young adults suffer from major depression or other disabling depressive disorders such as dysthymia and depressive disorder not otherwise specified [18].

Pharmacotherapy with selective serotonin reuptake inhibitor (SSRI) antidepressants either with cognitive behavioral or interpersonal psychotherapy for children and adolescents with major depressive disorder had been the first line and standard of treatment until 2003 and 2004 [1] when regulators in the United Kingdom, the United States, and the European Common Market, became concerned about possible or even causal links between youth suicidality and antidepressants of all classes. UK regulators went on to advise against the use of almost all antidepressants in persons below 18 years. Black box labeling and letters of warning from manufacturers to prescribers were issued in the United States. These expressed warnings and concerns were based on collective data comparing placebo to active medication in multiple different trials, which showed increased rates of suicidality on the active medications and have been extensively reviewed [19].

The stance of regulators was contrary to the opinion of many prescribers who felt the medicines to be very helpful in the real world of clinically complex populations. The warnings had both intended and unintended consequences. Internationally, warnings had the effect of reducing prescriptions to youth by some 20% in 2004 [20]. Coincidental to this decrease in prescribing of antidepressants was a marked increase in actual suicide rates among youth. There exists epidemiologic data showing an inverse correlation between the SSRI prescriptions and suicide rates in multiple population groups in several countries [21, 22]. Antidepressant prescriptions seem to have a protective effect by reducing suicide rates such that strong arguments exist regarding the potential harm resulting from a reduction of SSRI antidepressant use [23]. Indeed, according to the United States Center for Disease Control, after having dropped some 28% from 1990 until 2004, suicide rates for youth in the United States surged 8% leading to 4599 deaths in 2004 following the issuance regulatory letters and black box warning [17]. Prescribers have been left in a conundrum of needing to treat their patients with these medicines despite alarming warnings from regulatory authorities. The best practice to follow is to assure that the diagnosis is correct, the patient makes a full informed consent and to monitor for the development of new onset of suicidal ideations or agitation.

The results of the above-noted reviews [19], which used meta-analytic methods, suggest that there is no benefit to the use of tricyclic antidepressants in children and adolescents with depressive disorders and that the risks, given their toxicity in overdose, generally outweigh the benefits of their use in this population.

SSRI antidepressant medications remain helpful in the treatment of mood and anxiety disorders [24].

Antipsychotics. Antipsychotics are used in treating hallucinations, delusions, hostility, aggression, and disorganized thinking associated with major mental illness such as bipolar disorder, major depression with psychotic features, and schizophrenia. These diseases often manifest in late adolescence or young adulthood and often go undiagnosed for several years. Antipsychotics are also used in the treatment of children with autism and mental retardation who

exhibit prominent irritability, aggression, and self-injurious behavior.

It is thought that blockade of D_2 receptors in the mesocortical and prefrontal systems is responsible for the antipsychotic effects. With older antipsychotics, the degree of D_2 receptor blockade is predictive of the potency of antipsychotic effect on hallucinations, delusions, agitation, hostility, and disorganization. Many side effects are also a function of the medication's D_2 binding properties to receptors in the basal ganglia. Drug-induced Parkinson symptoms such as feeling stiff, shuffling gait, tremor, drooling, and masked facial expression led to the mislabeled term *chemical restraint* for this group of medicines that helped many people with mental illness to return to more normal lives.

The newer second generation antipsychotics (SGAs) (olanzapine, risperidone, paliperidone, ziprasidone, quetiapine, aripirazole, and clozapine) were promoted as having fewer side effects on movement and positive effects on motivational circuitry in the prefrontal cortex. The SGAs seemed to balance out many of the untoward effects of D_2 blockade through effects on serotonin 2A receptors, making them agents of first choice. Clozapine, however, because of its potential for causing dangerous agranulocytosis, is reserved for treatment refractory disease.

The number of studies supporting their efficacy and safety in children and adolescents is limited. Children, adolescents, and young adults are particularly susceptible to antipsychotic drug-induced movement disorders (Extra-Pyramidal Symptoms (EPS), akithesia, and diskinetic side effects). The newer medicines have proven to have fewer with drug-induced movement disorders in adults but have problematic effects related to weight gain, glucose regulation, lipid regulation, sedation, prolactin levels, and cardiac conduction. It is hypothesized that because of varying proportions of blockage and, in the case of aripiprazole, the partial agonism of the dopamine receptors, as well as the above noted blockade of serotonin receptors, the effectiveness and sensitivities to side effects in children and adolescents varies markedly between one medicine and another. This means caution should be exercised in their use, careful review of improvement of targeted symptoms and monitoring for side effects. Of note, risperidone received approval from the Food and Drug Administration (FDA) for an indication in the treatment of children with autism and severe problem behaviors [25, 26].

Children and adolescents are generally treated with the lowest possible effective dose of these medications with periodic monitoring for side effects including baseline and follow-up weight measures and laboratory testing for glucose and lipid abnormalities and abnormal involuntary movements all the while examining the benefits and the need for ongoing use. Because of the potential for significant and sometimes irreversible side effects, documentation of the consideration of the risk benefit ratio prior to initiation and while continuing with these medications is important.

Mood Stabilizers. Mood stabilizers are used in the treatment of bipolar disorder and schizoaffective disorders. The term *mood stabilizer* gathered wide use after publication of reports in the late 1980s demonstrating the efficacy of carbamazepine and divalproex in adult patients with bipolar disorder giving more choices than lithium and adjunctive agents [27]. Oxcarbazapine and lamotragine are now also widely used. Use of these medications has migrated into pediatric use. These medicines are associated with potentially serious side effects; some side effects are more prominent in children and adolescents, including hirsuitism and polycystic ovary syndrome in adolescent girls associated with divalproex and increased incidences of severe rashes with lamotragine in children and adolescents. Oxcarbazapine is metabolized more rapidly in preadolescents. Patient, parent, and caregiver education as to side effects is important.

Routine laboratory evaluations include complete blood-cell count with differential and platelet counts, metabolic profile including liver function tests, pregnancy tests, thyroid function monitoring, as well as plasma drug levels of lithium, valproate, and carbamazepine.

QiaAmp

The *QIAamp® DNA Micro Kit* DNA extraction method utilizes a silica-based spin column to separate DNA from other cellular components that are released after cell lysis. DNA binds, specifically, to the silica-gel membrane embedded within the microcentrifuge tube while other cellular components pass through. This process isolates a purified DNA extract as the washing steps remove inhibitory proteins and divalent cations, which are the cofactors for harmful nucleases. DNA is released from the silica column by the addition of an elution buffer. The entire procedure takes approximately 30 min. Lyophilized carrier RNA can be added to the lyzed sample at the beginning of the process to facilitate membrane binding. This is recommended for forensic samples; however, care must be taken to ensure that downstream quantitation methods are DNA specific. QiaAmp microextraction methods have the advantage of being a simple, reliable, flexible, single-tube technique that is highly amenable to automated liquid handling platforms. In many laboratories, QiaAmp is used as a postextraction purification step, particularly for degraded or severely compromised tissue.

Quality Systems: Toxicology

Introduction

Quality management (QM) aims to ensure that the activities necessary to design, develop, and provide a product or service are effective and "fit for purpose". QM including laboratory accreditation, i.e., inspection and independent certification of laboratories to ensure, as far as possible, the quality and reliability of the work produced, is becoming increasingly important [1]. A prerequisite for laboratory accreditation is to have a documented QM system. It was thought that the likelihood of examination in court was sufficient to ensure the accuracy and reliability of forensic toxicology results, but implementation of QM systems and accreditation of laboratories by regional or national accreditation bodies provide a far more robust method of ensuring quality. Obviously, all this has to be paid for and inspectors themselves have to be trained and accredited.

The ISO 9000 family (ISO 9000:2000 and 9001:2001) form a basis for many QM systems (Box 1) and are maintained by the International Organization for Standardization (ISO, http://www.iso.ch/iso/en/iso9000-14000/index.html, accessed 27f August 2007). A related set of standards, ISO 14000, is concerned with environmental management. ISO

Box 1. Some of the requirements in ISO 9001:2001

- A set of procedures that cover all key processes in the organization being managed
- Active monitoring of processes to ensure that they are effective
- Adequate record keeping
- Monitoring the quality of output, with implementation of appropriate corrective action if necessary
- Regular review of individual processes and the QM system itself for efficacy
- Implementation of a culture of continual improvement

works in collaboration with the International Electrotechnical Commission (IEC) and other metrological organizations.

ISO/IEC 17025:2005 is the main standard used by testing and reference laboratories to implement a QM system. It replaces ISO/IEC 17025:1999 (formally ISO Guide 25 and EN 45001). There is much in common with ISO 9000/9001, but ISO/IEC 17025 adds the concept of competence. There are two main sections: (i) management requirements that are primarily related to the operation and effectiveness of the laboratory QM system and (ii) technical requirements that address the competence of staff, methodology, and test/calibration equipment. ISO 15189:2007 defines standards for the operation of a medical laboratory, and is consistent with ISO 9000/9001.

Laboratory accreditation procedures and conformity assessment bodies (CABs) are assessed against ISO/IEC 17011:2004 (previously ISO/IEC Guide 58). CABs are defined as organizations providing assessment services such as testing, inspection, management system certification, personnel certification, product certification, and calibration.

Laboratory Accreditation

The International Laboratory Accreditation Cooperation (ILAC) website (http://www.ilac.org/, accessed 27 August 2007) gives details of accreditation bodies in many countries. Key elements are the Quality Policy, a statement of the quality aims of the organization, and the Quality Manual, which defines the organization's QM system. The layout of the Quality Manual should follow the outline of ISO 17025:2005.

Laboratory operations can be divided into preanalytical, analytical, and postanalytical phases (Box 2). Written procedures, usually known as *standard operating procedures* (*SOP*s), should describe all aspects

Box 2. Stages in analytical toxicology laboratory operation

- **Preanalytical**
  Procedures must be in place to advise on appropriate sample collection (including sample tubes) and to ensure the safe transport, receipt, and storage of biological samples once in the laboratory, and for arranging the priority for the analysis
- **Analytical**
  Validated (i.e., tried and tested) procedures must be used to perform the requested or appropriate analyses to the required degree of accuracy and reliability in an appropriate timescale
- **Postanalytical**
  A mechanism for reporting results and maintaining confidentiality by telephone, fax, or other electronic means and in writing must be in place. Proper interpretation of results, especially for less-common analytes, must be provided. Full records of the analysis must be kept for at least 5 years (10 or more years in forensic work) unless otherwise determined by statute. Residues of samples must be stored appropriately until disposed of safely in an agreed timeframe

of laboratory operation, including management and health and safety aspects. The Society of Forensic Toxicologists (SOFT) and American Academy of Forensic Sciences (AAFS) have published detailed guidelines for the operation of forensic toxicology laboratories, much of which is also applicable to clinical toxicology laboratories [2].

Implementation and documentation of internal audits, both vertical (when, for example, the documentation concerning the analysis of a particular sample is examined) and horizontal (such as examining operating or quality procedures for internal consistency), are important parts of laboratory accreditation. Clinical or operational audit, i.e., examining the results generated in the light of the purpose for which they were requested, although much more difficult to undertake, is also important in the accreditation process. The results of such audits provide valuable training material.

Documentation of "quality queries", i.e., instances when mistakes or failures in processing have occurred, even if the error or failure was detected and corrected before a result was issued, and implementation and monitoring of corrective action, are also important in the accreditation process.

Method Implementation and Validation

Whatever method is used for a given analysis it must be validated, i.e., it must be shown to be "fit for purpose" [3]. Assay validation should conform, as far as possible, with the US Food and Drug Administration (FDA) Center for Drug Evaluation and Research (CDER) guidance for bioanalytical method validation [4]. Data for within-day (repeatability), between-day, and total precision should be calculated according to the protocol proposed by the Clinical and Laboratory Standards Institute [5]. A number of terms important in understanding method validation are given in Table 1.

Quantitative methods must have good precision and accuracy. Selectivity (freedom from interference, specificity) is important when a single species is to be measured, but broad specificity may be useful when screening for the presence of a particular class of compounds. The recovery of the analyte, i.e., how much of the compound of interest is recovered from the sample matrix during an extraction, for example, is important if sensitivity is limiting, but need not be an issue if the lower limit of quantification (LLoQ), accuracy, and precision of the assay are acceptable.

Any quantitative analysis has associated errors, both random and systematic. In chromatographic and other separation methods, the "internal standard" method is often used to reduce the impact of systematic errors such as variations in injection volume, evaporation of extraction solvent, or mass spectrometry (MS) response during the analysis. Thus, a known amount of a second compound that behaves similarly to the analyte during the analysis, but elutes at a different place on the chromatogram or is otherwise detected independently of the analyte (the internal standard) is added at an appropriate stage in the analysis. Subsequently, the detector response of the analyte relative to the response of the internal standard is plotted against analyte concentration when constructing a calibration graph. Requirements for an internal standard for chromatographic assays are summarized in Box 3.

Stable isotope-labelled analogues are widely used as internal standards in MS (isotope dilution MS). Isotopic internal standards have virtually identical chemical and physical properties to the analyte and thus extraction, derivatization if needed, chromatography, and fragmentation are often virtually identical. However, the site of isotopic labeling should be chosen such that the bonds linking the isotope are not broken during fragmentation, as bonds involving heavier isotopes are more stable and the fragmentation pattern of the labeled compound could thus differ from that of the analyte. The vibrational frequencies of carbon–deuterium bonds are less than those of the corresponding carbon–hydrogen bonds, for example, so that deuterated compounds tend to be more stable than their unlabeled homologs. That labeled and unlabeled compounds may be partially resolved during the chromatographic analysis (deuterated analogs may elute slightly before the unlabeled analyte in GC-MS, for example) must be borne in mind not only with regard to choosing the correct integration parameters, but also because any ion suppression due to cochromatographed components may differ between the internal standard and the analyte(s). The internal standard may add to the degree of ion suppression in LC-MS, but generally both internal standard and analyte are affected equally by such phenomena [6].

Table 1 Terms used when reporting method validation

Term	Notes
Accuracy	The difference between the measured value and the accepted ("true") value
Calibration range	The range of concentrations between the highest and lowest calibration standards. This should encompass the range of concentrations found in the test samples
Coefficient of variation (CV)	An obsolete term for RSD
Higher limit of quantitation (HLoQ)	The highest concentration that can be quantified. Not always quoted, but important in assays with a clear upper "cutoff", for example, immunoassays and fluorescence assays
Internal standard	A second compound, not the analyte, added at an appropriate stage in the assay to correct for systematic errors in the analysis
Limit of detection (LoD)	The smallest amount of analyte that can be detected. Usually defined as some multiple (5, for example) of the baseline noise (signal-to-noise ratio = 5) or multiple of the SD of the blank signal
Linearity	A definable and reproducible relationship between a physicochemical measurement (e.g., UV absorption) and the concentration of the analyte, but not necessarily a straight line
Lower limit of quantification (LLoQ)	The lowest concentration that can be measured within defined limits. Usually a concentration for which the precision and accuracy have been set arbitrarily, e.g., RSD <20%
Precision	The scatter of measured values about a mean value. Usually quoted as RSD – within-assay (repeatability) and between-assay precision (reproducibility) is commonly given
Relative standard deviation (RSD)	The standard deviation of replicate measurements expressed as a percentage of the mean value: RSD = SD/Mean $\times 100\%$ Useful when comparing precision at different concentrations
Selectivity	The ability to distinguish between the analyte and some other compound
Signal-to-noise (S/N) ratio	Strictly, the response to the analyte divided by the amplitude of the random electronic noise of the detection system. In practice, the background signal due to interfering compounds is often greater than the electronic noise

Box 3. Requirements for an internal standard

An internal standard must:

- Be completely resolved from the known and unknown substances in the chromatogram, or detected selectively as in MS for stable isotopes
- Elute near to (preferably just after the last) peak(s) of interest
- Have a similar detector response (peak height or area) to the analyte(s)
- Have similar chemical and physical properties to the analyte(s)
- Undergo any derivatization reaction in the same way as the analyte(s)
- Be chemically and physically stable on storage in solution and during the analysis
- Be easily available with adequate purity

Deuterium is the most commonly used stable isotope label. This is because of not only cost, but also the availability of high purity reagents. The presence of each deuterium atom in the molecule increases the M_r of the molecule by 1 atomic mass unit (u). For high-sensitivity analyses, it is recommended that the mass of the internal standard is at least 3 u greater than the analyte to reduce interference from naturally occurring isotopes. When stable isotope-labeled analogs are not available or the procedure can be used to quantify a large number of analytes simultaneously, internal standards that have chemical properties close enough to the analyte(s) to yield reliable quantitative data are used.

Reference Compounds

A fundamental starting point in any assay is obtaining certified pure reference material, or at least the best approximation to such material that can be attained. When preparing primary standards, particular attention should be paid to the M_r of salts and their degree of hydration (water of crystallization). Analytical results are normally reported in terms of free acid or base and not of a salt. The supplier, batch or lot number, purity, expiry date, and any other relevant information supplied with a compound should be recorded. Compounds should be stored in the dark under conditions recommended by the supplier. Every effort should be made to obtain a certificate of analysis or other appropriate documentation, but supply of such documentation is at the discretion of the manufacturer.

Preparation and Storage of Calibration Solutions

Assay calibration is normally done by analyzing standard solutions containing each analyte over an appropriate range of concentrations prepared in analyte-free plasma, urine, or other appropriate fluid. The chosen medium should be analyzed prior to the addition of the analyte(s) to ensure the absence of interferences.

Balances for weighing reagents or calibration standards, and automatic and semiautomatic pipettes, must be kept clean and checked for accuracy on a regular basis. Weighing of balance check weights should be recorded. Pipette accuracy should be documented by dispensing purified water and recording the weight dispensed. Weighing of reference compounds should normally be performed by one analyst and witnessed by a second analyst, as should other steps, in preparing calibration standards and internal quality control (IQC) solutions such as calculating and performing dilutions.

The range of the calibration curve should cover the range of concentrations expected in the samples. The calibration curve should not normally be extrapolated beyond the lowest or highest standard solution. If the concentrations of some of the samples being analyzed are below the lowest calibration standard, then the assay may be repeated with the inclusion of lower concentration standards, if that is possible, or the result reported as less than the lowest standard. High concentration samples may be diluted to fit within the calibration range, provided the validity of doing so has been demonstrated during method development and if sufficient sample is available. Dilutions should be made with the same (e.g., blank plasma from the subject), or very similar (e.g., the matrix used for the calibration standards) matrix as the sample.

Neonatal calf serum is often used in the preparation of calibration solutions for plasma or serum assays. Newly prepared calibration solutions should be validated before use by comparison either with existing calibration solutions, or with IQC solutions prepared in human plasma or serum, and the results recorded. If, for any reason, neonatal calf serum proves unsuitable, human plasma or serum from an appropriate source should be used.

Blood-bank whole blood (transfusion blood) is sometimes used to prepare calibration standards. However, such blood and "plasma" derived from it (i) will usually be diluted with citrate solution, which has a high buffering capacity; (ii) may contain lidocaine and sometimes lidocaine metabolites; and (iii) may well contain plasticizers and other contaminants that may interfere in chromatographic and possibly other assays, and may alter the distribution of drugs between red cells and plasma by altering protein binding. Commercially available equine or bovine blood may suffer some of these same problems.

The question of "matrix matching" for preparation of calibration or IQC solutions is a vexed issue. Clearly true "matrix-matched" standards cannot be prepared for solid tissues such as liver or hair. Use of "blank" homogenized tissue samples or hair digests, for example, as the matrix for standard preparation is one way forward here. Analyte(s) may also be adsorbed onto hair prior to digestion.

Similarly, it is rarely possible to prepare standards in analyte-free sample from a patient or victim such that the standard has exactly the same composition as the sample submitted for analysis. The method of "standard additions" (adding known amounts of analyte to portions of the sample) is very difficult and inaccurate if only a limited sample volume is available, does not allow validation against existing calibrators, and does not permit the preparation of IQCs. Finally, "blank" human blood or urine can be used, as discussed above, but the volume of blood available is usually limited.

If newly prepared calibration standards and the IQCs meet the criteria for acceptance, portions may be transferred to labeled 3-ml plastic tubes and stored ($-20\,^{\circ}C$) until used. Cleaning records and lists of contents should be posted on all refrigerators and freezers including those used to store biological samples to meet Health and Safety requirements. Refrigerators and freezers should be fitted with failure alarms and temperature-monitoring devices and temperature records kept. Computerized temperature-monitoring devices (e.g., Tinytalk, http://www.tinytag.info/products/index.asp, accessed 10 October 2007) are available.

Calibration Graphs

Normally, a calibration graph of analyte response *versus* concentration in the calibration standards is constructed. In chromatographic assays, the response may be peak height or area, or peak height or area ratios to an internal standard. The relationship may be a straight line or a curve.

Blank samples, usually the drug-free matrix, should be prepared and analyzed along with the calibrators and unknown samples. The blank is an important part of quality control (QC). In a chromatographic assay, for example, there should be no interfering peaks in the region of the analyte(s) or internal standard(s). The response of the blank should not be so high as to limit the working range of the assay. The blank is not a zero calibrator, and normally must not be included in the calibration data. Replicate analyses of "blank" signal are necessary to define the limit of detection (LoD) and so it is important when using electronic data capture to ensure that the calibration curve is not being forced though zero.

An important criterion for an analytical method is the LoD, i.e., the minimum concentration (amount) of analyte that can be detected reliably and differentiated from any background signals measured in analyte-free samples. Defining the LoD is not as simple as it might at first seem to be, as there are random errors associated with both the blank sample and samples at or near the LoD. For chromatographic assays, the LoD might be quoted as some arbitrary multiple of the signal-to-noise ratio (S/N) such as 3, 5, or 10 times. This, of course, presupposes that the S/N can be measured and, with biological samples, the limiting factor is rarely instrument noise, but rather signals due (usually) to endogenous interfering species, in which case some multiple of the standard deviation (SD) of the blank signal may be used.

For quantitative analyses, it is usual to quote the lowest concentration or amount that can be measured with defined values of precision and accuracy; this is the lowest limit of quantitation (LLoQ). Again the criteria are arbitrary, and the relative standard deviations (RSDs) for precision and accuracy typically range from 10–15%, depending on the requirement of the assay. For trace analyses and pharmacokinetic experiments, it may be necessary to accept values as high as 20%, although the RSDs for concentrations above the LLoQ would normally be considerably lower. The concentration of the lowest calibrator may be set to the LLoQ, although for some applications it may not be necessary to measure such low concentrations. In any event, concentrations below the lowest standard should not be reported.

Reports do not always quote a higher limit of quantitation (HLoQ), particularly when the assay has a wide linear range. However, for some techniques, such as immunoassay and fluorescence detection in HPLC, the working range of the assay should be defined by both LLoQ and HLoQ. In some immunoassays, the presence of very high concentrations of an analyte can give a result suggesting the presence of a very low concentration ("hook effect").

Batch Analyses

Batch-assay calibration should normally be by analysis of standard solutions of each analyte (six to eight concentrations across the calibration range) prepared in the appropriate matrix (e.g., analyte-free neonatal calf or human serum). IQC procedures should be instituted. This involves the analysis of independently prepared solutions of known compositions that are not used in assay calibration; normally low, medium,

and high concentrations of each analyte are prepared in analyte-free human serum, for example. Calibration standards are normally analyzed in duplicate, once at the beginning and once at the end of the batch. IQC samples are analyzed at the beginning and end of the batch and also after every 5–10 test samples as appropriate. External quality assessment (EQA) samples are analyzed as appropriate to conform to the requirements of particular EQA schemes. Single-point calibration methods for emergency work must be validated and the results compared with those from multipoint calibration [7].

The performance of batch analyses (analysis of a number of samples in the same analytical sequence) and analysis acceptance criteria should be as set out in the method validation guidance [4]. Typical assay-acceptance criteria are (i) chromatography (reproducible peak shape and retention time, stable baseline) and (ii) calibration graph ($r = 0.98$ or greater, intercept not markedly different from zero), and mean IQC results within acceptable limits (generally within 10% of nominal value). Acceptance criteria for patient samples are (i) "clean" chromatogram, i.e., absence as far as can be ascertained of interferences; (ii) duplicate values (peak height ratio to the internal standard) within 10% except when approaching the limit of sensitivity of the assay when duplicates within 20% may be acceptable; and (iii) results within the calibration range of the assay. Sample analyses falling outside acceptance limits may be repeated if sufficient sample is available.

While immunoassays may be performed as batch analyses, they may, depending on the instrument used, be subjected to random access analysis. IQC in such circumstance is best performed at timed intervals at low, medium, and high concentration. Some immunoassays are used as screens for the presence of drugs or metabolites, and "cutoff" concentration values are used to define positives. It is particularly important to ensure that the analytical performance at this cutoff point is properly investigated (±25% of cutoff value) to minimize the risk of false positives and negatives arising from poor assay performance.

If a result above the calibration range is obtained, then, if possible, a portion of the sample should be diluted with "blank" plasma/serum and reanalyzed. If a sample is from a suspected overdose patient, then sample dilutions ($1 + 1$, $1 + 3$, $1 + 9$) should be made using "blank" serum at the time of the initial analysis (if the available sample volume permits) and analyzed at the same time as the normal sample analysis. Postmortem whole-blood samples or tissue digests from suspected overdose cases, for example, may be diluted $1 + 3$and$1 + 9$ with "blank" human serum prior to analysis using standard methods. If the information available suggests a massive overdose, further dilutions may be made as appropriate prior to the analysis.

Quality Control and Proficiency Testing

Once an analytical method has been validated and implemented, it is important to be able to show that the method continues to perform as intended. In qualitative work, known positive and negative specimens should normally be analyzed at the same time as the test sample. A negative control ("blank") helps to ensure that false positives (owing to, for example, contaminated reagents or glassware) are not obtained. Equally, inclusion of a true positive serves to check that the reagents have been prepared properly and remained stable.

In quantitative work, assay performance is monitored by the systematic analysis of IQC samples. Plotting the results for the IQC samples on a chart allows the day-to-day performance of the assay to be monitored and gives warning of any problems as they arise. When new batches of calibration and IQC samples are prepared, it is prudent to ensure comparability of the results obtained with those given by an earlier batch, or with the results obtained using external QC material.

FDA guidelines (for batch processing) require duplicate IQCs at three concentrations (high, medium, and low) to ensure that the assay is performing satisfactorily across the calibration range. The assay batch is deemed acceptable, provided four of the six controls (with at least one at each concentration) are within specification.

Quality Control Charts

QC charts are valuable in that they (i) produce evidence of satisfactory assay performance and (ii) give visual warning if assay performance begins to deteriorate. As with any QC method, it is important that reliable estimates of the parameters defining the control material are established. The mean value, μ, should be obtained from a minimum of 10 observations and the SD, σ, should be the between-assay

value (interassay value). Obviously, these parameters must be measured when the analysis is performing satisfactorily.

Analytical laboratories commonly use Westgard rules to establish that assay performance is adequate [8]. Five different control rules are used to assess the acceptability of an analytical sequence. Further details and a multirule worksheet can be obtained from http://www.westgard.com/mltirule.htm (accessed 27 August 2007).

External Quality Assurance

Participation in EQA or proficiency testing (PT) schemes is an important part of QM [9]. In such schemes, portions of (sometimes lyophilized) homogenized plasma, serum, whole blood, or urine specimens are sent to a number of participating laboratories. After reconstitution in deionized water, if appropriate, the specimens are analyzed as if they were real samples and the results are reported before the true or target concentrations are made known.

EQA schemes measure interlaboratory performance and allow individual laboratories to detect and correct systematic errors. The laboratories do not have to use the same analytical method, as is usually the case with collaborative trials that are designed to test the reproducibility of a particular method. The results of EQA schemes are usually given as the z-score:

$$z = \frac{x - x_a}{\sigma_p} \qquad (1)$$

where x is an individual result, x_a is the accepted, "true" value and σ_p is known as the *target value of SD*, which should be decided on the basis of what is required of the test, and should be circulated in advance. If the result needs to be measured with high precision, then a low value of σ_p would be used. Thus, z is a measure of a laboratory's accuracy and the organizer's judgment as to what is "fit for purpose". If the results of an EQA scheme are normally distributed with a mean of x_a and variance of 1, then z-scores <2 would be deemed acceptable, whereas those >3 would not.

Toxicology EQA Schemes

Quantitative EQA schemes are available for a wide range of therapeutic drug monitoring (TDM) analytes and some other poisons in many countries. The European Network of Forensic Science Institutes (ENFSI) website (http://www.enfsi.eu/page.php?uid=93, accessed 1 October 2008) and European Proficiency Testing Information System (http://www.eptis.bam.de/, accessed 1 October 2008) list EQA schemes for a range of analytes including drugs that are available in Europe, America, and Australia. The United Kingdom National External Quality Assessment Scheme (UKNEQAS) for therapeutic drug assays and the Dutch KKGT (Association for Quality Assessment in TDM and Clinical Toxicology) schemes, for example, have been operating for over 25 years.

There are, of course sometimes, concerns such as the possible effects of freeze-drying on analyte stability, and issues concerning the matrix used to prepare material for circulation (due to the cost of analyte-free human plasma or serum, neonatal calf serum may be used for some analytes). Nevertheless, from the datasets generated, scheme organizers can ascertain the methods that give the best performance, investigate sources of interference or bias, and, in extreme cases, report poorly performing methods to regulatory authorities. In the 30 years since the inception of these schemes, poorly performing assays have been identified and participants advised accordingly. The mean values reported have moved nearer to the intended value and the spread of results about the mean has been reduced [9].

EQA of qualitative work is also invaluable, as in drugs of abuse screening. Here, poor selectivity due to immunoassay cross-reactivity or gas chromatography (GC) injection port artifacts, as well as to manipulation of the sample by the patient, are real problems. Even with the ongoing educative role of EQA, errors (such as failure to detect morphine at $1\,\text{mg}\,\text{l}^{-1}$ in urine using LC-MS-MS) still occur. Often human error is the cause of such mistakes.

Well-run qualitative EQA schemes not only assess routine performance, but also add in hard-to-detect compounds or "spike" at concentrations around nationally agreed "cutoff" values. Good screening and confirmatory analytical performance from laboratories is required to ensure that the correct result is reported. Scoring of performance for a set of commonly encountered drugs such as morphine, 6-monoacetylmorphine for heroin, and 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP) for

methadone, for example, helps laboratories address any problems in their procedures.

Urine is the matrix used most commonly, but schemes to support analyses in oral fluid and indeed in other matrices, such as hair, are emerging (e.g., that organized by the Society of Hair Testing, http://www.soht.org/, accessed 15 October 2007). For urine testing, scheme cutoffs are quite generous, but laboratories may also be scored against agreed workplace cutoffs (see http://www.wdtforum.org.uk/, accessed 27 August 2007). A breakdown of the performance of each recognized method type should be given to help laboratories understand why false-positive or false-negative reports have occurred in a given distribution. Meetings with users and scheme organizers are helpful to both groups. Regular clinical/forensic toxicology case schemes have also been instituted.

User Support and Staff Training

Training is an important part of QM. Clinicians, especially Accident and Emergency staff, forensic physicians, pathologists, and police need guidance not only as to what toxicological assays are useful in a given set of circumstances but also on sample collection, transport, and storage, local assay availability and turn-around time, and the interpretation of results. Especially important is guidance on blood and tissue sampling postmortem since the homogeneity of such samples cannot be taken for granted [10] and the possibility of changes in composition having occurred since death must be borne in mind when reporting results [11].

Not only do laboratory staff providing analytical toxicology services need training in providing these services and in the interpretation of results, they will also need some training in dealing with requests for tests that will need to be referred to other analytical centers. Staff in regional or national analytical centers will require extensive training in the more complicated analytical methods that they will be called upon to use. This training must encompass not only the techniques themselves (TLC, HPLC, etc.), but also their application in analytical toxicology and related areas. Knowledge of the role of local hospital laboratories, coroners, police, and the local poisons center is important [12].

There are no internationally recognized training programs in analytical toxicology. However, a training scheme for a graduate clinical scientist specializing in analytical toxicology has been developed in the UK. The training program comprises 4 years full-time study, followed by a period of higher specialist training, in some cases, leading to the award of a research degree such as Doctor of Philosophy. The American Board of Clinical Chemistry hosts an examination in Toxicological Chemistry (http://www.abclinchem.org/tox_chem/Pages/default.aspx, accessed 30 September 2008).

Participation in continuing education (CE), continuing professional development (CPD), or revalidation programs is important when staff attain career grades, i.e., when initial and higher specialist training has been completed, and may be necessary for continued specialist registration in countries where such registration is mandatory. Compliance with CPD programs may require maintenance and external audit of personal records listing educational activities, such as scientific meetings attended, papers published, lectures given, etc. Details of such a scheme maintained by the UK Royal College of Pathologists are available (http://www.rcpath.org/index.asp?PageID=620, accessed 27 August 2007). Many other countries run similar schemes.

Nongraduate scientific staff will be normally trained in-house in specific aspects of laboratory operation, although training in the operation of newer specialized instruments may sometimes be provided by manufacturers. Proper recording of training is important.

Recording and Reporting Results

It is usually advisable to contact the laboratory by telephone in advance to discuss urgent or complicated cases. A request form must accompany the samples to the laboratory. Most clinical specimens, particularly blood and urine, may be sent by post if securely packaged in compliance with current regulations. Filter-paper adsorbed dried blood may be acceptable in certain circumstances and does not require refrigeration [11].

In forensic work, it is important to be able to guarantee the identity and integrity of the specimen. Thus, such samples should be protected during transport by the use of tamper-evident seals and should, ideally,

Box 4. Chain of custody documents

- Name of the individual collecting the specimen
- Name of each person or entity subsequently having custody of it, and details of how it has been stored
- Date(s) the specimen was collected or transferred
- Specimen or case number
- Name of the subject or deceased
- Brief description of the specimen
- Record of the condition of tamper-evident seals

be submitted in person to the laboratory by the Coroner's officer or other investigating personnel. *Chain of custody* is a term used to refer to the process used to maintain and document the history of the specimen (Box 4).

Fully validated assays must include data on the stability of the analyte in the appropriate matrix under specified storage conditions. In the absence of other information, biological specimens should be stored at 2–8 °C prior to analysis, if possible, and ideally any specimen remaining after the analysis should be kept at 2–8 °C for 3–4 weeks in case further analyses are required. In forensic work, any specimen remaining must be kept (preferably at −20 °C) until destruction is authorized by the investigating authority.

All results should be recorded in laboratory notebooks or on worksheets together with information such as the date, the name of the analyst, the name of the patient, and other relevant information, the number and nature of the specimens received for analysis, and the tests performed. All specimens received in laboratories are normally allocated a unique identifying number. This number is used when referring to the tests performed on the specimen.

UV spectra, chromatograms, calibration graphs, and other documents generated during an analysis should always be kept for a time after the results have been reported. Recording the results of color tests and TLC analyses is more difficult unless a digital camera is used. Electronic data storage is dependent on the availability of hardware and software to read the data.

Reporting the results of tests in which no compounds were detected in plasma/serum or in urine, the limit of sensitivity of the test (LoD) should always be known, at least to the laboratory, and the scope of generic tests (benzodiazepines and opioids) should be defined.

The results of urgent (emergency) analyses must be communicated directly to the client without delay, and should be followed by a written report as soon as possible. Ideally, confirmation from a second independent method, or failing this, an independent duplicate, should be obtained before reporting positive findings. However, this may not always be practicable, especially if only simple methods are available or if sample amount is limiting. In such cases, it is vital that the appropriate positive and negative controls have been analyzed together with the specimen.

When reporting quantitative results, it is important to clearly state the units of measurement used. In addition, any information necessary to ensure that the clinical implications of the result are fully understood must be available and should also be noted on the written report.

Although it may be easy to interpret the results of analyses in which no compounds are detected, such results are sometimes difficult to convey to others, especially in writing. This is because it is important to give information as to the poisons excluded by the tests performed with all the attendant complications of the scope, sensitivity, and selectivity of the analyses and other factors such as sampling variations. Because of the potential medicolegal and other implications of any toxicological analysis, it is important not to use laboratory jargon such as "negative" or "not confirmed", or sweeping statements such as "absent" or "not present". The phrase "not detected" should precisely convey the laboratory result, especially when accompanied by a statement of the specimen analyzed and the LLoQ.

While chain-of-custody procedures for sample submission are widely implemented, secure systems for reporting results are also needed – it is not unknown for a report to be altered by laboratory staff in order to subvert an investigation.

Summary

Implementation of QM principles and associated laboratory accreditation procedures helps ensure that reliable results are obtained and can be defended in court. With the increasing use of point-of-care testing (POCT) devices, the principles of QM also have to be applied to such procedures in order to ensure the reliability of results. Although QM principles are more difficult to apply to the clinical interpretation of analytical results, it is vital that this aspect of the laboratory's work is not neglected.

Radiocarbon Dating

Introduction

Radiocarbon dating is traditionally considered an archeological tool rather than a forensic one. Radiocarbon or carbon-14 (^{14}C) is produced naturally in the atmosphere by cosmic ray interactions with nitrogen. Single carbon atoms in the atmosphere are chemically reactive and are quickly oxidized to carbon dioxide (CO_2). The CO_2 from the atmosphere is incorporated into plants and works its way up the food chain to label every living thing with ^{14}C. The natural atmospheric concentration of natural ^{14}C with respect to all carbon has remained relatively stable at about 1.2 parts per trillion over the past several thousand years with the exception of the radiocarbon bomb-pulse over the past half-century (*see* **Bomb-Pulse Dating**). With a radioactive half-life of 5730 years, the radioactive decay of ^{14}C is minimal within the time periods of interest in most medical forensic cases and applicable for samples over 300 years of age. Willard Libby was awarded the Nobel Prize in Chemistry in 1960 for the development of radiocarbon dating [1].

Basics of Radiocarbon Dating

Radiocarbon dating relates the $^{14}C/C$ ratio in a sample to an extensive historical record to determine the age of a sample. The rate of radioactive decay of ^{14}C is relatively slow and predictable; hence, the concentration of ^{14}C changes slowly and reliably over time once a biological material dies and stops incorporating new carbon into its structure. The decrease in $^{14}C/C$ concentration from the contemporary value is used to determine the age of the sample. The natural production of ^{14}C does vary slightly over time. Extensive geological and archeological records are used to account for the variations in atmospheric ^{14}C concentration over the chronological range of radiocarbon dating (300–50 000 years before present) [2, 3]. Any sample greater than 50 000 years old has too little ^{14}C to measure accurately. There is some debate over the accuracy of the ^{14}C calibration between 40 000 and 50 000 years before present, but it is hard to conceive of a forensic sample of this age. Fossil carbon, either coal or petroleum, is older than 60 000 years and free of ^{14}C.

Measurement of Radiocarbon Samples

Today, most ^{14}C dating analyses are conducted using accelerator mass spectrometry (AMS), although some labs still use decay counting. AMS is much faster and generally more precise than decay counting since it measures differences in carbon atom mass and is not constrained to wait for atomic decay. AMS can also use smaller samples than decay counting, an important issue when analyzing evidence. There are about 100 AMS facilities worldwide.

Sample preparation and measurement details vary among AMS facilities, depending on the type of sample to be analyzed and the design of the spectrometer. Routine radiocarbon analyses using AMS are performed on samples containing about 1 mg carbon.

Samples as small as 50 μg carbon can be analyzed at some labs, but measurement uncertainties are larger. Nearly all AMS facilities that perform high-precision dating follow these general procedures to minimize contamination from outside sources of carbon and reduce measurement backgrounds. Samples are dried completely and then combusted with excess oxygen to produce CO_2. The CO_2 is purified to remove water vapor, nitrogen, oxides of nitrogen, and oxides of sulfur. It is then reduced to graphite or elemental carbon on metal catalysts, often cobalt or iron powder.

Primary standards, secondary standards, and backgrounds are similarly processed to produce graphite, which is the form of carbon analyzed by most AMS systems. Graphite is the preferred form of carbon because it can be made easily at high purity, produces intense negative ion currents, and can be prepared at satellite labs and shipped to AMS facilities for analysis. A handful of gas-accepting ion sources that take direct feed of CO_2 exist, but they are not typically used for high-precision dating. It is important to have consistent sample source material (e.g., all carbon graphite) because different molecules ionize with different efficiencies. Methods for producing graphite for elevated biological tracing experiments are generally unsuitable for radiocarbon dating because of larger sample-to-sample variation and higher background [4, 5].

The precision of radiocarbon dating depends on the ability to measure the ^{14}C concentration in a sample and the shape of the calibration curve. It is relatively easy to achieve 0.5–0.8% precision when analyzing relatively young, full-sized samples. This measurement precision translates to a chronological uncertainty of ±30–60 years in most samples less than 10 000 years old. Samples more than 25 000 years old can still be measured to 1% precision, but uncertainty propagation from backgrounds and the calibration curve typically yields uncertainties greater than ±100 years. The conventions for reporting radiocarbon dates are described by Stuiver and Polach [6].

Samples Amenable to Dating

Anything that was alive in the past is amenable to radiocarbon dating. Charcoal, wood, straw, hair, cloth, and bones are often dated in archeological sites. Historical documents and works of art are also routinely dated to confirm that the paper or canvas is of the appropriate age for the object.

Bone

Bone is the preferred sample matrix for dating human remains. Bone's ability to resist decay while containing a relatively high concentration of carbon makes it a desirable material for traditional dating. The carbon in collagen does turnover slowly while a person is alive; hence, the ^{14}C content is really a lifetime average rather than a snapshot in time. Traditional bone dating uses a collagen extraction procedure to avoid potential complications with mineral exchange of carbonates in bone in the environment. Collagen is a protein and is not affected by environmental carbonate exchange like the mineral component of bone.

Specific procedures for collagen extraction vary slightly among labs. In general, the mineral component of bone is dissolved in acid to free the collagen into solution. A variety of washing, rinsing, and filtering techniques are then applied to purify the collagen. Once purified, it can be combusted like any organic sample.

If human remains are found without any other evidence, radiocarbon analysis of bone collagen or hair can determine whether the authorities have a crime scene (*see* **Bomb-Pulse Dating**) or an archeological site. If the ^{14}C content of the collagen is elevated above the level in 1950, the person died sometime after 1955. The decrease in ^{14}C concentration due to decay can be measured over a 100 years, but the small differences in natural production between 1650 and 1955 and the decay combine to make it very difficult to separate samples chronologically over this time. Collagen before 1650 can be clearly distinguished.

In the United States, a ^{14}C date can determine the ownership of remains or precipitate a court battle over ownership, such as the case of Kennewick Man [7–10]. The Native American Graves Protection and Repatriation Act (NAGPRA) requires institutions that receive U.S. federal funding the return of human remains and sacred artifacts to ethnic descendants when they are available.

Documents and Art Objects

Radiocarbon dating of documents and art objects is routinely done by museums to confirm that the item's age is consistent with its provenance. This approach only confirms that the paper, cloth, or canvas is of the appropriate age, but it does not confirm authenticity.

A radiocarbon analysis that contains recent bomb-pulse carbon identifies a forgery of an older item.

Acknowledgment

This work was performed under the auspices of the U.S. Department of Energy by the Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

BRUCE A. BUCHHOLZ

Radiology

Within months of Roentgen's announcement of his new discovery in 1895, the "X-ray" had been employed to examine a variety of objects including the human body, suspicious packages, Egyptian mummies, welded metal, and fine art, and had developed a whole range of other such uses throughout the medical and scientific world. Radiology was quickly adopted as a tool of the forensic sciences and was employed in a wide range of scientific investigations during the initial period of discovery. Some applications were quickly superseded, but many have developed into essential tools of the forensic investigator. Radiological techniques have many applications in forensic science today, including the examination of fingerprints and documents and a range of applications within the field of forensic engineering [1] (*see also* **Friction Ridge Examination (Fingerprints): Interpretation of**; **Interpretation: Document Evidence**; **Documents: Authentication of**; **Forged and Counterfeit Documents**).

Medical Radiological Techniques

Recently, radiological images were acquired using the same basic techniques of radiography and fluoroscopy that Roentgen himself employed. While these basic techniques still form a major part of radiological investigation, they have been supplemented by newer techniques employing sophisticated computer technology, some of which rely on X-rays

and others that employ radioactive materials, sound waves, and magnetic fields. The majority of methods now employed permit images to be acquired and stored digitally.

The main medical radiological imaging techniques may be summarized as follows:

- **Radiography**

The term *radiography* is generally used to describe a static or "still" image produced by means of a single exposure to X-rays (an energy form of ionizing radiation). Such images are now usually recorded and stored digitally but were previously recorded photographically on X-ray film.

- **Fluoroscopy**

The term *fluoroscopy* is used to describe an image directly visualized in real-time motion produced by a continuous exposure to X-rays.

- **Nuclear medicine (radionuclide imaging)**

Radioactive materials or isotopes can be used to highlight internal organs or tissues by injection, inhalation, or ingestion. The radiant energy escaping from the body is detected by sensitive phosphors to create images of these body parts.

- **Ultrasound**

Ultrasound scanning uses the same principle as sonar whereby sound waves generated by a transponder are reflected by internal structures in the body and measured and converted into real-time or static images.

- **Computed axial tomography**

Computed axial tomography (CAT) or CT scanning employs a computerized X-ray machine that uses an array of photoreceptors to detect minute differences in attenuation of X-rays emitted by an X-ray tube as it rotates around the body or body part. A computer generates an image of the body part in the axial or cross-sectional plane and modern multislice CT scanners permit multiplanar, multidirectional sectional images to be displayed and/or reconstructed as three-dimensional images.

- **Magnetic resonance imaging**

Magnetic resonance imaging (MRI) utilizes strong magnetic fields to generate electromagnetic signals from chemical elements and compounds within the bodily structures. Measurement and computer analysis of these signals allows multiplanar, multidirectional sectional images to be displayed and/or reconstructed as three-dimensional images in the same manner as CT scans.

- **Interventional radiology**

Using imaging techniques to guide them, the interventional radiologist uses a range of devices and instruments to enter the body *via* small puncture wounds, not only to produce images and make diagnoses but also to treat disease processes or correct anatomical abnormalities [2].

Clinical forensic radiology employs the entire spectrum of imaging techniques to the diagnosis of disease and injury, and the forensic radiological examination of live subjects may be undertaken with any one or more of the above techniques. Forensic radiology of deceased subjects has, until very recently, been limited to the use of still-image radiography and occasionally fluoroscopy [1]. Increasingly, however, some of the more complex imaging techniques, such as MRI or CT scanning, are being employed for postmortem imaging either as a precursor to invasive autopsy or, in some cases, in place of an invasive autopsy examination.

Medical Imaging Specialists

Following Roentgen's discovery, radiology is rapidly developed as a distinct specialism within medicine and is now undertaken by highly specialized medical and scientific staff.

Radiologist

The radiologist is traditionally described as a specialist physician dedicated to the study of images of the internal structures of the body, but now also increasingly involved in the treatment of disease through "interventional radiology", a form of "keyhole surgery" in which the treatment is guided by the use of real-time imaging techniques.

Radiographer or Radiologic Technologist

The radiographer is traditionally described as the technician who produces the images from which diagnoses are made but are now also increasingly undertaking diagnosis of injury or disease from these images.

Forensic Radiologists and Radiographers

As with many other branches of forensic science, forensic radiology and radiography is practised by professionals of both disciplines with experience of the application of their specialist skills within forensic medicine. The College of Radiographers (United Kingdom), in association with the Association of Forensic Radiographers (AFR), produces professional guidelines for the provision of forensic radiography services [3] and has supported the development of education and training in this field, with a number of post-graduate courses now being offered by UK universities. From January 2007, radiographers in the United Kingdom have been eligible for registration with the Council for Registration of Forensic Practitioners (CRFP)

The Forensic Uses of Medical Radiology

The use of medical radiology within forensic medicine falls into three categories:

- diagnosis
- identification and
- detection and retrieval of concealed or embedded objects [2].

Diagnosis

Radiology assists forensic medical investigation through diagnosis of the cause of injury or death by radiological means. Forensic radiological examination may be undertaken upon deceased subjects as part of a forensic pathology examination or upon living subjects within the clinical setting. Applications for radiology of the deceased follow the indications for forensic pathological examination in both accidental and criminal deaths: sudden death, sudden infant death, suspicious deaths, adverse medical events, road traffic accidents, terrorist incidents, war crimes, and genocide. Indications for examination of live subjects may include suspected abuse of children, the elderly or other vulnerable individuals, assault or criminal injury, industrial injury compensation, medical negligence, torture, other suspected human rights abuses, etc. [4, 5] (*see also* **Autopsy**; **Cardiac and Natural Causes of Sudden Death**).

Radiology of the Deceased

As previously indicated, the use of radiological methods in forensic pathology investigation has, until recently, been restricted to radiography and, in some cases, fluoroscopy. Over the past 5 years, however, a number of institutions, both in the United Kingdom and overseas, have been investigating the potential of modern imaging methods, such as the MRI and in particular CT scanning. Perhaps the most well known of these projects is the Virtopsy® group in Bern, Switzerland [6–11]. It is thus likely that an increasing number of radiological examinations of the deceased will be undertaken by CT or MRI scanning. Given the increasing pressure on forensic pathologists and an increasing awareness and respect within society of different cultural and religious beliefs surrounding death, it is possible that, in certain cases, such as sudden, nonsuspicious death, or accidental death the noninvasive "virtual" autopsy will, in time, replace the traditional dissection.

Accidental Deaths. Forensic pathology plays a significant role in the investigation of accidents as a cause of death. Individual demonstration of all fractures present after a fatal accident is a very time-consuming process and the routine X-ray examination simplifies the procedure. In addition, some fractures are difficult to demonstrate by postmortem dissection and are more adequately demonstrated using radiological methods such as X-ray or CT scanning [2].

X-ray diagnosis is not confined to the study of bones and useful information regarding soft-tissue changes can also be obtained. CT scanning with three-dimensional reconstruction in such cases permits documentation of hard and soft-tissue injuries without the requirement for a full invasive autopsy, and this may prove to be one area where CT scanning proves to be cost-effective.

In some cases, the injection of a radiological contrast medium may be beneficial to the forensic pathology examination. Contrast media can either be "positive", i.e., radiopaque (and thus absorb X-radiation to a greater degree than the surrounding tissues) or "negative", i.e., radiolucent (and thus absorb x-radiation to a lesser degree than the surrounding tissues).

For example, a traumatic subarachnoid hemorrhage arising from a lesion in one of the intracranial arteries may be difficult to demonstrate by dissection.

However, an X-ray examination following injection of an iodine or barium-based (positive) contrast medium into the arteries prior to dissection may provide proof of rupture. In the same way, radiology may be employed to detect the presence of air (a radiolucent "negative" contrast medium) in the thorax, the tissues surrounding the heart, the abdominal cavity, or as an embolus in the heart, brain, or vascular tree to assist the pathologist to determine the cause of death. For this reason, radiography and, in particular, CT scanning is an essential tool in the examination of hyperbaric accidental death in divers (*see also* **Traffic Fatalities**).

Homicidal Death. The most obvious use of X-rays in cases of suspected homicide is to demonstrate bullets and other missiles within the body. Projectiles may be found some considerable distance away from the entry site and radiography can be used to locate these. The deployment of a dynamic imaging method, such as fluoroscopy, will accelerate the process of retrieving ballistic material. Even if the missile is recovered without the aid of radiography, fragments of bullets or of bomb casings or contents can easily be missed in an unaided dissection and important information may be lost to the ballistics expert (*see also* **Gunshot Wounds**).

Terrorist explosions are often caused by uniquely constructed homemade devices. Location and retrieval of fragments from the victims of the attack is often of vital forensic importance and radiography is particularly indicated following such events. For this reason, a full radiological survey is recommended in all such cases in order to locate all projectiles and fragments. Any radiographs that have been taken for the purpose of investigation can be retained as permanent records and, if necessary, used as exhibits at trial [12–15] (*see also* **Explosions: Scene Investigation**).

Radiology is also invaluable in the investigation of large-scale killings such as suspected war crimes and human rights abuses. Radiology will assist in the location of ballistic material, the evaluation of gunshot and/or explosive injuries and the investigation and documentation of any antemortem trauma. Systematic application of radiology in such incidents will be essential [13] (*see also* **Mass Grave Investigation**).

Other forms of homicide are also well illustrated by way of X-rays. Of significance is the radiography of the larynx in cases of strangulation in which fractures of the thyroid cartilage or hyoid bone can be demonstrated, particularly if the cartilages are calcified, a process that increases with age.

Routine radiological examination of suspicious infant deaths is specifically indicated. X-ray examination in cases of suspected nonaccidental injury may yield far more than simply demonstrating the presence of fractures. Radiology may demonstrate the nature of the trauma that caused the fracture, for example, by severe twisting, thus differentiating it from trauma sustained following an accidental fall. It may also be of significance in proving the infliction of injury at various times by demonstrating healing and fresh fractures and such evidence is essential to the concept of systematic abuse. It may also indicate parental inattention to fractures sustained; callus formation at the fracture site is particularly marked when the fracture has not been properly treated by immobilization [2]. Demonstration of active bone replacement can be more accurately determined by using radionuclide imaging, in which the uptake of injected radioisotope-labeled phosphate by bone which is being actively formed can identify an active healing process [16]. Positive findings are not, however, confined to trauma and this should be combined with radiography to make a certain diagnosis. It is of course important to rule out other possible alternative causes of multiple fractures and radiological evidence is essential to this process.

The most common cause of death from child abuse is trauma to the head [17]. Intracranial injury is frequently associated with abusive head trauma and includes subarachnoid and subdural hemorrhage, intracerebral and intracereballar hemorrhage, and massive edema. In addition, intracranial injury and, in particular, subdural hemorrhage is associated with violent shaking of an infant (the so-called shaken baby syndrome), even in the absence of direct trauma to the skull. Such injuries are best demonstrated on CT or MRI scanning and these techniques are recommended in such cases (*see also* **Shaken Baby Syndrome**; **Battered Child Syndrome**).

Examination of Live Subjects

Physical Abuse. Radiological investigation of abuse described above is of course not restricted to the examination of deceased subjects or indeed solely to the examination of children but is routinely

employed in the investigation of all forms of physical abuse of vulnerable adults, e.g., elder abuse, spousal abuse, etc (*see also* **Battered Spouse Syndrome**; **Elder Abuse: Policy**).

Accidental and Criminal Injury. Radiological examination is likely to have been undertaken in the initial diagnosis and management of cases of accidental and criminal injury that later become the subject of legal action. Such cases include road traffic accidents, assault, negligence, etc., and images and radiological reports will thus have medicolegal significance.

Human Identification

Radiology is extremely valuable in the analysis and identification of unidentified human remains and can be used in two main ways:

- deductive identification and
- determination of an individual's personal identity *via* comparative methods.

Deductive Identification

Radiology has the advantage of enabling the examination of remains in a variety of states of decomposition from fully fleshed to completely skeletonized. As such, it affords the opportunity to obtain a considerable amount of data without the need to clean and completely deflesh the remains and thus provides the investigative team with a rapid method of triage and classification by answering a number of fundamental questions:

- determination of human *versus* nonhuman remains;
- recognition of commingling of remains of more than one individual;
- evaluation of the biological profile (age, sex, stature, and ancestry); and
- recognition of embedded/hidden foreign objects and personal effects.

- **Determination of human *versus* nonhuman remains**

Radiographic examination of the bone structure and trabecular pattern can be useful in determining human from nonhuman remains [18, 19] (*see also* **Postmortem Interval: Anthropology**).

- **Recognition of commingling**

In cases involving large amounts of fragmented remains, such as a mass fatality incident, remains may be commingled and mixed with large amounts of debris and artifacts. Physical examination of such remains, particularly in cases of fire damage where there is a uniformity of discoloration of all samples retrieved, is both difficult and time consuming. In such cases, radiological examination can prove useful both in determining the presence of one or more individuals and also in identifying and locating small body parts, especially teeth, which may otherwise be overlooked in the absence of a thorough and time-consuming fingertip search [13, 14, 20] (*see also* **Length Measurement**).

- **Age estimation**

The age of a cadaver at death is particularly well estimated radiologically. In infancy and childhood, the presence of centers of ossification can be demonstrated with accuracy and the union of these centers can be observed up to approximately 25 years of age. In clinical forensic medicine, a radiograph of the wrist of a live subject can be used to determine the "bone age" of individuals claiming to be under the age of majority, either for reasons of seeking asylum or in cases where more lenient sentencing would apply in criminal cases. In later life, degenerative changes may give some indication of maturity, but analysis will only provide a wide age range. The main value of X-rays will thus be to distinguish between two or three bodies who are known as a group but are of unknown individual identity [18, 21, 22] (*see also* **Sex Determination of Remains**).

- **Sex determination**

Differentiation of sexes by skeletal radiology is unreliable until after puberty, as the features that distinguish male from female are not sufficiently developed until this point. In the case of the remains of an individual that has reached puberty, the sex can be established with some certainty and without the need for extensive cleaning processes if suitable bones are available for X-ray. The pelvis and skull are the most useful bones in this respect [18, 23, 24] (*see also* **Species Determination of Osseous Remains**).

- **Stature estimation**

Physical anthropologists are able to make estimations of stature by direct measurement from unfleshed human remains. The length of the femur is usually

used, as this has been shown to be reliable In the case of fleshed remains, the same measurements can be made radiographically, provided that correction for magnification is made [18, 25] (*see also* **Anthropology: Age Determination of Remains**).

- **Determination of ancestry**

Determination of ancestry is challenging, especially when the remains are badly decomposed or skeletonized. Similar methods to those used by physical anthropologists to determine ancestry from skeletal remains can be applied radiographically with fleshed remains. In particular, examination of the skull and mandible the distal end of the femur and the ratio of long-bone length can be useful in the determination of population ancestry [18, 26].

Comparative Identification

Radiology has long been used for the identification of human remains and is well documented. Radiological identification of human remains requires specific and unique findings on postmortem images to be matched with antemortem images of the individual. In some cases, identification can be made from a series of relatively common or nonspecific pathological anatomical changes that appear in identical locations in ante- and postmortem images. In other cases, a single unique feature is sufficient [9, 27–36]. Provided that radiological images taken in life are available, any similar radiograph taken after death can be used for comparison. Radiographs taken for medical purposes are often required to be retained for long periods. With the advent of digital imaging and the decreasing cost of digital storage, many institutions are retaining medical images far beyond their previously applied practice for X-ray film. Records are thus, on the whole, fairly accessible.

Of the structures traditionally used for comparison, the skull, sinuses and the frontal sinues, in particular, are the most useful. The number of variations in shape and size that are potentially available makes a radiographic outline almost unique to the individual. Radiographic examinations of the skull have declined dramatically since the advent of CT scanning, and antemortem radiographic data is thus less likely to be available. However, positive identification can be established by CT, either by comparison with other CT scans or some conventional radiographs [30, 37, 38], although this may prove far more complex and costly to achieve.

Abnormalities that may be useful are numerous; while some congenital abnormalities such as absence of bones, displacement, or malformation may be so rare as to be diagnostic of identity, others, such as fusion of the ribs, are not uncommon and should only be regarded as confirmatory of other circumstantial evidence. Pre-existing disease in the form of changes in bone density, arthritic deformities, etc., may provide evidence of identity if antemortem images are available for comparison. In the same way, unusual calcification in the lungs or lymph nodes or due to degenerative changes in many organs may show a pattern as individual as is that of a fingerprint. The presence of healing fractures in bones known to have been broken in life provides strong evidence of identification as does the presence of surgical prostheses or of supportive implants such as plates, pins, or orthopedic screws. Not only can the X-rays be compared but also the appliance can be removed from the cadaver and superimposed [27, 29, 31, 34] (*see also* **Identification of Human Remains**).

Radiology is particularly valuable for identification following mass disasters, and the routine use of radiological screening in such incidents can lead to rapid identification of individuals known to have had previous fractures, surgery, surgical prostheses, or known anatomical variants. Radiological screening will also facilitate the rapid localization of personal possessions, either concealed within clothing or embedded in charred tissues. It will also enable items of potential forensic significance (e.g., projectile fragments) to be located and retrieved and injuries sustained as a result of explosion to be documented [11, 13–15, 20, 39, 40] (*see also* **Biometric Devices**).

Dental identification of both the single unknown body and in the mass casualty situation is of great importance and radiography very greatly enhances the contribution of the odontologist. The presence of a single or double restoration in one or two commonly filled teeth would be insufficient to prove a positive identification as opposed to an exclusion of identification. The precise shape of the fillings is, however, likely to be unique and identification can be made from a comparison of post- and antemortem radiographs of a single filling. Dental radiography may also show up significant root shapes, socket outlines or abnormalities of tooth eruption, development, or decay [31, 41] (*see also* **Odontology**).

Other Methods

In some difficult cases, facial reconstruction may prove useful in creating a likeness of the individual that stimulates a response to a public appeal for information. Traditionally, reconstruction methods have relied on the skills of the forensic artist to model the features using clay. Computerized reconstruction using CT scanning methods has been proposed as an alternative [42] (*see also* **Facial Reconstruction**).

Detection and Retrieval of Concealed or Embedded objects

In addition to the main applications of diagnosis and identification, radiology is also regularly employed to detect and retrieve objects concealed in, on, or about the person as well as objects that have become embedded in the tissues as a result of a penetrating injury, which may have additional forensic interest to the investigator.

An example of such an application is the retrieval of shrapnel from the subcutaneous tissues of victims of a terrorist bomb attack. Radiology in such circumstances is employed not to diagnose but to guide the treatment of the patient and ultimately retrieval of fragments that may be of forensic significance to the investigation.

Smugglers and, in particular, narcotics traffickers often make use of "body packers" or "mules" to smuggle prohibited goods across borders in packages concealed in the carrier's rectum, vagina or alimentary canal. Radiology is regularly employed to detect packages of narcotics in the alimentary canal that have been swallowed by the carrier. A radiograph of the abdomen has traditionally been employed in such circumstances, but increasing sophistication on the part of smugglers has rendered packages more difficult to detect *via* this method and CT scanning may therefore be used in such cases [43, 44].

Whatever technique is employed, such examinations of the live subject should not be undertaken without the consent of the individual [3], subject to the usual exigencies of a life-threatening medical emergency that renders the patient unconscious and unable to consent. Such emergencies may follow the rupture of one or more of the packages, releasing a high dose of the drug within the alimentary canal.

Rape Trauma Syndrome

Rape trauma syndrome (RTS) is a cluster of common reactions experienced by victims of rape. The term was first used by Burgess [1], a psychiatric nurse, and Holmstrom, a sociologist, to describe the great uniformity of responses they observed among 92 survivors of rape. They divided RTS into two phases: an acute phase characterized by intense symptoms experienced in the days or weeks immediately following a rape and a reorganization phase of more moderate disturbances in the general functioning that may last for years. Subsequent research has conceptualized RTS more in terms of specific symptoms rather than general stages of recovery. RTS is also often used to describe a specific type of posttraumatic stress disorder (PTSD) (*see* **Posttraumatic Stress Disorder**).

Numerous symptoms have been reported in connection with the RTS. The most common symptoms experienced immediately after the rape are the fear and anxiety. Physiological manifestations of fear and anxiety include shaking or trembling, a racing heart, pain, tight muscles, rapid breathing, and numbness. Many survivors report feelings of denial, shock, and disbelief. The experience is often relived in intrusive thoughts and nightmares. Changes in sleeping and eating patterns are typical. Some appear to be confused and disoriented while others may be dazed and numb. The common symptoms are depression, decreased self-esteem, guilt, and self-blame. Hostility and aggression have been observed. Self-doubt and helplessness can replace previous feelings of competence and autonomy. Distorted perceptions such as distrust, pessimism, and paranoia have also been reported.

There are also a variety of more long-term reactions. Many victims develop phobias of things associated with the rape such as being alone or going out at night. Significant changes in the lifestyle such as quitting a job or moving to another residence is not unusual. Disturbances in the general functioning are often manifest by an inability to carry out the routine aspects of life or engage in social activities. Rape also tends to negatively impact the victim's enjoyment of intimate relationships and sex.

Since RTS has multiple connotations, there is no consensus regarding the number, severity, or combination of symptoms required for a diagnosis. The Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-R) American Psychiatric Association [2] does not define RTS as a disorder; therefore, PTSD is more commonly assessed after a rape. The majority of rape victims meet the criteria for PTSD shortly after a rape and about 50% after one year [3]. To meet the diagnostic criteria for PTSD a person must have experienced, witnessed, or have been confronted with a traumatic event that involved actual or threatened death or serious injury – or threat to the physical integrity of self or others – and the person's response must have involved intense fear, helplessness, or horror. Furthermore, the person must persistently re-experience the event, persistently avoid stimuli associated with the trauma and have a numbing of general responsiveness, and display persistent symptoms of increased arousal. Although there is overlap between these criteria and the aftereffects of rape, PTSD and RTS are not necessarily synonymous. Some are critical that PTSD was constructed primarily in response to the studies of adult, male war veterans and does not account for symptoms such as depression, guilt, anger, humiliation, and sexual dysfunction that are common among the rape survivors.

Applications within the Legal System

In addition to assessment and treatment considerations, an understanding of the RTS can be useful in a forensic context. Expert testimony can be used to educate a jury about rape myths, or incorrect assumptions about the causes and consequences of rape (e.g., women cannot be raped against their will,

women secretly wish to be raped, and most accusations of rape are fake). An expert can testify that the victim's psychological reactions are consistent with having been raped if the defendant claims the sex was consensual. RTS can also help explain seemingly inconsistent behavior for a rape victim (e.g., delay in reporting the attack and lack of memory). In civil suits, RTS testimony can be used to support a claim of damages. Finally, it can even be used as a defense for culpable behavior from a rape survivor (e.g., attempted murder of attacker) [4].

Court rulings concerning the admissibility of testimony on RTS and the impact of rape on victims have not been consistent. When it is admitted, there are often strict limitations on its use. Additionally, some appellate courts have reversed trial court decisions regarding RTS testimony. As of 2004, only 20 states allowed medical evidence of RTS when the issue is whether the sex was consensual [3]. There are three major issues that are examined by the courts regarding RTS testimony. First, is whether the testimony is probative or helpful to the jury. Second, is the scientific reliability of RTS (e.g., *Daubert* standard) (*see* ***Daubert v. Merrell Dow Pharmaceuticals***). Finally, and most critical, is the potential prejudicial impact of RTS testimony [5].

Court rulings have fallen on both sides of all the three of these issues. Testimony that describes common reactions to rape and general diagnostic criteria for RTS or PTSD is usually allowed. Testimony regarding whether the victim has RTS or PTSD, or that their behavior is consistent with a diagnosis, is sometimes allowed under certain conditions. Testimony that goes beyond a diagnosis and states that the defendant is telling the truth and was raped is almost never allowed. In general, the term *PTSD* is considered more acceptable in court than RTS because it is included in the DSM-IV-R and does not necessarily imply that a rape occurred [6].

Recollective Accuracy of Posttraumatic Stress Disorder ***see*** Recollective Accuracy of Traumatic Memories

Recollective Accuracy of Traumatic Memories

Canonical traumatic events are life-threatening experiences that produce overwhelming terror in victims who experience them. The memory of such an experience may generate symptoms of posttraumatic stress disorder (PTSD) in some people [1]. Traumatic stressors differ from ordinary stressors in terms of their capacity for threatening life and limb and for inciting extreme fear. Accordingly, researchers have investigated whether memory for trauma differs from memory for other experiences.

By definition, traumatic memories differ from nontraumatic memories in one sense: the former are about trauma, and the latter are not. But do they differ in other, nontrivial ways? For example, are traumatic memories especially likely to be accurate? Contrary to a popular view, memory does not operate like a videotape machine, faithfully storing the sensory impressions of our lives, enabling us to replay the tape upon recollection.

Rather, when people recall an episode from their lives, they reconstruct the memory from encoded elements distributed throughout the brain [2]. The reconstructive character of autobiographical memory ensures that whatever is recalled will inevitably be incomplete and possibly inaccurate. That is, not only will certain aspects of the experience be omitted during recall, but the person may inadvertently remember things differently than how they occurred. In the extreme case, a person may have a vivid "memory" for something that never occurred at all.

The aforementioned facts about memory pose problems for ascertaining the accuracy of memory, traumatic or otherwise. Only in unusual circumstances are veridical records of a trauma available that might serve as a gold standard against which to compare a person's memory. For example, robberies of stores and banks are sometimes videotaped by monitors, thereby permitting evaluation of eyewitness accounts of the event. In other cases, archival records sometimes enable researchers to gauge the accuracy of memories of war trauma [3]. In any event, for memories of trauma, corroborated by independent evidence that the trauma occurred, victims almost always recall their experience [4, 5]. This implies that victims retain, at the very least, memory for the essence or gist of what happened even when some details are altered or omitted [6].

Studies designed to ascertain the accuracy of recollections of trauma usually involve comparing later recall with previous accounts of the event provided by victims. Strictly speaking, these studies pertain to the consistency of traumatic memories overtime rather than to their accuracy *per se*. That is, there is seldom an infallible record of what happened to the person during the trauma, and so lacking such a "gold standard", psychologists have had to compare the testimony of victims long after the trauma with their testimony shortly after the trauma. For example, Wagenaar and Groeneweg [7] found that concentration camp survivors had remarkably good recollection of their traumatic experiences 40 years after they had been released from the concentration camp, relative to their accounts provided shortly after their release.

In an important longitudinal study, Porter and Peace [8] had subjects describe a recent traumatic memory and a recent very positive memory. Subjects rated the memories in terms of vividness, quality, and sensory components. The researchers recontacted subjects between 3.45 and 5 years later, and they found that memories of trauma are highly consistent over time relative to positive memories. Vividness, quality, and sensory features remained high for trauma memories, but declined sharply for positive memories. Severity of stress-related symptoms was unrelated to memory consistency.

Mechanisms of Traumatic Memory

What characterizes traumatic memories and do they differ from memories of neutral, or even positive, events? Several scholars claim that memories of traumatic events have special properties that distinguish them from ordinary memories. By this view, traumatic memories are *qualitatively* different (i.e., processed and stored differently) from other types of memories, thereby involving mechanisms different from those associated with general memory functioning [9].

This view asserts that many survivors of a trauma invoke mechanisms such as repression and dissociation, which result in traumatic amnesia for the stressful event itself. Moreover, it is argued that survivors of a trauma suffer from intrusions with strong

sensory qualities. There are several versions of this theoretical stance [10, 11], but the core assumption they have in common is that trauma has a *special* impact on the way in which memories of traumatic events are organized.

In contrast, other scholars hold that traumatic events do not impair memory for the central gist of the experience (for a discussion, see [12–14]). In fact, they can even enhance the quality of a memory. That is, traumatic events are remembered quite well [4]. Suffice to say, how people remember and forget trauma has been a highly controversial issue in psychiatry and psychology [4, 15].

Several studies on personally involving traumatic events provide evidence *against* the notion that such experiences are poorly remembered. For example, Kuch and Cox [16] studied 124 holocaust survivors and found that traumatic amnesia, with an estimated lifetime prevalence rate of 3%, was quite rare in this group. Likewise, Merckelbach *et al.* [17] found in a group of 29 Dutch concentration camp survivors only one survivor reporting mnemonic experiences that might be taken as evidence for traumatic amnesia. The authors noted that in this case there was a possibility that drug abuse contributed to the poor memory of the traumatic episode. Similarly, Geraerts *et al.* [18] found that in a sample of Croatian war veterans who had been confronted with extremely aversive events during the Balkan wars, traumatic amnesia was rarely reported. It is unclear, however, whether "amnesia" in these studies refers to an inability to recall an encoded aspect of the trauma or whether it signifies a failure to encode certain aspects of the event in the first place.

Porter and coworkers conducted several studies comparing traumatic memory characteristics with memory for other emotional experiences in life. For example, Porter and Birt [19] asked undergraduates to give detailed accounts of their most traumatic memory as well as a description of a positive emotional event, and to rate the number of details in the narrative among other characteristics such as vividness of the memories. They found that the traumatic memories were associated with greater vividness and detail in memory relative to positive memories. Relatedly, Peace *et al.* [20] found that in a sample of survivors of sexual abuse, memories of the abuse were not impaired or fragmented relative to memories related to a nonsexual trauma, or to memories related to a positive event. Instead, memories for sexual trauma were associated with a remarkably high level of vividness and detail.

Confusions about the Clinical Science

These studies indicate that victims tend to remember their traumatic experiences very well. Some clinical theorists, however, believe that a significant minority of victims may dissociate, repress, or otherwise be incapable of recalling their trauma, except under very special circumstances (e.g., psychotherapy; [21]). Unfortunately, these theorists often misunderstand the very studies they cite in support of the alleged phenomenon of repressed memory of trauma. In the following section, we briefly review the most common misunderstandings. For detailed critiques, see [4, 22]

Confusing Everyday Forgetfulness with Traumatic Amnesia

After having experienced a traumatic event, some people report difficulty concentrating and remembering things in everyday life [23]. This kind of memory impairment, however, refers to everyday forgetfulness that develops following the trauma; it does not refer to difficulty remembering the trauma itself.

Confusing Psychogenic Amnesia with Traumatic Amnesia

The term *psychogenic amnesia* is sometimes used as a synonym for traumatic amnesia. They are, however, distinct phenomena. Typical cases of psychogenic amnesia are characterized by an abrupt, immense retrograde memory loss, including loss of personal identity that cannot be attributed to a physical insult to the brain [24]. The syndrome is sometimes preceded by exposure to a stressful event, but these events are often ordinary stressors of uncertain etiologic significance (e.g., difficulties with one's job or marriage). The term *psychogenic* implies the absence of an obvious organic cause rather than an identified psychological one. Most cases of psychogenic amnesia remit within hours, days, or weeks, and often without any therapeutic intervention. With alleged traumatic amnesia, a person is unable to recall a specific traumatic event rather than being entirely unable to recall his or her past.

Confusing Organic Amnesia with Traumatic Amnesia

Clinical theorists occasionally confuse organic amnesia resulting from direct damage to the brain with amnesia resulting from psychic causes. For example, according to Brown *et al.* [25], "Dollinger [26] found that 2 of the 38 children studied after watching lightning strike and kill a playmate had no memory of the event" (pp. 609–610). Brown *et al.* [25], however, failed to mention that both amnesic children had themselves been hit by side flashes from the main lightning bolt, knocked unconscious, and nearly killed. Those children who were not struck by the lightning remembered the disaster quite well, and many had marked symptoms of psychological distress. Hence, the physical, not psychological, aspects of the lightning strike were responsible for the amnesia in these two youngsters.

Confusing Incomplete Encoding with Traumatic Amnesia

The *Diagnostic and Statistical Manual of Mental Disorders Fourth Edition Test Revision* (*DSM-IV-TR*) [1] lists "inability to recall an important aspect of the trauma" (p. 468) as a symptom of PTSD. Accordingly, some clinicians have adduced this symptom as relevant to traumatic amnesia [27]. Unfortunately, the meaning of this symptom is ambiguous. If someone does not remember an aspect of the trauma, one cannot tell (i) whether the person is unable to recall something that was encoded into memory, or (ii) whether the person never encoded the information in the first place. However, not all sensory input arising from an experience, traumatic or otherwise, gets encoded into memory. Under conditions of high arousal, attention often narrows to the most salient feature of an unfolding event such that central aspects get encoded at the expense of peripheral ones. For example, consider "weapon focus" [28]. Individuals robbed at gunpoint sometimes fail to encode the face of the robber, often because their attention is directed to the weapon. Being unable to recall the robber's appearance would not constitute amnesia because the person failed to attend and encode the face of the robber. Therefore, failing to recall something that was never encoded in the first place does not count as amnesia. Amnesia denotes that the material was encoded, but cannot be retrieved.

Confusing Nondisclosure with Traumatic Amnesia

Several studies have shown that a significant minority of adults with documented childhood abuse histories do not disclose these events [29, 30]. This failure to disclose abuse does not necessarily mean that one is unable to recall it. For example, Femina *et al.* [31] recontacted respondents who had described their abuse during a first interview, but had denied it during a second interview. When queried about the discrepancy in a follow-up interview, each respondent affirmed having recalled it during the second interview. The nondisclosing respondents gave several reasons why they had been unwilling to disclose the abuse during the second interview (e.g., did not want to talk about an upsetting experience; dislike of the interviewer). Therefore, one cannot equate failure to disclose abuse with an inability to remember it. Although it may indicate forgetting, practitioners should first rule out the more parsimonious explanation (i.e., a reluctance to disclose).

Confusing Childhood Amnesia with Traumatic Dissociative Amnesia

Most people can remember very little of their lives before age 4 or 5. Brain maturation and cognitive changes make it difficult for older children – let alone adults – to recall events encoded during their preschool years. Accordingly, a failure to recall an episode of childhood abuse from the preschool years may reflect childhood amnesia rather than traumatic amnesia. For example, several of the respondents in Williams's [30] classic study were very young when they had been taken to the hospital for suspected, and often confirmed, childhood sexual abuse (CSA). Their inability to recall the episode many years later was likely a function of childhood amnesia, not traumatic amnesia.

Confusing not Thinking about Something for a Long Time as Traumatic Amnesia

Some researchers have reported that nearly 60% of adult patients who report having been sexually abused as children answer affirmatively when asked whether there was ever "a time when you could not remember" the abuse [32, p. 24]. Such findings have been interpreted as evidence for "sexual abuse-related repression" (p. 26). An affirmative response to this question implies that the patient had spent a period

of time trying unsuccessfully to recall his or her molestation. But if the patient was entirely unaware of having been abused (i.e., had repressed the memory of the experience), why would he or she attempt to recall it in the first place?

On the other hand, if patients had interpreted this oddly worded question as asking, "Was there ever a time when you had not thought about your abuse?", then their affirmative replies make sense. Yet not thinking about something for a long time does not mean that the person was incapable of recalling it during the period when it never came to mind. Only an inability to remember encoded material should be considered amnesia. Had patients been interviewed during the time of their supposed amnesia, recollections of the abuse may very well have surfaced.

Recovered Memories

Aside from the concept of traumatic amnesia, there is much debate concerning whether a traumatic memory can be forgotten, only to be recalled later in life. The authenticity of these so-called recovered memories has often been a reason for discussion. This discussion has mainly focused on memories for CSA.

During the past decade, researchers have begun studying cognitive functioning in people who report having recovered memories of sexual abuse after many years of allegedly not having thought about it. Some research has shown that individuals reporting recovered CSA memories are more prone than other people to falsely remember words that were *not* presented in a list-learning paradigm [33, 34]. This suggests that people reporting recovered memories may be more prone in general to remembering events that they have not experienced, consistent with the possibility that some recovered memories may not refer to genuine abuse episodes.

In contrast, Schooler *et al.* [35] described several case studies of individuals who recalled apparently long-forgotten memories of corroborated CSA, demonstrating that at least some recovered memory experiences pertain to real events. In some of these cases, the partners of the women who reported recovered memory experiences said that the women had talked about the abuse *before* the recovered memory experience. The women were surprised to learn that they had talked about the abuse prior to when they thought they had first recalled it. Evidently, these women had forgotten their prior recollections. Schooler *et al.* proposed that these cases illustrate a "forgot-it-all-along" (FIA) phenomenon, in which remembering an event in a qualitatively new way (e.g., more emotionally) leads the individual to fail to recall prior occasions of recollecting that event.

Using a laboratory analog of the FIA phenomenon, we found that people reporting recovered CSA memories exhibit an FIA effect twice as large as that observed in people reporting continuous memories of CSA [36]. These findings, together with Schooler's observations, are consistent with the possibility that some recovered memories reflect genuine abuse episodes that may have been recalled before, but for which people had forgotten these previous recollections. That is, the FIA effect may result in the illusion that memories of certain events had not surfaced in many years when, in fact, people may simply forget their prior recollections.

Different Recovered Memory Experiences

Both these findings suggest radically different interpretations for how recovered memory experiences come about. How can these phenomena be integrated? Careful inspection of the nature of the recovered memory experience led us to identify two qualitatively different types of recovered memory reports. The differences in these types of reports suggest a way to understand the discrepant findings mentioned above. In one type, people come to believe that they are abuse survivors, commonly attributing current life difficulties to their repressed memories of abuse. Here, recovered memories arise following a prolonged and intensive effort to uncover the repressed memories, often by suggestions of a therapist. There are reasons to believe that some such recovered memories are illusory [37].

In the other type of recovered memory experience, people are suddenly reminded of events that they believe have not come to mind in many years. These recovered memory experiences occur spontaneously – outside therapy – when individuals encounter suitable reminders of the abuse episodes. Such recovered memories are more likely to be genuine than those surfacing during "recovered memory therapy" [37]. For example, it may be that in many such cases the individual underestimates prior knowledge about the abuse. That is, some spontaneously

recovered memory experiences may arise when people fail to remember prior recollections of an authentic abuse episode.

We examined whether there are different cognitive origins of these different types of recovered memory experiences [38]. We found a double dissociation between these groups with respect to performance on laboratory measures of memory designed to target the cognitive mechanisms that may underlie their experiences: People reporting CSA memories recovered during therapy scored high on a measure of susceptibility to false memories, but performed similarly to control subjects on a measure tapping the tendency to forget prior experiences of remembering (the FIA effect). Conversely, people with spontaneously recovered memories of abuse were especially prone to forget their prior remembering (showed larger FIA effects) but scored similarly to control subjects on false memory tasks.

This double dissociation indicates that there are important differences in the cognitive profiles of people who recover memories of CSA either through suggestive therapy or, more spontaneously, without extensive prompting or attempts to reconstruct their past. As a group, people who come to believe that they have recovered a memory of CSA through suggestive therapy showed a pronounced tendency to claim incorrectly that they have experienced events when they demonstrably have not experienced them.

To the extent that this pattern is indicative of a broader deficit in monitoring the source of one's memories, such a finding suggests that these reports of recovered memories should be viewed cautiously, as they may reflect the interaction of suggestive therapy with preexisting deficits in source memory. This concern is reinforced by recent findings that of 16 cases of memories recovered through suggestive therapy, 0% could be corroborated by independent evidence [37]. Nevertheless, it should be stressed that these findings at the group level cannot speak to the validity of any individual's recovered memory experience, and it is possible that some memories recovered in this way are accurate, even if they cannot be corroborated.

In contrast, people who report spontaneously recovering a memory of CSA showed no evidence of heightened susceptibility to the creation of false memories in the laboratory. This group did, however, show a striking tendency to forget prior recollections. Thus, even when prior accessibility of simple events studied in the laboratory could be objectively demonstrated, this group, as a whole, was significantly more likely to deny having remembered those events on previous occasions.

To the extent that performance on such a simple laboratory test is indicative of a broader vulnerability to forgetting in the face of shifts in context, such findings suggest that many members of this spontaneously recovered memory group may have failed to remember their prior thoughts about a genuine incidence of CSA (perhaps because their way of thinking about the event has changed). Consistent with that possibility, memories recovered spontaneously were corroborated by independent evidence at a significantly higher rate (40%) than those surfacing during recovered memory therapy (0%), suggesting that they often may reflect real memories of abuse [37]. These studies do not address *why* people who have spontaneously recovered memories of CSA show a stronger tendency to underestimate their prior remembering, relative to the other groups. One possibility is suggested, however, by recent findings establishing that this population shows, in laboratory measures of thought suppression, an enhanced ability to suppress unwanted thoughts, especially if those thoughts concern negative experiences [39]. If so, then memory for prior thoughts concerning the target CSA event may have been more effectively suppressed because they were unpleasant, impairing their long-term accessibility. If prior retrieval events are forgotten in this way, a subsequent recovery experience is more likely to be judged as novel, creating the experience of discovering a memory for the first time.

Finally, other research on recovered memories of CSA, most occurring spontaneously outside psychotherapy, indicates that the events were not experienced as overwhelmingly terrifying when they first occurred [40, 41]. In this research, the typical victim was nonviolently fondled by a known person, and the young school-age victim did not fully understand that he or she was being sexually exploited. The experience was upsetting, unpleasant, and puzzling, but not traumatic in the sense of being terrifying or life-threatening. These facts increased the likelihood that the victim would not think about the abuse during the ensuing years. However, after encountering reminders much later in life, the person recalls the experience, and is extremely distressed by the realization that it signified sexual abuse.

Conclusion

Several conclusions emerge from our brief survey of the literature. First, memories of traumatic experiences – overwhelmingly terrifying, often life-threatening events – are nearly always remembered very well. Second, because the mind does not operate like a videotape machine, autobiographical memories are not literal reproductions of the original experience. Therefore, even memories of trauma can be incomplete, either because certain details never got encoded in the first place or because peripheral ones have faded with time. But the gist of the experience is highly memorable. Third, questions about the relative accuracy of traumatic versus nontraumatic memories usually are addressed in terms of consistency over time rather than correspondence with a veridical record of what transpired.

Despite being subject to distortion like all memories, memories of trauma tend to be more detailed and more resistant to distortion and forgetting than memories of nontraumatic events. Fourth, there is little or no convincing evidence that memories of genuinely terrifying events that get encoded in memory can later become inaccessible to recall because of repression or dissociation. Fifth, memories of CSA, especially those that did not involve violence, repetition, and terror, can seemingly be forgotten for long periods of time. However, not thinking about something for a long time is not the same thing as being unable to recall it during the period of time when it did not come to mind. Recovering (recalling) a memory of sexual abuse does not imply that the memory had previously been repressed, dissociated, or otherwise blocked from awareness by inhibitory mechanisms. The person may simply not have encountered relevant retrieval cues during the time when the memory never came to mind.

Sixth, individuals who report having spontaneously recovered memories are more prone than others to forget their prior experiences of remembering. Hence, even when people have seeming forgotten memories of CSA, this does not confirm that the memories never surfaced during the long period of apparent forgetting. Seventh, people who recover memories of sexual abuse during psychotherapy designed to foster recall of presumably repressed memories are more prone to false memory effects in the laboratory than are people who recover their abuse memories outside of psychotherapy, and their memories are corroborated far less often than spontaneously recovered memories. Eighth, some people who recover memories of CSA did not understand it as abuse or experience it as traumatic at the time it occurred. Accordingly, because it did not evoke overwhelmingly terror when it occurred, it was especially likely to slip from awareness.

Reconstruction *see*
Reconstruction: Accident

Reconstruction: Accident

Physical Evidence in Accident Reconstruction

The objective of automobile accident reconstruction is to determine how a collision occurred, based on the physical evidence. Vehicle speed, direction of travel, and position on the roadway at impact are often the elements of interest.

The physical evidence may consist of tire marks on the road, damage to the vehicles, debris patterns, and vehicle rest positions. If a police report was prepared, the scene evidence may be documented or recorded with a varied amount of detail. Vehicles are sometimes moved from their initial rest positions by the driver, or at the direction of law enforcement. Tire marks fade with time, and debris fields are quickly cleaned by rescue crews. Generally, few accident scenes are photographed by law enforcement, witnesses, or independent photographers. Because of these variations, accident reconstruction is necessary to determine the most accurate sequence of events.

Classical reconstruction starts with the data postincident and works backward in time to determine the preincident sequence of events. The physical evidence is used to establish the pre- and postimpact motion of the vehicles, the impact orientation between the vehicles, and the vehicle impact speeds. The process of analyzing and utilizing the physical evidence to understand how the accident took place is like putting the pieces of a puzzle back together to compose the original image. Ultimately, the quantity and quality of the physical evidence determine what can be learned about how the accident happened.

A physical inspection of the accident scene provides measurements of the roadway geometry, slope, and surface characteristics, which can be used as the basis for a scaled diagram of the collision site. Any photographs of the scene, taken at the time of the accident, are used to verify vehicle rest positions and other evidence locations. Possible vision obstructions are identified and their location noted. Vehicle tire marks, gouges on the roadway surface, and any damage to curbs, poles, and signs are recorded. Photographs are taken at specific locations to demonstrate the visibility available to the drivers and to document the information or evidence that may degrade or vanish over time. Physical evidence from all available sources is collectively considered to establish the postincident conditions.

Measuring of the vehicular damage assists in the determination of the impact-force direction and quantification of collision energy. Tire damage and tire-to-vehicle interference contribute to postimpact speed calculations. Worn tires, separated drive shafts, and frame bowing are documented for vehicle speed, trajectory, and collision energy analysis.

Photogrammetry utilizes postincident photographs of the scene to reconstruct the location of evidence visible in the photos when actual measurements of the evidence were not documented, and/or the evidence is no longer visible at the scene. Computer-based analytical photogrammetry, using postincident photographs and precision measurement of unchanged scene features, may be used to reestablish the locations of tire marks, gouges, and other physical evidence. This technique can also be used to determine the damage measurements from vehicle photographs when the vehicle has been dismantled.

Vehicle Speed from Skidmarks, Digital Data Acquisition, and Computer Simulation

The speed of an automobile that skids to a stop, without impacting another vehicle or object, can be computed from the length of the skidmarks and the friction value between the vehicle tires and the roadway or driving surface. The mathematical

equation used to compute the speed of a vehicle at the start of skidding is calculated as shown in equation 1.

$$V = \sqrt{254.3 \cdot f \cdot d} \quad (1)$$

where V is the vehicle speed (kilometers per hour, kph), f is the tire-road coefficient of friction (dimensionless), and d is the length of skidmarks (m).

Equation 1 is mathematically derived from the principle of the conservation of energy – any energy in motion is converted to other forms to stop the motion (e.g., heat). Owing to the speed of the vehicle, its kinetic energy is dissipated in the work done by the tires skidding on the road. Note that the calculation is within limits and is not affected by the weight of the vehicle. Therefore, a 2000 kg vehicle will stop in the same distance as a 1000 kg vehicle from the same initial speed utilizing the same type of braking systems.

The coefficient of friction between the vehicle tires and the roadway is affected by several factors. Asphalt, dirt, gravel, and grass yield different friction values with the identical automobile tire. Water on an asphalt roadway may reduce the coefficient of friction for an automobile tire. However, tread depth on tires has a significant effect on tire–road friction on wet surfaces, or when driving in snow or mud.

Partially effective or defective brakes affect the result of a speed from skidmark calculation. One or more tires may be braking at a significantly reduced level or may not be braking at all. Adjustments to the equation must be made to account for this condition. The form of the equation is the same with the addition of a new variable that accounts for braking efficiency.

Table 1 outlines some representative values of the coefficient of friction for automobile tires on various surfaces.

Table 1 Automobile tire coefficient of friction values

Surface	Coefficient of friction
Dry asphalt	0.65–0.85
Wet asphalt	0.45–0.80
Dry dirt	0.55–0.75
Gravel	0.45–0.65
Mud	0.40–0.50
Packed snow	0.10–0.20
Ice	0.02–0.08

Many automobiles are equipped with crash data recorders (CDR). These recorders use sensor-based technologies to measure and track relevant data over time. Data is stored for later reading and enables real-time access to the information. The ability to monitor, record, and analyze vehicle and equipment behavior is an asset to accident reconstruction.

As an example, one American manufacturer provides the postimpact connections to a diagnostic link connector (DLC) or directly to the air bag module, which relates data to supplement the accident reconstruction. Data available varies by manufacturer. Examples of accessible information include vehicle speed, engine speed, brake status, and throttle position (all 5 s before impact), driver's seat belt status, passenger's air bag state (enabled/disabled), as well as change in velocity (ΔV) versus time graph for the deployment event.

Computer simulation programs can be used to predict the movement of colliding vehicles. These models incorporate vehicle dimensions and weight, vehicle inertial properties, tire properties, roadway surface friction, and driver steering and braking inputs. Predicted, postimpact trajectories from simulations that include tire mark information can be used to supplement and/or verify the results of computations based only on vehicle impact and rest positions. Scene and tire mark evidence can be imported into the simulation model for direct comparison to the simulation results. Simulation programs can include vehicle stiffness information that is used to predict the postcollision damage profiles on the vehicles. The predicted damage from the program may be compared with actual vehicle damage measurements or damage photographs to confirm the alignment of the vehicles at impact.

Speed Analysis of Angled, Two-Vehicle Collisions

Two-vehicle collisions, where the vehicles approach impact at a distinct angle to each other, are relatively common. This category of collision can occur at intersections, in parking lots, and on highways when a vehicle crosses into oncoming traffic. Establishing the speed of the vehicles at impact is typically the objective of the analysis.

The approach and departure paths of the vehicles are obtained from physical evidence including tire

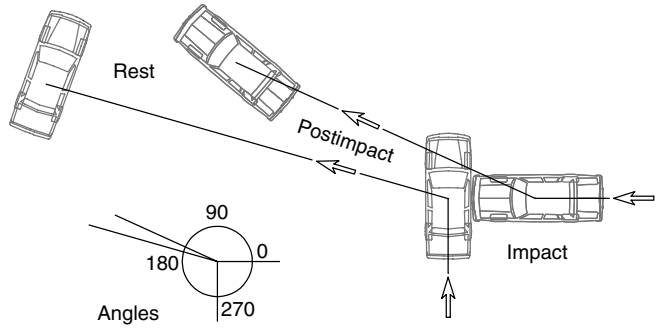

Figure 1 Principal elements of a simple, angled, two-vehicle collision

marks, points of rest of the vehicles, debris fields, and blood stains. A calculation of the postimpact vehicle speeds utilizes various forms of equation 1 or other analytical techniques. The postimpact speed analysis may become quite involved when vehicular rotation/sliding occurs before impacting a roadside object and coming to rest. One equation used to compute the postimpact speed of a vehicle that has been stopped by a roadside object after sliding is shown in equation 2.

$$V\mathrm{p} = \sqrt{V\mathrm{o}^2 + 254.3 \cdot a \cdot d} \qquad (2)$$

where V_p is the vehicular postimpact speed (kilometers per hour, kph), V_o is the vehicular impact speed with roadside object (kilometers per hour, kph), a is the deceleration rate of vehicle while sliding (g units/1 g = 9.81 m s^{-2}), and d is the distance of vehicle sliding before impact with object (m).

The impact speed at the roadside object and the vehicle deceleration rate during sliding must be determined. The impact speed at the roadside object usually involves an energy-based analysis of the vehicle damage from the object.

The postimpact deceleration rate is often computed using a technique that determines the total force on the vehicle, based on the individual forces at each tire, as the vehicle slides and rotates along the roadway. Since some tires may be locked from the initial collision, while others continue to roll, the analysis requires careful interpretation of the physical evidence and vehicle damage.

The principle of conservation of linear momentum is used to compute the impact speeds once the postimpact speeds, departure angles, and approach angles are determined. Figure 1 illustrates the simplified principal elements of a simple, angled, two-vehicle collision.

A number is assigned to each vehicle, and an angular coordinate system is established to allow the formulation of solution equations for the impact speed of each vehicle.

Using linear momentum, the equation for impact speed of vehicle 1 is calculated as shown in equation 3.

$$V_1 = \frac{m_1 \cdot V_1 p \cdot \sin(\theta_1 p - \theta_2) + m_2 \cdot V_2 p \cdot \sin(\theta_2 p - \theta_2)}{m_1 \cdot \sin(\theta_1 - \theta_2)} \qquad (3)$$

where V_1 is the vehicle 1 impact speed (kph); m_1, m_2 are the mass (kilogram) of vehicles 1 and 2, respectively; θ_1p, θ_2p are the postimpact departure angles for vehicles 1 and 2, respectively (degrees); θ_1, θ_2 are the approach angles for vehicles 1 and 2, respectively (degrees); and V_1p, V_2p are the postimpact speeds for vehicles 1 and 2, respectively (kph).

A similar equation is developed for vehicle 2. The impact speed for both vehicles may now be computed using the reconstructed speeds and angles.

Angled collisions may also change the vehicle's direction and speed. Since the preimpact and postimpact speeds and directions have been computed for the vehicles, this "speed change" quantity can be determined for each vehicle. The magnitude of speed change is one of numerous important parameters in assessing the occupant trauma potential of a collision. The speed change direction or principal direction of force is utilized to study the motion of occupants in the vehicle during the collision (termed *occupant kinematics*) as well as the use and/or effectiveness of occupant restraint systems.

Speed Analysis of Inline, Two-Vehicle Collisions

Two-vehicle collisions, with contact between the front of one vehicle and the rear of the other vehicle, with no significant angle or offset, are referred to as *rear-impact inline impacts*. In this type of collision, the impulse (force–time) vector passes through the center of mass of both vehicles. Figure 2 illustrates a rear-impact inline collision.

This kind of collision frequently occurs at low-to-moderate speeds in stop-and-go traffic and at stop signs. The struck vehicle may be stopped or moving forward when impacted from behind. Occasionally, a vehicle will back into the car behind it. Rear-impact inline collisions also occur at high speeds when a faster driver strikes the rear of a slower moving vehicle. Determining the impact speed of the striking vehicle, collision closing speed, and speed change of the struck vehicle are some generalized objectives of accident reconstruction analysis.

The principle of conservation of energy is used to analyze inline collisions where crush damage to the vehicles is significant. Specialized techniques have been developed to analyze low-speed-change, rear-end collisions with minor amounts of vehicle damage, and may involve quantifying the speed change of the struck vehicle using test data for the energy-absorbing bumper systems on the vehicles.

For collisions with significant vehicle deformation, measurements of the crush damage to each vehicle are made using a standard protocol documented in the literature published by the Society of Automotive Engineers. If the vehicles are no longer available, the crush profile may be estimated from photographs, or computed using photogrammetry and control dimensions from an exemplar vehicle. Stiffness values for each vehicle are obtained using the results of crash-safety tests or from other independent sources. The energy associated with the damage to each vehicle is then computed from the stiffness values and crush measurements.

The mathematical equation used to compute the damage energy for a vehicle with a straight crush profile, described by two damage measurements, is calculated as shown in equation 4.

$$E = w \cdot \left[G + \frac{A}{2} \cdot (C_1 + C_2) + \frac{B}{6} \cdot (C_1^2 + C_2^2 + C_1 \cdot C_2) \right] \cdot (1 + \tan^2(\theta)) \tag{4}$$

where E is the vehicle damage energy (N-m), w is the crush damage width (meters), $G = A^2/2B$, A is the stiffness coefficient for no residual damage (kg/meter), B is the damage stiffness coefficient for crush depth (kg/meter^2), C_1, C_2 are the crush depth measurements (meter), and θ is the angle between impact force and vehicular long axis (degrees).

The damage energy is computed for each vehicle separately. Using conservation of energy, an equation is developed to compute the closing speed between the two vehicles at impact. The closing speed equation is calculated as shown in equation 5.

$$Vc = \sqrt{\frac{2 \cdot Ec \cdot g \cdot (w_1 + w_2)}{(w_1 \cdot w_2)}} \tag{5}$$

where V_c is the closing speed between the vehicles (meters per second), E_c is the total damage energy for both vehicles (N-m), w_1, w_2 (N) are the weights of vehicles 1 and 2, respectively, and g is the gravitational acceleration (9.81 m s^{-2}).

The closing speed indicates the rate at which the striking vehicle is approaching the struck vehicle and is equivalent to the differential impact speed (difference between the velocities of the two vehicles). A collision where a stationary vehicle is struck by another vehicle traveling at 10 miles per hour has a closing speed of 10 miles per hour. If the struck vehicle is moving at 40 miles per hour and the striking vehicle is traveling at 50 miles per hour, in the same direction, the closing speed equals 10 miles per hour.

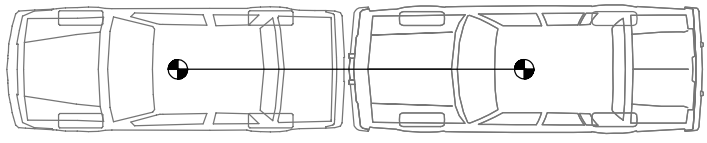

Figure 2 Illustration of a rear-impact inline vehicular collision

Theoretically, both collisions will result in the same speed changes and the same damage to the vehicles.

Once the closing speed is computed, the equations for conservation of energy and momentum are combined to determine the change in velocity (ΔV) or speed change of the struck vehicle. For a rear-end collision, where the struck vehicle is at rest initially, the speed change of the struck vehicle is calculated as shown in equation 6.

$$\Delta V_2 = \frac{1+\varepsilon}{1+w_2/w_1} \cdot V_1 \tag{6}$$

where ΔV_2 is the speed change of struck vehicle (kph), V_1 is the impact speed (closing speed) of striking vehicle (kph), ε is the coefficient of restitution (dimensionless), w_1, w_2 are the weights (N) of vehicles 1 and 2, respectively.

The coefficient of restitution is the ratio of the relative rebound velocity to the relative impact velocity and is a measure of the plasticity or elasticity of the collision. Restitution may be estimated based on the collision closing speed or computed based on test data. Several research studies have produced data for estimating the coefficient of restitution over a relatively wide range of closing speeds.

The value of the coefficient of restitution is within a range of zero (0, for a mathematically plastic collision) to one (1, for a mathematically elastic collision). Collisions tend to be more elastic at low closing speeds and more plastic at higher closing speeds. At a closing speed of 5 kilometers per hour, the coefficient of restitution may equal 0.6. At a closing speed of 25 kilometers per hour, the same two vehicles may have a coefficient of restitution of 0.2. The effect of restitution on speed change calculations is more significant at lower closing speeds.

Autopedestrian Incidents

Collisions involving automobiles and pedestrians may result in the pedestrian being projected some distance beyond the point of impact. In many autopedestrian accidents, there may not be any skidmarks from the vehicle, and therefore, a speed-from-skid mark analysis cannot be conducted. If the physical evidence can be used to determine the impact location and the postimpact trajectory of the pedestrian, a speed analysis for the striking vehicle may be conducted.

Pedestrian travel speeds toward the point of impact cannot be reliably calculated in most cases. Research data from crosswalk observations, pedestrian planning studies, and independent researchers provides a basis for estimating pedestrian speeds by age group. Usually, witness testimony is used to determine if a pedestrian is walking, jogging, or running. Pedestrian walking speeds are generally in the range of 0.31–1.83 meters per second, with an average walking speed of 1.37 meters per second. Running speed may exceed 4.27–4.88 meters per second for young adults, but drops off to about 2.44 meters per second for an adult over 60 years of age. Normally, a range of speeds is used to encompass the specific characteristics of the pedestrian.

Basic principles of physics and empirical data, developed from actual and staged collisions, are used to compute vehicular impact speed from pedestrian projection distance. The relative height of the pedestrian's center of mass must be considered in the analysis as the hood of a typical sedan will contact an adult pedestrian below their center of mass and a child pedestrian above their center of mass. Vehicle impact speed, braking level at impact, and frontal vehicular geometry, along with pedestrian center of mass height and contact location on the vehicle, are general variables influencing the postimpact trajectory of the pedestrian.

At high impact speeds, the pedestrian may pass over the top of the vehicle and not travel appreciably from the point of impact. In some autopedestrian accidents, the pedestrian is carried on the hood of the vehicle and falls to the ground after some travel distance. Not all pedestrian accidents leave physical evidence that establishes the point of impact. In these situations, the projection analysis presented here may not be applied.

One equation, derived from principles of physics, used to analyze vehicle impact speed in autopedestrian accidents is calculated as shown in equation 7.

$$Sp = \frac{V \cdot \sqrt{H}}{8} + \frac{V^2}{202} \tag{7}$$

where S_p is the pedestrian projection distance (meters), H is the pedestrian center of mass height (meters), and V is the vehicle impact speed (kilometers per hour, kph).

The above equation can be solved by simply iterating on the speed variable until a match to the projection distance is obtained, or solved directly for speed using the quadratic formula.

The graph in Figure 3 yields vehicle impact speed from pedestrian projection distance based on the results of field data from actual and staged autopedestrian impacts. This graph is for an adult pedestrian.

Since people are operating the involved vehicles, an evaluation of human performance may also be included. The disciplines of experimental psychology and human factors provide data and general guidance about the human aspects of collisions. Driver perception–response may be analyzed, using the physical evidence and testimony, to access a person's ability to avoid the collision.

Perception/Response

The analysis of automobile accidents relies upon the use of physics and engineering.

The time required for a driver to perceive and react to an unexpected hazard is associated with mental processing and physical action. The components of the process illustrate the complexity of the event:

- Detection – The perception–response time begins when the hazard enters the driver's visual field.
- Identification – Enough information about the hazard is obtained to reach a decision about what action is required.
- Decision – The driver decides what action is appropriate. The driver may brake, swerve, or change speed.
- Response – Commands to the proper muscle group carry out the chosen action.

Experimental studies show considerable variation in the way drivers respond to a given hazard. Some experimental data indicates the perception–response time depends on the evasive action chosen by the driver. Measurement of perception–response time using "real-world" driving hazards is difficult since participants cannot be involuntarily subjected to potentially dangerous situations.

A generally accepted recommendation for driver perception–response time to a reasonably clear hazard and a fairly straightforward situation is 1.5 s. Research data indicates about 85–95% of drivers will respond to the hazard in this time.

Several factors can affect the perception–response time: driver age, fatigue, alcohol, legal and illicit drugs, and driver expectancy. Some collision situations present complex and ambiguous information to the driver. Poor visibility, due to fog, rain, or darkness, complicates a driver's ability to identify a hazard. Adjustments to the perception–response time may be required when one of the components is affected by the circumstances of the collision.

The total distance required to bring an automobile to a stop includes the braking distance and the distance traveled during the perception–response interval. Braking distance increases in proportion to the square of the vehicle speed, and perception–response distance increases in direct proportion

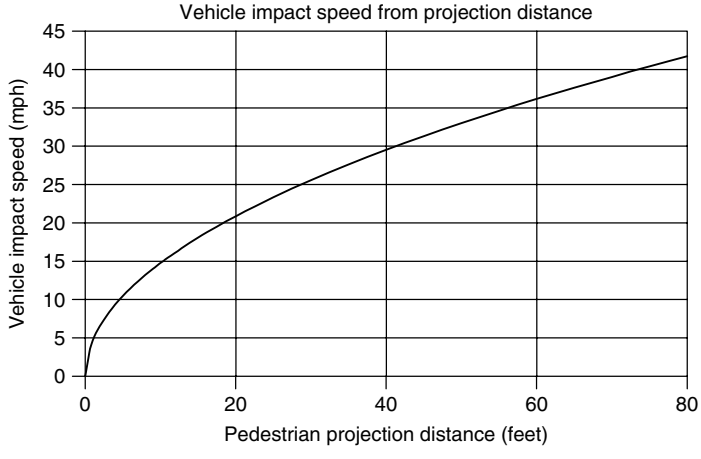

Figure 3 Vehicle impact speed from pedestrian projection distance based on the results of field data from actual and staged autopedestrian impacts (Appel [1])

to speed. Higher speeds give longer total stopping distances.

A driver's ability to avoid a collision, by braking to a stop before impact, is limited by the available stopping distance. The available distance may be determined by visibility obstructions or may be a computed value based on a speed and perception–response analysis. If the analysis shows that a driver was traveling in excess of the posted speed limit when the collision occurred, an avoidance calculation may be conducted to determine if the driver could have stopped ahead of the collision, had he or she been traveling at the speed limit.

Table 2 gives the values of the braking and perception–response distance for a range of vehicular speeds. The table also outlines total stopping distance for a dry road with a coefficient of friction of 0.76 and a driver perception–response time of 1.5 s.

Summary

Reconstruction begins with the examination of physical evidence and the accumulation of essential information. Traffic collision reports, supplemented with scene and vehicle inspections, as well as photographic analysis (from computer-based photogrammetry) may disclose crucial incident data.

After further analysis, pre- and postimpact speeds of the vehicles can be calculated. Vehicular speed prior to impact, if unknown, can be determined with skidmark length, braking efficiency, and quantification of roadway friction (coefficient of friction). The angles of impact and principal direction of force must also be considered. Angled and inline two-vehicle collisions require unique consideration, but necessitate the same insight as to the nature of the collision relevant to vehicular speeds. The magnitude of speed change is an important parameter in understanding occupant kinematics and potential trauma in a collision.

Analysis of automobile–pedestrian incidents may also indicate the nature of the collision and the vehicular speed prior to impact. Driver perception and response time, as well as the relationship of pedestrian projection distance to vehicular impact speed are often utilized in collision analysis.

Examination of available evidence in conjunction with accepted principles in order to further understand the precise nature of collisions is the strength of accident reconstruction. Depending upon the quantity and quality of such data, further analysis and calculations may determine much of the subject incident's unknown variables and lead to an understanding of passenger kinematics and potential trauma.

Table 2 Braking and perception–response distance for a range of vehicular speeds

Vehicular speed (kph)	Perception–response distance (meters)	Reaction distance (meters)	Breaking distance (meters)	Total stopping distance (meters)
5	3.8	3.8	0.1	3.9
10	7.5	7.5	0.5	8.0
15	11.3	11.3	1.1	12.4
20	15.0	15.0	2.0	17.0
25	18.8	18.8	3.1	21.8
30	22.5	22.5	4.4	26.9
35	26.3	26.3	6.0	32.3
40	30.0	30.0	8.1	38.1
45	33.8	33.8	10.5	44.2
50	37.5	37.5	13.2	50.7
55	41.3	41.3	16.3	57.6
60	45.0	45.0	19.5	64.5
65	48.8	48.8	23.1	71.9
70	52.5	52.5	27.1	79.6
75	56.3	56.3	31.6	87.9
80	60.0	60.0	36.6	96.6

Forensic 3D definition

Forensic 3D reconstruction is a new forensic tool to assist scientists, attorneys, judges, and juries to reconstruct a shooting case and explain material traces at scene of crime, on a suspect or victim. Forensic 3D technology uses a visual approach and presents critical evidence by use of pictures, video, and interactive 3D technology. Forensic 3D technology can be used to document crime scene with relevant traces and allows the expert to take measurements on 3D model of crime scene back in the office.

Forensic 3D technology can also be used in preliminary stages of investigation when an investigator wants to test several competing scenarios. Verbal explanations lack precision and are very often misleading when it comes to an explanation of the posture and position of a suspect, a victim, and a witness at the moment of shooting.

Using visual (multimedia) tools in the court, it is possible to present several competing scenarios of the shooting incident and estimate the likelihood of a particular scenario versus others.

Forensic 3D technology overcomes some of the limitations of the classical court reconstruction. Typical problems of the classical court reconstruction are as follows:

- Very often a scene of crime has changed so much or even has completely destroyed; hence, it is impossible to perform a real-court reconstruction.
- Very often the victim was wounded so badly that he is not able to move or demonstrate his positions or postures on crime scene during court reconstruction.
- Forensic 3D technology allows simulation of different conditions of light (day, night, artificial light sources) and weather conditions (wind, rain, snow, and fog). The insertion of sounds is also an option.
- Forensic 3D technology is effective in visualization of results of blood spatter analysis and reconstruction of position and posture of the victim and the suspect during critical moments at the crime scene.

Computer 3D reconstruction of shooting cases must always be based on the material traces found at the crime scene, the victim, and the suspect. This means a special attention must be paid to

- position of the cartridge cases;
- position of the bullet holes in the walls, doors, and similar solid and inanimate objects at the crime scene;
- gunshot residues (GSR) on a suspect's hands, clothing (face, hair, nostrils, etc.);
- GSR on a victim's hands, clothing (face, hair, nostril, etc.);
- report of a medical examiner concerning the wounding channel;

- traces of blood on a suspect's body and clothing;
- traces of blood on a victim's body and clothing;
- traces of blood on a scene of crime; and
- other traces relevant for a specific crime case.

Instead of reconstruction of the dynamics of the whole shooting incident/homicide case, it is sometimes better to reconstruct just some of the important segments of the incident that are capable of being reliable. This means it is better to freeze the suspect and the victim in their positions and postures in 3D space at the moment of the impact/hit according to the material evidence mentioned and reserve 3D reconstruction of the dynamics for the evaluation of different shooting scenarios.

Typical Input for a Forensic 3D Reconstruction

- All the data from the crime scene (measurements, sketches, maps, etc.);
- video data from surveillance cameras;
- versions of the incident provided by the suspects, victims, witnesses, etc.;
- ballistic identification of the weapon used;
- shooter identification/estimation according to the GSR from hands/clothing of the suspect;
- entrance/exit hole determination according to the GSR on clothing/skin of the victim;
- estimated position of the shooter according to known extraction of shells;
- ballistics and GSR analysis results evaluation and comparison with medical examiner report;
- result of blood spatter analysis; and
- estimation of posture and position in 3D space of the suspect and the victim at the moment the bullet hit the victim.

3D technology in the forensic field of application demands multilevel knowledge including engineering skills within the following:

1. Applications not exclusively forensic:
   (a) geodetic (by a total station, laser scanner, or photogrammetry);
   (b) cartography;
   (c) digital video editing;
   (d) 3D modeling using computer-aided design (CAD)/computer-aided modeling (CAM) software.
2. Forensic applications:
   (a) forensic ballistic examination;
   (b) GSR analysis;
   (c) forensic medical examination; and
   (d) forensic blood pattern analysis.

This is the reason why forensic 3D technology needs teamwork on the reconstruction of specific case. The team may typically include the following:

- crime mapping specialist;
- geodetic specialist;
- cartography specialist;
- specialist with skills in 3D modeling, animation, and simulation;
- specialist with skills in the digital video editing field;
- forensic ballistic expert;
- GSR analysis expert;
- forensic medical examiner;
- forensic blood spatter examiner; and
- other types of expert depending on the case.

Typical Forensic 3D Workflow

Typical forensic 3D workflow consists of the following:

- crime scene modeling;
- character modeling;
- inserting the characters in the crime scene;
- simulation of different versions of the shooting incident; and
- creation of the version of the ballistic expert.

Crime Scene Modeling

Manual crime scene modeling is a basic form of crime scene modeling. On the basis of the measurements from crime scene, we model every detail to which importance is ascribed in a specific shooting incident. The modeling is executed by the use of typical 3D modeling tools such as polygon modeling, splitting, extruding faces and edges, Boolean tools, as well as nurbs and subdivision surface tools. Manual modeling can be based on the police sketches, maps and diagrams, or photographs may be used as templates for modeling (Figures 1 and 2).

3D technology allows us to create a virtual "camera" and place it anywhere inside 3D model of crime

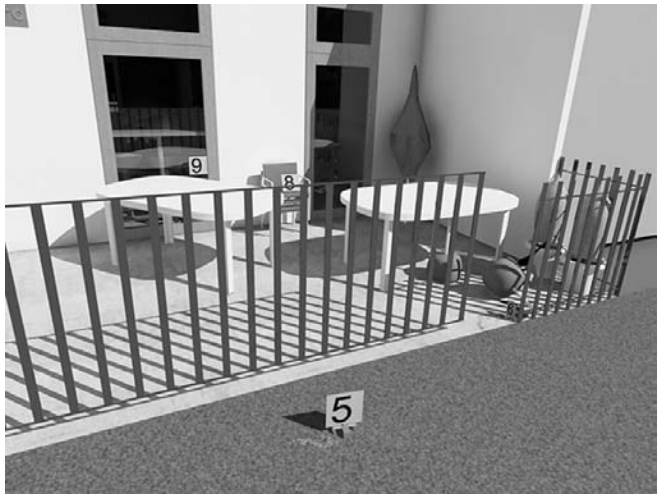

Figure 1 3D model of crime scene – exterior

Figure 2 3D model of crime scene – interior

scene. The advantage of this approach lies in the retention of freedom to choose any camera angle and position so that a shooting incident can be observed from every viewpoint and the "camera" itself can be animated. A "camera" so animated can show not only the crime scene but also a suspect and a victim "frozen" in time in some specific postures and positions in 3D space, while the "camera" is moving around and recording video sequences from different positions and angles, showing details important for the reconstruction of the dynamics of a shooting incident. This concept is known as the "*path animation of a camera*". The disadvantage of this approach is in the amount of work needed manually to model the crime scene itself. The final result is always an approximation of the reality because forensic expert decide what is important in the specific shooting case and what details may be discarded (Figure 3).

The disadvantages of this approach could be overcome by the use of a terrestrial photogrammetry programs that helps us make an exact 3D model of a crime scene based on a sequence of overlapping

photographs of the crime scene (Rollei Metric, Photo Modeler, etc.) or by the use of laser scanners (Ilris 3D, DeltaSphere, etc.).

To get an extremely precise and fast 3D model of a crime scene itself we can use a combination of computerized geodetic equipment (total station) and a laser scanner. Modern laser scanners such as Ilris 3D can scan a whole crime scene (3–1 km) in short time, with an average precision measured in centimeters or even in millimeters. The typical horizontal and vertical precision of the total station for a crime scene ranging from 200 to 300 m is about 10 mm, while laser scanners can achieve a precision measured in millimeters.

This 3D model can be imported into the 3D software and the reconstruction continued. 3D modeling of crime scene is a time-consuming job. To speed up the process it is possible to combine video taken on the scene of crime with a real video camera with computer-generated animated 3D models of the

Figure 3 High-quality 3D model of crime scene with all relevant traces

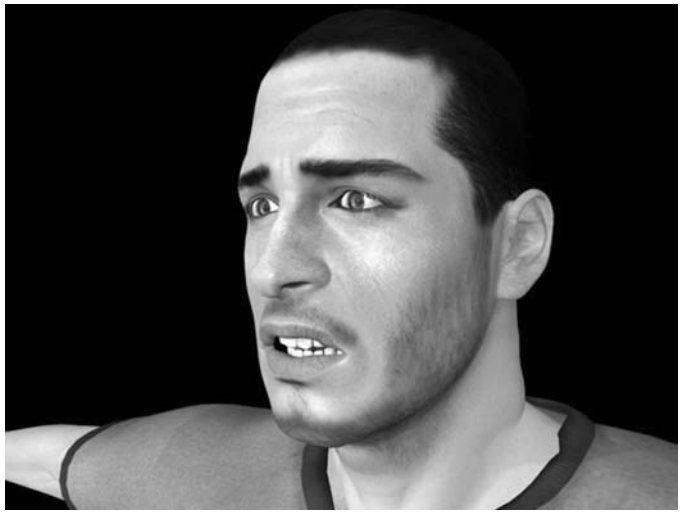

Figure 4 Detailed 3D model created using front and side photographs

suspect and the victim. Techniques used in film industry such as camera match moving and compositing can help to speed up the process. Camera match moving and compositing are special effects techniques that allow the insertion of computer-generated 3D models into video taken with real camera while maintaining correct position, scale, orientation, and motion in relation to the filmed objects in the scene of crime. Same techniques can be used to extract data from film footage taken by surveillance cameras during bank robberies, for example. Height of a perpetrator can be estimated in relation to dimensions of objects in surrounding.

Character modeling

Character modeling can be accomplished in several ways:

- Manual modeling is the most exact type of modeling and unfortunately the most complex one. Using front and side photographs and the "crossed plane method", we can make an exact 3D model of a suspect or a victim (Figure 4):
- creating 3D models of a person, skeletons, and animals using specialized software and
- creating a highly realistic 3D model of a particular victim/suspect by use of specialized laser scanners such as InSpeck.

After a 3D model of human (skin) has been made, it is necessary to create a skeletal system that will drive the parts of the skin. To have better control during the animation process, controls are created for arms, elbows, legs, knees, pelvis, and head, inserted inside the skin, which is bound to the skeletal system (Figures 5 and 6).

In most of the shooting cases where pistols or revolvers are involved, cylinders attached to a certain part of a body can approximate wounding channels. Visualization of wounding channels with a semitransparent body can be a great help in the case of multiple wounding channels (Figures 7 and 8).

Inserting Characters in a Crime Scene

3D models of a victim, suspect, and witness are imported into the 3D model of a crime scene. It is also possible to import 3D models of all the objects necessary for a particular shooting case, such as firearms, knives, cars, and trees (Figure 9).

Simulation of Different Versions of the Shooting Incident

Using character controls of imported 3D models of a suspect and a victim into a 3D model of a crime scene, their posture and position in 3D space can be controlled according to different versions of the

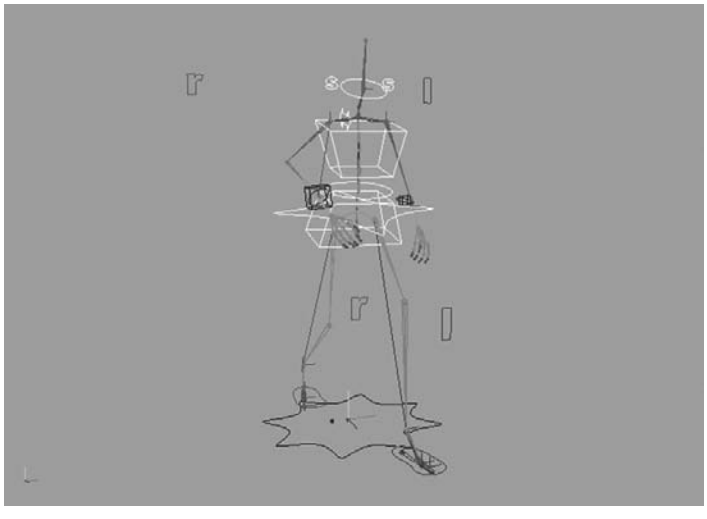

Figure 5 Detailed rigg of a character

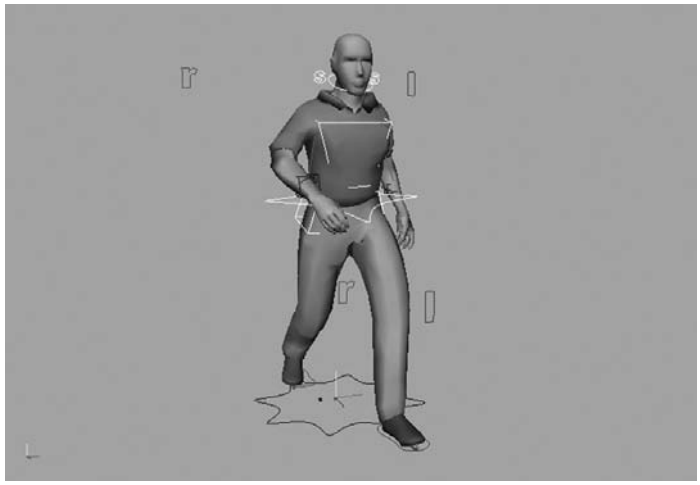

Figure 6 Rigged 3D model of a character

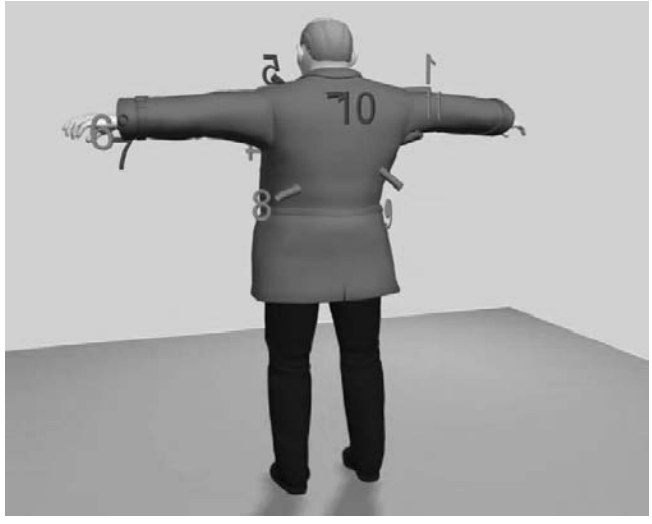

Figure 7 Visualization of wounding channels

incident and the results of forensic examinations (Figures 10 and 11).

The slow and complex work of character animation can be accelerated and greatly simplified by using motion capture systems. Those systems are capable of extracting motion from real people and exporting them in the form of motion capture files that CAD/CAM software can interpret as animation clips. Motion capture systems enable the operator simply to record the motion of a real actor and later to assign that animation clip to a particular 3D model.

Practically, in all shooting cases where several witnesses are involved, different versions of the same incident will be offered. Using the same 3D model of a crime scene suspect, victim and witnesses can be animated according to their versions of the shooting accident. With this technique it is possible to simulate different shooting scenarios. By taking into account all the relevant data from the crime scene and from

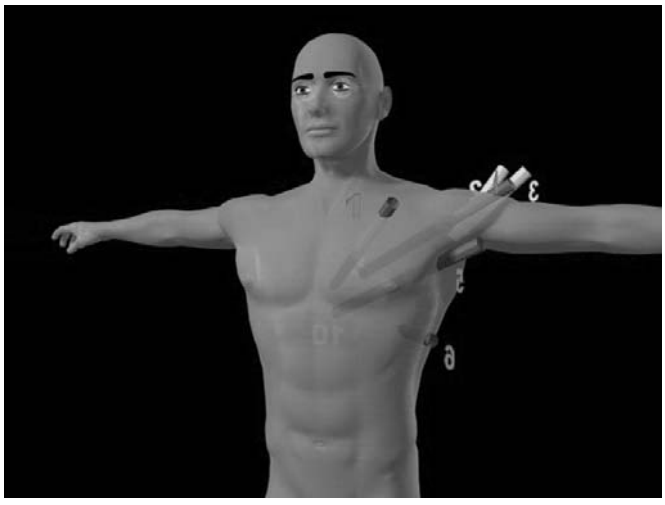

Figure 8 Visualization of wounding channels

Figure 9 Forensic 3D reconstruction of a shooting incident

the laboratory, the ballistic expert can conclude what really happened and hence formulate a version of the shooting incident. Moreover, ballistic expert can show his/her version of the incident in the form of a 3D animation or even in a form of forensic 3D interactive virtual reality (Figure 12).

Forensic 3D Interactive Virtual Reality (VRML)

Forensic 3D interactive virtual reality is a major improvement on Forensic 3D technology since Virtual Reality Modeling Language (VRML) technology permits the interactive inspection of a 3D model

Figure 10 Forensic 3D simulation of a version of shooting incident

Figure 11 Forensic 3D simulation of a version of shooting incident

of crime scene and all versions of particular shooting case. Interactive forensic 3D on the basis of the VRML technology allows virtual entrance inside the crime scene and inspection of every detail (Figure 13).

Contrary to forensic animations where it is impossible to change previously defined angle of a view of a virtual camera, interactive forensic 3D on the basis of the VRML technology allows complete freedom during "navigation" inside 3D model of scene of crime (Figure 14).

The 3D reconstruction of a shooting incident is an invaluable tool for the reconstruction of all dynamic situations where a ballistic expert is required to discriminate among competing versions of a particular shooting case (Figure 15).

Figure 12 Forensic 3D simulation of a version of a shooting incident

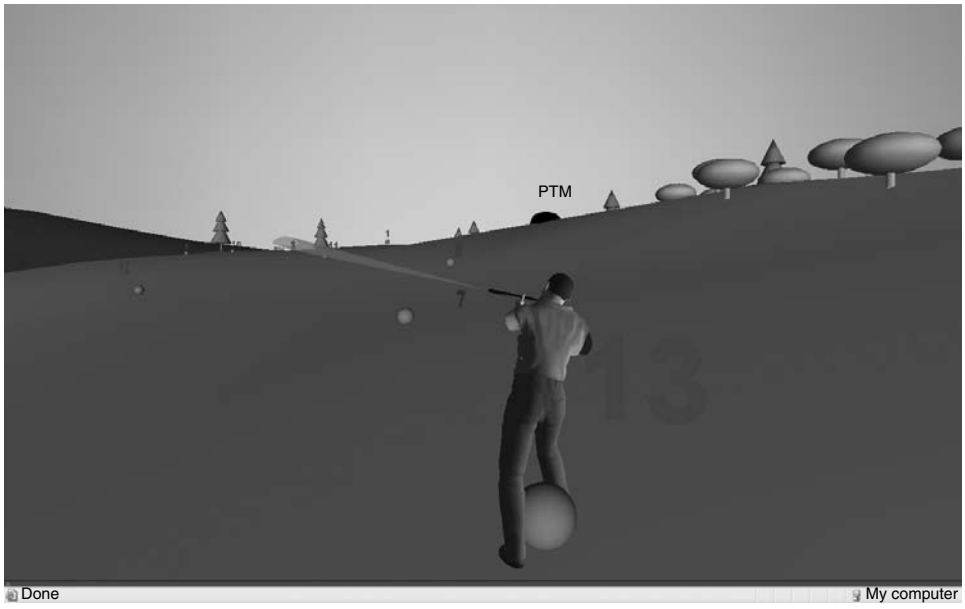

Figure 13 Forensic 3D simulation of a version of a shooting incident

The Errors and Inaccuracies that Exist in 3D Animations

The errors and insecurities that exist in 3D animations merely come from the fact that 3D models of a victim's body and wounding channels are only approximations. 3D models of people involved in a shooting case are only proxies and differ from real persons. A cylinder attached to the victim's body roughly approximates wounding channel produced by the impact of a bullet. The Virtopsy project [1] of Dr Richard Dirnhofer and Dr Michael Thali has

Figure 14 Forensic 3D simulation of a version of a shooting incident

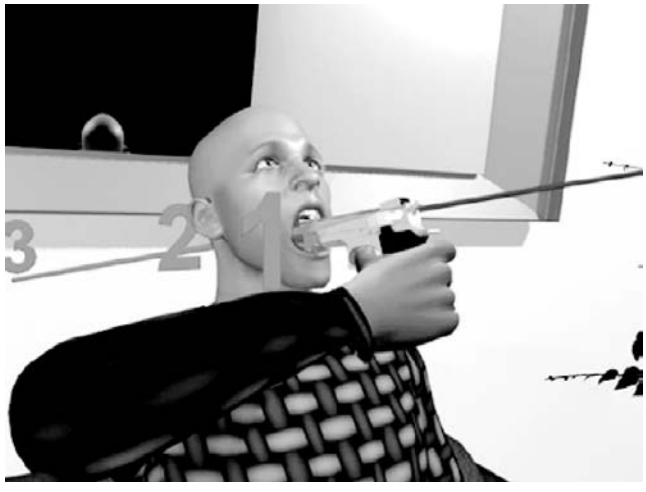

Figure 15 Forensic 3D simulation of a suicide showing version of a "thumb triggering"

a full potential to solve some errors and inaccuracies. The VIRTOPSY project is a unique project that uses imaging methods such as photogrammetry, optical surface laser scanning and multidetector computed tomography or multislice computed tomography (MDCT/MSCT), and magnetic resonance imaging (MRI) techniques [2]. Using laser scanner and photogrammetry software an exact textured 3D model of a victim is produced. Wounding channels are documented using the MDCT/MSCT and MRI techniques. Merging 3D/CAD photogrammetry with 3D radiological scanning, VIRTOPSY project reaches the highest level in 3D Surface and Body Documentation in Forensic Medicine.

The drawback of this approach is that the highly detailed 3D model of a victim and the wounding channel is not applicable for Forensic 3D reconstruction because the VIRTOPSY is applied to a static

body, whereas reconstruction is normally based on the dynamic movement of the body at the time of the incident.

Possible Future Developments of Forensic 3D

- Combination with terrestrial photogrammetry software (Roleimetric, Photo Modeler, GOM TRITOP/ATOS, etc.);
- combination with laser scanners (Ilris3D, DeltaSphere, etc.);
- combination with VIRTOPSY project;
- combination with Compositing and Camera Match Moving software (combination of 3D reconstruction with live footage: video film of a crime scene taken with a physical video camera);
- combination with motion capture systems (capturing motion files of real actors);
- combination with GSR analysis by the use of SEM/EDX;
- combination with terminal ballistics (replacing cylinder with realistic 3D model of a wounding channel);
- combination with game engines used to produce 3D games (This complex technique premises total interactivity inside crime scene with animated characters.); and
- combination with classic Photo-Robot technique (results of Photo-Robot analysis can be extended to a 3D model of the suspect).

Summary

- Forensic 3D is not a new photographic technique. It is rather a new visual analytical technique.
- Forensic 3D should be applied very carefully and be always based on the facts and material evidence.
- Forensic 3D has its limitations.
- It is reasonable to adopt forensic 3D as a novel technique and improve it.

Report Writing for Courts

Introduction

Expert witnesses occupy a unique position within the law and their role in legal proceedings highlights their ability to offer *opinion* evidence, rather than merely evidence of *facts*. Concomitant with the privilege of offering opinions as to the conclusions which may be drawn from the results of their work, experts bear a heavy responsibility. In many jurisdictions, expert witnesses explicitly owe a fundamental and overriding duty to the court, rather than to the party retaining them. For example, the *Civil Procedure Rules* in England and Wales state, "It is the duty of an expert to help the court on the matters within his expertise. This duty overrides any obligation to the person from whom he has received instructions or by whom he is paid" [1]. It is this duty that must be at the forefront of an expert's mind when writing a report for the court.

Given the gravity of the task and the potential for expert evidence to significantly impact upon the outcome of the legal proceedings, there arise several important steps for an expert to take when contemplating on writing a report for the court:

1. When a case file or exhibits are presented to an expert for analysis, first the expert must identify what sort of analysis or assessment needs to be done, in their expert opinion. Although working within a single discipline may provide an expert with case after case of similar evidence, it is important for the administration of justice in every individual case to consciously analyze what needs to be done *in this case*.
2. The expert must identify *why* they think that sort of analysis or assessment needs to be done in this case. This is not a rhetorical question, as lawyers, jurors, and judges who do not share the expert's specialized knowledge will not be familiar with why a particular technique or method of assessment was chosen or rejected in this case. For example, a forensic biologist may decide not to conduct low copy number (LCN) DNA testing on a set of crime scene samples. If a DNA profile has not been obtained using standard techniques, the decision not to use an LCN may seem to investigators, lawyers, jurors, or the judge to be illogical and incomprehensible. It is imperative that the expert in this scenario is conscious not only of why they chose to use standard DNA profiling methods but equally of why they did not use LCN testing (for example, because sufficient precautions were not taken to avoid contamination at the scene and of the samples) [2]. This necessarily requires specialized knowledge of the technique, method, examination, or assessment, and a conscious evaluation by the expert of the appropriateness, validity, reliability, and limitations of the options available to them in the circumstances of the individual case.
3. Which techniques, examinations, or assessments were, in fact, carried out? This may differ from what the expert anticipated in steps 1 and 2. The report must reflect what was actually done, rather than any sort of idealized version of what

the methods/techniques should have been and the results should have shown. If the results indicated that further or different examination/assessment needed to be conducted, the expert must be able to identify why this was or was not done, and what the results (or lack of results) mean. The report must reflect the work that was done and the results that were obtained, including the negative results.

4. In writing the report, the expert should be conscious of each of the previous steps. Sufficient details must be given in the report so that a lay audience is capable of comprehending the results and assessing the reliability and significance of the examination and/or assessment.

Legal Requirements of an Expert Report

Although the details vary depending on the jurisdiction, expert reports usually require consideration of some or all of the elements set out below [3]. In common law countries, these arise both from legislation and from case law; in some instances, it has been case law that precipitated changes to legislation. For instance, in England and Wales, the *Civil Procedure Rules* model the guidelines for expert witnesses set out in the *Ikarian Reefer* case [4].

1. The expert must be independent. As discussed above, the primary duty of an expert is to the court. This means that the evidence given by the expert should not vary on the basis of the side paying the expert's fee. That is not to say that the form and content of the expert's report cannot vary. Naturally, each side to a legal dispute would ask different questions of the same expert and it is entirely permissible for an expert report to focus on answering the questions asked by the side that retained them. What is important is that, if the expert was asked the *same* question by both parties, the expert's answer should be the same. Experts should consult with the lawyer who retained them to ensure that they are addressing the issues required by the retainer, and that they are not addressing matters that are not issues in the case and do not need to be included in the report.
2. The expert should not act as an advocate. If the specialized knowledge of the expert supports the case of the side which called him/her, then the expert is entitled to assist the court with this knowledge. It is not necessary, desirable, or permissible, however, for an expert to have any vested interest in seeking to support one side or the other in a legal dispute. Neither the expert's report nor oral testimony should move beyond their objective opinion and into the territory of advocacy.
3. The expert must remain within his/her area of expertise. "An expert should make it clear when a question or issue falls outside his expertise and when he is not able to reach a definite opinion, for example, because he has insufficient information"[5]. There are two important principles in this statement. First, an expert must be able to clearly identify, to themselves and to the court, their area of expertise. Judges and juries rely on expert witnesses to provide assistance in areas in which the judge/jury does not have specialized knowledge. It is important for experts to stay within their area of expertise, both when writing their report and giving evidence in court. Secondly, expert opinions and conclusions must be scientifically justifiable. The nature of the discipline or a lack of available information may make it scientifically impossible for the expert to reach a definite opinion. This is sufficient and important information for the judge or jury. It is legally, scientifically, and morally imperative that expert witnesses do not fabricate knowledge or certainty they do not have. In addition, it is necessary to identify in writing any other persons who assisted in the examinations or assessments recorded in the report. This usually includes a reference to other experts, laboratory staff, etc., who have handled/tested/participated in the testing of exhibits. This safeguards the expert who may not have handled the exhibits or samples at every step of the forensic process, but who has been asked to write a report setting out the work that has been carried out and their expert opinion of the results.
4. The expert must state the facts and assumptions that underlie his/her opinion. This is an important tool, which seeks to enable judges and juries to assess the expert's opinion. For example, under the *Civil Procedure Rules* in England and Wales, the expert's report must state the substance of all material instructions, whether written or oral, on the basis of which the report

was written [6]. In addition, if the expert is relying on professional literature as a source of facts or assumptions in their report, this should be made clear. It is not necessary to provide a thesis explaining the basis of the discipline; however, particularly if the methods used are at the forefront of science, the expert should refer the court to relevant published literature. Despite their expertise, expert witnesses are not the final word on technical, scientific, or medical questions in a legal dispute. The judge or jury must ultimately decide whether or not they accept the opinion of the expert, and to do this they must know the facts and assumptions that created the basis of the expert's opinions. When writing a report, an expert should also make clear the distinction between facts and opinions. Although the expert is allowed to give evidence of both (unlike ordinary witnesses, who are not generally allowed to offer opinions), the judge or jury needs to know which aspects of the expert's report are accepted facts and which are the opinions of the particular witness.

5. The expert must consider all material facts. In order for the expert opinion to be useful to the judge or jury, the expert must consider not only the facts that support the case theory of the side that retained them but also all of the material facts. Case law amply demonstrates instances of individuals deciding that particular pieces of information are not relevant to the case at hand, when, in fact, if each of those individual pieces of information was disclosed, a significant picture could emerge. This was the case in *R v. Ward*, where seemingly innocuous individual decisions by police officers, prosecutors, counsel, and others, combined to remove a significant body of evidence from the trial, resulting in a successful appeal by the accused. "Taken by itself, [the omitted statement] may well have been thought to have no bearing on the question of the appellant's responsibility for the offences with which she was charged, but when compared with the other [evidence that was withheld], its relevance to the crucial problem of discovering the truth or falseness of the appellant's various statements becomes apparent"[7].
6. Other requirements and considerations. Most jurisdictions specify other requirements for expert reports, which may include a list of the expert's qualifications and experience, a list of prior court testimony, a list of documents or exhibits used to prepare the report, and compensation received for the expert's opinion. Experts are advised to consult the lawyer who retained them to ensure that such requirements are met for the jurisdictions in which they have been asked to write the report. Other considerations such as the length and format of the report vary widely and should be clarified on a case-to-case basis. In all jurisdictions, it is helpful if the expert report is written using plain language, and that jargon and abbreviations are used only when necessary and are defined in the report. Draft reports should be marked as such; these may be subject to discovery in some jurisdictions (*see* **Discovery of Expert Findings**; **Discovery: Depositions**; and **Discovery: Discovery Motions**).

Risk Assessment

Risk assessment comprises the initial and periodic steps taken in determining the quantitative and qualitative risk related to a concrete situation from a recognized threat. Risk assessment is applied in a wide range of situations from public health to presidential protection. In the context of behavioral forensics, risk assessment can be viewed from two perspectives.

The first perspective relates to threat assessment or analysis of threat as it relates to the vulnerability of an individual, facility, or network to outside attack by an individual or group of individuals whose identity may or may not be known. (*see* **Threat Assessment: School** and **Threat Assessment: Workplace**).

The second perspective is risk assessment, which relates to the assessment of a person or persons who may present a threat. (*see* **Dangerousness: Risk of**; **Risk Assessment: Patient and Detainee**; and also **Duty to Warn**).

The principles and tools of risk and threat assessment often overlap, and have evolved steadily over the past half decade. Techniques that prove effective and appropriate in one context may not be applicable to another, however, and, therefore, procedures should be viewed in context and in relationship to specific objectives. Moreover, there are settings in which a professional assessment may both involve objective questions of external risk as well as threat to the evaluator and professional colleagues (*see,* e.g., **Violence Risk Assessment for Mental Health Professionals**).

Risk Assessment: Patient and Detainee

Risk assessment is required in a variety of legal and clinical settings. Nevertheless, there is still substantial disagreement about its scientific validity and how best to implement it into practice, which has led to extensive empirical research into its tenability. Violence risk factors can be grouped into four categories: (i) dispositional, reflecting personal traits and tendencies to act in a particular way; (ii) historical, indexing events in the past that may predispose a person to become violent; (iii) contextual, referring to elements in the current environment that are conducive to violence; and (iv) clinical, including features of mental illness, level of functioning, and substance abuse (*see also* **Duty to Warn**; **Threat Assessment: Workplace**).

Over the years the primary goal of risk assessment has shifted from simple determination of who would become violent in the future, to risk management, which allows for reduction of violence. There are two primary approaches to risk assessment: unstructured, based solely on clinical experience and professional opinion, and structured, which requires professionals to follow specific rules of identification and definition of risk factors. Structured risk assessment in turn includes two approaches: (i) actuarial, which relies on an algorithm to combine risk factors, which enter the final decision regarding future violence, and (ii) structured professional judgments (SPJs), which allow the decision maker to consider how nomothetically supported risk factors are relevant to a given individual, and what management strategies would mitigate risk. Commentary and research addressing the strengths and weaknesses of these approaches is provided.

Risk Assessment

History and Context

The task of risk assessment has come to occupy one of the more controversial positions in corrections, forensic mental health, and related fields. On the one hand, it is legally or professionally required in dozens of contexts [1, 2]. On the other hand, there remains substantial disagreement about the scientific validity of this enterprise [3, 4]. Further, even among researchers and professionals who support the enterprise in principle, there is disagreement about the best way to put it into practice (compare and contrast [5–7]).

Until the late 1960s, it was assumed that psychiatrists and other mental health professionals simply had the ability to forecast the violence of their patients [8]. A seminal and groundbreaking series of studies and commentaries in the late 1960s and early 1970s, however, seriously challenged this assumption [9–14]. In fact, according to Ennis and Litwack [10], we were merely "flipping coins in the courtroom".

Yet, various legal pressures and movements solidified a place for violence risk assessments within the law. The groundbreaking case of *Tarasoff v the Regents of the University of California* [15] established a common law duty to protect certain third parties from the violence of patients and clients. Although this duty has changed over the years, and varies according to jurisdiction, it essentially remains "good law" in many jurisdictions. Numerous legislative enactments, such as Sexually Violent Predator acts in the United States, Dangerous and Long-Term Offender law in Canada, and Dangerous Severe Personality Disorder law in the United Kingdom, all require formal risk assessments to inform the legal decision-making process (for a detailed explication of the legal and clinical evolution of the concept of "dangerousness", see **Dangerousness: Risk of**).

Needless to say, such legal entrenchment has spurred volumes of empirical research into the tenability of violence risk assessment. Early research focused on its weaknesses, claiming that mental health and other professionals should have no place in violence risk assessment [10]. More moderate professional opinion asserted that, as yet, there was not a solid demonstration of the accuracy of risk assessment, but that certain approaches (i.e., empirically based short-term predictions of violence) held more promise than others (longer term predictions of the amorphous construct of "dangerousness") [12]. Monahan's book [12] was influential in terms of charting a course for risk assessment research to investigate specific risk factors, and more empirically based predictions, as opposed to clinically based predictions. In what follows, we review what has been accomplished in the risk assessment field, starting with a review of promising violence risk factors, and then

moving to a description of the common approaches to violence risk assessment.

Risk Factors

Although the existing research corpus on violence risk factors is extensive, we categorize these into the following categories presented by Monahan *et al.* [16]. They described four areas of risk factors: (i) personal or dispositional; (ii) historical or developmental; (iii) contextual or situational; and (iv) clinical or symptom-related factors. Following is a brief description of each of the risk categories along with a summary of the current research findings on this topic.

Personal or Dispositional Risk Factors. This category of risk factors reflects personal predispositions, traits, and tendencies to behave in a particular way that elevates one's risk for violence [17]. They are thought to be generally enduring throughout the lifespan. There are a number of risk factors that fall within this domain and could be further grouped as (i) demographic variables such as age, gender, and race, (ii) personality variables such as impulsivity, anger, and psychopathy, and (iii) neurological factors such as head injury [16]. The most prominent risk markers for violence in this category, however, are impulsivity, anger, and psychopathy. On the basis of research by Raymond Novaco, anger problems and lacking the ability to control its expression have been closely linked to violence [17]. This was found to be particularly true for patients in clinical settings [17].

Further, impulsivity is often linked to aggression, and as such is considered to be a prime precursor to violence. According to Ernest Barratt, who has done extensive research on this topic, personality traits of impulsiveness and anger-hostility are associated with a particular form of aggression – namely, "impulsive aggression" [17]. Individuals possessing such personality traits are likely to experience learning difficulties and behavioral disinhibition [17]. Further, psychopathy is currently known to be a robust predictor of violence among individuals suffering from mental illness and those not so afflicted [18]. Finally, antisocial (procriminal) attitudes have been shown to be important risk factors [19].

Historical or Developmental Risk Factors. This category of risk factors essentially indexes events in the past that may affect a person and predispose him or her to act violently, and can be grouped into three subcategories: (i) social history, (ii) history of mental hospitalizations, and (iii) history of violence [17]. Such events can include modeling of violence by caregivers or authority figures, which eventually can lead people to become inclined to engage in violence. This can occur when children are the victims of abuse and/or neglect. In addition, factors that can moderate the occurrence of violence, such as parental supervision and nurturance, also fall within this domain. Further, parental loss resulting from separation, divorce, or death, as well as psychiatric hospitalization of caregivers, or familial history of drug abuse have also been linked to violence [20]. Such factors may be more detrimental for individuals under the age of 15 [16]. Furthermore, factors such as cognitive impairment are likely to interact with other factors and can essentially predispose people to act violently. Therefore, they too are included in the historical risk factor domain [20]. Also, prior violence and criminality are quite strongly related to risk for future violence, especially among individuals suffering from a mental illness [16]. Finally, factors such as group norms play a significant role in affecting the acceptability of violence, and are also incorporated in this domain. Examples of such factors include cultural and subcultural norms, or membership in particular peer groups, such as Nazis or Ku Klux Klan (KKK) groups [20].

Contextual or Situational Factors. This category includes elements in the current environment which may influence one's behavior and be conducive to violence [17]. There are a number of risk factors that fall within this category, but the most prominent ones can be grouped in the following subcategories: (i) composition of social networks and perceived social support, (ii) perceived stress, and (iii) available means for violence (e.g., weapons). Social networks comprised of high percentage of relatives and low percentage of mental health professionals appear to be positively correlated with violence [21], as do social networks comprised of antisocial peers [19]. Also, violence has been found to be linked to perceived threat and hostility from significant others, however, the predictive power of this association needs to be further examined [21]. Finally, high levels of stress, adverse neighborhood conditions and

easy access to weapons have been found to relate positively with violence incidents [16].

Clinical Risk Factors. Within this category are features of mental illness (i.e., symptoms as well as Axis I and II diagnoses), level of functioning, and substance abuse [17]. Mental illness, defined broadly, has been found to be only moderately related to violence. This relationship, however, appears to be much stronger if mental disorders are comorbid with substance abuse [16], which itself is an important risk factor, or when measured at the symptom as opposed to diagnostic level. Various studies have examined the relationship between hallucinations or delusions and violence [17]. It appears as though there is a positive relationship between hallucinations and violence, but it is nonetheless contingent upon many other factors, such as the course of the disorder or compliance with medications [17]. For instance, in a large-scale study of psychiatric patients, command hallucinations were associated with increased likelihood of violence only if the voices commanded the commission of a violent act [16]. Further, the association between delusions and mental disorders is somewhat unclear. Some studies support an association [22]. However, in others, the presence of delusions has failed to predict higher rates of violence, although nondelusional suspiciousness resulting from perceived hostility in others was positively related to violence [23]. Finally, the presence of certain personality disorders – such as antisocial (or psychopathic) or borderline–appears to be strongly associated with violence, more so than a diagnosis of a major mental illness [16].

It is important to clarify the distinction between risk domains that play role solely in risk assessment (relatively stable, or static, risk factors) versus those that can be used for the purposes of both risk assessment and management (changeable, or dynamic risk factors) [24]. Personal and historical risk factors generally fall within the domains that are mainly relevant to risk assessment. Though they may influence the intensity of risk management, they do little to direct the specific type of risk management that is needed to curtail risk [24]. Contextual and clinical factors, on the other hand, are not only relevant for risk assessment, but are also malleable, and hence important for the purposes of risk management. Since these factors can change owing to direct interventions from clinicians or as a function of circumstances surrounding the individual, they should be assessed on an ongoing basis, and form an important part of risk management [24].

The concept of dynamic risk factors – or, as Andrews and Bonta [19] have termed it, criminogenic needs – plays an important role in more contemporary models of risk assessment and management, a topic to which we now turn. We provide a brief overview of the primary models of risk assessment, how they have evolved over time, and what their main strengths and weaknesses are.

Risk Assessment Models

Risk assessment allows professionals to make informed decisions about individuals' risk for future violence, which is required in numerous legal or clinical settings. Traditionally, the primary goal of risk assessment was to determine who will become violent in the future. Recently, there has been a drastic shift within the risk assessment field in the direction of risk management where the primary objective is not only to estimate future likelihood of violence, but to assess risk factors' variability over time, so as to determine strategies that allow reduction of violence and mitigation of risk [24–27]. This reconceptualization of the primary goals of risk assessment is reflected in the evolution of risk assessment models.

There are two primary approaches to risk assessment that have been employed by professionals: unstructured and structured. Unstructured risk assessment, also known as *clinical prediction or judgment*, is based solely on clinical experience and professional opinion, and does not involve any rules for decision making [28]. Essentially, it embodies Meehl's original description of clinical prediction [29]. Structured risk assessment, on the other hand, requires professionals to follow specific rules in terms of identification and definition of risk factors, and to base their decision about the risk of future violence on those rules [28]. Structured risk assessment includes two approaches: (i) actuarial, and (ii) SPJ. In general, a structured approach includes a fixed set of risk factors and their operational definitions, and provides directions for scoring, coding, and integration of risk factors in the final decision [30]. However, while the former approach (i.e., actuarial) relies on an algorithm that is used to determine the final risk decision on the basis of a rule-based combination of risk factors,

the latter does not. Instead, SPJ requires the decision maker to determine the level of risk on the basis of the specific risk factors present, their individual relevance to the case at hand, and the anticipated degree of intervention required to mitigate risk [26]. Next, we address the strengths, weaknesses, and empirical evaluation of each of these three approaches.

Unstructured Clinical Prediction. Unstructured professional judgment probably has been the most commonly used "method" for the assessment of risk for violence (perhaps owing to a lack of validated, structured tools until well into the 1990s). Technically, it is defined by the absence of combinatory rules at the item integration phase of decision making [29]. There clearly are strengths to a purely clinical approach – it can be used in any setting, it facilitates attention to the individual case, and it tends to be highly relevant to treatment and management considerations.

Nevertheless, this approach is subject to serious limitations when it comes to forecasting the risk of any future behavior [5, 31]. First, given a lack of rules, clinicians often rely on dissimilar sources of information, which inevitably leads to lack of consistency between professionals. In addition, there is often disparity between the risk factors that are taken into consideration, where on occasion important factors are being omitted and instead irrelevant factors are attended to. Further, unstructured professional judgment is highly subjective and informal, and often does not improve upon chance [28]. Finally, the lack of standardization of risk assessment results in low accuracy owing to bias susceptibility and lack of transparency of decision making, which is particularly relevant in legal settings [30]. Currently, there appears to be an agreement among professionals that sole reliance on unstructured clinical judgment is inadequate for comprehensive and reliable risk assessment [32].

Empirical evaluation of the unstructured clinical prediction method supports these criticisms. Early research did not paint a favorable picture of such unaided clinical judgments [9, 33] and later investigations have exhibited mixed findings. Whereas the results of a number of studies provided some – if only limited – support for clinical risk assessments [34–41], many others failed to support this method [42–47]. As such, risk assessment researchers reached the consensus that the lack of procedural guidance characteristic of unstructured clinical assessments generates inadequate interrater reliability which, in turn, represents a major threat to the predictive validity of violence risk evaluations [5, 32, 48]. Consequently, structured decision-making approaches, in the form of actuarial or SPJ frameworks, have been forwarded. We review these in turn.

Actuarial Prediction. To address the shortcomings of a purely unstructured risk assessment approach, professional attention turned to the actuarial method. Technically, this involves an algorithmic combination of risk factors [29], but most (though not all – [49]) actuarial risk assessment schemes also involve empirical item selection. That is, items are selected to be risk factors on a certain risk assessment instrument because they have shown an empirical association with violence, typically in a single sample. Actuarial procedures, by relying strictly on an algorithm to combine risk factors or to make a final decision regarding future violence, tend to improve the consistency (between and within evaluators) and validity of predictions [50]. Further, since the rules for inclusion of risk factors in any given assessment remain unchanged across assessments, actuarial risk assessment approaches can be easily reviewed, or are transparent, which is a desirable feature of a risk assessment procedure.

A number of actuarial violence risk assessment tools have been developed. For instance, Quinsey and colleagues developed the "Violence Risk Appraisal Guide (VRAG)" [5, 51, 52]. Scores on this instrument were highly predictive of future violence in their construction sample (multiple $R = 0.44$). Generally, subsequent studies of the VRAG tend to show that it bears, on average, a moderate relationship to violence. However, some results evidenced generalizability concerns, particularly as it pertains to the performance of the VRAG probability bins that purport to offer precise estimates (i.e., 54%) of future violence [53]. Monahan and colleagues [6, 17, 54–57] developed a risk assessment instrument on the basis of the MacArthur study [6, 16] that, in its original sample, showed highly impressive predictive accuracy – 1% of the low-risk group was violent, compared to 76% of its high-risk group. Upon cross-validation in a new sample, however, predictive accuracy degraded substantially. Now, 9% of the low-risk group was violent, and 35–49% of the

high-risk group was violent [6]. The area under the curve dropped from 0.88 to 0.63–0.70.

These findings illustrate one of the key weaknesses of a purely actuarial approach–precision estimates based on a given sample may not generalize to new samples. In fact, the psychometric properties of actuarial risk assessment instruments cannot be guaranteed for samples other than the sample of development for which those instruments were optimized [32]. Further, actuarial approaches are rather rigid and often fail to incorporate relevant information simply because such information is not contained in the predetermined set of risk factors [58], which, again, is often based on a single sample of participants. Similarly, low base rate risk factors are often ignored by actuarial approaches. Furthermore, even though it would be theoretically possible to incorporate dynamic risk factors, most actuarial models tend to focus mainly on static risk factors, and hence are less relevant to risk management and the reduction of violence [24]. Finally, actuarial procedures that attempt to apply group-derived probability estimates at the individual level may produce highly error-prone estimates [7]. To contend with these actuarial difficulties, some researchers have developed another structured approach to risk assessment and management – SPJ.

Structured Professional Judgment. The SPJ approach to risk assessment was developed to address the limitations of actuarial and unstructured risk assessment. As in actuarial practices, the professional conducting the assessment follows theoretically, clinically, and empirically based guidelines which recommend that a fixed set of risk factors be considered [26]. There are two main differences between SPJ and actuarial approaches. First, whereas most (though not all) actuarial approaches select risk factors based on their performance in particular (usually single) samples, all SPJ measures select risk factors rationally on the basis of a review of their performance in the scientific violence literature broadly. In principle, this practice should enhance generalizability of SPJ approaches. Second, SPJ approaches do not base risk decisions on algorithms or cutoff scores, or offer specific numeric estimates of risk. This is done to avoid the pitfalls associated with such practices, including the generalizability problem mentioned earlier and the tendency of specific numeric estimates to vary considerably between samples [53].

SPJ approaches have been criticized for permitting discretion to enter the decision-making process [5]. The argument is that discretion lowers reliability and validity. However, discretion is incorporated within a structured framework, and is intended to prompt the decision maker to consider how nomothetically supported risk factors are relevant for a given individual, and what management strategies are necessary to mitigate risk.

In fact, empirical evaluation of SPJ approaches tends to support both their interrater reliability, and their predictive validity [30]. All in all, SPJ practices are more structured than traditional clinical prediction, but they also provide more flexibility than actuarial assessment practices in the final decision making by allowing professional discretion in combining risk factors to fit each individual case. Thus, the SPJ model has been forwarded to (i) maintain reliability and validity, and also to (ii) enhance the individual applicability of risk assessment and management [26]. The following section provides a brief summary of the literature on two of the most commonly used SPJ schemes.

The "historical clinical risk management-20" HCR-20 [59], one of the most researched and established SPJ guides, has demonstrated good interrater reliability, construct validity, and concurrent validity with other commonly used instruments, and generates moderate to large effect sizes with regard to violent recidivism [8, 32, 48, 60–68]. Moreover, the predictions based on the SPJs of low-, moderate-, or high-risk exhibit incremental validity beyond those solely based on the HCR-20 total numeric scores. Hence, this SPJ model of decision-making appears to yield useful structured clinical decisions mentioned earlier and beyond what can be anticipated from the actuarial scores on the instrument alone [32, 62, 69].

Another SPJ scheme, The "short-term assessment of risk and treatability" (START) [70], demonstrates promising results in terms of reliability and validity analyses [71]. In addition to the predictive accuracy of the instrument, its associated multidimensional model of violence risk assessment offers uniquely meaningful possibilities in terms of the preventative goals of such psychosocial and forensic enterprises [72]. One of the ways in which it does so is by incorporating patient strengths and weaknesses into its framework.

Conclusion

Both the actuarial and SPJ models of risk assessment hold promise for improving clinical risk assessments. The actuarial approach, however, seems best suited to group decision making, and is hampered by a potential lack of generalizability, and difficulty in meaningfully applying nomothetic data to individual cases. The reliability and validity evaluation of the SPJ approach is promising, and also attempts to enhance generalizability, individual relevance, and risk reduction. Future research should continue to evaluate the strengths and weaknesses of these two approaches, with the eventual goal of minimizing weaknesses associated with both approaches, but facilitating their strengths.

Sampling and Estimation of Quantities

Introduction

A sample is a subset of a population. The population is assumed to consist of discrete units. A sample is a subset of these discrete units. One example is that the units may be bags and the bags may contain powder, as in a drugs case. Another example is that the units may be computer files and the files may contain pornographic images.

Let the population size be N. A census would inspect all N items in the population. There are several disadvantages to a census.

- If N is large, inaccuracies inevitably occur in the inspection process because of resource constraints, hence exact results cannot be guaranteed.
- If testing is destructive, no evidence would remain for any trial.
- Inspection of all items may expose the inspectors to potential health hazards, for example, from airborne dust, physical contact, or mental stress.

Two requirements were given by Wigmore [1] for a sample, presented to show the quality or condition of the population from which it was taken, to be admissible in evidence. They are as follows:

- The population should be substantially uniform with reference to the quality in question (homogeneous).
- The sample should be of such a nature that it is fairly representative of the population.

There are three types of sampling that can be considered in a forensic context. These are simple random sampling, stratified or multistage sampling, and composite sampling. The bulk of the article considers inferences from simple random samples. The extensions to other forms of samples have to be considered carefully.

A simple random sample is one in which all members of the population are equally likely to be selected. A stratified sample is one in which there are several layers or strata in the population. For example, there may be several containers and many packets within each container. The stratified sample would take a random sample of containers and then a random sample of packets from within the random sample of containers.

Consider the following example involving a drug seizure as an illustration of a composite sample [2]. Assume that there are several packets containing tablets. A random sample of the packets is taken. From the contents of each selected packet, a certain number of core samples of tablets are removed. These are combined, placed into a mortar, and ground up

with a pestle into a fine powder. This is the composite sample. The powder is mixed by repeated tossing and stirring to look as homogeneous as possible. A number of subsamples are randomly scooped up from around the mixture and placed into weighing dishes where they are tested for the presence of an illicit drug. If a drug is present in at least one of the core samples prior to mixing, then a subsample from that mixture will, in high probability, test positive for that drug. If the subsample tests negative for that drug, then no further sampling or testing would be carried out and all packets would be declared free of that drug.

Sample sizes and the interpretation of data from samples are discussed from both the frequentist and the Bayesian perspectives.

With reasonable assumptions in the Bayesian context, a probability distribution for the true proportion of illicit units in a consignment may be derived on the basis of the scientist's prior beliefs (i.e., prior to the inspection of individual units) and the outcome of the inspection of the sample. The strength of the scientist's prior beliefs may be expressed by a probability density function. For example, if the scientist believes that the consignment is either all illicit or all licit with only a small probability of anything in-between, the probability density function that represents the scientist's prior beliefs would be U-shaped on the interval (0,1) (corresponding to 0–100%) with most weight at the 0 and the 1 ends with little weight in-between. It is possible to choose the function in such a way that the effect of the scientist's prior beliefs is very small (or very large). The choice of the model that is used to represent the uncertainty introduced by the sampling process is a subjective choice influenced by the scientist's prior beliefs. The choice of a binomial model, for example, requires assumptions about independence of the probability for each unit being illegal and the choice of a constant value for this probability.

The methods are illustrated with reference to sampling from consignments of drugs. However, they apply equally well to sampling in other forensic contexts, for example, glass [3] and pornographic images.

Simple Random Samples

The most well-known type of sample is the simple random sample. This is a sample in which every member of the sample has an equal probability of being selected at any draw from the population.

In order to draw a sample from a population, it is highly desirable to be able to associate a unique identifier with each member of the population. In certain populations, this is relatively straightforward. For example, a population of voters in an election is provided by the electoral register and the identifiers on the electoral register may be used. In other populations, it is not so straightforward. For example, in a large consignment of white tablets, it would be very difficult to associate a unique identifier to each tablet. When it is possible to construct a list, the list of unique identifiers is known as the *sampling frame*.

> In the use of random numbers, the material must first be broken up in some manner into *sampling units*. Moreover, each sampling unit must be identifiable by a serial number, actual or by some rule. For packaged articles, a rule is easy .... In the case of bulk material, ... the problem of defining usable sampling units must take place at an earlier stage of the manufacture, or in the process of moving the materials. [4]

Once the sampling frame has been constructed, the choice of a member from the population for inclusion in the sample is made at random. This can be done using electronic calculators, computers, tables of random numbers, or, in the special case of equal probability (0.5, 0.5) of selection or not, even by the simple toss of a fair coin.

It may be that it is not possible to take a simple random sample. If so, the following comments are also of relevance. The comments are made in the context of sampling for the estimation of allelic frequencies in DNA profiles but are applicable to other areas of forensic science.

> ... every case must be treated according to the circumstances within which it has occurred, and the next response is that it is always a matter of judgement .... In the last analysis, the scientist must also convince a court of the reasonableness of his or her inference within the circumstances as they are presented as evidence. ([5], pp. 44–45)

Some comments extracted from the appendix of ASTM E 105-04 are also of relevance in the discussion of randomness.

> Note that calculation of the margin of error or the risk in the use of the results of samples is possible only if the selection of the items for test is made at

> random .... For a method of sampling to be random it must satisfy statistical tests .... Randomness is obtained by positive action; a random selection is not merely a haphazard selection, nor one declared to be without bias .... One may declare that a lot of item is "thoroughly mixed" and hence that any portion, even the top layer, would give every item an equal chance of selection. In the absence of elaborate steps to mix the product, followed by careful tests for randomness, such assumptions are risky, as they often lead to wrong results.
>
> Nonrandom and judgment sampling are not of no value. If the material being inspected is known to vary but little, a 'grab' sample will be helpful in assessing the level of the characteristic concerned.
>
> Systematic sampling, in the absence of knowledge concerning the order of the material, does not permit a valid calculation of the standard error.

For small samples, the sampling units may be taken to be sampling without replacement. The hypergeometric approach is used [6] in the frequentist context. The Bayesian approach also has different methods for analyzing large and small samples.

The ratio of the sample size to the population size is known as the *sampling fraction*.

Criteria for Sample Size Determination

Frequentist Criteria for Determination of Sample Size

Frequentist procedures for choosing a sample size from a consignment are described in Tzidony and Ravreboy [7]. Distinction is drawn between an approach based on the binomial distribution and an approach based on the hypergeometric distribution. The former can be used for large consignments (greater than 50 in size) in which the sampling of units may be taken to be sampling with replacement.

Various institutions issue guidelines on sample size choice. These include the United Nations, the European Network of Forensic Science Institutes (ENFSI), and the Scientific Working Group for the Analysis of Drugs (SWGDRUG) of the US Department of Justice Drug Enforcement Administration.

United Nations guidelines differentiate between powders, licit tablets, and capsules where a high level of quality control may be assured, and illicit tablets and capsules where a high level of quality control is not assured. The guidelines are given in Table 1.

For small samples of opium, morphine, and heroin, the United Nations guidelines provide tables for sample sizes based on the hypergeometric distribution, using the criterion that an inference is made at the 95% confidence level and that 90% or more of the packages in an exhibit containing the controlled substance should be accepted as sufficient proof in such cases ([8][6]).

Guidelines on representative drug sampling are also provided by ENFSI [9], with comments.

- Sample all: advantage – 100% certainty about the composition of the population; disadvantage – excessive sample sizes for large populations.

Table 1 Sample size guidelines from the United Nations for various drugs

Consignment size N	Sample size	Drugs
Powders		
< 10	All	Methaqualone, cocaine, barbiturates
10–100	10	Cannabis, benzodiazepine, psilocybin
> 100	$\sqrt{N}$	Opium, morphine, heroin, mescaline
Tablets and capsules (licit) (du = dosage unit)		
$1 - 50$ du	$N/2$ (up to 20)	Methaqualone, barbiturates
$51 - 100$	20	Benzodiazepine, psilocybin
$101 - 1000$	30	Mescaline
> 1000	$\sqrt{N}$	
Tablets and capsules (illicit)		
≤ 10	All	Methaqualone
$11 - 27$	$3N/4$	Lysergide
≥ 28	$N/2$	
	$21 \leq N/2 \leq 50$	

- Proportion of N: advantage – simple; disadvantage – excessive sample sizes for large populations.
- A function of $\sqrt{N}$: advantage – widely accepted; disadvantage – too small for small populations, excessive sample sizes for large populations.
- $n = 20 + 10\%(N - 20)(N > 20)$: advantage – heterogeneous populations likely to be discovered before the analysis is complete; disadvantage – excessive sample sizes for large populations.

$$\text{for } N < x \qquad n = N$$
$$x \le N \le y \qquad n = z$$
$$N > y \qquad n = \sqrt{N}$$

(where x, y, and z are arbitrary numbers; $x < y$ and $x \le z < y$) advantage: United Nations Drug Control Program recommended method ($x = 10$, $y = 100$, $z = 10$); disadvantage – excessive sample sizes for large populations.

- $n = 1$: advantage – minimum amount of work; disadvantage – least amount of information on the characteristics of the seizure.

The Scientific Working Group for the Analysis of Drugs (SWGDRUG) of the US Department of Justice Drug Enforcement Administration recommendations for a sampling plan has several components.

- The issue of homogeneity.
- For inhomogeneous bulk material, several samples from different locations may be necessary to ensure that the test results are representative of the bulk material and false negative results are avoided.
- Statistical approaches are applicable when inferences are to be made about the whole population, as in
  - the probability that a given percentage of the population contains the drug of interest or is positive for a given characteristic,
  - the total net weight of the population is to be extrapolated from the weight of a sample.

Bayesian Criteria for Determination of a Sample Size

A Bayesian approach provides summaries in probabilistic terms such as

> "How big a sample should be taken for it to be said that there is a $100p\%$ probability that the proportion of units in the consignment which contains drugs is greater than $100\ \theta\%$?"

Or, for a particular case, with $p = 0.95$ and $\theta = 0.50$,

> "How big a sample should be taken for it to be said that there is a 95% probability that the proportion of units in the consignment which contains drugs is greater than 50%?"

See the SWGDRUG comments on the applicability of statistical approaches to illustrate the relevance of this approach.

Choice of Sample Size for Discrete Data

Large Consignments

A consignment of drugs containing N units is considered as a random sample from some superpopulation of units, which contain drugs. Let θ $(0 < \theta < 1)$ be the proportion of units in the superpopulation (of which the consignment is a member) that contain drugs. Let m be the number of units sampled from the consignment. The sampling fraction is m/N. Denote the numbers (out of m) that are found to contain drugs by $z(\le m)$. Then, the probability distribution for z, given m and θ, is the binomial distribution

$$Pr(z|m, \theta) = \binom{m}{z}\theta^z(1-\theta)^{m-z}; \quad z = 0, \ldots, m \tag{1}$$

The purpose of the inspection of the sample is to determine an estimate for θ.

A Frequentist Approach. The sample proportion that contains drugs $p = z/m$ provides an estimate of θ. The variance of p is given by Cochran [10] as

$$\frac{\theta(1-\theta)}{m}\left(\frac{N-m}{N-1}\right) \tag{2}$$

The term $\theta(1-\theta)/m$ is the standard deviation of a sample proportion z/m from the binomial distribution in (equation 2). The factor $(N-m)/(N-1)$ is known as the *finite population correction* (fpc). Provided the sampling fraction m/N is low, the size of the population has no direct effect on the precision of the estimate of θ. For example, a sample

of 500 from a population of 200 000 gives almost as precise an estimate of the population proportion as a sample of 500 from a population of 10 000. The estimated standard deviation of θ in the second case is 0.98 times the estimated standard deviation in the first case. Little is to be gained by increasing the sample size in proportion to the population size. Given a desired magnitude δ for the standard deviation, it is possible to choose the sample size necessary to achieve this. Set δ equal to $\sqrt{\{\theta(1-\theta)/m\}}$. Then, $m = \theta(1-\theta)/\delta^2 < 1/(4\delta^2)$, the maximum value attained when $\theta = 1/2$. A sample of size m equal to the smallest integer greater than $1/(4\delta^2)$ is the smallest sample size that satisfies the requirement that the standard deviation be less than δ.

A Bayesian Approach. This approach is based on combining a binomial likelihood for the number z of members of a sample of size m that contain drugs with a beta-distribution, with parameters α and β for the proportion θ of the superpopulation of which the consignment is a subset. The prior distribution for θ is taken to be a beta-distribution with the probability density function given by

$$f(\theta|\alpha,\beta) = \frac{\theta^{\alpha-1}(1-\theta)^{\beta-1}}{B(\alpha,\beta)},$$
$$0 < \theta < 1,\ \alpha > 0,\ \beta > 0 \qquad (3)$$

denoted $B(\alpha,\beta)$, where

$$B(\alpha,\beta) = \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha+\beta)} \qquad (4)$$

and Γ is the gamma function, where

$$\Gamma(t+1) = t!\ \text{ for integer }\ t > 0 \qquad (5)$$

A scientist who believes that the consignment is either all illicit or all licit with a small probability of something in-between would choose values of α and β close to zero. Then, combining the beta prior (equation 3) with the binomial distribution (equation 1), the posterior distribution for θ given m, z, α, β is

$$\Pr(\theta|m,z,\alpha,\beta) = \frac{\theta^{\alpha+z-1}(1-\theta)^{\beta+m-z-1}}{B(\alpha+z,\beta+m-z)} \qquad (6)$$

a posterior beta distribution for θ, given the sample size m, the number of illicit units $z(\leq m)$, and prior parameters α and β.

Consider the criterion that the scientist wishes to be 95% certain that 50% or more of the consignment contains drugs when all units sampled contain drugs (i.e., $m = z$). Then the criterion may be written mathematically as

$$\Pr(\theta > 0.5|m,m,\alpha,\beta) = 0.95 \qquad (7)$$

where m replaces z as the second term to the right of the conditioning bar to show that $z = m$. This criterion may be written in integral form as

$$\int_{0.5}^{1} \frac{\theta^{m+\alpha-1}(1-\theta)^{\beta-1}\mathrm{d}\theta}{B(m+\alpha,\beta)} = 0.95 \qquad (8)$$

The general question of Section (3) in which p and θ are specified may be answered by finding the value of m, which solves the equation

$$\int_{\theta}^{1} \frac{\theta^{m+\alpha-1}(1-\theta)^{\beta-1}\,\mathrm{d}\theta}{B(m+\alpha,\beta)} = p \qquad (9)$$

Such integrals are easy to evaluate using standard statistical packages, values for m, α, and β being given. Given specified values for θ and p and values for α and β chosen from prior beliefs, the appropriate value of m to solve (equation 9) may be found by trial and error. See Table 2 for examples of values of p for given values of m, α, and β.

There may be concerns that it is very difficult for a scientist to formalize his prior beliefs. However, if α and β are small, large differences in the probabilities associated with the prior beliefs do not lead to large differences in the conclusions. This is not the case, however, if there is a probability of a misclassification error [11]. A frequentist approach using the hypergeometric distribution, with an adaptation to allow for false positives and false negatives is described in Faber *et al.* [12]. The methodology can be extended to allow for units that do not contain drugs.

The dependency of the sample size on the values of p and θ is illustrated in Table 3. The prior

Table 2 The probability that the proportion of drugs in a large consignment is greater than 50% for various sample sizes m and prior parameters α and β

		m			
α	β	2	3	4	5
1	1		0.94	0.97	
0.5	0.5	0.92	0.97	0.985	0.993
0.065	0.935		0.90	0.95	0.97

Permission needed from JFS

Table 3 The sample size required to be $100p\%$ certain that the proportion of units in the consignment that contains drugs is greater than θ, when all the units inspected are found to contain drugs. The prior parameters $\alpha = \beta = 1$

	p		
θ	0.90	0.95	0.99
0.5	3	4	6
0.6	4	5	9
0.7	6	8	12
0.8	10	13	20
0.9	21	28	43
0.95	44	58	89
0.99	229	298	458

Permission needed from JFS

parameters α and β are set equal to 1. Consider $p = 0.90$, 0.95, and 0.99 and consider values of $\theta = 0.5$, 0.6, 0.7, 0.8, 0.9, 0.95, 0.99. The sample size m required to be $100p\%$ certain that θ is greater than the specified value is then given by the value of m that satisfies the equation

$$\Pr(\theta > \theta_0 | m, m, 1, 1) = 1 - \theta_0^{m+1} = p \quad (10)$$

a special case of (equation 9). The value of m is thus given by the smallest integer greater than

$$\left[\frac{\log(1-p)}{\log(\theta_0)}\right] - 1 \quad (11)$$

Variation in the prior beliefs, expressed through variation in the values of α and β, may have little influence on the conclusions, once some data have been observed. Figure 1 illustrates the prior probability that the true proportion of illegal units in a consignment is greater than a value θ, for $0 < \theta < 1$ for three choices of α and β. Figure 2 illustrates the posterior probability that the true proportion of illegal units in a consignment is greater than θ, for these choices of α and β, once four units have been examined and all are found to be illegal.

Small Consignments

Suppose now that the consignment size N is small, say $N \leq 50$. A sample of m units from the consignment is examined and $z(\leq m)$ units are found to contain drugs.

A Frequentist Approach. Consider a frequentist approach based on the hypergeometric distribution.

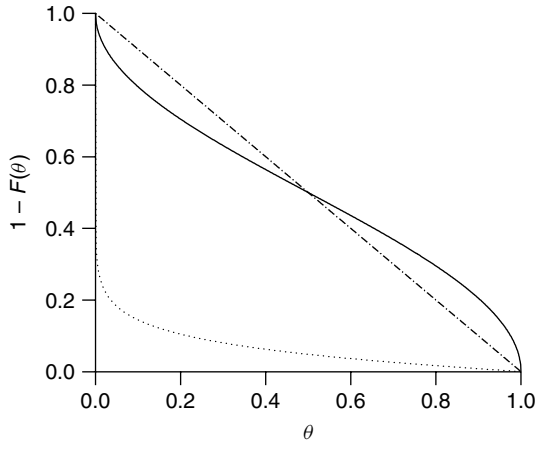

Figure 1 The prior probability $1 - F(\theta)$ that the proportion of units in a consignment is greater than θ, for various choices of α and β: $\alpha = \beta = 1(- \cdot -\cdot)$, $\alpha = \beta = 0.5(-)$, $\alpha = 0.065, \beta = 0.935(\cdots)$ [Reproduced with permission from JFS.]

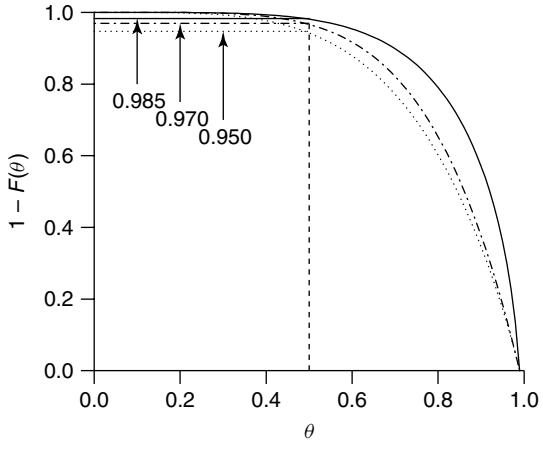

Figure 2 The posterior probability $1 - F(\theta)$ that the proportion of units in a consignment is greater than θ, for various choices of α and β: $\alpha = \beta = 1(- \cdot -\cdot), \alpha = \beta = 0.5$ $(-), \alpha = 0.065, \beta = 0.935(\cdots)$, after observation of four units all found to be illegal. The corresponding probabilities that at least 50% of the consignment contains illegal units is marked as $0.985(\alpha = \beta = 0.5), 0.970(\alpha = \beta = 1), 0.950$ $(\alpha = 0.065, \beta = 0.935)$ [Reproduced with permission from JFS.]

Examples are given in Bates and Lambert [13] and Faber *et al.* [12]. Let $R = Z + Y$ be the total number of units in the consignment that contains illicit drugs,

where Z is the number of units in the sample of size m and Y is the number of units in the remainder $(N - m)$ that contain drugs. Then, the distribution of Z is hypergeometric with

$$\Pr(Z = z) = \frac{\binom{R}{z}\binom{N-R}{m-z}}{\binom{N}{m}}, \quad z = 0, 1, \ldots, \min(R, m) \tag{12}$$

The lower limit for θ is R/N, where R is the maximum number of illicit units in the population, which satisfies the following inequality

$$\sum_{i=0}^{r} \frac{\binom{R}{m-i}\binom{N-R}{i}}{\binom{N}{m}} \leq \alpha \tag{13}$$

where r is the number of nondrug items in the sample and the confidence level is $100(1 - \alpha)\%$ [7]. When $m = z$, the inequality is

$$\frac{R!(N-m)!}{N!(R-m)!} \leq \alpha \tag{14}$$

A Bayesian Approach. A Bayesian approach for small consignments using the hypergeometric distribution is described in Coulson *et al.* [14]. A discrete prior distribution is chosen for the $(N + 1)$ possible divisions of the consignment into licit and illicit items. The likelihood function is based on the hypergeometric distribution sampling m from N and a posterior distribution obtained.

An alternative Bayesian approach for small consignments uses a so-called β-binomial distribution. This distribution provides a probability statement (as distinct from a confidence statement) about the number of units in the consignment that contains drugs.

As before, let θ $(0 < \theta < 1)$ be the proportion of units in the superpopulation that contains drugs. The probability distribution of z, given m and θ, may be taken to be binomial. For each unit, independently of the others in the consignment, the probability that it contains drugs is taken to be equal to θ. The posterior distribution of θ is another β distribution with parameters $(\alpha + z)$ and $(\beta + m - z)$.

Since the consignment size is small, a better representation of the variability of the number of units Y, which contain drugs in the uninspected section of the consignment, is obtained by considering a probability distribution for Y explicitly. There are n units in the remainder of the consignment $(m + n = N)$, which have not been inspected. Then Y (unknown and $\leq n$) is the number of units in this remainder that contain drugs. Given θ, the distribution of $(Y|n, \theta)$, similar to that of $(Z|m, \theta)$, is binomial. However, θ has a β distribution and the distribution of $(Y|n, \theta)$ and the distribution of $(\theta|m, z, \alpha, \beta)$ can be combined to give a Bayesian predictive distribution for $(Y|m, n, z, \alpha, \beta)$, a β-binomial distribution.

$$Pr(Y = y|m, n, z, \alpha, \beta) = \frac{\Gamma(m + \alpha + \beta)\binom{n}{y}\Gamma(y + z + \alpha) \times \Gamma(m + n - z - y + \beta)}{\Gamma(z + \alpha)\Gamma(m - z + \beta)\Gamma(m + n + \alpha + \beta)}, \quad (y = 0, 1, \ldots, n) \tag{15}$$

From this distribution, inferences can be made about Y, such as probability intervals or lower bounds for Y.

Quantity

The standard of proof is relevant to the estimation of quantity. In state courts in the United States in 2001, the value of Q in a drug trial was defined to be an essential element of the possession charge. As such, the value of Q had to be proved by a jury beyond reasonable doubt. However, in Federal courts, Q was considered an issue of fact and had only to be established on the preponderance of the evidence. This should be borne in mind when interpreting the estimation processes. For further information about procedures in the United States, see the Sentencing Guidelines [15]. The importance of quantity estimation was illustrated in the drug smuggling case of *U.S. v. Shonubi*. At issue was the estimation of an unknown total amount of heroin that was imported illegally in the digestive tract of the defendant during several trips from Nigeria to the United States. The only quantitative piece of information available was the amount of heroin found in the defendant's possession on his last trip. This amount was itself the result of a sampling process. Shonubi was found to be carrying internally 103 multicolored balloons, each filled with a white powdery substance. Four of the balloons were selected randomly for testing and inference. The total net weight of the heroin in all 103 balloons was estimated by multiplying the average net weight of the heroin in the four balloons by 103 [16].

The estimation of the quantity of a drug is treated in two stages. First the proportion of the units in the consignment that contain illicit drugs is modeled. Second, the total weight of the illicit material in those packets that contain anything illicit is estimated. Uncertainty in the prior belief in the proportion of packets that are "illicit" may be represented by a β distribution. It is assumed that there is no prior information for the mean and variance of the distribution of the quantity of drugs in the packages. Details of how such prior information may be considered are given in Aitken *et al.* [17].

Given the sample size, and thus an estimate of the proportion of a consignment that contains drugs and an estimate of the mean and standard deviation of the weight in the consignment, a *confidence interval* for the true quantity of drugs may be calculated [7]. A *probability interval* is appropriate in a Bayesian context. In this context, a probability distribution is associated with a parameter (Q, say) denoting the total quantity of illicit material in the consignment and probability statements of any desired kind may be made. For example, these could include the probability that Q is greater than a certain value, q say, which will be of importance in sentencing hearings; here q may be a borderline between two base offense levels.

Frequentist Approach

It is only possible to make a statement about the consignment as a whole with certainty if the whole consignment is analyzed. Once it is accepted that a sample has to be considered, then it is necessary to consider what level of proof is adequate. This is strictly a matter for the court to decide.

The method described by Tzidony and Ravreboy [7] considers the consignment as a population and the packages (or units) examined as a sample. The quantities (weights) of drugs in the units are assumed to be random variables that are normally distributed, with population mean μ and population variance σ^2, say. The mean quantity in a unit in the consignment is estimated by the mean, denoted by $\bar{x}$, of the quantities found in the sample. A confidence interval is determined for μ based on the sample size m, the sample mean $\bar{x}$, the sample standard deviation s of the quantities of drugs in the units examined, and an associated t-distribution. The general expression for the relevant confidence interval is

$$\bar{x} - t_{(m-1)}(\alpha/2)\frac{s}{\sqrt{m}}\sqrt{\frac{(N-m)}{N}} \leq \mu \leq \bar{x} + t_{(m-1)}(\alpha/2)\frac{s}{\sqrt{m}}\sqrt{\frac{(N-m)}{N}} \quad (16)$$

where $\sqrt{(N-m)/N}$ is the finite population correction factor. The term $t_{(m-1)}(\alpha/2)$ denotes the $100(1-\frac{\alpha}{2})\%$ point of the t-distribution with $(m-1)$ degrees of freedom, e.g., for the 95% confidence interval, $\alpha = 0.05$, and $t_{(m-1)}(\alpha/2)$ is the 97.5% point of $t_{(m-1)}$. The interval is the $100(1-\alpha)\%$ confidence interval for the mean quantity in a package [7].

The corresponding confidence interval for Q, the total quantity of drugs in the consignment, is obtained by multiplying all entries in the inequalities by $N\hat{\theta}$, where $\hat{\theta}$ is an estimate for θ based on the sample of size m. This gives as a $100(1-\alpha)\%$ confidence interval for Q [7].

$$N\hat{\theta}\left\{\bar{x} - t_{(m-1)}(\alpha/2)\frac{s}{\sqrt{m}}\sqrt{\frac{(N-m)}{N}}\right\} \leq Q \leq N\hat{\theta}\left\{\bar{x} + t_{(m-1)}(\alpha/2)\frac{s}{\sqrt{m}}\sqrt{\frac{(N-m)}{N}}\right\} \quad (17)$$

A corresponding $100(1-\alpha)\%$ lower bound for Q, which may be deemed more appropriate in a legal context, is given by the left-hand side of the inequality

$$N\hat{\theta}\left\{\bar{x} - t_{(m-1)}(\alpha)\frac{s}{\sqrt{m}}\sqrt{\frac{(N-m)}{N}}\right\} \leq Q \quad (18)$$

Bayesian Approach

Consider the consignment as itself a random sample from a larger superpopulation of units or packages, some or all of which contain illegal material. Then, θ $(0 < \theta < 1)$ is the proportion of units in the superpopulation, which contains drugs. The variability in θ may be modeled by a β distribution.

Let n be the number of packages in the consignment that is not examined. Then, N equals $m + n$. Let $(x_1, \ldots, x_z)$ and $(w_1, \ldots, w_y)$ be the weights of the contents of the units examined and not examined respectively, which contain drugs. It is assumed that these weights are normally distributed. The total

Table 4 Estimates of quantities q g. of drugs, in a consignment of $m + n$ units, according to various possible burdens of proof, expressed as percentages $P = 100 \times Pr(Q > q|m, z, n, \bar{x}, s)$ in 26 packages when six packages are examined (m = 6, n = 20) and z = 6, 5, or 4 are found to contain drugs. The mean ($\bar{x}$) and standard deviation (s) of the quantities found in the packages examined, which contain drugs, are 0.0425 g and 0.0073 g. The parameters for the beta prior are $\alpha = \beta = 1$. Numbers in brackets are the corresponding frequentist lower bounds using the finite population correction factor

Percentage P	Number of units examined which contain drugs			Possible burden of proof (illustrative)
	6	5	4	
97.5	0.689 (0.930)	0.501 (0.744)	0.345 (0.575)	
95	0.750 (0.968)	0.559 (0.785)	0.397 (0.613)	Beyond reasonable doubt
70	0.944 (1.067)	0.770 (0.885)	0.603 (0.704)	Clear and convincing
50	1.015 (1.105)	0.862 (0.921)	0.704 (0.737)	Balance of probabilities

Permission needed from JFS

weight, q, of the contents of the units in the consignment is then given by

$$q = z\bar{x} + y\bar{w} \tag{19}$$

Also, let $s^2 = \sum_{i=1}^{z}(x_i - \bar{x})^2/(z-1)$ be the variance of the measurements on the units that were examined and found to contain drugs. In the absence of prior information about the mean or variance of the distribution of the weights of drugs in the packages, a uniform prior distribution is used.

The distribution and corresponding probability density function of Q may be determined from the relationship $Q = z\bar{x} + y\bar{W}$. Let $f_{t,z-1}(.)$ denote the probability density function of the t-distribution with $(z-1)$ degrees of freedom. The probability density function $f(q)$ of Q is then given by [18]

$$f(q) = \sum_{y=0}^{n} f_{t,z-1}\left\{\frac{q-(z+y)\bar{x}}{sy\sqrt{\frac{1}{z}+\frac{1}{y}}}\right\} \left\{sy\sqrt{\frac{1}{z}+\frac{1}{y}}\right\}^{-1} Pr(Y=y) \tag{20}$$

An example in which a seized drug exhibit contained 26 street doses is given in Tzidony and Ravreboy [7]. A sample of six ($m = 6$) units was taken and each was analyzed and weighed. Twenty ($n = 20$) units were not examined. All six of the units examined contained drugs. The average net weight $\bar{x}$ of the powder in the six units was 0.0425 g. with a standard deviation s of 0.0073 g. A 95% confidence interval for the total quantity Q in the 26 doses is $1.105 \pm 0.175\,g$. Note that this interval incorporates the finite population correction factor from (equation 2) to allow for the relatively large sample size ($m = 6$) compared to the consignment size ($N = 26$).

The Bayesian approach described here does not require a finite population correction.

The values for Q obtained from the Bayesian argument and corresponding to appropriate percentage points of the distribution may be determined from (equation 20). Some results are given in Table 4, together with corresponding results with the method of Tzidony and Ravreboy, and in Figure 3.

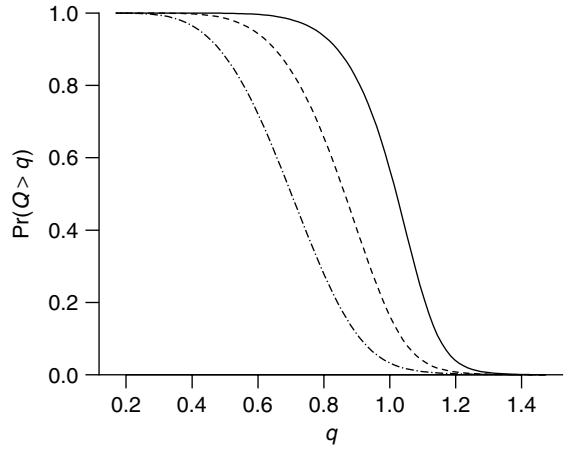

Figure 3 The probability that the total quantity Q of drugs (in grams) in a consignment of 26 packages is greater than q, using a Bayesian argument, when six packages are examined and 6(−), 5(− − −), or 4(− · −·) are found to contain drugs. The mean and standard deviation of the quantities found in the packages examined, which contain drugs, are 0.0425 g and 0.0073 g. The parameters for the β prior are $\alpha = \beta = 1$ [Reproduced with permission from JFS.]

Note: A general introduction to sampling techniques is given in Cochran [10]. Reviews of the statistical and legal aspects of the forensic study of illicit drugs are given by Izenman [2, 19]. These includes a discussion of various sampling procedures, various methods of choosing the sample size, a strategy for assessing homogeneity and the relationship between quantity and the possible standards of proof. Further comments on sampling issues are given in various chapters of Gastwirth [20], such as Aitken [21], Gastwirth *et al.* [22], and Izenman [16, 23, 24], with respect to the *Shonubi* case.

Sampling Trace Evidence

Introduction

Sampling can be defined as the removal of a part of a substance to assess the materials present in the whole. In a forensic context, sampling has a broader definition as it occurs throughout the forensic process from selection of items at the crime scene to subsampling in the laboratory.

Trace evidence by its nature is small in size such that examination commonly requires the use of a microscope [1, 2]. Sampling of trace evidence encompasses the selection, recovery, and removal of material and can include sampling of a single item, similar items, or different items. The reasons for sampling include reducing the number of analytical determinations necessary, time constraints, presentation for instrument analysis, and cost.

The first stage in sampling is defining the sampling strategy. The sampling strategy chosen is dependent on the question being asked, the purpose of sampling, the use of results. Therefore, a sampling strategy is necessary, which must satisfy all aspects above including forensic evidential requirements. The second stage is defining the target population for what is being sampled. A sampling plan is established for reasons of effectiveness and efficiency and to ensure the sampling strategy is implemented. The sampling plan forms the third stage.

Finally, the sampling methods used ensure the sampling plan is implemented [3].

This section reviews sampling of trace evidence, in particular, paint (*see also* **Paint**), glass (*see also* **Glass**), fibers (*see also* **Paint**), hairs (*see also* **Hair: Animal**), soil, and particulates (*see also* **Particles: Form**). Sampling of DNA (*see* **DNA**), explosives (*see* **Explosions: Scene Investigation**; **Explosion Debris: Laboratory Analysis of**), drugs, and firearms is beyond the scope of this section. The following aspects of trace evidence sampling are covered:

1. principles of sampling trace evidence;
2. population determination;
3. sampling plans used for trace evidence;
4. sampling questions; and
5. methods of trace evidence sample recovery.

Principles of Sampling Trace Evidence

Sampling Trace Evidence at the Crime Scene

The Locard exchange principle is quoted as "every contact leaves a trace" [4]. Usually, things are not so simple. When sampling for trace evidence, determining the type(s) of trace evidence one is looking for is crucial in the decision making process. Sampling is based on the case circumstances, the evidence type being looked for, and the items available for analysis. The investigator may be directed by the available case information, although there are occasions when information is scarce, thereby increasing the need for care in the sampling procedure so as not to compromise one evidence type while sampling for another. Sampling processes employed determine what is ultimately examined and the conclusions that can be drawn from the testing results.

When sampling for trace evidence, it is necessary to take samples from the area where the transferred trace evidence may have been deposited and take a representative sample from the original source of the trace evidence. Where a house is burgled and the suspect gains entry through a broken window, crime scene investigators seize the articles of clothing worn at the time of the alleged offense by the suspect and take an adequate representative control sample of glass from the window.

When a crime scene is examined, it is rarely practical nor is it necessary to examine all of the items available. The initial selection of items to be examined is determined by what is known to have happened (from witness, victim, and suspect statements) and where one is likely to find the evidence type. For example, if one wishes to see if there is evidence that two people were in contact, then selecting the clothing that they were wearing at the time of the alleged contact and looking for evidence of fiber transfer are required.

Sampling and Subsampling in the Laboratory

In the laboratory, the sampling plans and recovery methods chosen depend on the trace evidence type, the case circumstances, and the question being asked. For example, sampling done to determine the presence of paint, glass, particulates, etc., or to determine both the presence and quantity of the substance(s).

Some reasons for sampling in the laboratory are as follows:

- Taking samples to carry out different tests on the population of trace evidence.
- Taking samples from the population of trace evidence to carry out the same test repeatedly to determine reproducibility of results.
- Taking a sample from the population to carry out destructive testing (sample is destroyed and no further testing can be carried out on the sample selected).
- Sampling for practical considerations in relation to presentation for instrument analysis.

Once the decisions have been taken regarding the trace evidence type to sample then one has to decide how that will be done, i.e., what sampling plan will one follow and what recovery method will be used?

In essence, sampling at the crime scene and in the laboratory involves risk assessment and risk management. When sampling for trace evidence the operator is always working in a context. No matter how good the sampling process is, it introduces a level of uncertainty. Risk management of sampling involves assessing the level of uncertainty introduced by sampling and adopting sampling plan(s) and methods of recovery such that one has confidence in the sampling decisions taken and the interpretation of the results.

Population Determination

One has to decide what to sample before you decide which sampling plan to use. This is the need to define the relevant population. There are two possibilities: (a) a homogenous population where all items look the same e.g., 100 pieces of green glass that look visually similar or (b) a heterogeneous population, for example, 100 pieces of green glass and 100 pieces of clear glass. When one has a heterogeneous population, one would sample from both green and clear glass populations if the case involved a broken green and clear stained glass window, but would sample only the clear glass population if the case involved a broken clear glass window.

Population determination is based on the case circumstances and the trace material sources available [5].

Sampling Plans Used for Trace Evidence

In trace evidence analysis, the most common sampling plans used, divide into numerically based and nonnumerically based.

Numerically Based Plans

Numerical plans can be statistically based or nonstatistically based.

Statistically Based Sampling Plans. Statistically based sampling is used when one is defining a population based on the analysis of the sample taken from that population, for example, defining a population of glass fragments as being from a putative source based on the refractive index of the sample of selected glass fragments. There are two different approaches to statistical sampling, the Frequentist approach and the Bayesian (*see also* **Bayesian Networks**) approach [6]. In general, the Frequentist approach is that a fixed but unknown proportion of the population is positive and the proportion of positives in the sample can be used to estimate the proportion of positives in the population. The proportion of positives varies over different samples. This method gives a confidence level that a defined minimum in the population is positive. The most commonly used Frequentist method in trace evidence is the hypergeometric method. The following publications give a good overview of the subject [7–12].

The Bayesian approach assumes that the proportion of positives in the sample is fixed. There is no consideration for repetition of sample testing [11, 13, 14]. The Bayesian approach allows prior information about the population to be taken into account whereas the Frequentist approach does not. Prior information, for example, could be that all the suspect fibers look visually the same and were found on the victim's jumper. The disadvantage of the Bayesian method is that the values attached to the prior knowledge are subjective. However, using the Bayesian approach is more intuitive and flexible as the results obtained

from the evidence can be expressed as probability statements and prior information is taken into account [11, 13].

Nonstatistically Based Sampling Plans. Nonstatistical sampling plans have been documented in relation to drugs analysis [6]. A number of these are also used for trace evidence [12]. Examples of nonstatistical sampling plans used in relation to trace evidence include testing all the samples, testing one, and testing 20.

Nonstatistical sampling is simple to apply; however, only limited inferences can be made about the overall properties of the population [6].

Nonnumerically Based Sampling Plans

While numerically based sampling plans are well documented, the same cannot be said for nonnumerically based plans. Analysis of trace evidence involves many nonnumerically based sampling plans. Frequently used nonnumerical sampling plans are probability sampling, judgment sampling, and bulk sampling.

Probability (Random) Sampling. Probability sampling occurs when every unit in the population has a known probability of being included in the sample and is often referred to as random sampling [15]. For example, if 100 pieces of glass were removed from a suspect's jacket, randomly picking 10 of them for analysis would constitute random sampling. Depending on the trace evidence type, this may not be practical. In the case of fiber examination, if one had numerous blue fibers on an adhesive lift, one would sample the longest fibers, as long fibers allow destructive testing to be carried out while still allowing retention of some of the original fiber.

Judgment Sampling. Judgment sampling involves selecting items based on traits or aspects they have in common with other items in the case. If a pale blue car knocks down and kills a person, one would select pale blue paint found on the victim's clothes for analysis. The selection is made on the basis of the similarities the sample has with other item(s) in the case. The presence of a dark blue paint on the victim's clothes may introduce other questions, such as, could a different car have been involved?

Bulk Sampling. This type of sampling happens when a sample is taken from a large amount of material that does not consist of separate units and is often a feature of subsampling in the laboratory. Bulk sampling occurs when one takes a sample of soil from a field. Considerations include as to where the sample is taken from, how much sample is taken, and whether the sample is representative of the lot.

Trace evidence analysis frequently involves the use of many sampling plans used sequentially or at the same time. When a burglar enters a house through the window and the crime scene examiner comes to examine the scene, he uses judgment sampling to target the areas where the intruder may have left trace evidence. When a suspect is caught, judgment sampling is used to select the items of clothing to be taken from the suspect based on what the suspect was seen to have worn at the time. Judgment sampling is used in the laboratory to target paint flakes on the suspects jumper of the same color as that of the paint on the window, and bulk sampling is used to select fibers from the suspect's jumper to compare with the fibers found on the window.

Problems Associated with Sample Plan Selection. While the hypergeometric sampling is used commonly when sampling glass, there is disparity when it comes to deciding what an appropriate sample size is for the other trace evidence types. In the area of fibers, for example, Faber *et al.* [12] determined that there was a disparity in sample size analyzed between different laboratories. They observed that an objective criterion is needed to determine optimal fiber sample size in casework and suggested the use of the hypergeometric method [12]. Various international forensic organizations have been tackling this problem, e.g., European Network of Forensic Institutes (ENFSI) and European Fibres Group. If an internationally accepted norm were established for different aspects of trace evidence it would greatly enhance sampling norms across different countries. The conclusions drawn from trace evidence are largely influenced by the sampling methods and plans used. It is important that forensic scientists are aware of the methods and plans they are using, and the veracity of the conclusions they reach based on that evidence [16].

Sampling Questions

To identify the factors that influence sampling plans and methods, asking questions is helpful. The following are some questions that are relevant when making sampling decisions:

- What background information is available?
- What question(s) need to be answered?
- What will the testing results be used for?
- What type of trace evidence is of interest?
- Are there any legal requirements?
- Is identification of material all that is required?
- What accuracy and precision is required?
- What is to be sampled and how?
- Is it necessary to sequence the sampling that is to take place?
- Should statistical sampling be employed?
- Is the sampling plan chosen adequate to answer the question asked and does it fulfill the purpose?
- Is the plan chosen cost effective and efficient?
- Is there literature to back up the sampling plan chosen?
- Will it be possible to defend the conclusions drawn from the sampling plan employed?

Finding the answers to some or all of these questions should guide one to appropriate sampling plan(s) and sampling method(s).

Methods of Trace Evidence Sample Recovery

While the sampling strategy and sampling plans used influence the testing results so also do the methods of trace evidence sample recovery. Commonly used methods of recovery of trace evidence are removal of the whole item, 'hand' picking, taping, brushing, vacuuming, and scraping [4, 17].

Removal of the Whole Item

It may not always be possible or appropriate to remove trace evidence at the crime scene. In this situation the whole item is brought to the forensic science laboratory for trace evidence removal.

'Hand' picking

'Hand' picking of trace evidence is the method of choice when the quantity of evidence, size, and appearance allow. Items are usually collected by hand (gloved) or by using a sharp pointed tweezers using strong light and magnification. This method has the advantage of establishing the position of the material on the item.

Taping

The use of adhesive tape is a reliable method of removing very small particles of trace evidence [18, 19]. A short length of adhesive tape is passed repeatedly over the surface of the item ensuring the entire surface under examination is sampled. This is then applied to a sheet of rigid plastic and placed in a clean plastic bag appropriately labeled. Taping is used routinely to remove fibers, hairs, and particulates. This method protects trace evidence from contamination and allows the trace evidence of relevance to be separated from nonrelevant material. The tape-lift is examined under a microscope and the trace evidence removed by circling the evidence on the back of the tape and lifting the tape to remove it, or by circling the evidence and cutting and lifting the section of tape to remove it. The latter method prevents contamination of the lift from elements in the atmosphere.

Brushing

Brushing is the method of choice for the removal of paint, glass, and soil. A clean paintbrush or toothbrush is used to brush down the item in question and the resulting debris is collected for examination. It allows retrieval of trace evidence from areas that are difficult to access. Using this method one does not encounter the difficulty of retrieving small fragments of paint, glass, or soil intact from an adhesive lift.

Vacuuming

Vacuuming is an efficient way to remove trace evidence. However, its efficiency is a disadvantage in that recently deposited material is mixed with that deposited long ago and the volume of material retrieved lengthens the process of trace evidence retrieval. Vacuuming is performed in a systematic manner and filters changed frequently so that the debris retrieved can be associated with a specific area e.g. sleeves of a jacket. Vacuuming is not recommended for routine use because of the difficulty in interpretation, the rigorous requirements to avoid contamination, and the length of time taken to analyze the contents retrieved.

Scraping

Scraping has limited use as a method of sample removal of trace evidence. However, it can be used

to collect a control sample of a source of paint. This involves using a clean blade to remove a representative paint sample from the surface (e.g. a painted door) that is collected on clean paper, in a paper envelope, or a tweezer is used to mount the sample on a glass slide.

Selection of a suitable method of trace evidence removal is vital to minimize loss of potential evidence, avoid contamination, and to facilitate trace evidence analysis [20].

Conclusion

Trace evidence analysis is a valuable tool in crime scene investigation. When sampling for trace evidence, it is important to realize that the methods of sampling and the sampling plans used ultimately affect the evidence obtained and the interpretation of that evidence. It is vital that sampling is carried out correctly and is understood to eliminate loss of potential evidence and to avoid overestimation or underestimation of the significance of the evidence found. Currently sampling of trace evidence is an area that has received little in-depth analysis leading to a lack of uniformity in approach.

Scientific Method Compared to Legal Method

The acquisition and interpretation of information (data) used by scientists compares, superficially, to the legal method used in determining controversies in a legal forum. Both methods attempt to use a rational approach; both also use an inductive method of solving problems. The differences, therefore, do

not lie in the methodologies chosen to obtain a result, but are rather heavily influenced by the disparate purposes sought to be served [1].

Science seeks to analyze data or information obtained during prior experiments or inquiries in an essentially neutral fashion to obtain the best explanation as to why certain results were manifested, in order that the course of future events may be reliably predicted. Rarely does the scientific method focus on an individual, particular incident. The case to which it is being applied is important only insofar as it permits the scientist to formulate a general hypothesis on how to deal with similar events that are yet to occur.

The purpose of the legal method in resolving disputes or controversies is to determine what ought to be, rather than what is. After having considered certain information, the legal system is interested in knowing how findings and conclusions that arise out of the information impact on a specific case that is currently pending before the court. Thus, lawyers are less interested in what the impact of the evidence will be on other cases, but instead are concerned with applying the results to the normative values upon which behavior in our society is conditioned. While it engages in this balancing of values, the legal system may also be creating new norms and values, which will affect future behavior [1].

When differing or opposing values are represented by the parties in a legal controversy, the adversary system, which is the hallmark of the Anglo–Saxon judicial process, casts each participant into an adversary posture. Unlike the neutrality of interpretations with which the scientist seeks to clothe his testimony, the trial lawyer will be interested primarily in advocating the values that favor the party by whom he was retained [2–5].

Failing to recognize the different aims and purpose of science *vis-a-vis* those at stake in a legal contest has pitted scientists and lawyers against each other in uncomfortable battles. Lawyers often hold experts in disdain because they believe that an expert's opinion is for sale and that the expert will come to almost any conclusion that is desired by a litigating party. By contrast, scientists may feel estranged from the judicial process because of the intensive cross-examination to which they may be subjected, a process wherein the experts feel that their dignity is impugned and their honesty questioned. The acerbity of cross-examination has driven some experts to refusing to testify in court cases.

An increased understanding of both sides and the different aims that are the goal of the scientific method, as opposed to those of the legal system, will enhance the effectiveness of experts in offering testimony, and of attorneys seeking to elicit the experts' opinion testimony [6].

Seizures: Behavioral

A seizure is a set of behaviors that occurs in association with excessive, aberrant neuronal activity within the brain. Seizures are generally characterized by altered consciousness, motor dysfunction, or sensory dysfunction. Epilepsy is a chronic condition in which the patient experiences recurring seizures.

Definition, Prevalence, and Cumulative Incidence

At any given time, approximately 1% of the population manifests epilepsy. There is a total lifetime incidence rate of approximately 4% by age 80. This makes it one of the most common neurological disorders.

Classification of Seizures

A classification of seizures is important to facilitate clinical diagnosis and communication, to assess prognosis, and to evaluate whether specific drugs are the most appropriate ones for therapy. Dating back to the 1981 classification proposed by the International League Against Epilepsy (ILAE) [1], seizures are classified first into partial or generalized seizures. Seizures are generally classified as to whether they are partial (seizures that begin in a focal portion of the brain), or whether they are generalized (occurring bilaterally and diffusely without a local onset). Seizures are termed partial if there is either clinical or electroencephalogram (EEG) evidence indicating onset in a focal area of one hemisphere, whereas generalized seizures appear to begin simultaneously in both hemispheres. Partial seizures are divided into three categories: (i) simple partial (not affecting consciousness), (ii) complex partial (involving alteration of consciousness), and (iii) partial seizures evolving into secondarily generalized tonic–clonic (GTC) convulsions, which could begin as either simple partial or complex partial seizures. Simple partial seizures are marked by no loss of consciousness. They are manifested by behaviors specific to the locale of the seizure origin. Motor seizures involve either an involuntary jerking or stiffening movement or rarely paralysis of a given limb or region of the body. The focal movements can remain localized or involve a progression, for example, beginning in a finger and then spreading to the entire arm and face. The latter is called a *Jacksonian seizure*. The simple partial motor seizure may also involve versive head turning, postural changes, forced speech or inability to speak, or vocalization. Simple partial somatosensory or special sensory seizures can manifest themselves as tingling, numbness, or as specific visual, auditory (such as buzzing sound), olfactory (such as peculiar smell), or gustatory sensations. Autonomic simple partial seizures are marked by autonomic symptoms, such as nausea, sweating, or goose bumps. Simple partial psychic seizures are manifested by dysphasia (such as trouble with verbal expression), deja-vu (feeling of familiarity), or affective symptomatology (fear, elation). Complex partial seizures are marked by a loss or alteration in consciousness. These can begin as simple partial seizures, and then progress to alterations of consciousness, or can begin with loss or changes of consciousness at the onset. If the complex partial seizure is heralded by a subjective experience, we call this an aura, but the experience actually represents subjective simple partial seizure activity. Clouding of consciousness and automatisms reflect bilateral seizure spread. Automatisms are repetitive, purposeless movements of the extremities (particularly hands) and face, such as lip smacking, chewing, scratching, or rubbing. Less frequently, they can also involve complex behaviors such as reaching for an object, walking, running, or disrobing. Partial seizures can also secondarily generalize into GTC activity. A "postictal" state of confusion, drowsiness, and tiredness often follows the seizure itself. This is least pronounced with simple partial seizures and most pronounced with secondarily generalized seizures.

Generalized-onset seizures, seizures that begin bilaterally, can take different forms as well. Generalized seizures are divided into six types: (ii) absence seizures, (ii) myoclonic seizures, (iii) clonic seizures, (iv) tonic seizures, (v) tonic–clonic seizures, and (vi) atonic seizures. Generalized absence seizures

are characterized by brief (several seconds) loss of awareness or responsiveness and arrest of activity. Absence seizures (also called *petit mal*) involve a sudden loss of consciousness that typically only lasts a few seconds. There may or may not be associated minor motor activity, such as automatisms, blinking, slight twitching, decreased tone, or increased tone. GTC seizures are characterized by loss of consciousness at onset, a sudden tonic muscular contraction, and sometimes a movement of air through a closed glottis, producing a "cry", as well as cyanosis. After the tonic phase, the seizure then evolves into generalized clonic or rhythmic jerking activity from a 4- to 8-s tremor, sometimes accompanied by grunting. The clonic activity is initially fast, and the frequency of the jerks decreases before the seizure stops. GTC seizures are often accompanied by tongue biting and urinary incontinence. Generalized myoclonic seizures are brief, sudden contractions that may be generalized or confined to a group of muscles, or even a single muscle. They can be single and isolated, or occur in a cluster. Consciousness is usually preserved. Some forms of myoclonus are not epileptic and have no associated EEG discharge. Myoclonic seizures usually have a concomitant discharge on the EEG. Generalized clonic seizures are characterized by repetitive clonic jerks, without an initial tonic component. Generalized tonic seizures manifest with a muscular contraction that may vary in duration, severity, and the parts of the body involved. The muscular contractions are more sustained than those of myoclonic seizures. Generalized atonic seizures are characterized by a sudden decrease in muscle tone, which is variable in severity and extent, so that there may simply be a slight head drop, or an abrupt fall to the ground.

Status epilepticus is a state of continuous seizure activity or repetitive seizures without recovery in between seizures. When the status epilepticus seizure activity is generalized convulsive, this represents a life-threatening medical emergency due to the potential for damage to the brain. Brain damage is estimated to begin at approximately 20 min after the onset of status, so it is critical to intervene early.

Classification of Epilepsies and Epileptic Syndromes

In addition to classifying individual seizures, the epilepsy condition as a whole can be classified. In 1989, the ILAE has recommended a classification that remains in wide use [2]. It is recognized, however, that advances will necessitate a revision. Most patients with epilepsy will have only partial-onset or only generalized-onset seizures. Hence, the classification has two major categories: localization-related epilepsies (partial epilepsies is an acceptable synonym) or generalized epilepsies. Each category is further subdivided into idiopathic or symptomatic epilepsies. The idiopathic epilepsies are typically characterized by the absence of acquired brain insult and are widely considered to be of genetic origin. The symptomatic epilepsies have known insults that have caused the epilepsy. In addition, some patients are suspected to have had a brain insult, but one that cannot be definitively identified. These patients are referred to as *probably symptomatic* (cryptogenic was used as a synonym but has fallen out of favor). Most partial epilepsies are symptomatic or probably symptomatic, while most generalized epilepsies are idiopathic or probably idiopathic. However, it is recognized that many patients have both genetic predisposition to seizures as well as acquired brain insults.

Some patients have additional characteristic features that help to group them into recognized epileptic syndromes. The characteristics of syndromes may include specific age at onset, a particular combination of seizure types, a predictable response to treatment, and a variety of other clinical features.

Epidemiology

Not all persons who experience seizures have epilepsy. In fact, most do not. Epilepsy is not diagnosed if the seizure is acutely provoked by an insult such as trauma or stroke, or if the seizure accompanies exposure to certain drugs or a derangement in metabolism. Even single unprovoked seizure recurs in less than half of individuals. Of those persons who do have epilepsy, approximately half of them have no known precipitating event or injury.

Many factors can provoke seizures. Some reversible alterations that can trigger seizures include metabolic changes, such as low blood sodium, calcium, or magnesium, kidney failure, or liver failure. Many toxins and drugs can trigger seizures. This includes psychoactive prescription drugs such as tricyclic antidepressants, bupropion (Wellbutrin), antipsychotic drugs such as clozapine (Clozaril),

and illicit agents such as cocaine or phencyclidine (PCP). In addition, withdrawal from alcohol, benzodiazepines, or barbiturates can also trigger seizures. In general, seizures do not recur after removing the offending agent or after the withdrawal period has passed.

Many factors may contribute to the development of epilepsy. Any disease or condition that injures the cerebral cortex can cause epilepsy. This includes brain infections and inflammations such as encephalitis, head trauma, brain tumors, brain malformations, and degenerative conditions such as Alzheimer's disease. Chronic alcohol use increases the risk of epilepsy, and this is not due to alcohol withdrawal seizures.

Head trauma is a common etiology for epilepsy. The most epileptogenic head trauma is penetrating head injury, with an epilepsy incidence as high as 53% following such injuries. Moderate-to-severe closed head injuries are associated with a significantly increased risk of epilepsy, from 3 to 25 times greater than in the absence of head trauma [3]. Among closed head injury patients, brain contusions and intracranial hemorrhages appear to be strong risk factors for the development of seizures. The presence of skull fractures or prolonged loss of consciousness or posttraumatic amnesia (greater than one day in length) are also risk factors, though not as strongly predictive. Mild head trauma, defined by loss of consciousness or posttraumatic amnesia for less than 30 min, is associated with a slightly greater risk of epilepsy (1.5-fold increase in risk) that is not statistically significant [4]. Other potential causes of seizures or seizurelike episodes should be carefully ruled out in the mild head injury patient presenting with apparent seizures, including withdrawal from alcohol or other substances, hypoglycemia or other metabolic conditions, and psychogenic seizures. The latter are particularly common following mild traumatic brain injury [5]. Even after moderate-to-severe head injury, 33% of patients experiencing seizurelike phenomena were actually experiencing psychogenic seizures [6].

A common legal question is how to prove causality between an injury and epilepsy. Before addressing causality, it is important to first prove the presence of epilepsy. The injury has to be sufficiently severe to cause epilepsy. For example, mild head injury may not stand in court as a cause of epilepsy. Additional requirements are absence of any manifestation of epilepsy before the injury in question and absence of other known causes of epilepsy. Of course, it is also possible that a preexisting epilepsy can be worsened by an injury [7].

Diagnostic Methods

The clinical interview and medical history taken are critical to the assessment of seizures and epilepsy. The history is obtained from both the patient and observers who have witnessed typical attacks. In the description of clinical seizures, evidence for focal seizure onset is sought, for example, the presence of an aura, initial focal sensory symptoms, or motor signs. In addition, the type of aura and the first signs in partial seizures help to localize the seizure onset within the brain. The past history, including prenatal, birth, and early development, and family history may provide insight into the etiology. All of the above may provide the clinician with the opportunity to classify the seizure types and the epileptic syndrome, and identify etiologic factors. The neurological examination is important to identify the focal signs of neurological dysfunction, which would favor partial epilepsy.

If the description of the events is strongly suggestive of epileptic seizures, the EEG is an important test to help confirm the presence of a seizure tendency. The EEG is a measure of electrical brain activity, usually recorded from scalp electrodes. Patients with epilepsy frequently have EEG abnormalities in between seizures, called *interictal* abnormalities. Some of these abnormalities, such as spikes or sharp waves, are fairly specific for epilepsy and are referred to as *interictal epileptiform* discharges. In partial epilepsies, the interictal epileptiform discharges tend to be focal or regional. These discharges generally have a topographic correlation with the epileptogenic zone, the zone from which seizures are generated. Recordings obtained during seizures will generally show a rhythmic discharge. In generalized epilepsies, epileptiform discharges tend to be generalized and synchronous in the two hemispheres. Approximately 50% of persons with epilepsy will show abnormal electrical activity on their first EEG recording and more than 90% by the fourth recording. There is no apparent benefit to additional EEGs after the fourth recording.

The EEG yield can be enhanced with prolonged recording and simultaneous video monitoring, allowing for a direct correlation to be made between

the behavioral manifestations of the seizure and the changes observed on the EEG. This procedure is usually needed when there is some question about the nature of the seizure, such as whether the spells experienced by the patient might represent psychogenic seizures or pseudoseizures. The psychogenic seizure patient will evidence no EEG changes concomitant to the seizure being videotaped. EEG/video recordings also allow for the localization of seizure onset and evolution. Thus this method is particularly useful for the epilepsy patients considered for surgery.

The recording of a seizure on EEG/video can provide a definitive proof of the existence of epilepsy. The recording of interictal epileptiform discharges indicates a seizure tendency and suggests the presence of epilepsy, but cannot prove the presence of epilepsy beyond doubt. It is much harder, almost impossible, to prove the absence of epilepsy. If typical attacks are recorded and are determined to be nonepileptic, and the EEG is always normal in between seizures, then the presence of epilepsy becomes very unlikely.

In the patient with seizures, imaging techniques are useful to identify a cause of epilepsy. A structural imaging study of the brain, preferably with magnetic resonance imaging (MRI), should be sought to identify structural abnormalities that may be epileptogenic. In the epilepsy surgery candidate, positron emission tomography (PET), which measures glucose uptake by the brain, is useful to identify functional deficits corresponding to the seizure focus. The epileptogenic focus generally has decreased glucose uptake in between seizures and increased glucose uptake during a seizure.

Differential Diagnosis

Several medical conditions can imitate seizures, thus requiring careful differential diagnosis. These conditions can be broadly divided into psychiatric and physiological imitators.

Several psychiatric disorders can imitate seizures. Panic disorder is marked by spells of autonomic hyperactivity, including shortness of breath, heart palpitations, sensations of heat or cold, gastric distress, and motor tension. Panic attacks are usually characterized by intact awareness throughout the spell, including fear of having a heart attack or losing one's mind, and an absence of postictal state or incontinence. Episodic dyscontrol syndrome, intermittent explosive disorder, or "rage attacks" also must be differentiated from seizures. The patient with intermittent explosive disorder, though perhaps reporting amnesia for the event, will not evidence altered consciousness or a postictal state. Typically, precipitants for the rage events will be readily identifiable.

One of the most common imitators of seizures and epilepsy is the condition of psychogenic nonepileptic seizures (PNES), often called *pseudoseizures* or *pseudoepileptic seizures*. PNES are episodes of alteration in movements or responsiveness, which resemble epileptic seizures in some ways, but are purely emotional in nature and lack a concomitant cerebral electrical discharge. They occur most commonly through unconscious "conversion reactions", but less frequently through voluntary malingering. PNES may account for an estimated 20–30% of patients referred for intractable seizures. PNES are more common in young people, with a relative female predominance. The clinical manifestations of PNES are extremely variable. There may or may not be a reported aura. The onset is often gradual, and always occurs when the patient is awake, even if the patient appears to be asleep. PNES often include motor manifestations, but physical collapse or altered responsiveness may be the only observable manifestations. Many clinical features have been used to diagnose psychogenic attacks and to distinguish them from epileptic seizures. Features that support a diagnosis of PNES include out-of-phase upper and lower extremity movements, side-to-side head movement, and forward pelvic thrusting. Other suggestive clinical features include a gradual onset, "preictal" behavioral changes, "pseudosleep" before seizure onset, discontinuous seizure activity, prolonged duration ("pseudostatus epilepticus" is common), gradual cessation, absence of postictal state, high seizure frequency, excessive variability in ictal manifestations, nonphysiologic progression, eye closure during unresponsiveness, eye fluttering, resistance to eye opening, vocalizations consisting of gagging, retching, gasping, screaming, crying or moaning, retained consciousness and recollection of events with bilateral jerking activity, emotional displays such as crying during events, the presence of an emotional trigger, and the occurrence of events only in the presence of others. If the examiner can suggest the patient into initiating or stopping seizure activity, a psychogenic seizure is suspected. Documented incontinence, tongue biting, and self-injury during attacks

suggest epilepsy, but these features are also reported by patients with PNES. No feature alone is definitive, but a combination of the features noted above can improve the ability to distinguish PNES from epileptic seizures. An elevated serum prolactin level 15–30 min after a seizure also suggests epilepsy, but a normal level does not exclude epilepsy. Prolonged EEG/video monitoring is usually necessary for the definitive diagnosis of PNES. A history of childhood sexual or physical abuse is commonly obtained (approximately 30%). Depression, anxiety, personality disorders, and somatoform disorders are also common and are important to identify and treat. About 10–20% of patients with PNES also have epilepsy. The investigation for coexistent epilepsy is important for treatment, but the exclusion of coexistent epilepsy can be very difficult.

An important condition in which seizurelike episodes are consciously generated is Munchausen syndrome or factitious disorder. Patients with this condition have a strong intrapsychic need to fill the patient role. Munchausen's syndrome by proxy refers to individuals who have a need for another (typically their child) to fill a physically ill patient role. Affected individuals are often very knowledgeable through study of medical works and accounts of seizure symptoms. Other patients may malinger seizurelike events in order to obtain personal injury or worker's compensation benefits, or to obtain antiepileptic medication. It is possible that malingering patients choose an episodic disorder to simulate in order to avoid direct scrutiny of their symptoms in the examination room.

Among physiological disorders imitating epilepsy, syncope is a common symptom related to a transient global reduction in cerebral blood flow. A cardiac origin, such as an arrhythmia, is more of a concern in older individuals, whereas in adolescents and young adults, syncope is most often neurally mediated. Neurally mediated syncope usually features a prodrome of nausea, lightheadedness, and dimming of vision. An observer may witness pallor. This prodrome is usually longer than the aura preceding an epileptic seizure. Up to 90% of syncope is associated with motor activity, predominantly brief multifocal myoclonus that lasts for a few seconds. This is to be distinguished from epileptic tonic–clonic activity, which is longer in duration and synchronous on the two sides. Recovery is usually much faster with syncope than with a seizure, without a "postictal state". Syncope is usually not associated with tongue biting or incontinence. In neurally mediated syncope, the patient usually has enough warning to sit down or at least break his or her fall, whereas patients with epileptic seizures may collapse suddenly, without any warning. If there is doubt, an EEG can be helpful.

Other medical disorders that can be confused with seizures include migraine headaches, which can have a prodromal period marked by visual or somatosensory symptoms, vertigo, or confusion. The characteristic headache and nausea that follow the prodrome usually make the diagnosis clear, but they are not always present. Migraine symptoms tend to have a more gradual onset and a longer duration than those of seizures. Transient ischemic attacks (TIAs) are usually characterized by negative symptoms and signs, such as numbness, visual loss, or weakness, whereas seizures most often produce positive phenomena, such as paresthesias, hallucinations, or involuntary motor activity. Other conditions that can be confused with seizures are transient global amnesia, a transient amnestic state that may mimic a temporal lobe seizure, and "drop attacks of the elderly", a syndrome of sudden falling without self-described loss of consciousness or postictal state. Hypoglycemia can cause lightheadedness, a sense of hunger, and an alteration of consciousness, which can lead to syncope or in some instances seizure activity, if the patient does not ingest glucose. Movement disorders such as hemiballismus, dystonia, and myoclonus can occasionally be confused with seizures. A few sleep disorders such as parasomnias and REM behavior disorder occasionally masquerade as seizures. Parasomnias such as sleep walking, sleep talking, or night terror arise from deep, slow wave sleep, whereas seizures more often arise in light sleep. REM behavior disorder arises from an abnormal REM sleep in which inhibition of motor activity is impaired. Narcolepsy includes sleep attacks, cataplexy, or loss of tone with emotion or startle, visual hallucinations upon falling asleep or waking up, and sleep paralysis, an inability to move upon waking up.

Adverse Consequences of Seizures and Epilepsy

There is an increased risk for epileptic patients to suffer from injuries, primarily due to falls and other accidents caused by the seizures themselves. Burns due to seizures are very common and account for

0.8–3.7% of burn center admissions [8, 9]. There is an increased risk of fractures, concussions, and spinal cord injuries as well. There is likewise an increased risk of mortality among seizure patients, including those caused by drowning and other accidents. Sudden unexplained death in epilepsy (SUDEP) is one of the leading causes of epilepsy mortality. Death occurs most often in association with a seizure, and disproportionately during sleep. There is no apparent structural cause, and the most likely cause of death is either respiratory depression or cardiac arrhythmia, or a combination of both. Seizure control is the most important measure for reducing mortality due to SUDEP.

Occupational impairment and disability are conditions complicating the lives of many persons with epilepsy. A large proportion of individuals with epilepsy lose their jobs upon acquiring the illness. For many others, the threat of seizures occurring while at work is a significant burden. The Social Security Administration identifies epilepsy as a "listed impairment" for which disability benefits are awarded, though many individuals even with intractable seizures often have difficulty obtaining their benefits through the Social Security disability determination system.

Driving restrictions due to epilepsy account for a considerable portion of the impairment in daily activities encountered by epilepsy patients, and is a factor that figures heavily into epilepsy patients' ratings of their quality of life. In the United States, in 28 states patients must be seizure-free for a specific period, ranging from 3 to 12 months, before they are allowed to drive. In other states, medical advisory boards and/or the patient's physician play a role in determining fitness to drive. Many states do not shield the physician from legal liability for their decision. Factors that reduce the likelihood of accidents include the presence of a 6- to 12-month seizure-free interval, and, in the individual patient, the presence of reliable auras, monitoring and adjustment of antiepileptic drugs (AEDs), and the absence of previous accidents. Patients with an established pattern (more than six months) of seizures occurring exclusively in sleep or seizures without change in awareness or responsiveness do not need to be restricted from driving [10].

Discrimination against persons with epilepsy is a serious obstacle to employment and the maintenance of normal social relationships. The stigma perceived by epilepsy patients, and internalization of shame about their condition, are factors in their perceived quality of life. The appearance of stories about seizures in the print media have been shown to often exaggerate the risk of dying during a seizure, to overestimate the curative powers of anticonvulsant medications, and to use demonic imagery in stories about seizures. The use of the term *epileptic*, discouraged by epilepsy associations, is often used in the print media. The American with Disabilities Act provides guidelines and regulations to employers and employees in the workplace regarding seizures and the management of and responsibilities of employees with epilepsy.

Treatment

There is general agreement that treatment has to be initiated after two seizures, because the risk of recurrence is very high. However, it is not clear if treatment is necessary after a single seizure. A number of factors predict a higher risk of seizure recurrence and encourage initiation of therapy after a single seizure. These factors include the presence of a known cause of epilepsy and the presence of epileptiform discharges on the EEG. Patients with a low risk of seizure recurrence have to be involved in the treatment decision and have to balance the risk of seizures and the risks and inconvenience of medication therapy.

The initial treatment of epilepsy is with one AED, chosen based on efficacy for the specific seizure type, and taking into account the specifics of each patient. Approximately 50% of patients will become seizure-free with the first AED. For those who are resistant to the first AED, a second AED is substituted or added. Other treatment methods for treatment-resistant patients include the ketogenic diet, particularly in some forms of pediatric epilepsy. The patient is put on a restricted high fat and low carbohydrate diet, which causes ketones to accumulate in the body, with resultant anticonvulsant effects. The vagal nerve stimulator is the only device that is currently approved for epilepsy therapy. An electrode is implanted in the neck and wrapped around the left vagus nerve and a pulse generator and battery are implanted over the chest and connected to the electrode. The optimal stimulation parameters are identified through gradual titration. Approximately

two-thirds of patients with epilepsy are resistant to treatment. If the epilepsy is focal, surgical resection of the epileptogenic zone is considered and can be highly effective.

AEDs can have a problematic impact on patient behavior and cognition. Many of these agents have side effects of sedation, impaired attention, irritability, and impaired memory. Adverse effects that are of potential legal relevance include suppression of intelligence and learning ability in children taking AEDs, as well as the potential for impaired intelligence and overall neuropsychological functioning in children born to mothers taking AEDs during pregnancy. Evidence-based practice parameters promulgated by the American Academy of Neurology conclude that AEDs in general are implicated in teratogenic effects during pregnancy. The risk may be greatest for mothers taking valproic acid and carbamazepine, or for those taking multiple medications. The risk of major malformations (structural abnormalities requiring surgery to prevent death or dysfunction) is approximately doubled in children exposed to AEDs *in utero*, from 2–3% to 4–6%.

For patients who become seizure-free on seizure medications, treatment is continued for at least two years. The decision to stop the seizure medications has to take into consideration factors that predict a higher recurrence rate. These factors include an abnormal EEG and the presence of brain damage. The patient also has to understand the potential consequences of seizure recurrence. There is a small risk that recurrent seizures may not be as easy to control as the initial seizures.

Seizures, Aggression, and the Law

In criminal trials, the contention that violent behavior has occurred as a result of a seizure disorder is sometimes offered as a criminal defense. In such cases, the question is whether the defendant possessed a culpable mental state at the time of the alleged events, or whether the act was an automatic, nonvolitional one caused by a seizure or its after effects. Technically, such a defense is not an insanity defense (*see* **Insanity: Defense**), but is a defense based upon alleged automatism. The law views acts carried out in a seizure as automatic, with no volitional component, hence there is no criminal culpability (*see* **Automatism as a Defense to Crime**).

Ictal aggression, the commission of a violent act during a seizure itself, is thought to be very rare. Presumably, such an action would be part of an often-repeated, stereotyped automatism typically manifested by the person with the seizure disorder. Such aggression is rare, and would be accompanied by a confused mental state in which the person attacks another in a haphazard, involuntary fashion without a triggering event. The attack is usually limited to pushing, clutching, or shoving. According to Treiman, all documented cases of possible ictal aggression reviewed by him showed that the behavior was either (i) nonaggressive violent automatisms that were stereotyped and repetitive from seizure to seizure, (ii) reactive automatisms manifested by directed aggression after the onset of a clearly identifiable complex partial seizure, or (iii) resistive violence at the end of a complex partial or GTC seizure occurring while the individual was being restrained while still in a postictal, confused state [11].

In the case of aggressive automatisms, the patient's behavior before the episode would be normal, and no specific triggers for the aggression will be present. The onset is quite sudden, with normal behavior one moment and the next displaying inappropriate behavior. Observers will typically report that the patient suddenly stopped, began to stare, and began to show evidence of confusion and automatisms. The aggression will be poorly defined and inappropriate, with attacks on those who happen to be physically nearby, rather than on those with a psychological connection to the patient. Following the conclusion of the episode, consciousness will return. The patient will likely not recall the incident.

Treiman has described guidelines for determining whether there is a relationship between a violent event and epilepsy prior to proffering an expert legal opinion [11]. These include that the diagnosis of epilepsy should be established by a neurologist with a special competence in epilepsy, the presence of epileptic automatisms should be documented by the history and EEG/video monitoring, the presence of aggression during epileptic automatisms should be verified in a video-recorded seizure, the aggressive act should be characteristic of the patient's habitual seizures as shown in the history and should be of short duration and not in response to any external stimulus except restraint, and that the neurologist should judge whether the act followed the known sequence of behavioral changes in complex partial

seizures or whether it was too complex a behavior to have been carried out as part of an epileptic automatism.

The presence of interictal violence is also sometimes in question in cases in which an individual with a seizure disorder commits a violent act, but not during a seizure itself. There does not seem to be an association between epilepsy and violence, other than perhaps beyond the known association between mild brain dysfunction and impulsivity. There is no evidence that seizure disorder itself predisposes individuals to violent acts. Thus, there is no reason to question criminal responsibility in cases of alleged interictal violence, though Fenwick has attributed some cases of mild aggressiveness to prodromal irritability occurring prior to seizure activity [12]. Such irritability is not likely to contribute to an insanity defense, though it may lead to an argument of decreased culpability for a given act of aggression (*see* **Mitigation Testimony**).

Sentencing: Demographic Factors in

A jury trial is a complex process that includes many factors for jurors to consider when trying to render a judgment of guilt or determine sentencing length for a guilty defendant.[a] Evidence shows that jurors try to make good decisions by considering the case at hand, the strength of the evidence, and other appropriate factors; but there is also ample research to show that jurors' decisions are also affected by extralegal factors. In particular, demographic factors of the defendant such as race, age, and gender have also been shown to affect decisions. These factors can make expert testimony appropriate to the extent that knowledge of their impact may assist the trier of fact (*see* **Mitigation Testimony**).

Race of the Defendant

Although racial inequalities are not as prevalent as they were a century ago, subtle inequalities continue to exist in the American courtroom. Most of the research, focused on the racial disparity between Caucasians and African-Americans, reports prejudiced decisions from white jurors when the defendant is of African-American decent [1–4]. White jurors are also more likely to convict and impose harsher sentences on a member of another race than on a member of their own race. However, Caucasians are not the only ones displaying racial bias; juries predominantly made up of African-Americans are less likely to convict a black defendant compared to a white defendant who commits the same crime [2, 5, 6] and individual jurors of African-American decent are also more likely to convict a Caucasian defendant than they are to convict a fellow African-American [3, 7]. Although these studies suggest that racial bias is still an important part of the American legal system, other studies have failed to detect a racial bias in verdict decisions [e.g., [8]] and sentencing judgments [e.g., [9]]. Two relevant theories can explain these disparate findings and help explain why some studies have found an effect of racial bias while others have not.

The phenomenon of ingroup/outgroup bias is a robust finding in the psychological literature [3] and is one explanation for why jurors of one race are more lenient with members of their own race and harsher when defendants represent a different racial group. According to this explanation, individuals display a strong preference for members of their own group (e.g., race) and have negative attitudes towards outgroup members [e.g., [10, 11]]. The ingroup/outgroup bias has been found in a variety of studies and across many different contexts [e.g., [12, 13]]. For example, Pettigrew [13] found that positive behavior of ingroup members is attributed to an inherent disposition, whereas positive outgroup member behaviors are attributed to situational factors. The opposite would be true for negative behaviors. This theoretical perspective would explain why juror bias could be exhibited when the defendant is of another race than the juror. However, the ingroup/outgroup bias phenomenon cannot explain why some studies have failed to detect racial bias in juror sentencing and verdict decisions.

Gaertner and Dovidio [14] postulated a second explanation for the research findings. They suggest that a new form of racism, namely *modern racism* or *aversive racism*, can explain the failure to detect juror bias in several studies [9, 15]. According to Gaertner and Dovidio, the fact that there has been a decline in the display of overt prejudice and explicit racist beliefs does not mean that racism does not exist any more, it simply means that individuals censor their public display of racism, because society does not condone most forms of racism today and Caucasians have moved toward an egalitarian value system [4].

This implicit racism is more likely to manifest itself in public policies (e.g., affirmative action) and is usually not blatantly displayed. Gaertner and Dovidio [14] suggest that Caucasians make a conscious effort to appear egalitarian as long as they are aware that a racial issue is relevant. Thus, it is only when Caucasians interact with members of another race, and no explicit racial issue is presented, they will show prejudice.

When a motivation to appear egalitarian is "not" activated individuals will display racial bias. Taken to the jury level, verdict and sentencing decisions should be most impacted by race when racial prejudices are not made salient to jurors [3, 4, 14, 16, 17]. If race is made salient in a case, white jurors are less likely to act prejudicial when making sentencing recommendations [3] than when it is not particularly mentioned or weighted as important [3].

Finally, it should be mentioned that under certain circumstances jurors might be "more" likely to impose harsher sentences on members of their own race. When ingroup members perceive a member of their group negatively and as threatening to the positive image of the ingroup, they are more likely to evaluate this member in a negative way [18]. This phenomenon is known as the *black sheep effect* (BSE) and was first introduced by Marques and colleagues [19–22]. Kerr *et al.* [23] applied the BSE to a mock juror paradigm and found support for the notion that negatively perceived ingroup members would be punished more harshly and be given longer sentences than outgroup members. This however, was only the case when the evidence against a negatively perceived ingroup member was strong. When the evidence was weak, white jurors displayed the typical ingroup bias in their judgments.

Age of the Defendant

A defendant's age can be construed as either a mitigating or extralegal factor. On the one hand, the court system makes allowances for youthful offenders. Defendants under the age of 18 are often separated from adults, seen in courts designed specifically for youthful offenders, and court outcomes often focus on rehabilitation instead of punishment. In this way, age serves as a mitigator.

The age of the defendant is also an extralegal factor because once jurisdictional decisions are made age should not affect jurors' judgments in a particular case. However, numerous studies have shown that age does influence jurors' judgments. As with race, jurors should not be influenced by the age of a defendant. The adult court system imposes a just-desserts rationale for sentencing, meaning harsher offenses should receive harsher punishments [24, 25]. Age should not be a factor in such decision making. However, numerous studies show that this not the case [e.g., [26, 27]]. Young defendants (those under the age of 13) are often treated more leniently than older defendants and some studies have found that older adolescents who are tried as adults may be treated more harshly than adults who commit the same crime [27].

Several researchers have suggested that jurors' decisions may follow a utilitarian (rather than a just-desserts) approach [24, 25, 28], meaning that factors such as perceived deterrence, incapacitation, and rehabilitation will influence jurors sentencing recommendations. For example, the utilitarian approach would predict that younger offenders would be treated with more leniency than adult offenders because jurors may believe that a young offender has a better chance of being rehabilitated and being harmed more by prison than a middle-aged adult offender [29]. Also, an elderly offender could be perceived as less dangerous and blameworthy than a middle-aged adult offender and therefore, sentenced more leniently [25]. Both archival [30, 31] and experimental [28, 29] studies have supported the utilitarian perspective during sentencing.

Elderly Offenders

Wilbanks [31] examined secondary records for elderly (60 years old and up) and nonelderly (25–59 years old) offenders throughout the criminal justice process. Wilbanks found that nonelderly offenders were more likely to be incarcerated and sentenced to longer prison time than elderly offenders, whereas the elderly were slightly more likely to be convicted, but not necessarily sentenced to serve time in prison. This archival data illustrates that elderly offenders may be treated more leniently than middle-aged adults during sentencing, supporting the utilitarian perspective.

Evidence toward this leniency during sentencing of the elderly has also been found in empirical studies. Bergeron and McKelvie [29] presented mock jurors with either a murder or theft vignette in which the defendant was a 20-, 40-, or 60-year-old man. In the murder case, the 20- and 60-year-old defendants were treated with more leniency than the 40-year-old defendant. The 40-year-old defendant was sentenced to serve more prison time and was not recommended for parole as quickly as the 20- or 60-year-old defendants. These data are congruent with the utilitarian perspective and suggest that age is an important factor during sentencing that jurors consider, even if only unconsciously when rendering their decisions.

Juvenile Offenders

The other end of the age spectrum that is of importance during sentencing is that of adolescent, or juvenile offenders. As with elderly offenders, the age of juvenile offenders influences juror's judgments

of guilt. Several studies [27, 32, 33] have found a positive relationship between age and perceptions of guilt, meaning, the younger the juvenile defendant is, the less culpable he or she is perceived. Furthermore, younger defendants are also less likely to be convicted [33]. These findings are congruent with research on adolescent development [e.g., [34–36]] that postulates that adolescence is a period of poor decision making skills because of significant cognitive and social developmental changes, resulting in a decrease of blameworthiness of the adolescent for his or her behavior.

Though most young offenders are seen in juvenile courts, many states in the mid 1980s and early 1990s passed laws that would ease the prosecution of juveniles as adults [37, 38] allowing harsher punishments compared to the rehabilitative juvenile system [39, 40]. For example, some states passed laws that allowed the juvenile system to be bypassed entirely for children who reached certain ages and who committed specific crimes.

However, to date only three field studies exist that compared the differential outcomes for adults and juveniles tried as adults [41–43]. Eigen [41] found that juveniles who were charged with nonfelony killings in Philadelphia were more likely to be convicted than adults and more likely to receive a verdict of first- or second-degree murder (68%) than adults (38%). Strom *et al.* [43] obtained similar results when they compiled crime statistics in 75 counties in the United States. The authors found that juveniles tried as adults who were charged with violent crimes were more likely to be convicted compared to adult defendants. The most recent field study by Rainville and Smith [42] however found no difference between juveniles and adults who were prosecuted in an adult criminal court.

The above-mentioned field studies illustrate that juveniles who are charged with violent offenses and tried as adults often receive the same punishment as adults and sometimes even harsher punishments. Experimental research that has examined how juveniles are sentenced in an adult criminal court compared to adults has obtained similar findings [e.g., [26, 27]].

Tang and Nunez [27] examined undergraduate mock jurors who were either prosecution-biased (PB) or defense-biased (DB). These mock jurors read a murder trial involving a 19-year-old adult offender, a 16-year-old juvenile offender who was tried as an adult, or a 13-year juvenile offender who was tried as an adult. The authors found that PB jurors were more likely to convict the 16-year-old juvenile offender and had higher confidence in their verdicts. These results illustrate that juvenile offenders who are tried as adults and charged with a serious offense can be at a disadvantage compared to adult offenders. Other studies of younger defendants have found that the harsh treatment of juveniles may not extend to juveniles younger than 13. In fact several studies have found that children younger than 13 are treated more leniently by mock jurors [26, 44]. This suggests that a certain cutoff age exists that would predict when juvenile offenders will or will not be treated more harshly than adult defendants.

Gender of the Defendant

Gender of the defendant has received less research attention; however, several consistent findings have emerged. Early work on gender differences in sentencing decisions found that women were at an advantage compared to men [45, 46] during sentencing. Since then not much has changed with regard to the differential treatment of women and men during sentencing. The finding that women receive lighter sentences than men has become a robust one in the literature [e.g., [47]]. Extensive literature reviews [48, 49] emphasize the strength of the association between gender and sentencing and some scholars [48–50] even argue that the gender of the defendant is the strongest demographic predictor during sentencing, even more so than race or age.

The gender disparity becomes most profound at the point in the judicial process when a defendant is either sentenced to jail time or receives a nonincarcerative sanction such as probation [47]. Women are typically 12–23% less likely to spend time in jail compared to men [e.g., [25, 49, 51]]. However, if a defendant is sentenced to jail, the research is mixed and the disparity between men and women is not as profound. Some studies have found an effect of gender that suggests that women are sentenced with more leniency [25, 51–56] while others found no differences between men and women during sentencing [49, 56–59]. Some other studies have even found women to be at a disadvantage during sentencing [e.g., [44, 60]], but these studies involved cases with juvenile defendants.

Only a few studies have examined how various crime types affect this gender bias during sentencing. Rodriguez *et al.* [e.g., [47]] found in a large sample of convicted offenders in Texas that for minor offenses, such as property or drug offenses, women were sentenced less harshly than men. For violent offenses, women are just as likely as men to be sentenced to jail, however, if sentenced to jail, women received substantially shorter sentences than men.

There are two theoretical explanations that aid in explaining the differential treatment for men and women during sentencing, namely the chivalry thesis and the focal concerns theory. The chivalry thesis postulates that women are generally stereotyped as childish and not as blameworthy as men and therefore should not be punished the same way as men are [51, 57]. However, much of the current research fails to completely support this thesis. A more recent theory, the focal concerns theory, which is similar to the utilitarian approach mentioned above, stipulates that judges or other criminal justice investigators do not have enough time to adequately evaluate all the information for a given case and that their judgments often incorporate some form of human error. They therefore rely on shortcuts that will help them make the best decision at hand. Three focal points that will typically aid them in their decision making are blameworthiness, dangerousness of the defendant, and practical constraints [47]. Men may be perceived as more likely to survive prison than women [25] or may be perceived as more dangerous than women [56]. Focal concerns theory is at the core of explaining why women receive milder sentences and if sentenced to jail they may receive shorter sentences than men.

Conclusion

On the basis of the literature reviewed here, it appears that extralegal factors still play an important role in the way defendants are treated by the criminal justice system and especially during sentencing decisions [25]. However, a jury trial is far too complex to reduce jurors' decisions down to a few variables and it still remains difficult to determine with absolute certainty what factors will ultimately influence jurors' decisions. Another level of complexity that this article did not address is that of jury deliberations [e.g., [61, 62]] and how decisions after deliberations often vary greatly from that of individual jurors. Furthermore, several demographic characteristics have not been discussed in this article, such as socioeconomic status or relationship status of the defendants, which can also impact jurors' judgments in a case. Nevertheless, it can be said that demographic factors continue to influence jurors' decisions and should not be ignored by judges or lawyers during trial proceedings.

End Notes

[a.] In most states jurors do not make sentencing decisions in felony cases. Only Arkansas, Kentucky, Missouri, Oklahoma, Texas, and Virginia allow jurors to sentence defendants in felony cases.

Serial Homicide

Introduction

The term *serial murder* (and serial killer) was not even a part of the forensic lexicon until the 1970s, when it was popularized by one of the authors (RR), then an investigator with the Behavioral Science Unit of the US Federal Bureau of Investigation (FBI) [1]. The precise definition of serial murder has been the subject of some debate, which has somewhat hampered research efforts. However, most proposed definitions share the following elements common: (i) there have been at least two victims (some definitions require three victims), (ii) victims are killed in a noncontinuous manner (i.e., there is an emotional "cooling off" period between murders), and (iii) the murders usually involve a sexual component [2–4].

Serial murder may be a universally terrifying concept, but it is an extraordinarily rare event. In a study of the frequency of serial sexual homicide, it was found to account for only 0.5% of all homicides over a 10-year period in Virginia [5]. In contrast to the sensationalized perception that serial murder is a growing "epidemic", there does not appear to be solid evidence that this is the case. An analysis of homicide victims from 1960 to 1998 indicates that the percentages of female homicide victims have actually decreased [6]. Because the victims of serial murderers

are overwhelmingly female, it has been argued that this data supports the notion that serial murder is not increasing in frequency. However, this data does not address the rate of serial murder in which victims are men or children.

Other research has challenged prior beliefs about serial murder. For example, it had previously been widely accepted that a disproportionate number of serial murderers are Caucasian. Yet researchers have demonstrated that the number of African-American serial murderers closely corresponds to the overall proportion of African-American males in the United States [7].

When a serial murderer begins to commit homicides, the local community is often dramatically impacted. Media coverage is unrelenting, and residents generally live in fear until the perpetrator is apprehended. Residents living in a community exposed to serial murder may even experience post-traumatic stress disorder symptoms for varying periods of time [8]. Yet, despite the high level of interest, there is no universally accepted theory that adequately explains the etiology of serial murder [9]. This may be partly reflective of the fact that serial murder is an event with an extremely low base rate, and therefore difficult to study *via* rigorous scientific methods [5].

Once the concept of serial murder gained widespread recognition, one expert noted that the "tendency of the press, public, and public officials to regard such individuals as mad solely on the basis of their crimes reflects the widespread need to attribute such behavior to alien forces" [10]. This tendency may be understood as the desire to disavow the notion that another human being could commit such atrocities. Could serial murder "simply be part of the spectrum of human possibility, a brutal dark side of man, not representing demons or disease"[11]? Or, do we have reliable evidence of biopsychosocial deficits in certain cases? This article provides a broad overview of the literature and research in an attempt to address these questions.

History

While the term *serial murder* may be relatively new [12], its occurrence is not. It is quite possible that serial murderers have always been among us. Perhaps the first documented serial killer was a first century Roman woman named Locusta. She was a "professional poisoner" who lived in the time of Nero (54 AD), and was ultimately executed [13]. In the fifteenth century, Gilles de Rais, a wealthy French aristocrat, raped and killed some 100 young boys because it brought him "pleasure" [14]. In sixteenth century France, it is likely that myths such as "werewolves" were used to explain the deeds of serial murderers that were too horrifying to attribute to human beings [14]. In the United States, there have been documented cases of serial murder as far back as the 1800s.

In 1886, psychiatry professor Richard von Krafft Ebing wrote the classic *Psychopathia Sexualis*, in which he described the characteristics of individuals who appeared to obtain sexual gratification from acts of sadistic domination. The next major contribution to the understanding of serial murderers was in 1970, when forensic psychiatrist Robert Brittain produced detailed clinical descriptions of sadistic murderers he had encountered over his career [15]. Beginning in the early 1970s, media coverage of notorious cases such as Ted Bundy and the Hillside Stranglers produced a sense of urgency to study and explain the phenomenon.

In the 1980s, experts working in the FBI's Behavioral Science Unit began the pioneering study that ultimately established the foundation for scholarly research of serial murder. To emphasize the sexual nature of the crimes, and to distinguish these offenders from others who murder serially for other reasons (e.g., contract killers), the term *sexual homicide* was adopted [4]. In a sexual homicide, the perpetrator engages in some form of sexual activity before, during, or after the murder. For each individual serial sexual homicide offender, the performance and meaning of the sexual element may vary.

Typology

FBI researchers gathered data from exhaustive interviews of 36 convicted serial murderers. From this data, they were able to extract and analyze core personality and behavioral characteristics [16]. The traits and behaviors identified allowed distinctions to be made between different types of serial murderers. For ease of conceptualization and communication, offenders were categorized into either "organized" or "disorganized" types. These terms

Table 1 Serial murder organized – disorganized typology

Organized offender traits	Disorganized offender traits
Good verbal skills, socially adept	Poor verbal and social skills
May live with spouse	Loner or lives with parents
Reasonably intelligent	Low intelligence
Usually employed	Under or unemployed
Planning of crime	Little-to-no planning of crime
Ruse or con to gain control of victim	Blitz or surprise attack of victim
Targeted victim	Victim of opportunity
Crime scene: suggests control, order	Crime scene: disarray
Crime scene and death scene not the same	Crime scene and death scene often the same
Movement of body	Body left at death scene
Attempts to conceal evidence	Little-to-no attempts to conceal evidence

were initially meant to help law enforcement interpret crime scenes, and are best understood as generalized distinctions occurring on a continuum. The organized–disorganized typology provided illustrative descriptors of personality and behavior, and had the advantage of being easily grasped by both law enforcement and mental health professionals. The major organized–disorganized typology traits are listed in Table 1. The term *mixed* sexual homicide was used to describe the offender, whose crime scene reflected aspects of both the organized and disorganized types, thus lying on the continuum between them. Finally, the term *sadistic* murderer describes the offender who is primarily a sexual sadist, and derives the greatest satisfaction from the victim's response to torture [4].

Since the original organized–disorganized typology was advanced, a number of other typologies have been proposed. A clinically based typology has been advanced that categorizes perpetrators as either "compulsive" or "catathymic" [17]. The *compulsive* perpetrators are similar to the FBI's organized killers. They leave organized crime scenes, and can be diagnosed with sexual sadism, as well as antisocial/narcissistic personality disorders. The *catathymic* perpetrators leave disorganized crime scenes, and may be diagnosed with a mood disorder and varying personality traits. While the compulsive type displays emotional detachment and autonomic hyporeactivity, the catathymic type are less psychopathic. In contrast, the catathymic types are autonomically hyperreactive, and may have histories of abuse. Like the organized–disorganized typology, these types are generalized concepts, and any individual case is likely to fall on a continuum between the two.

A number of researchers have pointed out that nearly all serial murderers demonstrate a core of organized features, and that it is the degree of disorganization that most differentiates them [18]. Along a similar line of reasoning, a statistical analysis of 85 sexual murderers yielded a "five-cluster" model [19]. It was noted that most offenders shared core characteristics such as preparatory behavior, precautionary behavior, and some degree of sophistication. This core of behaviors was referred to as the *undifferentiated* pattern, and the other four patterns (predator, fury, rape, and perversion) were differentiated from it. The *predator* pattern is similar to the organized or sadistic offender as described by the FBI. This offender was characterized as older, more mobile, Caucasian and likely to be living with a partner. They tend to be well groomed, collectors of crime literature and sexual materials. This group may also operate with an accomplice. The *fury* pattern represents an unfocused, explosive obliteration of the victim, and is most similar to the FBI's disorganized type. The murder is characterized by excessive violence and overall disorganization. The chances of this offender having or not having a mental disorder are roughly equal.

The *rape* pattern consists of offenders whose primary goal is sexual intercourse. They use that amount of force that is necessary to carry out the rape. Application of force is typically minimal, and there is no indication of sexual dysfunction in the offender. Thus, this pattern may be conceptualized as a sexual assault that ultimately resulted in murder. The crime scene

will not reflect any great degree of perversion, but a relatively straightforward violent sexual attack. These offenders may have some prior peripheral acquaintance with the victim, such as living in the same apartment complex. The assault usually occurs in a single indoor location, such as the victim's home. The offense is usually unplanned, and characteristic of a younger offender who attacks a victim of opportunity. Thus, the scene may reflect elements of the FBI's disorganized type. The *perversion* pattern offender engages the victim in conversation by offering reassurances. Offenders tend to be older with bisexual or homosexual orientations, while their victims tend to be younger and male. The offense usually involves some type of pedophilic assault that culminates in murder.

In general, serial murderers do appear to share some core characteristics. However, research has begun to focus on the differences that distinguish various subgroups of serial murderers. The following descriptions represent a sampling of some serial murder subgroups that have been studied, and should not be considered exhaustive.

Female Serial Murderers

Relatively little has been written about female serial murderers as compared to their male counterparts. In a review of published literature on female serial murder, the most common motive identified was material gain [20]. Sexual or sadistic motives are believed to be extremely rare in female serial murderers. Psychopathic traits and histories of childhood abuse have been consistently reported in these women [20]. In a study of 105 female serial killers, the preferred method of killing was poisoning [21]. An analysis of 86 female serial killers from the United States found that the victims tended to be spouses, children, or the elderly [22]. Sometimes referred to as *black widow* killers, these women tend to be geographically stable and live in the same area where their offenses occurred. Their victims are not strangers, and the methods they use are covert or "low profile" [21]. On rare occasions, women may be involved with a male serial killer as a part of a serial killing "team" [23].

Perhaps one of the more high profile female serial killers in the United States was Aileen Wuornos, who was convicted of killing seven men in separate incidents. Wuornos had claimed that all of the men had raped her (or attempted to) while she was working as a prostitute. Thus, she did not fit the typical profile of a female serial killer. Her case received remarkable media and Hollywood attention. In a detailed case study analysis, it was theorized that Wuornos was biologically predisposed to psychopathy, and her abusive childhood resulted in serious attachment deficiencies [24]. Finally, her aggressive narcissism and antisocial lifestyle predisposed her to situations in which she was able to commit acts of predatory murder. Wuornos was executed by lethal injection in 2002 in Florida.

Juvenile Serial Murderers

Serial murder by children and adolescents is exceedingly rare, and little scientific information is available. In a study of six cases, juvenile serial murderers were found to exhibit signs of sexual sadism, predatory violence and the use of "hands on" methods of killing [25]. The average age of the juveniles when they committed their first murder was 14. There is somewhat more data on juvenile sexual homicide, and it is hypothesized that youths who go on to commit serial murder would have originated from this group [24]. In a study of 16 juvenile sexual homicides, 10 factors were commonly found in the perpetrators [26]. These factors are listed in Table 2. Three of these factors (impaired capacity to feel guilt, neuropsychiatric vulnerabilities, and serious school problems) were found in 100% of the offenders.

Owing to increasing law enforcement sophistication, it is possible that juvenile sexual murderers will be apprehended after their first offense, making juvenile serial murder even rarer [25]. Nevertheless, professionals working with juveniles should be sensitive

Table 2 "Big 10" factors in 16 juvenile sexual murderers [26]

1.	Impaired capacity to feel guilt
2.	Neuropsychiatric vulnerabilities
3.	Serious school problems
4.	Child abuse
5.	Family dysfunction
6.	History of interpersonal violence
7.	Prior arrests
8.	Sadistic fantasy
9.	Psychopathic personality traits
10.	Personality disorder diagnosis (especially schizoid or schizotypal)

to the fact that violent fantasies can develop early in the life of a sexual murderer [27].

Physician Serial Murderers

The study of medical serial killers has gone overlooked until relatively recently. This may be due to an unwillingness to perceive sworn "healers" as potential murderers. However, research has revealed that medical killers may actually be the most prolific of all serial killers. Doctors who serially murder their patients are considered to belong to a larger group of "career-assisted killers." The term *clinicide* has been used to describe "the unnatural death of multiple patients in the course of treatment by a doctor" [28]. Such murders may be difficult to detect, since they often occur in settings where death is expected to happen. Doctors accused of clinicide will be likely to put forth the defense that they were relieving suffering or providing euthanasia. Clinicidal doctors may have extreme narcissistic personalities, and may obtain pleasure by "determining" when a person will die.

One of the most deadly doctor serial killers may also hold the dubious distinction of being one of the most prolific serial murderers to date. Dr Harold Shipman, a UK physician, was convicted of killing 15 patients with lethal injections of narcotics. In a posttrial investigation, it was concluded that Shipman was responsible for 218 known victims [29]. Other estimates have suggested that the number is closer to 450 [30]. Most of Shipman's victims were not terminally ill, nor did they have an immediate life-threatening illness. Shipman refused to speak to anyone, and no complete psychological assessment was ever performed on him [29]. He committed suicide in prison in 2004.

Other healthcare professionals have been implicated in serial murder. In a study of 90 healthcare killers, 86% were nurses and 12% were doctors [31]. Injection was the most common method used, followed by suffocation, poisoning, and tampering with equipment. Fifty-four of the 90 cases were ultimately convicted. A total of 2113 deaths could be attributed to these 54 convicted healthcare killers.

Other Subgroups

As research has progressed, specific subgroups have been singled out for more detailed analyses. For example, sexual murderers of children have been singled out for separate study and comparison. It has been found that sexual murderers of children are more often victims of childhood sexual abuse, and have more deviant sexual fantasies than sexual murders of women [32]. In addition, sexual murderers of children are more likely than sexual murders of women to: use pornography prior to the offense, have contact with the victim, premeditate the offense, use strangulation, hide and dismember the body. Another body of research indicates that sexual murderers of elderly women present a particularly distinct profile [33, 34].

It has been suggested that sexual murderers of men may differ in certain respects from those who murder women. An initial typology has been proposed, although it was based on a study of only 10 cases [35]. The *avenger type* is usually involved in prostitution, and has a history of childhood abuse. A triggering event during a sexual exchange may elicit memories of abuse, which leads to severe expressive violence and murder. The *sexual predator type* premeditates his offense, and is motivated by deviant sexual fantasy. Victims of the sexual predator type are often adolescents or young men. The offense involves abduction, confinement, and sadistic acts. The *nonsexual predator type* sets out to rob a vulnerable, often older homosexual man. The victim may be seduced, and substance use by both victim and offender occurs prior to the offense. Usually, the victim is not sexually assaulted, and the murder may have resulted from an escalation of violence during the robbery.

Motivations

Most research on the motivations of serial murderers has focused on sexual fantasies and/or a need for control and domination. Indeed, one of the most reliable psychological findings in the mental lives of serial murderers is the presence of violent sexualized fantasy. Convicted serial murderers have consistently described a high frequency of violent fantasies that are both persistent and arousing [15, 36, 37]. In a comparison of 25 serial sexual murderers with 17 single sexual murderers, it was found that the serial murder group had a higher prevalence of paraphilias and violent sexual fantasies [38]. It was theorized that serial murderers' deviant fantasies may

be reinforced *via* repeated pairing with compulsive masturbation. This has led to the speculation that deviant sexual fantasy may serve as a rehearsal of sorts for eventual murder [39]. In fact, many cases of serial murder have involved strong components of sexual fantasy, use of pornography, or other media with sexually sadistic themes [40]. Internet and digital technology may provide a new and abundant source of deviant fantasy material for the sexual murderer [41].

A study of 28 sexual murderers suggested that they may be driven by certain "implicit theories" or cognitive schemas they had about life [42]. It was found that the offenders had commonly held beliefs such as "the male sex drive is uncontrollable", and the world is generally hostile and dangerous. Other guiding cognitions included anger and resentment toward women, and a sense of entitlement. Related findings came from a study comparing 19 sexual murderers to 16 nonmurdering rapists [43]. The sexual murderers, compared to rapists, reported higher levels of grievance toward females in childhood, higher levels of loneliness in adolescence and were more likely to portray themselves as victims, as adults.

Because a number of well-known serial murderers have served in the military, a social learning theory has been hypothesized, whereby the military may provide the associations and reinforcements to enable efficient killing [44]. Military training is seen as helping the offender objectify victims, and reinforcing the tendency to use lethal aggression. Hostility and aggression, in general, have been proposed as possible motives. This theory suggests that either anger, or anger fused with sexual arousal, drives serial murder [45]. This fusion theory was proffered to explain the murders committed by Jeffrey Dahmer [46]. Here, it is important to make the distinction between rapists who murder to silence their victims, *versus* the so-called lust-murderer who derives sexual satisfaction from the act of rape–murder [27].

Finally, a convincing argument has been put forth that anger is not *causative* in sexual homicide. This hypothesis stresses that the physiology of anger and sexual arousal are usually mutually incompatible. True anger, as opposed to aggression, has an inhibitory effect on erectile and sexual functioning. This reasoning holds that sexual motivation is the primary motive in sexual murders, whereas anger and/or control over victims are secondary [3].

Offense Behavior

The study of serial murderers' offense behavior provides important data for homicide investigators. Serial murderers often leave confusing and violent crime scenes, which must be carefully analyzed for behavioral evidence. A study that compared single and serial homicide offenses found that serial offenders targeted more women, and killed more strangers [47]. While single homicide offenders killed out of anger, serial offenders appeared to be sexually motivated. The serial offenders were significantly more likely to use strangulation, move the body from the death scene and dispose of the body in a remote location. Some commonly observed serial sexual murder offense behaviors are listed in Table 3. Serial murderers may clean the victim's genital area to remove evidence, and may take personal items from the victim as souvenirs [48]. Prostitutes may represent a common victim pool for serial killers [49].

In the analysis of serial murder crime scenes, the concepts of *staging* and *posing* may play important roles. Staging is a purposeful alteration of the crime scene by an offender to throw off investigators [52]. The offender may be concerned about being a likely suspect, and wish to direct the investigation away from him or her. Three types of staging have been described: (i) staging to appear like a suicide or accident, (ii) staging to appear like a sexual homicide, and (iii) arson to destroy evidence [53]. In contrast, posing is the positioning of the victim's body by the offender. Posing, a very rare offense behavior, often involves leaving the victim in a sexually degrading position. This may either be to shock police, or simply for the offenders own gratification [52]. Serial murderers who leave posed victims may also leave evidence of binding, stabbing, or bludgeoning.

Table 3 Serial sexual murder offense behaviors [16, 50, 51]

Binding, torture
Stabbing, biting
Attempted or completed sexual intercourse (oral, anal, vaginal)
Victim left nude or seminude
Sexual positioning of victim's body
Insertion of foreign objects into victim's body cavities
Semen on or near victim's body
Victim's personal items taken

It has been found that the geographic locations of serial murderers' offenses are critically important. The geographic sites of 155 serial killer disposal sites were analyzed, and a strong relationship was found between the location of the offender's home and the disposal site [54]. The vast majority (89%) of offenders lived within a circle defined by the disposal sites that were furthest from each other. The finding that serial murderers appear to operate in a certain spatial location around their home has been called the *circle hypothesis* [54].

Psychiatric Findings

Most data on psychiatric diagnoses of serial murderers comes from individual case studies and retrospective analyses. The majority of these studies have suggested a common constellation of diagnoses: *psychopathy, antisocial personality, sexual sadism*, and other *paraphilias* (especially voyeurism, fetishism, transvestism, and sometimes necrophilia). More recent and well-designed comparison studies have yielded similar findings. For example, a study comparing sexual murderers to other general sex offenders found that the sexual murderers had greater levels of psychopathy, sadism, fetishism, and transvestism [55]. In addition, the sexual murderers began their criminal careers earlier, and had stronger histories of fire setting and cruelty to animals.

The sexual sadism seen in serial murderers must be distinguished from sexual sadism between consenting adults that would not be considered criminal. The variant of sexual sadism seen in serial murderers is at the extreme end of the spectrum, as it ultimately involves killing for sexual excitement. Such individuals may engage in torturing victims to the point of death to obtain the "pleasure in complete domination" over them [56]. To better capture this distinction, the diagnosis *"sexual sadism, homicidal type"* has been proposed for serial sexual murderers [3]. It is noteworthy that a higher level of gratuitous and sadistic violence was found in the homicides committed by psychopathic sexual murderers when compared to nonpsychopathic sexual murderers [57].

There is considerable overlap between the construct of psychopathy, and another diagnostic construct described in serial murderers called *malignant narcissism. Malignant narcissism* has been defined as an extreme variant of narcissistic personality disorder, antisocial personality, sadism, and a tendency to paranoid reactions [58]. This clinical construct has been proposed by a number of theorists studying serial murder [59]. It is suggested that malignant narcissism is best viewed as an aspect of personality structure, as opposed to a formal mental disease. This theoretical concept has been used to explain the chronic sadistic arrogance and lack of empathy observed in most serial murderers.

Paraphilias

Paraphilias, particularly voyeurism and fetishism, have been described in many serial murderers. Over 70% of sexual murderers had these paraphilias in the early FBI studies [16]. Some individuals with voyeurism and fetishism may engage in burglaries that actually serve the purpose of gratifying these two paraphilias [60]. Offenders may steal sexually related items during a burglary, such as female undergarments. Such offenses may, in fact, be part of a progression to an eventual sexual homicide. In a descriptive review, it was found that serial murder was associated with multiple paraphilias [61]. It was speculated that multiple paraphilias served to enhance and reinforce the overall sexual experience of the offender.

Obsessive–Compulsive Traits

Focusing on the seemingly compulsive nature of the offenses, researchers have speculated about the significance of the obsessive qualities of the serial murderer, particularly the organized type. These individuals demonstrate a tendency toward orderliness, obsessive, fantasy, and ritualistic behavior (posing the body, biting, inserting objects, etc.) during their murders that suggest compulsive qualities. A study finding high rates of compulsive masturbation in sexually sadistic serial murderers may support the hypothesis of underlying obsessive–compulsive traits [62]. Other support comes from Rorschach studies of sexual murderers who evidenced high levels of obsessional thinking [63, 64]. Experts believe that these obsessive and compulsive traits, combined with higher than average intelligence, permit the organized offender to avoid apprehension.

Other Disorders

There appears to be a very low rate of psychosis among serial murderers, and approximately half

Table 4 Psychiatric disorders found in serial murderers

Psychopathy
"Malignant" narcissism
Antisocial personality disorder
Borderline personality disorder
Schizoid and Schizotypal personality disorders
Substance use disorders
Paraphilias (sexual sadism, voyeurism, fetishism, transvestism, and necrophilia)
Asperger's disorder

of perpetrators report substance use prior to their offenses [16]. At the present time, there is no conclusive evidence that specific organic factors play a causal role in the creation of a serial murderer. However, studies have found right temporal lobe abnormalities [65], as well as subtle neurological abnormalities in sexual sadists [66].

Neurodevelopmental deficits have been hypothesized as a possible contributing factor to serial murder (Table 4), most notably in the case of Jeffrey Dahmer [67, 68]. Investigators have described an association between autism spectrum disorders and a subgroup of serial murders, and propose that Dahmer may have suffered from Asperger's disorder. Along these lines, it is interesting to note that after exhaustive interviews with Dahmer, one author (RR) was impressed by the "peculiar" nature of Dahmer's presentation [69].

A possible neuropsychiatry genetic defect has been found in a few cases of sexual homicide. The sex chromosome abnormality XYY had previously been associated with criminal behavior [70]. More recently, researchers found three men with the XYY chromosome abnormality in a sample of sexual homicide offenders [71]. The rate was found to be higher than what would be expected among prisoners or the general population. All three men were diagnosed with sexual sadism and psychopathy.

Developmental Theories

A number of different psychosocial theories have been put forth regarding the developmental etiology of serial murder. Investigators have speculated that the behavior may result from a deadly convergence of (i) early childhood attachment disruptions, (ii) psychopathy, and (iii) early traumatogenic abuse [72]. However, there is conflicting evidence on the presence of child abuse in the development of serial murderers. When the FBI studied 36 serial murderers, many of them had a history of either abuse or neglect [16]. Forty-three percent reported a history of childhood sexual abuse, and 74% reported a history of psychological abuse, which typically involved humiliation. A study of 48 homicidal sex offenders found high rates of childhood abuse and removal from the family home [73]. In contrast, others have found that a majority of sexually sadistic murderers had no evidence of childhood abuse [56, 74]. One possibility accounting for these differences may be due to heterogeneity in the populations studied.

When sexual murderers with a history of sexual abuse were compared to murderers without such a history, significant differences were found [75]. Sexual murderers with a history of early sexual abuse were more likely to begin fantasizing about rape earlier. In addition, they developed more severe sexual deviancy. Besides sexual abuse, the family histories of many sexual murderers reveal unstable environments, which may predispose them to disordered early life attachments. Approximately 70% of sexual murderers' families had histories of alcohol abuse, and about 50% had family members with criminal histories [76]. It has been hypothesized that parental neglect, from either absence or preoccupation with their own life problems, may have further impaired these men's ability to form healthy attachments.

Animal cruelty has been a common finding in the childhood and adolescent developmental stages of many serial murderers. The link between animal cruelty during childhood and subsequent physical violence during adulthood has been demonstrated in a number of studies [77, 78], resulting in the addition of animal cruelty to the diagnostic and statistical manual of mental disorders, 3rd edition, revised (DSM III-R) as a symptom under the diagnosis of conduct disorder in 1987. In keeping with the developmental theme of conduct disorder symptoms, researchers have also commented on a possible link between childhood fire setting and adult serial murder [79]. The association between serial murder and enuresis has not been as strongly born out in the research to date.

Obviously, all children who are diagnosed with conduct disorder and/or engage in animal cruelty do not go on to become serial murderers. Nevertheless, it is thought that in the cases of those who do, an early "practicing" of violent and sadistic behavior on a living creature may play a role in desensitizing the individual to violence against humans. This notion

has been termed the *graduation hypothesis* to denote the progression or "graduation" from animal cruelty to sadistic acts against humans [80]. Thus, some individuals may progress past mere desensitization, toward intense pleasure from acts of cruelty and ultimately murder.

Psychodynamically oriented investigators have theorized that a sexually provocative mother may contribute to the formation of a serial murderer [17, 81]. It is important to note that this premise is far from another "blaming" of the mother theory. Rather, investigators point to documented instances of strikingly inappropriate sexual behavior on the part of the mother that would easily qualify as sexual abuse. Evaluations of some convicted serial murderers suggest that a displacement of aggression from their mothers onto to their female victims was present during their offenses.

Upon review of the developmental theories and individual case studies, the following traits are frequently observed in serial murderers: deviant sexual interests, a strong need for control of a victim, a very active deviant fantasy life, and psychopathic traits allowing for the objectification of victims. When these traits are synthesized into a gestalt, the clinical picture that emerges is one of an individual who spends excessive time in a reverie of deviant fantasy, has a tendency toward isolation, a need for totally submissive partners, and a preference for autoerotic pleasure [82]. As can be imagined, such an individual will be unlikely to have healthy relationships, and subsequently must depend on fantasy for gratification. However, at some point, mere fantasy becomes an insufficient source of pleasure for the potential serial murderer.

It is theorized that what follows is a gradually progressive series of "try outs," where he attempts to turn his fantasies into reality. For example, an offender may begin by simply following a potential victim. This may next progress to voyeurism or breaking into victim's homes [60]. During a burglary, the offender may steal fetishistic items for sexual pleasure. When this fails to provide sufficient satisfaction, the offender may progress to rape and ultimately murder. The behavior is positively reinforced over time through paired association with masturbation, making the deviant fantasies extremely refractory to extinction[38]. Each time the offender murders a victim, there is further stimulation of fantasy and an overall reinforcement of the cycle.

Assessment and Prevention

Evaluations of serial murderers may occur for a number of different purposes. Interviews may be conducted by law enforcement upon apprehension, by forensic mental health in the event that a mental disease defense is raised by the defendant, and after conviction for research purposes. Forensic assessments of suspected serial murderers are best done by those with experience evaluating psychopathic and serial sexual offenders. Dishonesty and underreporting of deviant fantasies and offenses are commonplace, and a meticulous review of collateral data prior to the evaluation is necessary. Individuals who have already confessed to murders may still be unwilling to discuss the sexual nature of their offenses for a variety of reasons, the most common being the fact that sex offenders are severely harassed by other inmates in prison. In the authors' experience, many such individuals will want to focus on the aggressive aspects of their crimes, and downplay the sexually deviant aspects.

Interviewing Strategies

Interviewing strategies and approaches will need to be tailored to both the purpose of the interview and the individual nuances of the case. Regardless of the purpose of the interview, it is essential to gather and review all relevant collateral data prior to interviewing the offender. This will not only lend important perspective but will also better allow the interviewer to realize when the offender is giving false or misleading information [27]. The use of a cointerviewer has been suggested both for safety purposes, as well as to provide added objectivity and oversight [83].

Very often, the quality of data obtained during an interview will only be as good as the rapport that the interviewer is able to establish. In studies of interviews of sex offenders, a "humanistic" style of interview has been found to yield the best results [84]. This style requires the interviewer to assume a sympathetic, nonjudgmental stance, as opposed to a "dominant" interrogation style of interview. In a study of interview styles of murderers and sex offenders, it was found that interviews marked by dominance were associated with a higher proportion of denials [85]. In contrast, a humanistic style was associated with greater admissions. Because many serial

murderers will be discerning, intelligent individuals, they will likely perceive even subtle critical or judgmental attitudes in the interviewer. Thus, verbal or nonverbal communication relating bias or disrespect should be avoided. Rather, a humanistic interview style that relies on an understanding and respectful approach is recommended.

While open-ended types of questions are recommended, the interviewer should consider using some type of interview protocol as a general guide for consistency and reliability. The interviewer should not assume that the offender's sexually related crimes are limited to those for which he has been charged or convicted. The interviewer should inquire about concurrent assaultive behavior or deviant fantasies that may have occurred during other, seemingly unrelated criminal acts such as burglary or breaking and entering. Finally, it has been observed that sexual offenders, for a variety of reasons, may be slow to reveal incriminating details [86]. Thus, repeated interviews may be a helpful consideration. Table 5 lists generally recommended strategies for interviewing serial murderers.

When serial murderers are interviewed for research purposes, it has been suggested that interviews should be conducted postconviction, as well as after the possibility of all appeals by the offender are exhausted [47]. In addition, researchers should consider offering some form of written assurance of confidentiality. These precautions have the aim of reducing the offender's motivation for giving deceptive or otherwise self-serving answers.

Prevention

Most experts believe that the prognosis for individuals who have committed serial murder is extremely poor [87, 88]. At the present time, a preventive approach has received the widest endorsement. It has been suggested that more attention be paid to prevention in child and adolescent sex offenders, given that future adult serial murderers may come from this population. Children and adolescents who demonstrate sexually sadistic fantasies, or other early warning signs should be followed closely by mental health professionals who are in a position to direct efforts toward extinguishing the reinforcing cycle, and conducting periodic risk assessments [37].

The field of juvenile sex offender treatment has been gaining increasing attention; however, it remains in its very early stages. Current reviews of treatment efficacy support the use of cognitive behavioral methods, residential treatment programs, supervision, family therapy, and psychosocial interventions [89, 90]. Pharmacotherapy remains understudied, but various psychotropic agents have been utilized, including testosterone lowering agents [91]. In a study of 21 adolescent sex offenders, the use of Naltrexone, a medication used to treat some obsessional and impulsive disorders, was associated with decreased masturbation and sexual fantasies [91]. Much more research in the area of juvenile sex offender treatment is needed to be able to establish a greater degree of confidence in treatment efficacy [92].

Possible Early Warning Signs

In an effort to help guide forensic risk assessments, a list of "10 ominous signs" has been suggested [93]. The list consists of traits, characteristics, and behaviors frequently found in the backgrounds of perpetrators of sexual homicides. It is suggested that when these signs are seen in combination, the juvenile may be predisposed to committing sexual homicides when older. The 10 ominous signs are listed in Table 6.

Table 5 Recommended interviewing strategies

Gather all relevant supplemental data
Thoroughly review data prior to interview
Consider a cointerviewer
Establish good rapport
Attempt to "understand" subject's perspective
Use "humanistic" interview style
Avoid "dominance" or interrogation interview style
Avoid a judgmental or critical approach
Consider repeated interviews

Table 6 Ominous signs [93] (when seen in combination)

Childhood abuse
Inappropriate maternal sexual conduct
Pathological lying and manipulation
Sadistic fantasy with a compulsion to act
Animal cruelty
Need to control and dominate others
Repetitive firesetting
Voyeurism, fetishism and sexual burglary
Unprovoked attacks on females and generalized misogynous emotions
Ritualistic behavior

Conclusions

Serial murderers have been described as representing an exceedingly small, yet "freakish side show in the circus of American punishment" [94]. Despite this very reasonable assertion, serial murderers captivate a disproportionately large amount of society's attention, study, and fears. In the case of serial murderers, we apparently have a substantial desire to know the face of evil. Perhaps this is driven by our fear that these "moral monsters", unbranded by physical stigmata, will be able to commit atrocities undetected. Indeed, a journalist covering the Jeffrey Dahmer trial was unable to fathom how ordinary Dahmer appeared, remarking that "there was nothing to him" [95]. Yet another reason may be that it is the tension between the killer's outer normalcy and inner deviance that elicits our tireless fascination [96]. Whatever the case, serial murderers' offenses represent the extreme pole on the continuum of human cruelty and selfishness.

In this article, some of the biological and psychological theories on serial murder have been discussed. However, it is important to recognize how limited our present understanding remains in terms of the etiology and development of serial murder, so that erroneous conclusions are not drawn. While researchers have identified traits and abnormalities common to serial murderers, there are many who possess these traits and do not go on to become serial murderers. What is it that leads some to act on their deviant fantasies while others do not? Until future research can help clarify this question, we must satisfy ourselves with the notion that "the leap from fantasy to action has much to do with character and the vicissitudes of life . . ." [97]

Serial Number Restoration: Firearm

Introduction

Many manufactured objects bear a serial number or other identifying numbers, letters or codes, which may be removed, altered, or obliterated. These markings are produced in various ways during the manufacturing process, such as etching, casting, engraving, or stamping. A range of restoration techniques are available, which makes it possible to restore the original alphanumeric marking in sufficient detail to be able to read it.

Most firearms are marked by their manufacturers with a serial number or a combination of numbers and letters in at least one location. On some firearms, the complete serial number may be repeated on all the major components, i.e., the frame, cylinder, and barrel of a revolver. In other instances, the last few digits of the main alphanumeric mark is repeated upon even relatively small components. These can appear in obvious exposed exterior areas or, in some cases, in locations that can only be revealed by stripping the firearm. It is common practice for criminals to obliterate the identifying marks on illegally owned firearms to make the tracing of them more difficult. Forensic firearms examiners are frequently tasked with restoring these obliterated marks or finding a secondary location where the marking is repeated.

Principles

In many cases, identifying numbers, letters, or marks, are produced using procedures that involve compression such as stamping. This process induces changes in the structure underlying the impressions. If the marking is then removed by filing or grinding so that it is no longer visible, the area of the altered structure remains. By applying etching solutions, with or without heat, the area of the altered structure can be made visible, as that the area will react in a different manner to the base metal.

Close examination of an object is required to verify that a marking should be present in a particular location and that it has been obliterated. The examination should indicate the method by which the numbers, letters, or mark were originally recorded and the method of obliteration. These assessments will dictate the available restoration options. The following are some of the common methods used to place identification marks on firearms.

Etching and Electrical Discharge Machining (EDM)

Etching and electrical discharge machining (EDM) refer to the production of identifying numbers, letters,

or marks by eroding the base material. The process involves discharges of electrical spark to erode conductive materials such as carbon or stainless steel. Little or no deformation of the underlying material occurs with this process and, as a result, completely obliterated serial numbers are almost impossible to restore.

Casting

As with etching and electrical discharge machining, casting involves little or no deformation of the underlying material. Therefore, when the markings are thoroughly obliterated, they are almost impossible to restore, especially if there has been neither 'cold working' nor the addition of any foreign material to the parent metal.

Engraving

There are two general methods of engraving, namely, rotating burrs and vibrating impact tools. Rotating burrs gouge the surface but do not deform the underlying material, whereas vibrating engraving tools have various shaped tips, generally rounded or chisel pointed, and they deform the underlying material while impacting it.

Stamping

Stamping is one of the most common methods of adding serial numbers, letters, or other markings to firearms. It is also known as *punching* and usually involves forcing a shaped tool into the base material. All variations of this method involve compression (cold working) of the base material, which provides the potential for restoration of the original identifying marks.

Obliteration

Different techniques are used in the attempt to obliterate numbers, letters, or marks. The most common methods of obliteration are described below.

Filing/Grinding

Mill Bastard or Bastard (1/2 round) metal files and grinding wheels are the tools most commonly used for this purpose. The metal surface is generally removed until all visible traces of the serial number, letters, or marks are removed. Restoration using acid etching or magnetic particle processes have a high success rate.

Center Punching or Over-Stamping

A line of holes is center punched into the serial number, letters, or marks using a hammer and punch. If deep enough, these alter the underlying structure of the metal and destructive restoration techniques are unlikely to be successful.

Other number or letter stamps are sometimes used to over-stamp existing ones in an attempt to alter the original digits. Nondestructive visual examination methods can be useful in identifying the remaining key areas of the original marking.

Milling or Drilling

Milling or drilling has a similar effect on the underlying structure of metal as filing or grinding, but this often removes more material. Visual examination can be useful on drilled areas to identify any remaining key areas of the original digits, but if the milling or drilling is deep enough, destructive techniques are unlikely to be successful.

Welding

Welding essentially remelts part of the base material, adding new material from the filler rod or wire. This produces gross changes in the underlying material, and acid etching techniques are generally unsuccessful in identifying the original markings.

Nondestructive Restoration Techniques

Visual Inspection

In many instances, when a drill or a punch has been used to obliterate the original serial number, it is possible to identify individual digits from the remaining fragments that are still visible, provided these fragments contain a key portion of the digit. A low-powered stereo microscope is generally required to aid recognition of the fragments; contrast techniques can also be useful. The most common are

rubbing chalk over the erased area or using a filtered light source (e.g., a Polilight lamp) to create ultraviolet or other light frequencies that may enhance the marking.

Wood

Some firearms have identification marks in their wooden stocks or grips. If the mark is burnt in or made by cutting with a chisel or a knife, it cannot be restored once obliterated. However, if the mark has been punched in, for example, the serial number or military marks on a Lee Enfield caliber. 303 British rifle, then the same considerations apply as with metals. The simplest and most effective method of restoration is to run a jet of steam onto the erased surface. The steam softens the wood and causes the bent fibers to spring back and the broken fibers to swell. As a result, the wood will project the marking above the surface and it can be read.

Destructive Restoration Techniques

On occasions an examiner can polish the defaced area flat with wet and dry abrasive paper to find the original markings are still visible under the correct lighting conditions, without the need for further treatment. If further treatment is required, then it is important to determine the metal type before commencing treatment.

Magnetic Particle

The concept of magnetic particle restoration was developed in 1957 in the United States of America. It relies on the principle that any change in density or of molecular structure causes a change of the magnetic flow lines from the north to the south poles. Therefore the magnetic particles tend to congregate around the obliterated number, letter, or marking, making it visible.

This process requires the surface area to be smooth and polished to achieve the best results. Once prepared, the object should be placed on an AC or DC powered magnet. Industrial magnetic crack testing devices have proved particularly successful using AC or direct DC power sources. Once the object has been charged, Ardrox white background lacquer can be applied to provide contrast and then Ardrox black magnetic ink can be sprayed over the treated area. The restoration usually appears almost immediately.

Acid Etching (Stainless Steel, Mild Steel, and Iron)

Before using this technique, it is important to identify what type of metal is to be worked on. This will determine the type of chemical solution to be used.

When acid etching stainless steel, mild steel or iron, the surface area must be cleaned with acetone to ensure it is free from oil or grease. The area to be treated is then polished with a fine grade of wet and dry abrasive paper (400 Grade) to make restoration easier to see. Badly scratched or scored areas should be lightly polished with a fine abrasive pad on the dermal tool. This simply reduces the amount of labor required to achieve a smooth surface.

There is debate over whether the use of heat is a necessary step in the restoration process. The principle surrounding the use of heat is that it will anneal the metal if a temperature of approximately 300 °C is reached. An indicator of this temperature is when the metal assumes a straw color. It is essential that the metal is not heated too strongly. The reason for annealing is to enable the compressed and distorted metal to adjust itself to the conditions. If the metal is heated to red heat, the temperature is sufficiently high to soften the metal and on cooling, the metal becomes homogeneous and can no longer be differentiated. A Bunsen burner or blowlamp is all that is needed to achieve the desired result.

Once the metal has been allowed to cool, Fry's reagent, which consists of a mixture of hydrochloric acid, cupric chloride, ethanol, and water, can be used to acid etch the metal.

Modified Fry's reagent can also be used; this mixture consists of the same ingredients except ethanol, but in a different proportion.

At the completion of the etching process, it is recommended that a lacquer is used to seal the restored numbers, letters, or marks. Alternatively, light oil should be applied to the treated area to protect it from corrosion.

Acid Etching (Aluminum and Aluminum Alloys)

The most common and effective solution is a 10% sodium hydroxide and water. Preparation of the

surface metal is the same as that described for Fry's reagent. Fry's solution can still be used on aluminum or aluminum alloys, but it reacts very quickly. Therefore it should only be used when a result cannot be achieved with 10% sodium hydroxide.

Hume-Rothery solution is an alternative to modified Fry's reagent; it contains cupric chloride, hydrochloric acid, and water in different proportions. This reagent reacts very energetically with aluminum alloys and deposits a layer of loose brown copper, which must be wiped off.

The procedure for using Hume-Rothery solution is basically the same as for mild steel, stainless steel, and iron, except that the aluminum surface should not be cleaned with abrasives. Instead, any paint or grease can be removed with acetone before commencing the acid etching process.

Vinella's solution is also an effective reagent on aluminum or aluminum alloys. It contains glycerine, hydrofluoric acid and nitric acid. However, hydrofluoric acid is extremely corrosive and a dangerous substance to work with. Therefore this reagent is not recommended for Occupational Health Safety and Wellbeing (OHS&W) reasons.

Heat

The use of heat has already been mentioned in combination with acid etching techniques on stainless steel, mild steel, and iron. It can also be used by itself on these metals after the surface area has been smoothed and polished. The process is commonly used on engine blocks to restore engine numbers, but greater care needs to be exercised on gun metals because they are far more fragile.

Sex Determination of Remains

Once one has verified that the remains are human and recent, the anthropologist must proceed to reconstruct the biological profile. This entails the collection of all possible information from the skeletal remains, which may lead to identification. This goes from sex, age, stature, and ancestry, to all dental (hence the strong link with forensic odontology) and osseous features (deformations, pathologies, nonmetric traits), and, finally, to facial reconstruction. In an ideal system, the biological profile should be compared with descriptions of missing persons in order to find the best possible matches. Then one should proceed to perform a comparison between antemortem and postmortem data by odontological, anthropological, or genetic analyses (sometimes fingerprints may also exist on the degraded remains, which are not completely skeletonized, but this is more the domain of the fingerprint expert or the forensic pathologist). Concerning the biological profile (sexing, aging, etc.), odontological aspects also will be taken into account in this Forensic Anthropology section (*see* **Anthropology: Age Determination of Remains**; **Odontology**), leaving the specific identification aspects mainly to the Forensic Odontology chapter.

Sexing is the first step in the completion of the biological profile. Determination of sex of human remains is frequently immediate even in severely decomposed cadavers, thanks to the fact that genital organs are among the last soft tissues to disappear. In skeletonized remains, however, such tissues are not present and thus one must rely on the dental and skeletal structure. In the past decade, DNA testing has started to prevail. However, although it is extremely sensitive as a technique, one must deal with the problem of extraction, degradation, contamination, and costs. Conservation of DNA depends on various environmental variables, still not completely known, even if sporadic DNA has been used for sexing even ancient remains. Anthropological criteria are quicker and cheaper for sexing; however, they too have their limits. On one hand, they are dependant on the integrity of the skeleton. Extremely fragmented remains may be impossible to sex (if crucial parts have been lost). On the other hand, they do not always give accurate and absolute results. Another limit to the skeletal analysis is subadults. Skeletons of children and adolescents cannot be sexed due to the incompleteness of morphological characteristics. Some authors have advanced the hypothesis concerning different dental dimensions and particularly the conformation of the auricular surface of the ilium, which, in infant ilia, is elevated when the sex is female and flat when it is male. However, extreme caution should be applied with such methods whose authors indeed warrant an error rate of 50–60%. Other hints on sex of a subadult can be given by the difference in maturation between the dentition and the skeleton. Girls usually have similar maturation stages for the skeleton and the teeth; boys seem to have a slower dental development. Thus a discrepancy between dental and skeletal development in a subadult may indicate a male sex. However, even this method may be full of pitfalls.

Determination of sex on adult complete skeletons, on the other hand, is quite reliable and has two main approaches: a morphological and a metric one. Both approaches are complementary and reflect sexual dimorphism in the shape and dimension in almost all bones, but particularly and more significantly, the cranium and the skull. Metric parameters reflect, on the other hand, different sizes between males and females, in particular, as concerns the diameter of articular extremities. There is, however, an intermediate zone of superimposition and only individuals whose dimensions fall below and above it can be safely classified as male or female [1–43].

The most reliable anatomical site for sexing is the hip. Female bones reflect the tendency to adapt to pregnancy and childbirth. The female pelvis is relatively lower and larger compared to the male one. Generally speaking, in front of an entire pelvis (left and right innominate and sacrum) this appearance can be quite diagnostic, as shown in Figures 1 and 2.

It is, however, less intuitive that there are other parts of the pelvis that may be, per se, indicative of sex. The most important bones remain the pubic ones, particularly that area constituting Phenice's triad, a series of three characters, which are very reliable sex indicators. These consist of (i) the ventral arc: this is an elevated bony crest, which extends across the ventral surface of the pubic body laterally from the center of the body until it reaches the ischiopubic ramus (Figures 3 and 4).(ii) the subpubic concavity, which is a small medial concavity at the medial extremity of the subpubic angle, present in females;

Figure 1 Female pelvis. The letter A is situated in the subpubic angle, which is very wide in the female

Figure 2 Male pelvis. The letter B is under a very narrow subpubic angle, typical of males. Also notice the much more narrow nature of the anterior pubic region with respect to the pelvis in Figure 1

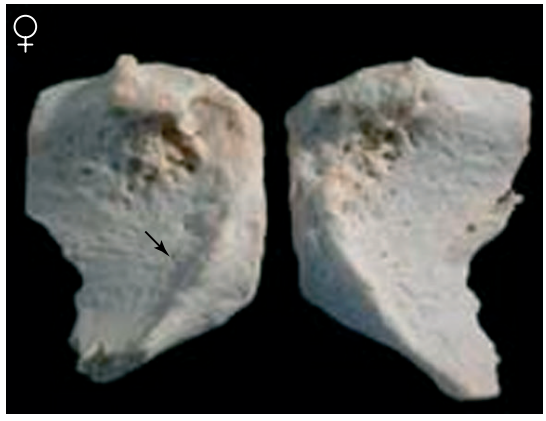

Figure 3 Pubis seen from the front. The arrow points to the ventral arc in the female pubis

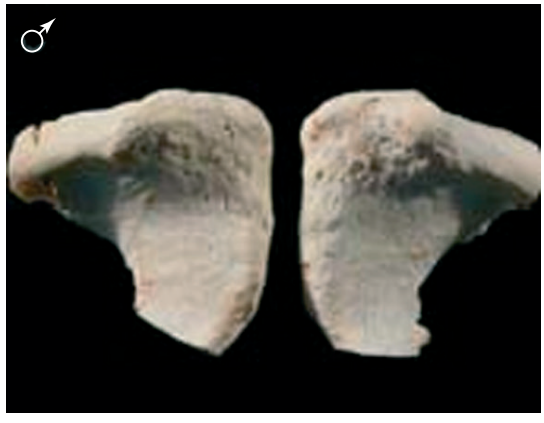

Figure 4 Isolated typical male pubic bone with no ventral arc

(iii) the shape of the ischiopubic ramus (or presence of the ischiopubic crest). The female ischiopubic ramus has a crest along the ramus and is narrower. The value of these parameters has been confirmed by several authors and this triad remains a fundamental sex indicator.

Other important sex markers of the pelvis are the shape of the sciatic notch: it is narrow in males and forms an obtuse angle in females (Figures 5 and 6).

The preauricular sulcus is an evident concavity (notch) beneath the auricular surface, which articulates the ilium with the sacrum. This is more commonly present in females than in males. Most authors will agree that the entire pelvis will reach a degree of accuracy in sexing between 95 and 98%. However, as all biological markers, a margin of overlapping of the two sexes must be taken into account.

Finally, the sacrum is also usually taken into account. A flat sacrum is generally female, while a concave one is male.

The cranium is the next best sex indicator, although reliability slides down to 80–85%.

The male cranium is, in general, larger and rougher with more marked muscular insertions.

Males tend to develop prominent crests near the muscle insertions, which move the head and mandible. These include the temporal lines, where temporal muscles insert, and the mastoid processes, which project inferiorly behind the auditory meatus.

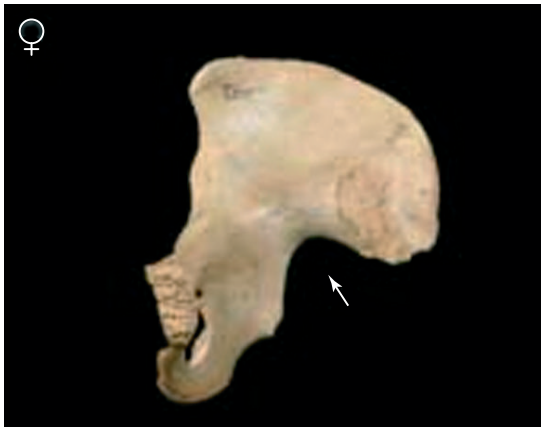

Figure 5 Female right innominate bone (medial view): the arrow indicates a large sciatic notch

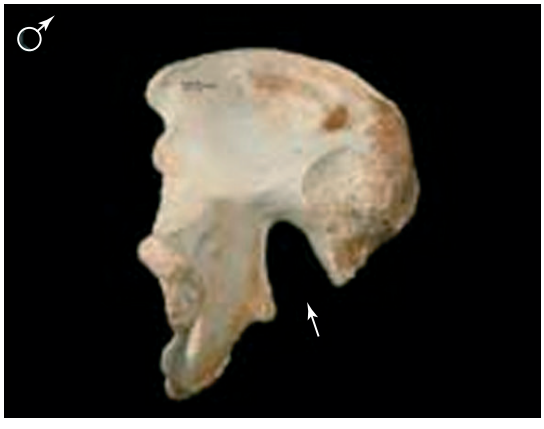

Figure 6 Male right innominate bone (medial view): the sciatic notch is much narrower

Figure 7 Female skull, where one can appreciate (1) flat glabella; (2) thin orbital margin; (3) a zygomatic arch that stops in length at the external auditory meatus; (4) small and medially inclined mastoid process; (5) (posterior) small nuchal crest; (6) no gonial eversion and delicate mandibular angle; and (7) round mandibular symphysis

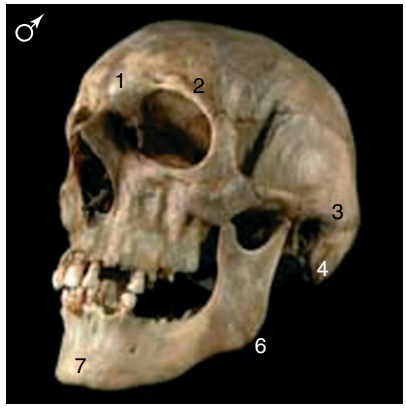

Figure 8 Male skull, where one can appreciate (1) pronounced glabella; (2) thick and rounded orbital margin; (3) a zygomatic arch that proceeds beyond the external auditory meatus; (4) large and vertical mastoid process; (5) (posterior) large nuchal crest; (6) gonial eversion and rough ridges on the mandibular angle; and (7) squared mandibular symphysis

However, such insertions may be marked even in women who have occupational stress in these areas. Ethnological studies show the development of such characters in women who prepare hides with their teeth or who carry weights on their heads.

In general, main sexual differences in the cranium can be seen in the anatomical areas shown in Figures 7 and 8.

As regards the anthropometric approach, numerous publications exist on metrical differences between sexes of almost every single bone. One can observe the diameters of the heads of humeri and femurs, and/or measure the ratios of pelvic structures, such as the ischiopubic index. An alternative is the discriminant function analysis. However, the single most commonly used parameters are the head of the femur, of the humerus and of the radius. Generally, if the diameter of a humeral head is greater than 47 mm, the person is a male and less than 43 mm it is a female; a female radial head is 21 mm or less and in males it is usually over 23 mm. The vertical diameter

of the femoral head is usually over 48 mm in males and less than 43 mm in females. There is then a vast literature on the metric analysis of various anatomical districts such as heads, diaphyses, and epicondyles of long bones and lengths and widths of tali, calcanei, sacrum, metatarsals, and metacarpals [25–43]. One advantage of metrical analysis is that it will entail a smaller error within nonexpert observers. Discriminant function analysis is also a valid, although more complex, support to sexing. It allows the combination of numerous measures in a single mathematical function in order to discriminate between two groups: male and female, based obviously on data taken from two known sample groups. With the combination of different measurements, discriminant functions give more weight to variables, which are more efficient in sexing and in distinguishing between two groups, namely, male and female. Discriminant functions have already been calculated and published for cranial, mandibular, pelvic, and other regions of the skeleton.

All these methods, however, both metric and morphological, are subject to variations within populations. It is therefore crucial, when sexing, to use morphological or metric parameters or discriminant functions tared on populations similar to the one that is being studied.

A final remark on sex should be made concerning signs of pregnancy. Some authors have indicated that notches on the dorsal surface of the pubis indicate that the woman underwent pregnancy. More marked ones even indicate several pregnancies. These theories, however, should not be taken too seriously as they have, in part, been revealed wrong by the presence of such notches in the bones of women known to have been nulliparous.

Sex Offenders: Treatment of

The term *paraphilia*, as defined by the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV), is used to refer to recurrent sexual fantasies, urges, or behaviors involving nonhuman objects, suffering or humiliation, children or

other nonconsenting persons. Paraphilic interests are fairly common in men and include a wide variety of behaviors typically seen in clinical populations seeking evaluation and treatment for paraphilias [1]. Those who most frequently seek psychiatric treatment for sex offenses are those accused of or involved in child molestation, voyeurism, exhibitionism, fetishism, frottage, and public masturbation [2]. The term *sex offender* is used to refer to an individual who has been legally convicted of a sex offense.

The terminology "sex offender" does not provide any information regarding the offender's reason for committing the sexual offense nor does it indicate the presence or absence of a paraphilia. The psychiatric treatment of sex offenders is distinct from other clinical populations. Recent changes in sex offender legislation have mandated treatment for offenders deemed "sexually dangerous" or "sexually violent" in psychiatric hospitals as civil committees. Such legislation has fueled long-standing debates on the diagnosis of paraphilias, the nature of mental illness, and the treatability of sex offenders [3].

Background

The efficacy of sex offender treatment is unknown. Although studies comparing treated and untreated sex offenders have been done, measurement of outcome is flawed, with recidivism rates underestimating the actual recurrence of the pathological behavior [4]. Methodological challenges such as sample selection, study design, and assessment of outcome represent significant problems in the treatment efficacy studies. The majority of treatment efficacy studies are conducted on incarcerated or civilly committed offenders. Those individuals who are incarcerated or civilly committed represent a unique population with treatment outcomes, which may not generalize to the nonincarcerated or community-residing sex offender. Many studies do not differentiate between types of offenders. For example, a study that evaluates child molesters may not differentiate between intrafamilial and extrafamilial offenders. Research suggests that incest offenders recidivate at approximately half the rate of extrafamilial child molesters [5].

A well-designed study of treatment efficacy in sex offenders would compare treated offenders with a matched, randomly assigned control group. However, the ethical and public safety implications of such a study impede its design. Sex offenders are extremely heterogeneous and when this is not recognized it is very difficult to make comparisons among treatment efficacy studies [2].

The determination of treatment success in sex offenders is arbitrarily defined. Investigators have not agreed upon a standardized measurement of improvement. Although all treatment studies report sex offender recidivism, recidivism is measured in various ways. Some studies measure recidivism based on an offender's self-report, whereas other studies define recidivism based on an offender's arrest records. Studies measuring sexual arousal by penile plethysmography define improvement as a reduction in deviant sexual arousal. In a meta-analysis by Hanson and Bussiere [6], erections to children (as measured by penile plethysmography) was the factor most highly correlated to recidivism in over 28 000 sex offenders. However, the use of penile plethysmography has not been generally accepted by the scientific community due to a lack of reliability between the different types and models of plethysmographs in addition to debate over the validity and appropriate use of penile plethysmography [7].

Biological Treatment

The scientific basis of biological treatment in sex offenders is the reduction of sexual behaviors by decreasing testosterone levels. Testosterone is a steroid hormone produced by the testes and responsible for the development of secondary sex characteristics in men. Testosterone helps maintain sex drive, the production of sperm cells, male hair patterns, muscle mass, and bone mass. Testosterone strongly influences both male and female sexual drive and the resultant sexual behavior [8]. Animal studies show that male copulatory behavior is almost entirely dependent on circulating levels of plasma testosterone [9].

The production of testosterone is mediated by follicle-stimulating hormone (FSH) and luteinizing hormone (LH), both of which are produced by the pituitary gland. LH signals the testes to produce testosterone. The hypothalamus senses whether the production of testosterone is too much or too little. If the testes are producing too little testosterone, the hypothalamus secrets a hormone called

gonadotropin-releasing hormone (GnRH) that signals the pituitary to increase production of LH, which results in an increase in testosterone production. If the testes are producing too much testosterone, the hypothalamus secretion of GnRH is inhibited. This process whereby the hypothalamus modulates the production of testosterone is called *negative inhibition*.

Surgical Treatment

Surgical treatment for sex offenders consists of two types: neurosurgery and castration. The neurosurgical procedure involves stereotaxic removal of parts of the hypothalamus to disrupt production of male hormones and decrease sexual arousal and impulsive behaviors [4]. This procedure had significant adverse effects and was considered largely ineffective. Surgical castration is the removal of the testes. The effect of surgical castration is to globally reduce available androgen by the removal of the testes [2]. Sturup [10] followed 107 castrated sex offenders and compared them with 58 sex offenders who were not castrated over a period of 18 years. The castrated individuals recidivated at a 4.3% rate. The 58 uncastrated individuals recidivated at a 43% rate. Postcastration follow-up studies provide the most comprehensive outcome data on the effect of reducing plasma testosterone and the resultant suppression of the sexual drive and deviant sexual behavior [11]. These studies have reported recidivism rates of less than 5% with follow-up periods of up to 20 years in a large sample size [11].

The introduction of antiandrogen and hormonal medications has rendered surgical castration nearly obsolete. The effects of surgical castration can be achieved through chemical castration, i.e., the use of medications to decrease testosterone production, without the invasiveness and irreversibility of surgery. Some states in the United States, such as Texas and California, mandate chemical or surgical treatment of dangerous sexual offenders. Controversy exists as to whether surgical castration should be offered as a treatment as chemical castration achieves the same results and spares the procedure.

Pharmacologic Treatment

Antiandrogens. Androgens are male sex hormones that promote the development and maintenance of male sex characteristics. Testosterone is the most common androgen in man. Antiandrogen treatment refers to treatment with drugs used to block production or interfere with the action of male sex hormones. Cyproterone acetate (CPA) and medroxyprogesterone (MPA) are the two most commonly used antiandrogen medications. CPA is not available in the United States but is widely available in Canada and Europe. Both CPA and MPA are synthetic progesterones that reduce the serum level of testosterone. Reduction of testosterone has been shown to reduce libido, erections, ejaculations, and spermatogenesis [12]. A meta-analysis of antiandrogen studies completed by Grossman *et al.* [4] suggests that recidivism rates in antiandrogen-treated offenders are less than that in untreated offenders. The studies report a spectrum of differences between patients treated with antiandrogens and those not treated, with recidivism rates as low as 1% for treated patients and as high as 68% for untreated patients [4]. In 1992, Copper *et al.* [13] performed the first direct comparison of CPA and MPA. The results suggested that MPA and CPA performed equally in decreasing sexual thoughts and fantasies, frequency of masturbation, and erection.

The risks associated with the use of antiandrogen agents include side effects such as weight gain, hyperglycemia, hot and cold flashes, liver dysfunction, hypertension, muscle cramps, phlebitis, gastrointestinal complaints, and feminization [4]. In addition there is little known about the long-term sequelae of antiandrogen treatment. The majority of antiandrogen studies follow patients for eight years or less. The patient who agrees to antiandrogen treatment should be educated about the absence of long-term data.

Hormonal Agents. Leuprolide and Triptorelin are hormonal agents referred to as *long-acting GnRH agonists*. These agents inhibit the secretion of LH with a resulting decrease in plasma testosterone levels and libido [14]. They produce a chemical castration in that the hypothalamic-pituitary axis is exhausted and there is a potent inhibition of gonadotropin [15]. Rosler and Witztum treated 30 men with severe long-standing paraphilias with triptorelin [16]. Treatment was associated with suppression of serum testosterone. A meta-analysis of pharmacotherapy of paraphilias with long-acting agonists of luteinizing hormone-releasing hormone was

conducted by Briken *et al.* [17]. In total, the studies reported on a sample of 118 treated patients. Patients previously treated with other agents like CPA, MPA, or selective-serotonin-reuptake inhibitors (SSRIs) reported better effects when taking luteinizing hormone-releasing hormone (LHRH) agonists. None of the treated patients had a relapse. The results indicated that all men showed a decrease in deviant sexual fantasies, desires, and abnormal sexual behavior. In an observational study, Krueger and Kaplan [18] treated 12 patients with various diagnosed paraphilias and comorbid psychiatric disorders with leuprolide. All patients reported a significant reduction or even cessation of deviant sexual arousal and/or interests.

The side effects associated with GnRH agonists include decreased bone mineral density or osteopenia, weight gain, hyperglycemia, diabetes, hypertension, and insomnia. The most commonly reported side effects are erectile/ejaculatory problems and gynecomastia [18]. In general, patients reported fewer side effects on GnRH agonists when compared to antiandrogens. The preliminary studies of GnRH agonist suggest that leuprolide and triptorelin may be more effective, better tolerated alternatives to antiandrogen treatment.

Selective-Serotonin-Reuptake Inhibitors (SSRIs). Although the pharmacologic mechanism is poorly understood, SSRIs have been shown to be effective in reducing paraphilic symptoms. Kafka [19] treated 21 subjects with paraphilic disorders or paraphilic-related disorders with SSRI monotherapy. A total of seventeen subjects showed a decrease in symptoms while being treated with an SSRI without significant side effects. Greenberg *et al.* [20] demonstrated that sertraline, fluvoxamine, and fluoxetine were equally effective in reducing paraphilic symptoms. Although data exists to suggest that SSRIs are effective in the treatment of paraphilias, presently there is insufficient data to conclude that SSRIs are equally efficacious as antiandrogens or hormonal agents.

Psychological and Behavioral Treatment

Psychological approaches to the treatment of sex offenders focus on direct treatment approaches to modify offenders' cognitions and attitudes. Cognitive approaches described the concept of cognitive distortions (minimizations, excuses, justifications) as one factor that may maintain offender behavior [21]. Relapse prevention and the sexual assault cycle are theoretical models purporting to describe the cognitions and behaviors of sex offenders before, during, and after their abusive acts [22]. An offender prevents relapse by the identification and arrest of the thoughts and actions, which lead to sexual offending. The majority of sex offender treatment programs offer a combination of cognitive-behavioral and relapse prevention therapies.

The rationale for the implementation of behavioral techniques to control sexual arousal is based on the clinical observation that abusive sexual fantasy is linked with abusive sexual behavior. The factor that most consistently distinguishes male sex offenders from other males is sexual arousal disorder profiles as measured by phallomteric assessment [23]. The modification of an individual's behavior is achieved by altering individual reactions to stimuli through positive and negative reinforcements. These reinforcements condition an individual by reinforcing positive behaviors and extinguishing negative behaviors. More specifically, the behavioral techniques used to control sexual arousal employ olfactory aversion conditioning, covert sensitization, and masturbatory satiation to extinguish deviant sexual arousal and reinforce appropriate sexual arousal.

Recidivism rates from cognitive and behavioral treatment programs range from 3% to 31% depending on the study [4]. In a meta-analysis by Hall [24], it was found that cognitive-behavioral treatment and antiandrogen treatment were comparable in their treatment effects and significantly more effective than behavioral treatment alone.

Models of Treatment

The treatment of individuals with paraphilias and sex offenders has primarily focused on two areas: cognitive-behavior group treatment and pharmacologic treatment. Treatment programs are based on recent research that reveals that victim empathy, remorse, responsibility training, and relapse prevention are integral components of a treatment program. A survey conducted by the Safer Society in 1994 asked sex offender treatment providers to identify the treatment modalities delivered in their program. The results revealed

that greater than 90% of programs utilized the following treatment modalities: victim empathy, anger management, and cognitive distortions; 75% of programs provided social skills/assertiveness training, approximately 42% prescribed SSRIs, and 19% prescribed antiandrogens [25]. Langevin *et al.* [26] queried the sex offenders in treatment about acceptable types of treatment. The preferred therapies were individual psychotherapy, social skills training, and group therapy, whereas aversion conditioning, castration, and sex drive–reducing drug therapy were the least acceptable forms of treatment.

Ethical and Legal Considerations

The legal and ethical issues that arise in the course of sex offender treatment are unique to this population. As such, the traditional codes of ethics employed in medical treatment are not applicable to the treatment of sex offenders. A significant percentage of sex offenders receiving treatment have been mandated by the courts as part of incarceration or to be released into the community. The concept of mandated or involuntary treatment raises the issue of whether informed consent is possible in sex offender treatment. A condition of informed consent for medical treatment is that the consent must be voluntary. Obviously, court-ordered sex offender treatment is not voluntary. Individuals who reject treatment are subject to punishment imposed by the courts. Individuals who have been ordered by the court to receive treatment do not have a choice regarding the type of treatment or the treatment provider. Sex offenders are required to complete particular programs, irrespective of any other treatment that they might be receiving, in order to gain community release or avoid imprisonment [27].

In the medical model, patients have a right to refuse various types of treatment. The right to refuse treatment is based on an individual's constitutional right to privacy. The court views sex offenders as incompetent patients, and as such the court becomes the decision maker regarding treatment.

Confidentiality and Privilege

Confidentiality refers to the physician's obligation to keep information learned in a professional relationship private from other parties. Privilege refers to the patient's right to prevent a physician from providing testimony about personal medical information. Both confidentiality and privilege are routinely breached in sex offender treatment. When individuals enter treatment, they are required to give permission for their cases to be discussed with both clinical and nonclinical personnel, correctional officers, members of their family, past and potential victims, and those associated with them and fellow offenders [27].

In response to the deviations from traditional ethical codes inherent in sex offender treatment, ethical and practice guidelines were developed by the Association for the Treatment of Sexual Abusers (ATSA). ATSA's code of ethics endorses standards of professional conduct that promote competent practice, and as such, they represent a public commitment to clients and society toward the goal of preventing sexual violence. The ATSA guidelines state that the ethical care of sex offenders is achieved by encouraging individuals to take responsibility for their behavior, that is, admission of guilt. ATSA maintains that the identification and collaborative management of risk and safety factors are indeed in the best interests of both sex offender patients and potential victims owing to the grave consequences incurred by sexual offender recidivism [28].

Castration of Sex Offenders

In 1996, California became the first state to authorize the use of either chemical or surgical castration for certain sex offenders who were being released from prison into the community. To date, additional nine states have authorized surgical or chemical castration for sex offenders, including Georgia, Montana, Oregon, Wisconsin, Florida, Iowa, Louisiana, and Texas. The American Psychiatric Association stated "these laws, which predicate release from prison on chemical castration by surgery or antiandrogenic agents, are objectionable because they are not based on adequate diagnostic and treatment considerations. They also improperly link medical treatment with punishment and social control" [2]. In some states informed consent for the procedure is not required, while in other states informed consent requires only that the offender be informed regarding the side effects [29].

Conclusion and Future Directions

Further Research

Although studies have demonstrated the effectiveness of some modalities of sex offender treatment, the scientific literature does not identify a definitive effective treatment. The literature suggests that both cognitive-behavioral therapies and antiandrogen medication decrease sex offender recidivism. However, the current sex offender legislation in the United States is not based on the literature. Rather, the legislation focuses on the preventive detention of sex offenders without concurrent evidence-based sex offender treatment. The future of research in the treatment of sex offenders lies in the development of evidence-based knowledge that will inform both clinical decisions and public policy. This effort may be afforded by interdisciplinary collaboration between the scientific community, correctional professionals, and policy makers.

Specialized Training

Many psychiatrists are unfamiliar with the fundamentals of the assessment and treatment of individuals with paraphilias. The advent of laws for the civil commitment of sex offenders has resulted in the need for psychiatrists trained in paraphilias. As a result of sex offender legislature, the treatment and release decisions regarding sex offenders have become a focus of attention for psychiatry [30]. Forensic psychiatrists or psychologists must render an opinion as to whether the sex offender has a diagnosed mental disorder and, as such, represents a risk to public safety if released from custody into the community [31]. In order to provide competent care to individuals with paraphilias, psychiatrists should be educated about the evidence-based approach to the treatment and evaluation of this population.

Education of the Public

The general public perceives sex offenders as a homogenous group of offenders who are not treatable. However, recent meta-analysis has demonstrated that sex offenders are a highly heterogeneous population with different rates of reoffending and responsiveness to treatment. The successful treatment of sex offenders is dependent, in part, on the support of the public and the courts. In order to implement an evidence-based treatment, the offender must be afforded the opportunity for treatment. The opportunity for treatment is created by an informed society that legislates treatment that is informed by scientific evidence. The education of the public is integral in the successful treatment of sex offenders.

Shaken Baby Syndrome

Introduction

The diagnosis "shaken baby syndrome" (SBS) has been widely accepted for over 30 years, but recent evidence from biomechanical and clinical observational studies questions the validity of the syndrome.

Definition

The diagnosis of SBS is based on the clinical triad of encephalopathy, retinal hemorrhage (RH), and subdural hemorrhage (SDH) in infants, usually under six months of age, who may die unexpectedly or survive with greater or lesser degrees of neurological damage [1]. The term non-accidental head injury (NAHI) has been preferred as it has no implications for mechanism of injury. Other features often associated include a sole carer at the time of collapse and a clinical history that is incompatible with the severity of the injuries. The diagnosis of inflicted injury becomes less problematic if there is objective evidence of violence, such as bruises, fractures, or burns, but objective evidence of trauma has not always been necessary in making the diagnosis.

Central to the assessment of these cases is whether the triad of findings can be regarded as diagnostic of abuse with any degree of certainty. This review examines the evidence base for each element of the triad and the current biomechanical evidence regarding mechanisms of infant head injury and its pathological investigation.

History

SDH has been associated with child abuse since the mid-19th century [2]. Kempe described SDH with multiple skeletal injuries and bruises as the battered child syndrome and Caffey described long bone fractures and SDH [3–5], but it is Guthkelch [6] who developed the hypothesis that the whiplash–like movements during shaking cause the characteristic bilateral thin film SDH of the syndrome. He based his hypothesis, that shaking causes tearing of the cerebral bridging veins leading to SDH, on the biomechanical studies of Ommaya [7] who was researching adult head injury in road traffic accidents. Following Guthkelch's paper, the "shaken baby syndrome" has become widely accepted as a form of child abuse [1].

The Triad of Injuries

The three elements of the triad are encephalopathy, RH, and SDH.

Retinal Hemorrhages (RHs)

RHs have been regarded as an important indicator of inflicted injury, but many other causes of retinal bleeding are recognized in infants, for example after normal birth, raised intracranial pressure, blood dyscrasias, hemoglobinopathies, extracorporeal membrane oxygenation, cataract surgery, and accidental

trauma [8]. Postmortem indirect ophthalmoscopy has shown RHs to be more common after natural disease and accidental injury than after inflicted injury [9]. These authors also noted that infants suspected to have been abused were more likely to have ophthalmological examination in life than infants with accidental injuries or natural diseases. This bias readily distorts the true incidence of RH in non-accidental injury. Indeed Vinchon [10] noted in his study of infant head injury that "*In the construct of our study we could not obviate the circularity bias, and the evaluation of the incidence of RH in child abuse remains a self-fulfilling prophecy*". These authors did, however, suggest that the extent and nature of retinal bleeds may be more important as indicators of inflicted head injury than their existence per se [10].

The main hypotheses for genesis of RH are that it is the result of venous obstruction, which in turn may result from compression of the optic nerve by raised intracranial or intravascular pressure, even transiently, or that the tissues of the retina are torn during the act of shaking. This latter hypothesis does not withstand biomechanical scrutiny [11].

Encephalopathy

This term may be widely interpreted to include a range of clinical manifestations from feeding difficulties, vomiting, and sleepiness to seizures and fulminating cerebral edema.

The specific neuropathological features of traumatic brain injury are contusions and traumatic axonal injury. Hypoxic-ischemic injury and brain swelling are frequently seen but are not specific for trauma. Contusions are very uncommon in infant brain trauma in the absence of skull fractures. Identification of axonal injury now depends on the immunocytochemical demonstration of beta amyloid precursor protein (BAPP). This is a very sensitive marker of interruption of normal axonal flow but may be upregulated after hypoxic–ischemic injury and metabolic disruption as well as trauma (Figure 1). Distinction of traumatic axonal expression of BAPP from other causes is fraught with difficulty, and depends in part on its distribution [12], [13], [14]. Neuropathological studies have shown that in babies who die following NAHI, the underlying brain pathology is widespread hypoxic-ischemic injury and not diffuse traumatic axonal injury as previously believed [12, 13]. In this series axonal injury was seen in a limited distribution in the lower brainstem and in only a minority of cases. Radiological studies have confirmed these pathological observations [15].

This observation is important as traumatic axonal injury will lead to immediate loss of function causing clinical symptoms from the time of trauma. In contrast, hypoxic-ischemic injury and ensuing brain swelling take variable periods of time to develop and a baby so damaged may not show immediate symptoms. Even fatal brain trauma may present with a lucid interval between injury and clinical collapse [16, 17]. Lucid intervals are more frequently seen in infants less than two years of age [18], reflecting the very different responses of the infant brain to injury due to the specific intracranial pathophysiology before the skull bones fuse [19].

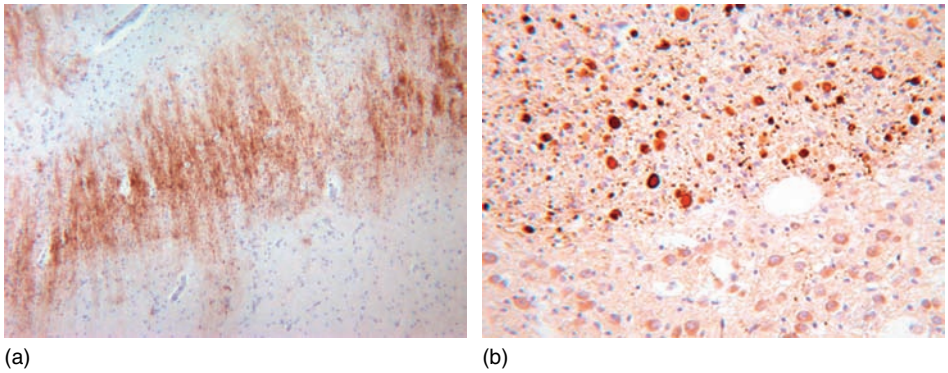

Figure 1 (a) Acute axonal injury. Bands of BAPP expression in an infarcted area of brain in acute hypoxic-ischemic injury. (b) Axonal swellings expressing BAPP restricted to the pontine cortico-spinal tracts, considered to indicate traumatic damage

Damage to the cervical nerve roots has been documented as part of the pathology of shaking injury [14]. It has not been established that this is the result of shaking, as cervical cord displacement resulting from brain swelling may also cause traction on nerve roots in the region. Autopsy studies in man and primates have shown that the spinal cord is displaced during extension and flexion of the neck [20, 21] and it remains a possibility that hyperextension and flexion could cause traction damage to nerve roots throughout the length of the spinal cord, but this has not been documented in living infants.

Subdural Hemorrhage (SDH)

SDH is perhaps the most important and consistent component of the triad. In the acutely sick infant, it is frequently the first clinical sign, identified on brain scan, to raise the question of abuse. There are no specific imaging patterns that can distinguish inflicted from accidental intracranial injury [22, 23].

Autopsy and imaging studies show that infant SDH is usually a thin bilateral film and not a thick, unilateral space occupying clot as seen in traumatic SDH in older children and adults [12, 13, 24]. This raises the question of whether the two forms have the same etiology and anatomical source.

Causes of Subdural Hemorrhage. The commonest cause of SDH in infants is said to be trauma [25] although a recent study has shown a significant incidence (26%) of birth-related SDH [26]. Other causes in infants include benign enlargement of the extracerebral spaces (BEECS), clotting disorders, hemorrhagic disease of the newborn, rare metabolic diseases, vascular malformations, and neurosurgical procedures [25, 27].

Traumatic SDH

Proposed traumatic causes of infant SDH are inflicted injury such as shaking and/or impact and accidental injuries such as falls. Impact includes blunt impact of an object on the head and that resulting from a fall or striking the moving head on a rigid surface. The biomechanical aspects of these injuries are discussed below. The vast majority of cases described as SBS have evidence of impact [28]. While the pathologist may be able to determine features indicative of impact, it is not, of course, possible to distinguish accidental from non-accidental injuries by pathology.

Low-Level Falls

Low-level falls have the potential, albeit only rarely, to cause SDH in infants and young children. Absolute height is not as important a criterion for injury as the exact nature of the fall for a particular infant, in a particular circumstance [29]. The effects of twisting, rotation, or crushing of the structures of the neck are crucial in terms of outcome. Biomechanical studies show that falls even from low levels of 3–4 ft can generate far greater forces in the head than shaking [11]. There are a number of case series demonstrating that infants and children may suffer intracranial damage including retinal and intracranial hemorrhage after falls from levels as low as 3 ft [10, 17, 30–33]. While most babies may suffer little from an apparently trivial fall, this is clearly not always the case.

Birth-Related SDH

Three studies, using magnetic resonance imaging (MRI), have shown a surprisingly high incidence of SDH after birth in asymptomatic infants. Whitby identified SDH in the first two days of life in 9% [32], while SDH was seen in up to 46% of otherwise normal neonates using higher resolution MRI scanning [26, 34]. With regard to method of delivery, ventouse or instrumental deliveries have been associated with a higher incidence of intracranial injury [35, 36]. Towner [37] found an increased incidence of intracranial hemorrhage after instrumental delivery with ventouse or forceps and emergency caesarean section, but the incidence was lower after caesarean section before labor had begun. However, it should be noted that all of Looney's cases followed normal vaginal delivery [26].

While neonates with SDH may be asymptomatic [26, 35] they may also have signs in the neonatal period including unexplained apnoea, dusky episodes, hypotonia, seizures, and lethargy [38].

Sources of SDH. Traditional belief is that in SBS the SDH results from tearing of the superficial bridging veins as they cross from the brain to the dural sinuses [6] (Figure 2). This has never been proved. Indeed it is very difficult to find documented evidence of torn bridging veins at surgery or at autopsy. Cushing, who operated on neonates with SDH and subsequently performed the autopsies wrote *"In two of the cases I have examined I have satisfied myself*

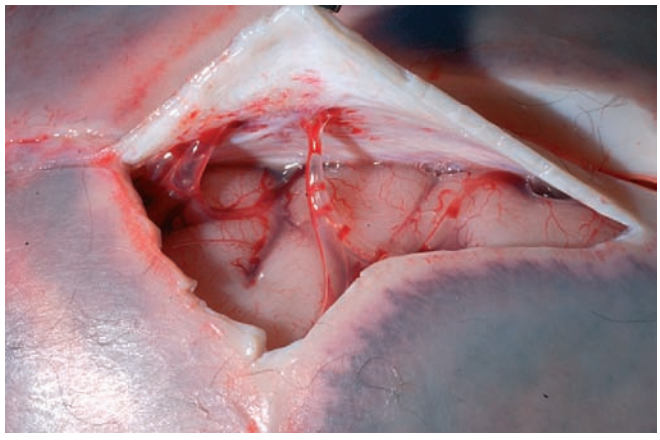

Figure 2 Infant bridging veins may be visualized by opening the skull very carefully, but they are readily torn in normal autopsy procedures. (Picture courtesy of Dr P. Lantz)

that such ruptures were present. A positive statement, however, cannot be given even for these cases, since the dissection and exposure, difficult enough under any circumstances, owing to the delicacy of the vessels is the more so when they are obscured by extravasated blood" [39]. More recently Maxeiner [40] addressed the problem by injecting radio-opaque dye into the veins at autopsy to assess their integrity after removing the top of the head in one piece, hard-boiled egg style. This approach is not widely used as it destroys much of the brain and injection pressures need to be carefully monitored if the veins are not to be ruptured artifactually.

Volpe [41] said that SDH was by no means always traumatic and suggested that in neonates without tentorial tears the bleeding may arise from the tributary veins of the dural sinuses. Autopsy studies from the older literature show bridging vein rupture is uncommon, Craig described 62 neonatal SDH, of which only 3 had torn bridging veins, all of those with overriding sutures [42]. Larroche described 700 autopsies 18% with SDH. [43] She noted an association with hypoxic-ischemic injury (Figure 3). She did not identify torn veins.

If SDH does not arise from torn bridging veins, what other sources may there be? Two obvious

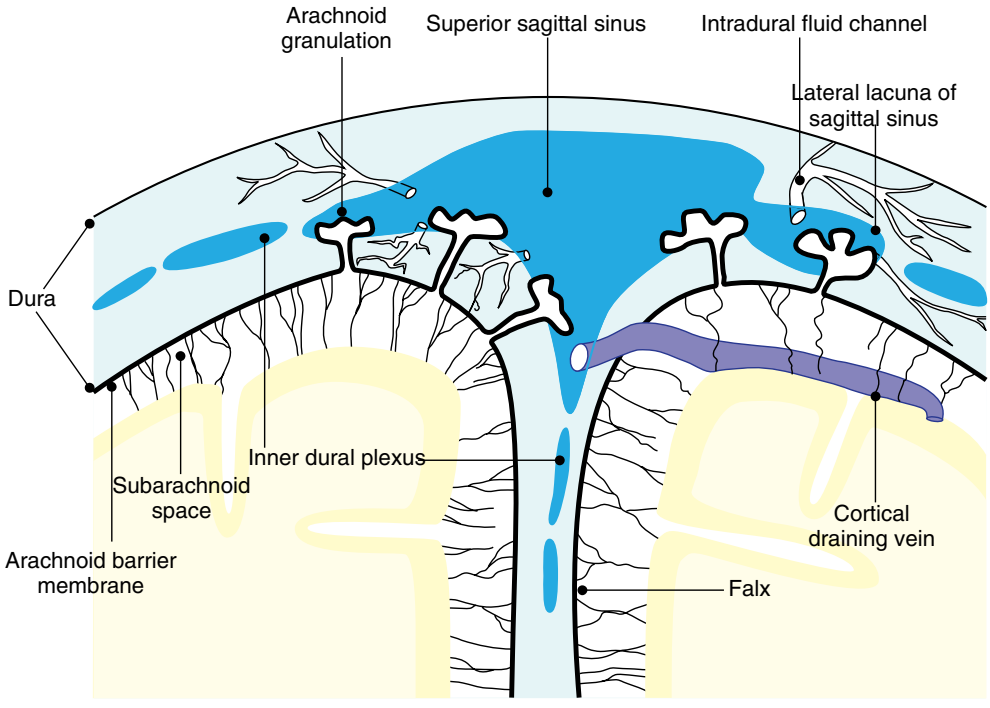

Figure 4 Diagram representing a coronal slice through the brain and dura indicating the intradural sinuses and their relationship to cortical surface veins, arachnoid granulations, and intradural fluid channels

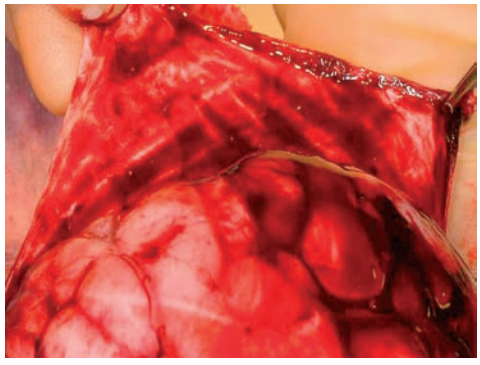
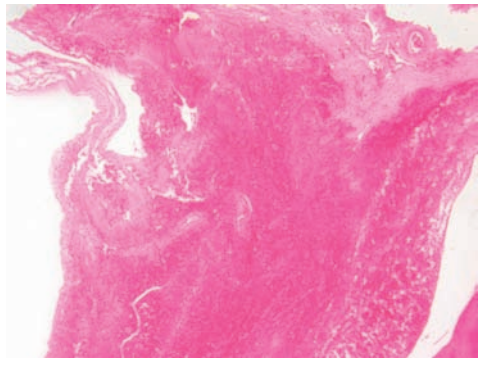


alternative sites of origin exist, the dura itself and the old subdural membranes (Figure 4).

Dural Hemorrhage



The dura is composed of two leaflets, the periosteal and the meningeal dura, separated by a thin vascular channel, which widens to form the large dural sinuses [44]. There are particularly extensive venous sinuses in the posterior falx, [45] a frequent site of high signal on brain scans in asphyxiated infants. Bleeding into the falx is well recognized in asphyxiated infants [46]. It has long been acknowledged that optic nerve sheath hemorrhage arises from the dura [47] and more recently the dura was proposed as the source of intracranial SDH in infants [48] (Figure 5). Careful microscopic examination of the dura confirms that intradural bleeding is common in asphyxiated infants, particularly in the dural folds of the falx and tentorium close to the large venous sinuses [49]. In some cases intradural bleeding leaks out on to the subdural surface leading to macroscopically evident subdural haematoma [50].

Healing Subdural Membranes

Healing of SDH is by formation of a thin, vascular membrane consisting of fibroblasts, macrophages, which often contain altered blood products, and wide thin-walled capillaries with a potential to rebleed [51] (Figure 6). It is uncommon in infants to see a double layered membrane around a localized mass of resolving clot, as seen in the elderly, probably because the infant SDH usually forms as a thin film rather than as a mass lesion. Contrast injection is required to identify the membranes radiologically [52]. In some cases, acute SDH leads to accumulation of fluid in the subdural space. The reasons for this are unknown. Fluid collections may result from immaturity of the arachnoid granulations and impaired cerebrospinal fluid (CSF) absorption [22], and be influenced by the method of treatment of the acute hematoma. Surgical evacuation or tapping may prevent later reaccumulation of fluid [53, 54]. The period of time for redevelopment of subdural fluid collections may be long, between 15 and 111 days [55]. It is likely that an important

(b) Microscope section showing an elliptical collection of fresh blood dorsal to the spinal cord. The blood is within a chronic subdural membrane indicated by the iron pigment, stained here by Perl's stain. Baby died three weeks after traumatic subdural hemorrhage

contribution to chronic subdural fluid accumulation is repeated rebleeding and oozing from a chronic subdural membrane [56, 57].

There is little information regarding the potential for birth-related SDH to evolve into chronic fluid collections. Whitby followed nine cases with a repeat scan at one month; none had developed a chronic collection [35]. Rooks followed 18 cases for up to 3 months, one developed a further subdural bleed [34]. However these studies could not identify membranes as contrast was not used. Chronic membranes have been seen at autopsy in up to 31% of infants dying unexpectedly without previous clinical evidence of chronic SDH [58]. In view of the potential for acute accidental SDH to evolve into a chronic collection several months later [55], it would appear likely that the same pattern would follow birth-related SDH. At this time, we simply have insufficient information.

Distribution. In the first few days after bleeding, subdural blood sediments under the influence of gravity and undergoes secondary redistribution to the most dependent part, the posterior falx and tentorium [59]. Radiological studies show that subdural blood tracks down around the spinal cord [60] and, if the spine of babies with intracranial SDH is examined at autopsy, blood is regularly seen in the subdural space and around sacral nerve roots in the most dependent parts of the dural sac (Figure 7).

Differential Diagnosis of SBS

The most common causes of the triad are impact, birth-related SDH, BEECS, coagulopathies, apnoea, asphyxia and choking, acute life-threatening events (ALTEs), osteogenesis imperfecta, osteopenia of prematurity, and metabolic diseases [14, 28, 61, 62, 63].

Choking/Asphyxia

In a considerable number of cases, vomiting and/or reflux are described at the time of collapse, and in some there is a history of feeding difficulties, gastroesophageal reflux, and choking or apnoeic episodes [14, 62]. SBS is commonly diagnosed in the first three months of life, the age of peak incidence of sudden infant death syndrome. Inhalation of feed or vomit may play a part in sudden infant death [64] and awake apnoea is associated with gastroesophageal reflux [65]. The physiological response to aspiration may be dramatic; foreign material on the larynx causes laryngospasm, which is associated with startle, cessation of respiration, hypoxaemia, bradycardia, and a doubling of blood flow to the brain [66]. These circumstances, with or even without vigorous resuscitation, may cause reperfusion injury and a pre-existing healing subdural membrane may bleed. The dura itself may become hemorrhagic and ooze blood into the subdural space (Figure 8). As long ago as 1905, Cushing suggested that coughing, choking, and

Figure 8 (a) Cortical vein thrombosis. Infant died 10 days after collapse following two choking episodes. Several surface veins are thrombosed (arrows). (b) Section of thrombosed vein shows a network of new capillaries growing into the periphery of the thrombus (CD31)

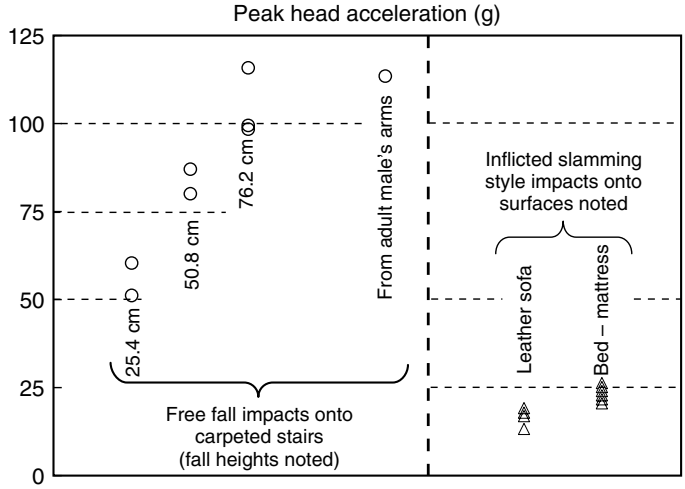

Figure 9 Comparative forces generated by dropping or shaking and slamming a dummy representing a six-month-old infant (C Van Ee, personal communication 2007)

venous congestion may explain some forms of infant SDH [39], a hypothesis recently revived by Geddes, [48, 67].

Biomechanics

Biomechanics is the application of principles of physics to biological systems and has been the mainstay of research into motor vehicle safety for six decades. It was just such research into noncontact head injury from rear-end shunts that stimulated Guthkelch to formulate his hypothesis for SBS in 1971 [6]. Ommaya [7] had caused concussion, SDH, and white matter shearing injury (diffuse axonal injury) in primates by whiplash. Guthkelch suggested that the rotational forces of shaking would cause tearing of bridging veins and bilateral subdural bleeding, although Ommaya himself warned that "*It is improbable that the high speed and severity of the single whiplash produced in our animal model could be achieved by a single manual shake or even a short series of manual shaking of an infant in one episode*".

More recent studies using "crash test dummies" indicate that impact generates far more force than

shaking (Figure 9) and that impact is required to produce SDH [68]. Cory and Jones [69] generated forces that exceeded the injury threshold for concussion, but not for SDH or axonal injury. Their adult shaker volunteers fatigued after 10 seconds. While they concluded that "*It cannot be categorically stated, from a biomechanical perspective, that pure shaking cannot cause fatal head injuries in an infant*", they noted that in their experiments there were chin and occipital contacts at the extremes of the shaking motion that could have caused impact. These authors expressed their concerns regarding the difficulties in extrapolating to human infants the findings in both dummy and animal models. Biomechanical studies have shown that falls and impact to the head produce significant rotational forces when the impacting forces are not aligned through the center of gravity of the head, due to hinging of the head on the neck. Shaking is not necessary to cause rotational acceleration.

Neck injuries may be underreported in babies dying after severe abuse [70]. In Ommaya's study, 11 of 19 primates had neck injuries; these were adult animals with mature neck structure and musculature. It is likely that the forces required to cause intracranial injury will also damage the weak infant neck [71]. In road traffic accidents, infants who suffer single severe hyperextension forces have cervical fractures, dislocations, spinal cord injury, and torn nerve roots, not SDH [72–74].

Investigation of Shaken Baby Syndrome

SBS or NAHI is most likely to occur in an infant dying suddenly under the age of six months. Autopsy should be performed with careful consideration of this diagnosis and appropriate steps taken to support or exclude it. The records of pregnancy and delivery must be carefully studied to look for any evidence of complications that could mimic NAHI. These include pregnancy disorders such as oligohydramnios, fetal hypokinesia, and prematurity, which lead to osteopenia and predispose to fractures. The birth history and method of delivery are important as SDH may arise at this time while being entirely asymptomatic in the neonatal period. Head circumference charts are important; head circumference measurements taken at birth and in the subsequent weeks may reflect abnormal head growth, which can indicate an accumulating subdural fluid collection and a propensity to rebleed.

The clinical history may give clues to other problems in the early weeks of life. Vomiting, feeding problems, and apnoeic episodes and ALTEs may indicate difficulties with coordination of breathing, sucking and swallowing, and vulnerability to choking. Any event that threatens life may also potentially end it.

The history of the baby's terminal collapse must also be carefully examined. Parents may describe events that reveal a cause for collapse. In any other field of medicine, the clinical history is regarded as the cornerstone of diagnosis and it should not be disregarded without serious critical evaluation.

The autopsy can reveal evidence of trauma such as deep bruises and fractures not seen in clinical examination. The examination of the intracranial contents is paramount. The scalp and skull require careful examination for evidence of bruising and fractures. Suture separation due to raised intracranial pressure and wormian bones can be mistaken for fractures. When the cranium is opened, the presence of any intracranial bleeding must be noted. Unclotted blood may escape from the subdural space as the skull is opened and be mistaken for bleeding from the dural sinuses. It is important to note the volume and nature of blood and the presence of xanthochromia, indicating older bleeding. As the cranium is opened, the bridging veins should be visualized and their integrity assessed. If there is a question of bridging vein rupture, histological examination may assist in establishing this. The dural sinuses and draining veins should be examined for evidence of thrombosis.

The dura must be carefully examined for evidence of older bleeding. A chronic subdural membrane may be thin and patchy and represented only by patches of light brown discoloration. Multiple samples should be taken from the dura, including the falx and tentorium, for histological examination to look for evidence of intradural bleeding and rupture onto the subdural surface. This may be the source of significant subdural blood.

The brain must be fixed for detailed histological examination.

In all of these cases, the time between collapse and death may play a significant part in the final pathology. A baby who has collapsed and becomes apnoeic with subsequent cardiopulmonary rescuscitation (CPR) and ventilation will be shocked and suffer multiorgan failure with altered clotting, loss

of integrity of vessels and membranes, oozing of blood into intracranial compartments, including the subarachnoid and subdural spaces, and development of the "respirator brain".

Review of the brain imaging in life is essential in assessing, as far as possible, just how much hemorrhage occurred at the time of collapse and how much may be the result of subsequent secondary changes. It is recognized that SDH may continue to bleed after initial onset [75] especially if a baby is very sick. Finding a large clot at autopsy may suggest traumatic rupture of a large vessel, but comparison with early brain scans may indicate that the bleed was only minor at the outset, indicating a slower oozing process with different implications for causation. It is becoming increasingly obvious that not all SDH arises from traumatic rupture of blood vessels.

Acknowledgment

I would like to thank Dr Irene Scheimberg and Dr Pat Lantz for providing pictures and Dr Chris Van Ee for valuable discussion and for preparing Figure 8.

Shooting Distance: Estimation of

Introduction

The range from which a weapon has been fired is an important component in the reconstruction of firearm-related cases (*see* also **Firearms: Scene Investigation**). The firing-distance estimation is based on the examination of the appearance of the bullet entrance hole and the examination of the firearm discharge residue (FDR) patterns around the hole using various techniques. In casework the patterns obtained in a case are compared to those obtained in test firings. Although many authors in the field use the term shooting-distance determination, many forensic examiners around the world, including the Israel Police, prefer to use the term estimation instead of determination because of the intrinsic inaccuracy of the examination. The reason for this is a high variability of the FDR patterns from shot to shot when using the same weapon and ammunition. To increase the accuracy of the examination, the forensic examiner should use, for test firings, the weapon and ammunition used in the case whenever possible.

In most of the shooting cases in which there is a need for a firing-distance estimation, the victim or the victim's clothing have to be examined. In many cases, bullets hit surfaces of various parts of the human body directly without passage through any intermediate medium. In some instances other exhibits which happened to be targets of shooting have to be examined. Such exhibits may be cars, walls, doors, windows, furniture, etc. Many of these cannot be processed in the laboratory.

FDR is projected from the muzzle of a firearm in a roughly conical pattern: the larger particles travel higher distances than the smaller ones before they are stopped by the air resistance [1]. Four ranges for shooting distance as described in the literature [2–5] are based on the appearance of the bullet holes on the human body: contact range, near contact range, intermediate range and distant range. In contact wounds, the muzzle of the firearm is held against the surface of the body at the time of discharge. The appearance of tearing, scorching, soot, or the imprint of muzzle, characterizes contact wounds. Virtually, no FDR is seen around the bullet hole. In near contact wounds, the muzzle of the weapon is a few centimeters away from the body. In this range, a wide zone of powder soot overlaying seared blackened skin surrounds the wound. An intermediate range gunshot wound is one in which the muzzle of the firearm is held a few tens of centimeters away from the body, producing "powder tattooing" of the skin. In distant range no damage effects or FDR particle patterns are observed around the gunshot wound. With most handguns and ammunitions, visually detectable FDR is not found in the case of shots fired at ranges greater than 30–45 cm [1].

In this text a review of the methods for visual/microscopic, color tests and instrumental analysis of the entrance bullet holes and FDR patterns around them for shooting-distance estimation is provided. Comprehensive reviews on the subject have been published over the years [2–5]. The aspect of shooting-distance estimation for targets shot by pellet loads from shotguns may be found elsewhere [1, 2] and is not discussed here.

Visual/ Microscopic and Color Tests

Clothing Targets

FDR patterns around the entrance bullet holes consist of propellant residues and metallic residues from the bullet, e.g., lead and copper, as well as gunshot residues (GSR) (primer residues). These residues may be detected visually/microscopically if the target cloth is of a bright enough color. However in most of the cases there is need for color chemical tests or instrumental analysis in order to assess the FDR patterns around the entrance bullet holes.

Walker [6] proposed to use Griess reaction to visualize free nitrite ions (on the shot target), originating from the combustion of ester nitrates (e.g., nitrocellulose (NC) and nitroglycerine (NG) in the gunpowder. In this test, the Griess reagent consisting of sulfanilic acid and α-naphthyl amine in acetic acid aqueous solution is used. The detection of nitrite ions is based on the formation of diazonium ion from sulfanilic acid and nitrite. The diazonium ion couples with α-naphthyl amine to form an orange azo dye.

In a series of three papers [7–9], Dillon reports on the modified Griess test (MGT) as a color test for nitrites and recommends a protocol for FDR examinations in muzzle to target distance estimations. In the modified test, Dillon proposes to use

α-naphthol instead of α-naphthyl amine (the Walker test) or *N*-(1-naphthyl)-ethylenediamine dihydrochloride. According to him both the replaced reagents are carcinogenic. However, in the literature on chemical safety data [10], *N*-(1-naphthyl)-ethylenediamine dihydrochloride is not reported as being carcinogenic. In fact, in Israel this reagent is used with sulfanilamide routinely for "the local" MGT [11]. The term MGT does not refer to one specific defined test. In fact, it appears that every author who introduces any modification to the original Griess test calls it an MGT. The proposed protocol [7] includes visual, microscopic and chemical (lead and nitrites) tests. It recommends to conduct first the MGT and then the sodium rhodizonate test (SRT) for lead. The reason for this sequence is because the rhodizonate is applied directly on the target. Dillon contends that particulate lead is a random nonreproducible phenomenon, whereas the presence of vaporous lead is quite significant in that it is found principally at closer ranges.

Glattstein *et al.* reported on an improved method for shooting-distance estimation on clothing [11]. The novel part of the method includes transfer of total nitrite (nitrite ions and unburned smokeless powder residues) from the target to an adhesive lifter. After the transfer, lead and copper deposits around the bullet entrance hole are partially extracted consecutively to the Benchkote (Whatman) filter papers moistened with dilute acetic acid and ammonia solutions respectively. Their patterns are visualized by rhodizonate for lead (red color) and rubeanic acid for copper (dark green color). The MGT is carried out after alkaline hydrolysis of the smokeless powder residues on the adhesive lifter. The purpose of lifting gunpowder residues from the shot cloth target is to eliminate interferences caused by conducting MGT directly on the target, with or without the hydrolysis step. It was found that almost a complete transfer of gunpowder residues to the adhesive lifter was obtained and the vaporous lead and copper are not transferred to the adhesive lifter. The widely used MGT detects only free nitrite ions formed from the combustion of smokeless powder. The unburned smokeless powder particles cannot be detected by this method. Alkaline hydrolysis prior to the MGT has been proposed to increase the sensitivity of the test for gunpowder residues. The purpose of the alkaline hydrolysis is to cause disproportionation of the unburned NC and NG to carbonyl compounds and free nitrite ion, thus increasing the available amount of nitrite ions for MGT.

Before starting the estimation of the shooting distance it is desirable to determine that the hole is a bullet entrance hole. This can be done by applying methods for chemical visualization of lead (rhodizonate) and copper (rubeanic acid) at the perimeter of the hole [12]. From the accumulated experience in the Israel Police it has been observed that, the color tests did not give positive results on all bullet holes in clothing, although it was known that a lead bullet or a full metal jacket (FMJ, brass) bullet were used.

Persistence of FDR on Clothing Targets

Several studies dealt with possible effects of various factors on clothing items after shooting with regards to the shooting-distance estimation [7, 13–16]. Most of these found that mechanical handling of clothing or soaking them in blood, in still or running water, considerably decreases the amount of FDR around the bullet entrance holes. Emonet *et al.* [16] reported that the medical manipulations of clothing lead to an increase of the loss of visible and nitrated FDR of about 30–40%. Even *et al.* [13], on the other hand did not find a significant effect of soaking in still water on the obtained FDR patterns. Sometimes casework requests are received to estimate shooting distance on clothing items that underwent machine washing. Vinokurov *et al.* [17] conducted a study to assess the effect of machine washing or brushing of clothing items on FDR patterns around bullet entrance holes. Results show that those treatments considerably decrease the amount and density of FDR (machine washing more than brushing).

Exhibits that Cannot be Processed in the Laboratory

Glattstein *et al.* [18] examined the feasibility of the method developed for clothing [11] as described above, for additional materials such as galvanized steel, glass, plywood, and high pressure laminated plastic sheets of melamine and phenolic materials (Formica). It was found that for the above tested target materials and shooting distances the amounts and densities of the FDR detected visually (without any treatment) were considerably smaller than those obtained after chemical treatments. Total nitrite

patterns visualized on the lifters applied on the various targets were similar to those obtained on the lifters from the cotton cloth at relatively short shooting distances, i.e., up to about 25 cm. As shooting distances become greater, the number and density of nitrite spots on the lifters from all the tested materials targets decreases considerably in comparison to the lifters from the cotton cloth for the same distance; the plywood target showed the most similar results to the cotton cloth.

If there is no possibility to conduct test firing at a material similar to the evidence, then test firings may be carried out on cotton cloth. In such a case the visualized pattern of the total nitrite will be sufficient to state that the shooting distance on the evidence was equal or below the shooting distance at which similar visualized patterns of the total nitrite are obtained on the cotton cloth.

The Human Body as a Target

In many shooting cases, bullets hit surfaces of various parts of the human body (mostly the head) directly, without passage through any intermediate medium. For the purpose of assessing the shooting distance, most of the forensic literature describes only visual/microscopic methods for the examination of appearance of the wound and FDR patterns around it [2, 4, 19]. Nonetheless, sodium rhodizonate and rubeanic acid reagents were proposed for the visualization of lead and copper patterns around the gunshot wounds [20, 21]. As in cases of clothing and other objects, implementing color tests (in addition to visual/microscopic visualization) might increase the accuracy of shooting-distance estimation. An additional unique problem pertaining only to the human body is that there is no possibility to conduct test firing on the same material as in the case of other exhibits. The proposed solution for test firings was to use various simulant materials. Recommendations for those materials were based on the studies comparing those materials to the skin of some animals, like rabbits or pigs.

Glattstein *et al.* [22] examined the feasibility of applying an adhesive lifter to the entrance bullet wound in human body surfaces to visualize the total nitrite patterns, as was reported for clothing and other exhibits above. Stahling and Karlsson [23] reported a similar method for lifting and visualizing gunpowder residues from skin.

Instrumental Methods

FDR patterns around the bullet hole may be visualized by infrared (IR) photography [24] and IR imaging devices [25] due to the considerably higher absorbance of IR radiation by the soot than by other materials like fabric. X-ray radiography may also be used for that purpose because of the much higher absorbance of X-radiation by metallic deposits of the FDR than by clothing. X-ray fluorescence (XRF), atomic absorption spectroscopy (AAS) and neutron activation analysis (NAA) have also been used by some laboratories to estimate the range of shooting [3].

Recently, with the advent of the Micro-XRF technology and its increasing use in forensic science for the elemental analysis of trace evidence, some laboratories examined its feasibility for shooting-distance estimation [26].

Short Tandem Repeats

Introduction

Short tandem repeats (STRs) or microsatellites are discrete sequences of DNA that are repeated end on end. STR repeats in the human genome are analogous to carriages on a train. They can be repeated up to 100 times in tandem in the genome and have fragment lengths of between 100 and 400 bp [1]. Figure 1 shows the basic structure of a simple repeat STR.

The repeated DNA sequence of an STR consists of 2–5 nucleotides as di-, tri-, tetra-, and pentanucleotide repeats. More than 23 000 tetranucleotide STR loci alone have been characterized since the completion of the human genome project [2]. Tetranucleotide repeats are the most common STRs used by forensic laboratories throughout the world. Trinucleotide and pentanucleotide loci are less common. Dinucleotide loci are the most common in the human genome; however, as they are more prone to artifacts that affect interpretation, they are not used for forensic purposes [3].

STRs used for human identity testing are located in the noncoding regions of the DNA, either within genes (introns) or between genes. They have been adopted universally by forensic biology laboratories as they are short and highly polymorphic, distributed throughout the genome, and are amenable to polymerase chain reaction (PCR) and automation.

STRs are analyzed using the PCR. Primers of known sequence bind to either side of the target STR sequence (see Figure 1). Using PCR, STR profiles may be generated from as little as 0.2 ng of input DNA.

Examples of Common STRs Used for Forensic Applications

The selection criteria for STRs in forensic use are based on their robustness, size, variability between individuals (polymorphic), and ability to be combined in a single test for ease of analysis (known as *multiplexing*).

Table 1 contains a list of STRs commonly used by the forensic community for DNA analysis. This list is not intended to be exhaustive. Table 1 also includes core loci for the combined DNA index

system (CODIS) and Interpol databases (discussed later).

Although not an STR, amelogenin is discussed in this work as it is routinely added to commercial STR assays for gender determination. Amelogenin is a gene that occurs on the X and Y chromosomes of the human genome [4]. The PCR primer set targets a 6 bp deletion that occurs on the X chromosome. This enables the X and Y chromosomes to be distinguished after electrophoresis. Female individuals are designated XX and males XY (see Figure 2). Amelogenin can also be useful for determining the ratio of male-to-female DNA in a mixed DNA profile.

There are several genetic variations at amelogenin that may cause difficulties in interpretation. In one, the Y chromosome fails to amplify, making the individual genotypically female [5]. Other amelogenin abnormalities that may impede interpretation include trisomic states (XXY, XYY, and XXX) and rare genetic disorders that may lead to differences of genotype and phenotype [6].

Nomenclature

Designation of Loci

An internationally accepted nomenclature for the designation of STRs is vital for interlaboratory comparison and databasing [7, 8].

STR sites analyzed on the DNA are designated on the basis of their position within the genome. Markers that are part of a gene have its name within the designation. For example, STR marker TH01 is located within intron 1 of the *t*yrosine *h*ydroxylase gene. STR markers that are not part of a gene are designated by the following pattern:

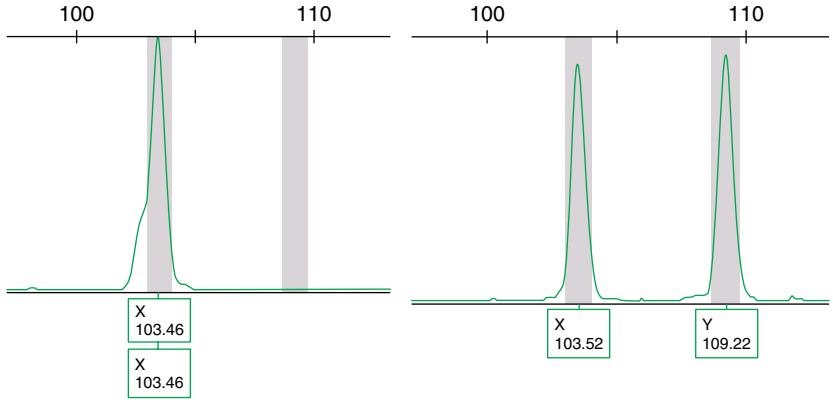

Figure 2 Amelogenin loci of a female (XX) and male (XY) individual

DxSy where D is DNA, x is the chromosome number, S indicates that the sequence only occurs once in the genome (single), and y is a counter for when the site was identified. For example, D21S11 describes the 11th site discovered on chromosome 21.

STR loci can also be preceded by the letters HUM, which indicate their human origin.

The repeat motif for each STR is defined according to the International Society of Forensic Genetics (ISFG) recommendations for nomenclature as being the first 5′ nucleotides on the GenBank[a] forward strand [9].

Designation of Alleles

Simply, STR alleles are designated by the number of repeats they contain. Repeats are designated on the basis of comparison with allelic ladders that incorporate all common alleles. STRs can be categorized by the length of their repeat unit (di-, tri-, tetra-, and pentanucleotide) and also by the type of repeat pattern they conform to. Different classes of STRs have been identified, depending on their repeat structure.

Simple repeats contain core sequences identical in sequence and length (for example, TH01). Compound repeats contain two or more adjacent simple repeats (for example, VWFA31). Complex repeats may contain several repeat blocks of variable repeat length with variable intervening sequences (for example, D21S11) [10].

Common examples of simple, compound, and complex STRs and their repeat structures are given below. The numbers outside the brackets surrounding the repeat unit sequence give an indication of the number of times the sequence may repeat.

Simple repeat, for example, TH01: $(AATG)_{5-11}$

Compound repeat, for example, VWFA31: $(ATCT)_2(GTCT)_{3-4}(ATCT)_{9-13}$

Complex repeat, for example, D21S11: $(TCTA)_{4-6}(TCTG)_{5-6}(TCTA)_3TA(TCTA)_6TCA(TCTA)_2TCCATA(TCAT)_{8-16}$

Complex hypervariable repeats are another, more complex, type of STR. A well-known example is ACTBP2 (also referred to as *SE33*). The common tetranucleotide repeat motif is $(AAAG)_n$; however, variants mono, di-, tri-, and tetranucleotides are also scattered through the locus. This makes ACTBP2 very polymorphic and for this reason it is a required STR for the German national DNA databank. However, the designation of alleles within this locus is problematic if based on solely counting repeats. For this reason, the size of the STR is measured and it is recommended that alleles be labeled "type-" to reflect this [7].

Microvariants

Where alleles at an STR locus do not contain complete repeat units, these are termed microvariants. The microvariants are designated by the number of complete units and the number of additional base pairs of the partial repeat. The most common microvariant is allele 9.3 at TH01. TH01 9.3 is actually 10 repeat units with the loss of a single adenine in the seventh unit [11]. The repeat motif for TH01 9.3 is $(AATG)_6ATG(AATG)_3$.

STR Analysis in Practise

Visualization of STRs

STRs are amplified using the polymerase chain reaction, which exponentially amplifies the target STR by a series of heating and cooling reactions. The size of the STR products is measured after PCR amplification by electrophoresis. Early STR analysis involved separating the PCR product on polyacrylamide gels followed by visualization using silver staining. Now, PCR products are labeled with fluorescent markers, which then undergo gel electrophoresis or, more commonly, capillary electrophoresis. The PCR product is loaded on the gel or capillary and subjected to an electrical charge. The negatively charged DNA travels through the medium dependent on its size. Smaller fragments of DNA travel faster through the gel or capillary. The actual size of the STR fragments is measured against two standard markers: an internal size standard that is injected with the sample and an allelic ladder that comprises common alleles with the STR loci.

The DNA fragments are labeled with fluorescent probes. As the DNA travels through the gel or capillary, the probes are excited by a laser and the fluorescence is measured by a camera. The use of different color dyes enables multiple, overlapping loci to be analyzed concurrently, which is important for multiplexed STR assays. STR profiles result in a string of numbers (the allele counts or number of repeat units for STR analyzed) associated with the loci analyzed. For this reason, the data can be easily stored and compared within databases.

Multiplexes and Commercial STR Assays

The primers targeting several STRs may be combined into one PCR reaction and amplified simultaneously. This is called *multiplex PCR* and is a rapid and convenient way to profile many STRs, thus generating a DNA profile. STRs present in multiplexed assays are chosen on the basis of their discriminating power, low levels of stutter, and compatibility with other loci. The choice of STR in commercial multiplexed assays can also be heavily influenced by demand from customers who must adhere to core loci, for example, CODIS and Interpol (discussed later).

Several different STR assays or multiplexes are commercially available for use in forensic DNA analysis and paternity or identity testing. These are used widely by the forensic community as they have been extensively validated and scrutinized in the courts of numerous countries, making them universally accepted. The use of commercial STR assays also promotes uniformity and enables database conformity.

Not all laboratories, however, use commercial STR assays. Some have developed in-house assays that may or may not have loci in common with commercial assays [12]. Indeed, even the commercially available kits do not share all loci in common with other laboratories. Two major suppliers of forensic DNA profiling kits and technology are Applied Biosystems, Foster City, California and Promega Corporation, Madison, Wisconsin. Both companies have developed several STR assays for forensic STR analysis (Table 1).

The development and optimization of STR multiplexes can be very demanding and both labor intensive and time consuming [13]. For this reason, many laboratories have opted to use commercial assays where validation papers and population databases are freely available. The quality assurance requirements for developmental validation are rightly very stringent.

Both Promega and Applied Biosystems have developed 15 loci STR multiplexes with amelogenin. Both kits incorporate all 13 CODIS loci and Interpol's standard set of loci. Initially, two STR assays were required to test all 13 CODIS loci: Promega's PowerPlex® 1.1 and PowerPlex® 2.1 or Applied Biosystem's Profiler Plus™ and COfiler™. See Figure 3 for an example of a male DNA profile generated using the 15 STR multiplex Identifiler™. Identifiler™ uses four different dyes to label the loci. The internal size standard is labeled with a fifth color.

Core Loci and Databasing (Interpol and CODIS)

STRs were first described as being potentially useful markers for forensic DNA analysis in the early 1990s [1]. The first national DNA database using STR profile data was started in the United Kingdom in 1995. This was followed by the establishment of the New Zealand National DNA Database in 1996 [14]. Several other European countries followed suit in the late 1990s. Many countries were analyzing different loci. To aid criminal investigation across the relatively open European borders, an Interpol working group proposed a European standard set of

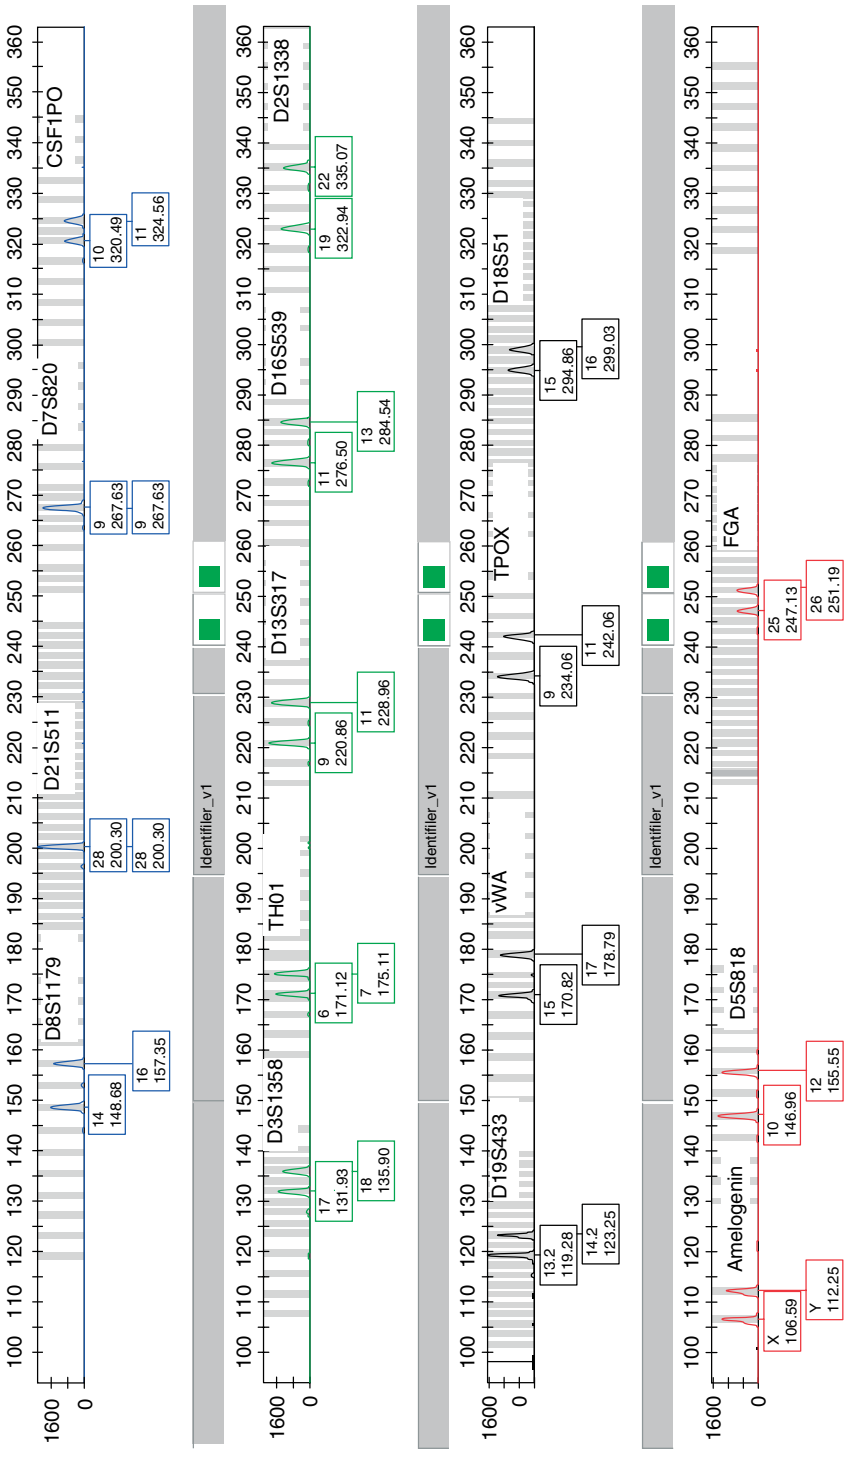

Figure 3 An Identifiler™ profile of a male individual

four loci in 1998. In 1999, this was expanded to seven loci (see Table 1) [15].

In 1997, the United States agreed to 13 core STR loci for their national DNA database, known as *CODIS* (see section "Core Loci and Databasing Interpol and CODIS").

Common sets of STR loci are required for collaboration between different testing laboratories within the same country or between different countries. Comparison of DNA profiles within national or international databases can be used to link individuals to crimes and to generate crime-to-crime links indicating recidivist offending patterns. The more core loci compared, the less likely adventitious links will be generated.

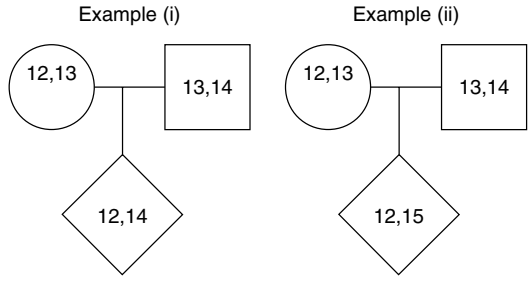

Figure 4 Two pedigrees of mother, father, and child at one loci. In example (i) the child must have inherited the "12" allele from the mother and the "14" from the father. In example (ii) a mutation has occurred most likely due to an insertion one repeat in length and the child has inherited a "15" allele

Linkage to Genetic Diseases

The number of repeats at STR loci is highly variable between individuals as they undergo no selective pressure and are thought to be noncoding. There have been reports, however, of several core STR loci being linked to genetic diseases, including certain TH01 alleles indicating susceptibility to schizophrenia [16]. To date, all claims have been disputed by further studies [17], and no STRs have been removed from the core sets of forensic loci examined.

Mutations and Rare Alleles

Mutation

STR loci are prone to mutation; the reason is their variability amongst individuals and therefore their usefulness in forensic DNA and identity testing. The high mutation rate of STRs is not problematic for routine forensic work. Generally, DNA profiles generated from crime samples are compared directly with reference profiles generated using the same DNA STR assays.

More problematic is parentage testing (paternity or maternity investigations). Mutation rates of STRs can be measured by analyzing many paternity trios (father, mother, and child) and comparing STR alleles. A child must inherit one allele from their father and one from their mother at each locus. This is demonstrated in Figure 4 with an example of two parent/child pedigrees at one STR locus. The first shows an expected pedigree and the second, a pedigree with mutation in the male germ line.

Brinkmann *et al.* investigated 10 844 parent/child sets at nine STRs used for paternity testing and reported a mutation rate of between 0 and 7×10^{-3} for the loci tested. The number of mutations in the male germ line is 5–6 times higher than the maternal germ line. Generally, the more polymorphic (variable) and complex STRs exhibit the most mutation [18]. All mutations observed in this study were due to either whole repeat loses or repeat gains (22 involving single unit repeats and 1 example of a double repeat). The stepwise mutation model has been theorized to explain how STR alleles mutate by an increase or decrease on one repeat unit [19]. The likelihood of mutation must be taken into account when investigating paternity cases as false exclusions may be possible on account of differences of only one or two alleles.

Mutation rates and their mechanisms are discussed in more detail in [20] and [21].

Other types of genetic mutations that give rise to microvariants are insertions and deletions of single nucleotides. The resulting allele often differs from full repeat units present in the allelic ladder by only a few nucleotides. These alleles are therefore sized as being "off-ladder" and many laboratories refer to them as being "rare" alleles. One example at the FGA locus is given in Figure 5.

Primer Binding Site Mutations

Discordant genotype profiles may result from the differences in primer sequences used between STR

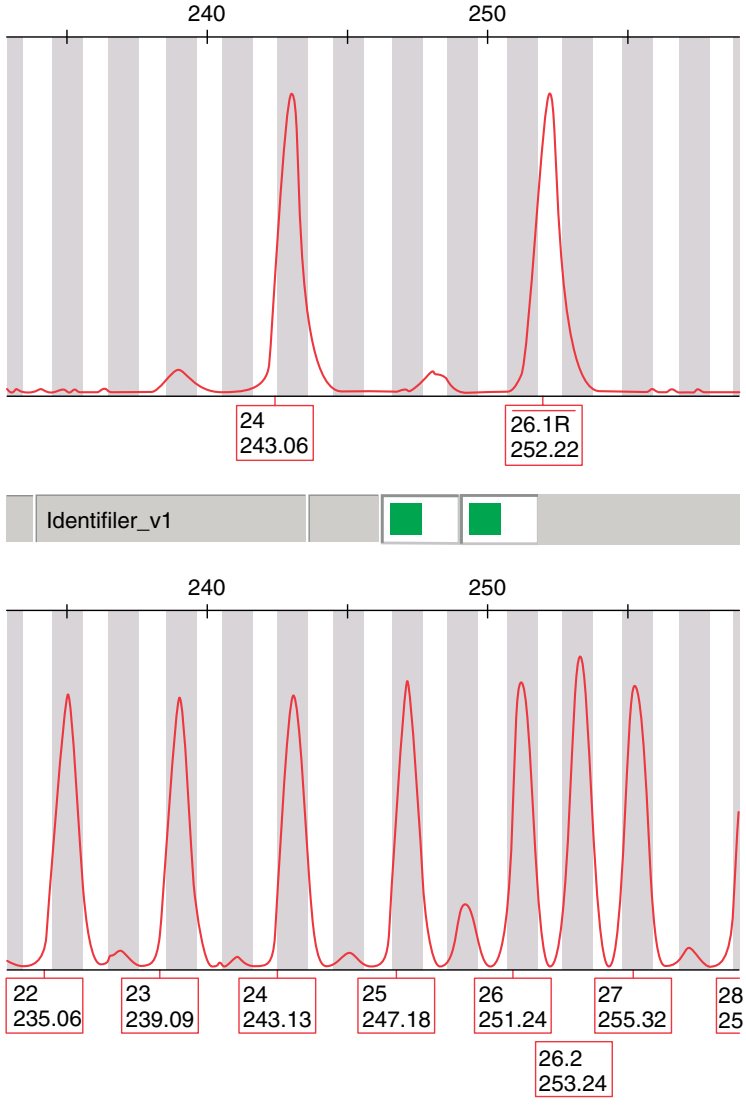

Figure 5 Rare allele at the FGA locus seen after amplification using AmpF/STR Identifiler™

assays produced by different manufacturers and different STR assays produced by the same manufacturer. The PCR amplification of STR alleles with mutations at primer binding sites may result in little or no extension during amplification. Total dropout of one allele at a locus leads to false homozygosity and the missing allele is called a *null allele*. A well-characterized primer binding site mutation is at the D8S1179 locus in the Chamorro (indigenous people of the Marianas Islands) and Filipino populations [22], caused by a single point mutation (G to A transition) in the reverse primer binding sequence.

The high frequency of homozygotes at D8S1179 in the Chamorro and Filipino populations was detected after performing a concordance study between Promega's PowerPlex®16 assay and Applied Biosystem's Profiler Plus™. In their Identifiler™ STR assay, Applied Biosystems includes an additional D8S1179 reverse primer specific for the variant

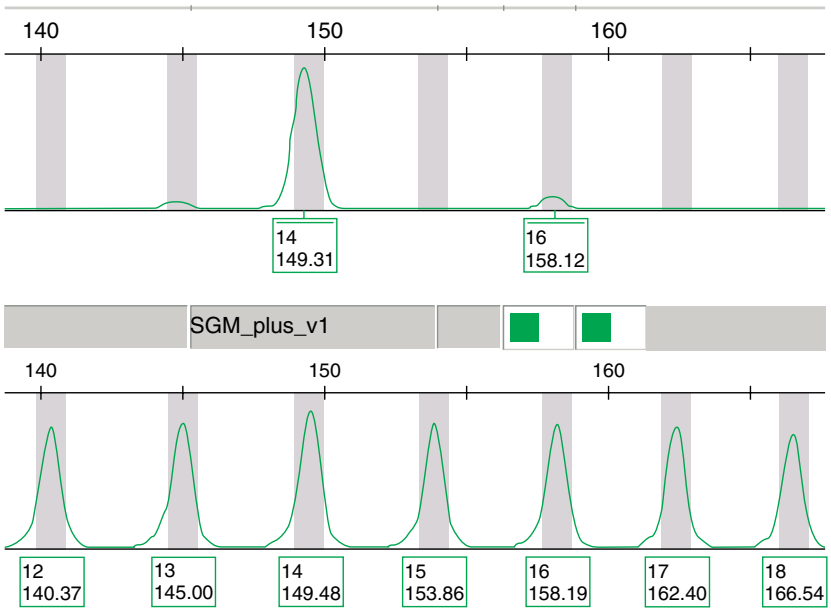

Figure 6 An example of a primer binding site mutation at D8S1179 using AmpF*l*STR SGMPlus™. This individual was subsequently typed as a D8S1179 14,16 using AmpF*l*STR Identifiler™

that results in recovery of the null alleles not previously amplified [23]. In Figure 6, a primer binding site mutation in the reverse primer of D8S1179 has resulted in only partial amplification of the second (16) allele after amplification with SGMPlus™. The amplification of this sample using Identifiler™ resulted in two alleles of equal height.

Another reported example of discordant genotypes between different commercial STR assays was at FGA where a heterozygote profile was observed using the PowerPlex™ 16 primers and a single homozygote allele was observed using the Profiler Plus™ primers [24].

When comparing profiles generated using different assays, for example between different national DNA databases or old crime profiles and reference samples subsequently typed using more recent STR assays, these discordant profiles may become problematic. Database searching can be flexible regarding the stringency with which STR profiles are compared. By incorporating one or more allowed allele mismatches between different profiles, mutations causing discordant profiles due to differing primers within assays can be investigated.

Triallelic Patterns

Triallelic patterns may be observed at individual STR loci. These can arise from trisomy (triplicated chromosomes), somatic mutation, or localized chromosomal rearrangement. There are only three known autosomal trisomies that are thought to be nonfatal; chromosome 21 resulting in Down's syndrome, 13 giving rise to Patau syndrome, and 18 giving rise to Edwards syndrome. All three result in individuals with birth defects, mental retardation, and reduced life expectancy.

The other types of triallelic patterns have been classified into two types: type 1 resulting from somatic mutations in one cell line giving rise to cells with two different genotypes and type 2 resulting from localized chromosomal rearrangement and appearing as three bands of equal height [25].

A high frequency of somatic mutations has been discovered in buccal cells of patients with oral cancer. In one study of 100 patients, 25 allelic nonconcordant profiles were detected following DNA typing of nine STR loci when compared with blood samples taken from the same individuals [26]. As for primer binding site mutations, somatic mutations and

localized chromosomal rearrangements do not complicate forensic investigations when directly comparing crime samples to reference samples. They may, however, make the interpretation of mixed DNA profiles more difficult by confusing the analyst when determining the number of individuals whose DNA may be present in a sample.

Nonstandard STRs

X-Chromosomal STRs

The application of X-chromosomal STRs (ChrX STRs) to forensic DNA analysis is not widely undertaken. Females possess two X chromosomes that recombine similar to autosomes (non sex chromosomes). Males inherit one X chromosome wholly from their mother and females share their paternal X chromosome with their father.

ChrX STR analysis is not as powerful as autosomal STR analysis for forensic identity testing; however, it may be useful for cases where traces of female DNA are present in stains of high male DNA content, for example, vaginal epithelial cells on a penis [27]. ChrX STR analysis is more useful in cases of complex parentage testing where DNA from close family members or the putative parents is not available. One example would be for investigating body remains from mass disaster cases. ChrX STRs are also useful for paternity testing of female offspring (see Case Study 1).

Case Study 1 ChrX STR typing was employed in a case of questioned paternity of a female where reference samples were unavailable for the putative father and paternal grandparents. Samples were available for two paternal "uncles" (putative father's brothers) and the child's mother. Using the ChrX STR types of the "uncles", the grandmaternal genotype was reconstructed. Using this, the putative father was excluded as being the true father as he did not carry some of the necessary paternal ChrX STR alleles [28].

Many ChrX STR loci have been identified and have been shown to be suited for forensic use due to their high variability. A commercial ChrX STR assay with eight ChrX STRs is available (Mentype® ArgusX-8 from Biotype AG) as is a website containing current research, nomenclature, and mutation rates [29].

Y STRs

Y STRs are located on the Y chromosome and are therefore only suited to profiling male DNA (*see* **Y-Chromosome Short Tandem Repeats**). Y STRs are useful in the presence of large amounts of female DNA that would have otherwise masked the male DNA, for example, male epithelial cells on vaginal swabs after digital penetration. A Y STR haplotype is also useful for determining familial relationships. As with ChrX STR analysis, Y STRs are useful in determining deficiency paternity cases, although with male offspring. Y STR profiles are haplotypes as they are noncombining and may be shared by many individuals.

Commercial Y STR assays are available from both Promega Corporation and Applied Biosystems, which test up to 12 and 17 Y STR loci, respectively [30].

miniSTRs

The Identifiler™ and PowerPlex®16 STR assays both have loci with total lengths of over 350 bp. While STRs are relatively small, which contributes to their success in the analysis of forensic samples, most of their lengths can be regions of DNA flanking the repeat units (see Figure 1). This flanking DNA increases the STR length, allowing more loci to fit into commercial STR assays. By removing the flanking sequences and moving the primers to immediately flank the repeat units, miniSTRs are created (*see* **Mini-STRs**). miniSTRs are advantageous as they allow more degraded and lower amounts of DNA to be successfully amplified by the PCR and analyzed. Lengths of miniSTRs can be up to 300 bp smaller than their counterpart PCR products in commercial standard STR assays. Generally, miniSTRs also maintain database compatibility as they target the same STR loci. However, because the primers are redesigned, some discordance is to be expected (see earlier discussion). Another disadvantage is due to the restriction in size of the miniSTR amplification product as this means that less miniSTRs can be squeezed into commercial assays [31].

The European (ENSFI and EDNAP) groups have already recognized the importance and usefulness of miniSTRs. They have recommended that European laboratories maintain their seven core loci and reengineer the primers to convert them to miniSTRs. They also recommend the adoption of three new European core loci, which are miniSTRs that have not been previously seen in major standard commercial STR assays: D10S1248, D2S441, and D22S1045 [32, 33].

Nonhuman STRs for Forensic Investigations

Plant STRs

The most common application of forensic DNA profiling to plant material is for *Cannabis sativa*. Cannabis is widely used as a recreational drug. The cultivation and possession of cannabis is illegal in many countries. However, in some countries its cultivation for fiber and seed oil may be legal. The DNA testing of *Cannabis* can be useful for forensic investigations in species identification, identifying drug versus fiber strains, linking hydroponic seizures, and, more recently, determining the source of origin (whether nationally or internationally) [34].

STR analysis of other plant material, however, has also been reported (see Case Study 2). This case highlights the potential of other plant material in forensic cases.

Case Study 2 STR analysis was undertaken on two Quercus geminata (sand live oak) leaves located in a murder suspect's vehicle. A DNA profile was generated at four STR loci for both of the leaves. This profile was compared with "reference" DNA profiles from several trees located near the burial site of the deceased. The STR profiles from the leaves located in the vehicle were different from samples collected from the trees [35].

Animal STRs

The forensic analysis of animal STRs has become more common in recent years. STR analysis of biological material from animals domestic or otherwise can link an animal to an individual where the animal is the perpetrator (for example, in dog attacks; see Case Study 3) or an individual to an animal where the link places the individual at the scene of a crime (see Case Study 4).

Case Study 3 In Budapest, in 2001, DNA was analyzed from possible saliva stains extracted from the clothing from two deceased infants thought to be killed by the family dog. DNA profiling analysis using a commercially available canine STR multiplex assay (StockMark Kit Canine I Ver.3 from Applied Biosystems) indicated that the DNA profile generated from the possible saliva stains was consistent with the DNA profile from a reference sample collected from the dog [36].

Case Study 4 In a now-famous case, an estranged husband was implicated in the murder of his wife on Prince Edward Island, Canada. Ten dinucleotide STRs were used to test snowy white cat hair found on a jacket located near the scene of the crime. The STR profile obtained corresponded to that of reference hair recovered from Snowball, the cat belonging to the estranged husband's parents [37]. Since this case, Menotti-Raymond et al. have published details for a 11 tetranucleotide STR multiplex intended for the genetic individualization of domestic cats [38].

Animal STRs are chosen and analyzed in the same fashion as human STRs. Many polymorphic STR loci have been identified for a wide variety of animals including dogs, cats, pigs, and badgers. Animal STR analysis can also be important for investigations into illegal trade, poaching, or endangered species where species identification is important.

Short Tandem Repeats: Interpretation

STR Profiles

Since around the mid-1990s, short tandem repeat (STR) profiles have been the most widely used form of DNA profile evidence, in both criminal and civil cases. They are used both to help establish the identity of the source(s) of a biological sample, and to evaluate claims of relatedness, for example, of a child with a putative father or a missing person with a parent or sibling. For further details of the biology and technology underling STR profiles, see [1]. Here, we give only brief details essential for appreciation of interpretation issues. Broadly speaking, these issues are similar for STR profiles as for other DNA profiles; for an introduction, (*see* **Evidence Interpretation: a Logical Approach**). There are some aspects that are specific for STR profiles, for example, the impact of population genetics issues, and analyses of paternity and other relationships, depend on details of the STR mutation process. Also stutter artifacts that arise in STR profiling have an important role in the analyses of unbalanced mixture profiles (for details, *see* **Mixture Interpretation: DNA**).

At STR loci, DNA sequence motifs (typically in forensic applications of length four base pairs) are repeated in tandem. The number of repeats tends to vary because of the relatively high mutation rate, around one mutation per STR locus every

500 generations, compared with about one mutation every 50 million generations at a typical genomic site. This variation can be captured cost-effectively by measuring the length of a chromosome fragment that includes the STR locus. Actually, this length is measured indirectly, inferred from the speed of the fragment under an electric field. The lengths of any flanking regions can be subtracted from the inferred length to deduce the number of repeat units. Thus, an individual's genotype at an STR locus can be reported as an unordered pair of integers, giving the number of repeats of the STR motif on each chromosome. For example, the pair (7,9) indicates seven copies of the repeat motif on one chromosome and nine on the other. Partial repeats sometimes occur: an allele designated as 9.3 has nine full repeats and one imperfect repeat having only three base pairs.

Single-Source Identification Using Likelihood Ratios

Suppose that we have a DNA sample from a crime scene, contributed by a single individual C who will be assumed here to be the offender. We also have a matching STR profile from a defendant s. Let E_d denote the two matching STR profiles. All the probabilities reported below are conditional on relevant background information, but this will be suppressed in the notation. The probability that $C = s$, given the evidence, can be written as

$$\mathrm{P}(C = s|E_d) = \frac{1}{1 + \sum_{i \in \mathcal{P}} w_i R_i} \qquad (1)$$

where $\mathcal{P}$ is the population of alternative possible culprits, and R_i denotes the likelihood ratio (LR) comparing the hypothesis $C = s$, with the alternative that C is some other individual, i:

$$R_i = \frac{\mathrm{P}(E_d|C = i)}{\mathrm{P}(E_d|C = s)} \qquad (2)$$

The *other evidence* (or *prior*) ratio w_i is the ratio of the probabilities that $C = i$ and that $C = s$, both evaluated in the light of the evidence other than E_d; that is,

$$w_i = \frac{\mathrm{P}(C = i)}{\mathrm{P}(C = s)} \qquad (3)$$

Most forensic authors define the LR with numerator and denominator interchanged. Our definition simplifies many formulas, and has the advantage that R_i can often be interpreted as a *match probability*. For us, small LRs indicate strong evidence against s.

Equation (1) is not directly useful to a forensic DNA expert in court, because the w_i lie beyond the domain of his/her expertise. Thus the expert is normally limited to advising on values for the R_i for various alternative possible suspects. However, familiarity with equation (1) is crucial for a clear understanding of evidential weight. For example, it is possible to reformulate the hypotheses so that the R_i and w_i change in value yet $\mathrm{P}(C = s|E_d)$ remains unchanged. This arises in the debate about the effect of database searches ([2], Sec 6.1). Thus, the LR is not an absolute measure of weight of evidence, but depends on the formulation of the hypotheses.

In the simplest scenario in which $R_i = r$ and $w_i = 1$ for all $i \in \mathcal{P}$, equation (1) simplifies to

$$\mathrm{P}(C = s|E_d) = \frac{1}{1 + Nr} \qquad (4)$$

where N is the size of $\mathcal{P}$. This unrealistic scenario illustrates the crucial point that a value for R_i does not measure the overall strength of the STR evidence against s. Here, N and r play equally important roles. More generally, the overall strength involves the sum of the $w_i R_i$ over all other individuals i.

The population $\mathcal{P}$ is assumed to include all the possible sources of the crime stain other than s. Note, in particular, that there is no need to invoke any "random man", which concept can cause confusion in the interpretation of DNA profile evidence ([2], Sec 8.2). Although $\mathcal{P}$ should include all realistic alternative suspects, there is some flexibility as to how many extra individuals are included. Often, it might be appropriate to include in $\mathcal{P}$ all men aged, say, between 16 and 65 living within, say, 1 h driving time of the crime scene. However, $\mathcal{P}$ could include everyone on earth except s, if desired. The value of w_i will typically be extremely small for i that reside far from the crime scene, and so it makes very little difference to equation (1) whether they are included in $\mathcal{P}$.

Since $\mathcal{P}$ can be large, it may seem impractical to compute a separate R_i for *every* member of $\mathcal{P}$. However, individuals with the same degree of relatedness with s will have the same value of R_i and hence can be grouped together to simplify equation (1). For example, the population $\mathcal{P}$ of alternative culprits may be partitioned into various categories

of direct relatives, such as siblings and cousins, while individuals apparently unrelated to s might be classified into three groups:

- same population, same subpopulation
- same population, different subpopulation
- different population.

To avoid overstating the evidence against s, if the value of R_i varies within a group then the largest value should be applied for all members of the group. Because of migrations and intermarriages, the population and subpopulation are difficult to define precisely. Nevertheless, such concepts often correspond to natural groupings, and they are useful in formulating population genetics models that can allow for the principle effects of population genetic structure on DNA profile match probabilities.

The Population Genetics Parameter θ, or F_{ST}

Suppose that the population is "UK Caucasians", and the subpopulations relevant to a particular crime might include regional subpopulations, or migrant or religious groups such as people of Polish or Jewish ancestry. STR allele frequency estimates are available from a database of individuals classified as UK Caucasians. The accuracy of the estimates will be affected both by the size of the database and the fact that it is not scientific random sample but a "convenience sample" of available individuals. Nevertheless, we can be reassured by the observation that different databases of Caucasian individuals give similar allele proportions at the STR loci in widespread forensic use. For subpopulations, however, direct frequency estimates are often not available: in practice this is always the case because the relevant subpopulation is not strictly defined. The similarity of allele frequencies in broadly defined Caucasian populations does not provide reassurance that narrowly defined subpopulations will also have similar allele proportions: their smaller sizes and distinct histories can make them more variable than large, well-mixed populations.

To deal with the problem of unknown subpopulation allele proportions, we make use of the coefficient F_{ST} [3], also called θ, which can be interpreted in terms of the variation of subpopulation allele proportions about a given reference value, which here would be taken to be the allele proportion, say p, in the UK Caucasian population. Although we cannot estimate the STR allele proportion directly relevant to the case, using θ we can, nevertheless, still calculate the required match probabilities in terms of the degree of variation of subpopulation allele proportions about p.

In some simple models, θ can also be interpreted as the probability that two alleles are descended identically from a common ancestor. Hence θ is also called a *coancestry coefficient* or *kinship coefficient*. Then θ can be thought of informally as the amount of shared ancestry within a population, and so is large for small, isolated populations with little immigration.

The Sampling Formula

Suppose that n alleles have been sampled in the subpopulation, of which m are green. Then the probability that the next allele sampled is also green can be expressed as

$$\frac{m\theta + (1-\theta)p_G}{1 + (n-1)\theta} \tag{5}$$

(see [2], Chap 5 for justification.) When $m = n = 0$, we obtain probability p_G that the first allele drawn is green. The probability that the first two alleles drawn are both green is

$$p_G(\theta + (1-\theta)p_G) = p_G^2 + \theta p_G(1-p_G) \tag{6}$$

Increasing θ raises the probability of observing two green alleles, because the second allele may be identical with the first through descent from a recent common ancestor. Conversely, increasing θ decreases the probability of a green allele followed by a blue, which is

$$(1-\theta)p_G p_B \tag{7}$$

Successive use of expression (5) can be used to build up joint probabilities for any ordered sequence of alleles.

Likelihood Ratios and Match Probabilities

Introducing the notation $x \equiv D$ to denote "x has profile D", E_d can be written succinctly as $C \equiv D$, $s \equiv D$, and the LR, equation (2), becomes

$$R_i = \frac{P(C \equiv D, s \equiv D \mid C = i)}{P(C \equiv D, s \equiv D \mid C = s)} \tag{8}$$

Here, we initially ignore the possibility of error, so that if $C = s$ then crime scene and defendant profiles

are certain to match. Assuming also that the fact that an individual committed the crime does not of itself alter the probability that they have a particular profile, equation (8) can be simplified further to

$$R_i = \frac{\mathrm{P}(i \equiv D, s \equiv D)}{\mathrm{P}(s \equiv D)} = \mathrm{P}(i \equiv D \mid s \equiv D) \quad (9)$$

Thus, under these conditions, R_i reduces to the conditional probability, called the *match probability*, that i has the profile *given* that s has it: population genetic effects arise, and can be dealt with, *via* this conditioning. Other evidence such as eyewitness reports and alibis are typically irrelevant to DNA profile match probabilities, but the background information to a case can include

- information about the relatedness of s with some other individuals;
- allele proportion information from population databases of DNA profiles;
- other relevant population genetics data and theory.

and these can be important for match probabilities.

An essential feature of the match probability is that it takes account of *both* the observed profiles that form the match. Some authors, for example [4], misleadingly refer to the population proportion of the profile as a *match probability* which is inappropriate since the concept of "match" involves two profiles, not one. Equation (9) indicates that the question relevant to forensic identification is not

> "what is the probability of observing a particular profile?"

but

> "given that I have observed an individual with this profile, what is the probability that another (unprofiled) individual will also have it?".

The parameter θ appears in our answer to this question, to take into account possible shared ancestry between the two individuals. Ignoring a defendant's coancestry with other possible sources of the crime stain is systematically unfair to him. Human population genetics is complicated, and inevitably, θ is an imperfect measure, but by choosing a suitable value defendants will not be systematically disfavored, while match probabilities remain small enough to form the basis of satisfactory prosecutions in most cases.

Single-Locus Match Probabilities

Consider the case that both i and s are homozygous for allele A. If we assume that they are unrelated, both come from the same subpopulation, and neither is inbred, then equation (9) corresponds to the conditional probability that two further alleles are both A, given a sample of two alleles that are both A. This is obtained as the product of two instances of expression (5), with $m = n = 2$ and $m = n = 3$:

$$R_i = \frac{(2\theta + (1-\theta)p_\mathrm{A})(3\theta + (1-\theta)p_\mathrm{A})}{(1+\theta)(1+2\theta)} \quad (10)$$

In the heterozygous case, under the same assumptions, we need the probability that two further alleles are A and B, given that two observed alleles are A and B. Taking two times expression (5) with $m = 1$, $n = 2$ times expression (5) with $m = 1$, $n = 3$, gives

$$R_i = 2\frac{(\theta + (1-\theta)p_\mathrm{A})(\theta + (1-\theta)p_\mathrm{B})}{(1+\theta)(1+2\theta)} \quad (11)$$

See Figure 1 for a graph showing how equations (10) and (11) vary with θ for some particular values of the p_j for $j \in \{\mathrm{A,B}\}$. Note that increasing θ does not always increase R_i. Table 1 gives numerical values of single-locus R_i for hypothetical genotypes and p_j values at four STR loci, for four values of θ that span the range used in practice.

These match probability formulas are conditional on the values of θ and the p_j. Thus, strictly, they only apply if these parameters are known exactly, which is never the case in practice. In a fully Bayesian approach, equations (10) and (11) should be integrated out with respect to probability distributions for the unknown values of θ and the p_j, based on the available background information, for example from forensic DNA profile databases and population genetics theory and data. A simpler and more interpretable approach is preferred, in which this background information is used to obtain estimates for θ and the p_j, which are then "plugged in" to the conditional formulas. Care is required to choose the most appropriate "plug-in" values for the parameters, as these need not satisfy the usual criteria for statistical estimators (see below).

Use of equations (10) and (11) implies an assumption of Hardy–Weinberg Equilibrium (HWE) within subpopulations, but not in the broader population from which the forensic database is drawn. Thus tests of deviations from HWE applied to

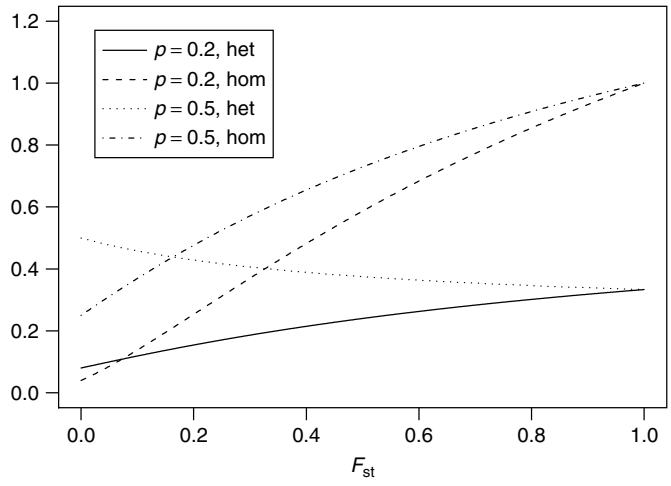

Figure 1 Single-locus match probabilities calculated using equations (10) and (11) for $\theta(= F_{ST})$ ranging from 0 to 1. In the heterozygote case, the proportions of the two alleles are both equal to p

Table 1 Single-locus match probabilities assuming i unrelated to s, for four STR loci and various values of θ, for the alleles specified in column 2 and assuming the population proportions given in column 3

STR locus	Geno-type	Population proportions	Match probability ($\times 10^3$)			
			$\theta = 0$	$\theta = 1\%$	$\theta = 2\%$	$\theta = 5\%$
D18	14, 16	0·16, 0·14	45	49	52	64
D21	28, 31	0·23, 0·07	32	37	41	54
THO1	9·3, 9·3	0·30, 0·30	90	101	112	145
D8	10, 13	0·09, 0·33	59	65	70	85

forensic databases are not directly relevant to match probability calculations. Deviations from HWE do directly affect the probability of observing a particular genotype, but not the conditional match probability given by expression (9).

Match probability formulas that take into account inbreeding within subpopulations, are more complicated than equations (10) and (11), but, nevertheless, relatively easy to apply [5]. The match probabilities are slightly increased for homozygotes, and decreased for heterozygotes; the overall effect on profile match probabilities is usually very small, but may be worth taking into account when highly inbred populations are relevant to a case.

Multiple Loci: The "Product Rule"

There has been much debate in the forensic science literature about the validity of the "product rule" for combining DNA match probabilities across loci. Combining probabilities *via* multiplication implies an assumption of statistical independence, and so the debate is equivalent to a debate about the *independence* of STR genotypes at different loci. This question can be rephrased:

> For two distinct individuals i and s, does the event that their genotypes match at one or more STR loci affect the probability that they will match at the next locus?

If i and s are directly related through one or more known common ancestors (e.g., grandparents), then matches at distinct loci are not independent, but an appropriate adjustment for the relationship can restore approximate independence. All humans are related at some level, and if i and s are apparently unrelated, this only means that the relationship between them

Table 2 Match probabilities for the four-locus STR profile of Table 1 under some possible relationships of s and i, and for various values of θ

	Match probability			
Relationship	$\theta = 0$	$\theta = 1\%$	$\theta = 2\%$	$\theta = 5\%$
Identical twin	1	1	1	1
Sibling ($\times 10^{-3}$)	17	19	20	23
Parent/child ($\times 10^{-4}$)	14	17	19	29
Half-sib ($\times 10^{-5}$)	23	29	35	61
Cousin ($\times 10^{-5}$)	6	8	10	20
Unrelated ($\times 10^{-6}$)	8	12	17	43

is unknown and presumed to be distant. However, it is not necessarily distant enough to be negligible for the purposes of calculating match probabilities.

Thus, use of the product rule based on an assumption of no relatedness at any level is unfair to defendants. However, the match probabilities given by equations (10) and (11) are conditional on a level of coancestry between apparently unrelated individuals measured by θ. Although match probabilities at many loci cannot readily be checked, the available population genetics theory and data support the view that, given a suitable value of θ, match probabilities obtained as products of the probabilities in equations (10) and (11) will not be systematically unfavorable to defendants.

Whole-profile match probabilities using the θ-adjusted product rule applied to the four STR loci of Table 1, and using various values of θ, are given in the final row of Table 2. Assuming $\theta = 5\%$ increases the four-locus match probability more than fivefold relative to the $\theta = 0$ case, and this extrapolates to more than a 50-fold increase for 10 loci, and about 200-fold for a 13-locus profile match.

Relatives of s

So far we have been considering alternative possible culprits i that are unrelated to s. Here we consider the possibility that i and s are directly related through one or more specified common ancestors. We continue to assume that the DNA profile of i is not available to the court: it would in principle be desirable to exclude close relatives of s from suspicion by examining their DNA profiles, but this is rarely possible in practice. Considering first a single locus, let Z denote the number of alleles at the locus that i and s share identical by descent (ibd) from a known, recent, common ancestor (e.g., parent or grandparent), and let

$$\kappa_j = \mathrm{P}(Z = j) \tag{12}$$

for $j = 0, 1, 2$. The values of κ_j under some regular (i.e., no inbreeding) relationships are shown in the first three columns of Table 3.

Table 3 Distribution of ibd status and coefficient of relatedness for some possible relationships of s and i. The value of κ_j is the probability that i and s share j alleles at a locus identical by descent (ibd) from a recent common ancestor, and $\overline{\kappa}$ is half the expected number of alleles shared ibd. The values for aunt, uncle, niece, nephew, grandparent, and grandchild are the same as for half-sib

Relationship	κ_0	κ_1	κ_2	$\overline{\kappa}$
Identical twin	0	0	1	1
Sibling	1/4	1/2	1/4	1/2
Parent/child	0	1	0	1/2
Half-sib	1/2	1/2	0	1/4
First cousin	3/4	1/4	0	1/8
Double first cousin	9/16	6/16	1/16	1/4
Unrelated	1	0	0	0

If $Z = 0$, then it is the same as if s and i were unrelated and we write M_2 for the appropriate match probability, either from equation (10) or (11). If $Z = 2$, a match is certain. For $Z = 1$, consider first the case that $s \equiv \mathrm{AA}$. Since one allele of i is ibd with an observed allele of s, we require the probability of observing a further A allele, given that two alleles have been observed to be both A. Using expression (5) with $m = n = 2$ we obtain

$$M_1 = \mathrm{P}(\mathrm{A} \mid \mathrm{AA}) = \frac{2\theta + (1-\theta)p_{\mathrm{A}}}{1+\theta} \tag{13}$$

If $s \equiv \mathrm{AB}$, the allele shared ibd by i and s is equally likely to be A or B. The match probability is then equivalent to the probability of observing the non-ibd allele, given that A and B have been observed:

$$\begin{aligned} M_1 &= \frac{\mathrm{P}(\mathrm{A} \mid \mathrm{AB}) + \mathrm{P}(\mathrm{B} \mid \mathrm{AB})}{2} \\ &= \frac{\theta + (1-\theta)(p_{\mathrm{A}} + p_{\mathrm{B}})/2}{1+\theta} \end{aligned} \tag{14}$$

The overall single-locus match probability for relatives is then

$$\kappa_2 + \kappa_1 M_1 + \kappa_0 M_2 \tag{15}$$

Four-locus match probabilities based on (14) and the product rule are shown in Table 2 for the four STR loci of Table 1. Notice that the value of θ still affects the match probability even when i and s are assumed to be closely related. This is because, as well as matches arising via alleles shared ibd from the recent known ancestor(s) of i and s, alleles can also be shared ibd from more distant common ancestors. However, the relative importance of θ declines as the known relationship between i and s becomes closer [6].

Values for the p_j

The population database to be used to estimate the p_j should be that most appropriate for i, the alternative possible culprit under consideration. The error arising from the database population not being exactly appropriate can be addressed using θ. Here we consider only the issue of accounting for the effects of sampling uncertainty in observed allele proportions. One way to address this issue is to estimate p_j at a heterozygous locus by

$$\widehat{p_j} = \frac{x_j + 2}{n + 4} \tag{16}$$

where x_j is the frequency of allele j in the database, and n is the total number of alleles [6, 7]. In the homozygous case, an analogous estimate is

$$\widehat{p_j} = \frac{x_j + 4}{n + 4} \tag{17}$$

These estimates can be thought of as adding both the crime-scene and defendant profiles to the database; such estimation methods are sometimes called *pseudocount* methods. They can be justified as approximations to the posterior mean given the sample allele counts and a uniform prior distribution for the allele proportions.

The value of θ

Published estimates of θ at STR loci, for subpopulations within the major human "racial" groups are often small, and typically less than 1%. See, for example, [8, 9] for estimates in some European Caucasian populations. Many other authors have estimated θ at forensic STR loci in various populations and using different methodologies; see [10] for a brief review. Typically, they report very small values.

There are several arguments for using larger values in forensic practice than suggested by these estimates. Recall that our goal is not to estimate a "best" value for θ, but to choose "plug-in" values that give a match probability similar to that which would be obtained from using the full Bayesian approach. Because of the skewness of appropriate distributions for θ, the "plug-in" value that mimics the effect of integration over θ may be much larger than, say, a maximum-likelihood estimate of θ. Moreover, published estimates of θ usually relate to the variation of allele proportions around the observed mean of the subpopulations studied, whereas in forensic applications, the reference value is the forensic database value. The θ estimate can vary substantially according to the choice of reference value, and is often much larger than when the reference value is estimated from the data. Broadly speaking, the less appropriate is the database for the genetic background of a possible culprit, the greater is the appropriate value of θ.

For these reasons (see [2], Sec 6.3, for a fuller discussion), it is suggested that a relatively large value, such as 2%, be used when both defendant and alternative possible culprit are drawn from a relatively well-mixed, large population, and perhaps 3% could be used if both are drawn from one of the large minority groups. In some small minority groups, $\theta = 5\%$ may be appropriate. These suggested values are based on informal judgements, and should not be regarded as prescriptive.

If i is not from the same racial group as s, then they have little coancestry and so a small value of θ can be justified. However, since the problem of representativeness of any database remains, as well as possibilities for some coancestry even across apparent racial groups, the use of a nonzero value of θ in every case, perhaps setting 1% as the minimum, is advocated.

Laboratory, Handling errors, and Evidence Tampering

There are at least two ways in which an observed STR profile match could have arisen even though $C \neq s$:

1. defendant and culprit happen to have matching DNA profiles and no typing error occurred ("chance match");

2. defendant and culprit have distinct DNA profiles, and the observation of matching profiles is due to an error in one or both recorded profiles ("false match").

Both (1) and (2) are typically unlikely, but (2) may not be negligible in comparison to (1), yet (2) is typically not explicitly considered in conjunction with (1). An argument that is often advanced for this is that error probabilities are difficult to assess. Even if error rates from external, blind trials are available, there will usually be specific details of the case at hand that differ from the circumstances under which the trials were conducted, and which make it more or less likely that an error has occurred.

Some critics of DNA profile evidence have argued that the match probabilities reported in court are irrelevant and potentially misleading because they relate to (1) only, whereas (2) is likely to be more important in practice. This argument has some force, and proponents of DNA profiling have been prone to mistakes and exaggeration in their attempts to discount it [11]. The chance of a false inclusion error due to genotyping anomalies is so remote as to be negligible, even relative to the match probability, because it is not the probability of any error that is relevant, but an error that causes a false match. Contamination is a distinct possibility in some settings, but because evidence and crime samples are routinely typed by different staff in different laboratories, sometimes with a substantial time gap, in many cases this possibility can also reasonably be ruled out.

This leaves the possibility of false inclusion due to handling or labeling error, or evidence tampering. A conspiracy theory, such as that police and/or judicial authorities colluded to manufacture evidence falsely linking the defendant with the crime scene, may be regarded by a reasonable juror as substantially more plausible than a 1 in a billion chance match, even when there are no particular reasons to suggest a conspiracy. For this juror, the probability of such a conspiracy based on all the other evidence, is more important than the chance match probability.

There seems no role for a forensic scientist to predict whether a juror might pursue such a line of reasoning, and hence the only reasonable option is to supply the juror with a match probability based on (1), but also to try convey an understanding of the possibilities for a false match and how these affect evidential weight.

Partial Profiles

So far we have assumed good quality crime-scene DNA samples and no profiling errors, so that a perfect match of crime-scene and defendant profiles is expected if s is the source of the crime-scene DNA. However, if the crime-scene sample is very small and/or degraded, the crime-scene profile may be subject to stochastic phenomena such as drop-out, drop-in, imbalanced peak heights and exaggerated stutter. Under these circumstances, a prosecution may proceed against s even though his profile does not exactly match the crime-scene profile. When all the crime-scene profile alleles are evident in the profile of s, but the converse does not hold, the crime-scene profile is sometimes referred to as *partial* and the prosecution case requires that drop-out has occurred. Strictly, we can only be sure that alleles have dropped out if there is a locus with no observed alleles: no conclusion about drop-out should refer to the profile of s.

The analysis of profiles in the presence of drop-out and related phenomena is a major current challenge for the forensic DNA community, and completely satisfactory solutions are not yet available. One unsatisfactory approach [12] that is often used in practice involves using the standard LR when two alleles are observed in the crime-scene profile, $2p$ when one allele is observed, and 1 when no alleles are observed. For a more advanced attempt at formulating appropriate LRs, see [13], but the software described there is not widely available.

Note that a "partial" profile that arises because some loci are not profiled does not raise any problem of interpretation: the fact that additional loci might have been profiled but were not, is irrelevant to the assessment of the loci that were profiled.

Database Searches

Many countries maintain national databases of the STR profiles of named individuals for criminal intelligence purposes. The question thus arises as to the appropriate method for assessing the DNA profile evidence when the defendant was identified following a search through a database. The number of individuals involved in such a search, and even the fact that there was a search, may not be reported to the court (*see also* **DNA Databases and Evidentiary Issues**).

Many commentators, including [4], have wrongly claimed that the fact that a DNA profile match is

more likely when it results from a search means that the evidence is weakened by the search. An analysis that focuses on the relevant question–is s the source of the crime-scene DNA profile?–shows that DNA evidence is usually slightly stronger in the database search setting than when no search has occurred. To see this, imagine an enormous database that records the STR profiles of everyone on earth. If the defendant's profile were the only one in this database to match the crime-scene profile, then the evidence against him would be overwhelming.

Although the DNA evidence may be (slightly) stronger in the context of a database search, the overall case against the defendant may be weaker because there is little or no non-DNA evidence against the defendant, see [14, 15].

Match Probability for Y Chromosome STR Profiles

Because the Y chromosome is paternally inherited, and for the most part does not undergo recombination, a Y-STR profile can be treated as a single allele, or "haplotype", characterized by the repeat counts at STR sites along the chromosome. The match probability involves the probability that a particular man has a certain haplotype given that another man has it. This is conceptually simpler than for autosomal loci because there is no need for multiplication of frequencies either within or across loci.

Using an approach analogous to that used to derive (10) and (11), the match probability for a Y haplotype with population frequency p is

$$R_i = \theta + (1 - \theta)p \tag{18}$$

Since p is typically unknown, a "pseudocount" estimator, analogous to equations (15) and (16) for autosomal loci, can be used:

$$\widehat{p} = \frac{x + 2}{N + 2} \tag{19}$$

where x denotes the database count of the observed Y haplotype.

Population structure is particularly important for Y haplotypes: values of θ are typically high, reflecting geographical clustering of males with common paternal ancestry [16]. There are only a few studies on the appropriate fine geographical scale. A specific Y haplotype that is frequent in many parts of Asia, and largely unobserved elsewhere, has been attributed to the consequences of historic Mongol conquests, possibly even to Genghis Khan himself [17]. Similar historical events on a smaller scale may have led to an unrecognized, local elevation of the concentration of a specific Y haplotype that is otherwise rare. For example, substantial microgeographical variation in forensic Y-chromosome haplotypes has been reported in the Cantabria region of Spain [18].

Although selection is thought likely to influence the distribution of Y haplotypes, because no assumption of either HWE or linkage equilibrium is made, it seems reasonable to assume that selection will not adversely affect the validity of equation (17).

Other Approaches to Assessing STR Evidence

Uniqueness

The current generation of STR profiling technology uses 10 or more loci, so that match probabilities for individuals unrelated to the defendant are typically extremely small, often less than 1 in a billion even with a generous allowance for θ. It thus seems reasonable to consider the possibility that the STR profile is unique, and if this could be established, then the need for calculating and reporting LRs could be avoided.

Although this idea is attractive, it encounters a number of difficulties, such as the choice of threshold for declaring a profile to be unique. Perhaps more importantly, the non-DNA evidence in a case also has a bearing on the question of uniqueness, but lies outside the domain of a DNA expert.

Under some simplifying assumptions on the numbers of individuals with different degrees of relatedness to the defendant, and assuming no evidence other than the STR profiles, 10 STR loci usually suffice to establish a probability greater than 99.9% that the STR of s is not shared by any individual in $\mathcal{P}$ [19].

Random Man Not Excluded (RMNE)

Another approach to the evaluation of STR profiles that avoids computing LRs is to report the inclusion probability of a crime-scene profile, or the probability that a "random man" would not be excluded as the contributor. In the case of a single-source crime-scene profile, the random man not excluded (RMNE) probability is the probability that a randomly chosen alternative possible culprit would match the crime scene

DNA profile. In this setting, the exclusion probability is numerically equivalent to the LR for i unrelated to s (but typically assumes $\theta = 0$). However, the two approaches are conceptually very different.

The rationale underlying the RMNE probability cannot adequately cope with relatives of the defendant among the alternative culprits, and can be highly misleading in the presence of drop-out (partial profiles). The idea of a random alternative suspect can lead jurors to ignore the role of the *number* of possible culprits in evidential assessments, and clear thinking about laboratory and other errors, and the effect of searches, can also be undermined. All of these aspects are readily dealt with in the LR framework.

One specific difficulty that "random man" can cause in this setting concerns the argument over which population the man is supposed to have been randomly drawn from [20]. Since "random man" is a fictional character, these arguments can never be resolved. The issue is important, since too broad a definition of the population leads to overstatement of the evidence, because a large population must contain many people sharing little ancestry with s. If we try to avoid this overstatement by specifying the narrowest possible population, we are led to the population consisting of s only, in which the match probability is one.

Numerical differences arise between RMNE and LR values for paternity, since the former makes no distinction between a homozygous and a heterozygous nonexcluded alleged father, whereas the LR correctly recognizes that the DNA evidence at this locus is about twice as strong against the homozygote. Even more important differences arise in the setting of crime-scene DNA profiles with two or more unknown contributors (*see* **Mixture Interpretation: DNA**). Here, the RMNE probability is usually taken to be the probability that a random unknown individual would have both alleles at each locus included among the alleles of the mixed crime-scene profile. This probability does not take account of the profile of the defendant, other than noting that it falls within a (usually large) class of profiles. In the case of two codefendants alleged to be contributors to the mixed crime-scene profile, the evidence can weigh more heavily against one defendant than the other, whereas the RMNE probability will be the same for both defendants.

The advantages of the RMNE probability include its being relatively easy to calculate and explain, and that it does not require any assumption about the number of contributors to a mixture. Because it ignores relevant information, the RMNE probability is usually larger than the LR, often considerably so. This statistical inefficiency is sometimes seen as a virtue, in that use of the RMNE probability is regarded as "conservative". However, conservativeness is not guaranteed, and by using an appropriate θ-value we can make the LR conservative while still relatively efficient.

Paternity

The principles of combining LRs to evaluate a probability of paternity are similar to those underpinning equation (1). However, in practice DNA evidence is often assessed differently when paternity rather than identification is at issue. Many forensic scientists, lawyers, and academic commentators seem reluctant to consider in the paternity setting the very low prior probabilities that are now often accepted for identification. Indeed, there is a shamefully high prevalence of an unjustified assumption that both s, and an unrelated "random man" i, have a prior probability 1/2 of being the father [21]. This "even prior" assumption is convenient, since in the absence of relatives of s it implies that the likelihood ratio R_i is also the posterior probability that s is not the father. It may often be based on the assumption that equal prior weight should be assigned to the, typically conflicting, claims of s and the mother m. However this ignores, for example, additional background evidence, and multiple alternative fathers.

Likelihood Ratios for Paternity

Typically, the STR evidence consists of the profiles of the mother m, alleged father s, and child c, in which case

$$R_i = \frac{\text{P(profiles of } c, s, \text{ and } m \mid \text{father is } i)}{\text{P(profiles of } c, s, \text{ and } m \mid \text{father is } s)} \quad (20)$$

Here, the fact that m is the mother of c is regarded as background information in both probabilities, but is not explicit in the notation. It is usually reasonable to assume that the probabilities that s and m have particular profiles is unaffected by whether s is the father of c, and it follows that we can rewrite equation

(20) as a ratio of conditional probabilities for the child's profile:

$$R_i = \frac{\text{P(profile of } c \mid \text{profiles of } s \text{ and } m, \text{ father is } i)}{\text{P(profile of } c \mid \text{profiles of } s \text{ and } m, \text{ father is } s)} \quad (21)$$

in which the profile probabilities for s and m have cancelled.

The denominator is easily evaluated using Mendelian transmission probabilities, and is, for example, equal to one if $m \equiv$ AB, $s \equiv$ CC, and $c \equiv$ AC.

For the numerator, we require the conditional probability of c's paternal allele, given the profiles of s and m and the hypothesis that i is the father. First, suppose that the coancestry of i and s is specified by θ, but m has no coancestry with either (for example, she is from a different racial group). Then the profile of m is uninformative about the profile of i, and the paternal allele of c may be regarded as a third allele drawn from the subpopulation of i and s, given that two observed alleles (from s) are both C. Invoking the sampling formula (5) with $m = n = 2$ we obtain

$$R_i = \text{P(C} \mid \text{CC)} = \frac{2\theta + (1-\theta)p_C}{1+\theta} \quad (22)$$

Reasoning similarly in the heterozygous case $s \equiv$ CX, the denominator is 1/2 and

$$R_i = 2\text{P(C} \mid \text{CX)} = 2\frac{\theta + (1-\theta)p_C}{1+\theta} \quad (23)$$

If i, s, and m are all assumed to have the same level of coancestry, then the sampling formula (5) can be used again but now with $n = 4$ because of the four alleles observed in s and m (*see* **Missing Persons and Paternity: DNA** and [2], Chap 7). for examples and further details.

Mutation

If an STR profile consists of around ten loci, there is very roughly a 2% probability that there will be a mutation in transmission from father to child, in which case ignoring the possibility of mutations could lead to a false exclusion. If the profiles are consistent with s being the father of c at many loci, but there is an apparent exclusion at just one or perhaps two loci (Table 4), it may still be the case that the STR evidence overall supports the claim that s is the father. A systematic treatment of this question when the mother's profile is available, but ignoring coancestry is given by Dawid *et al.* [22]. The latter omission is rectified by Ayres [23], who treats the case that any two of m, s, and i have the same level of coancestry, θ, correcting formulas given in [24] that neglected the possibility of maternal transmission.

Table 4 Three examples of scenarios in which a mutation is required to sustain the the hypothesis that m and s are the parents of c

Scenario		(i)	(ii)	(iii)
Child c	$\equiv$	AB	AB	AB
Mother m	$\equiv$	AC	AC	DD
Alleged father s	$\equiv$	CD	AD	AC

Perhaps the most common theoretical model for STR mutation is the stepwise mutation model (SMM) in which a mutant allele has either $k-1$ or $k+1$ repeat units, each with probability 1/2, where k is the current repeat number. The SMM has no stationary distribution, so that two similar populations isolated from each other do not converge under the SMM to the same allele frequency distribution. Thus, substantial between-population diversity is expected under the SMM for populations that exchange few migrants. By contrast, there is typically little between-population variation at human STR loci, suggesting high migration rates and/or the invalidity of the SMM.

In fact, the strict SMM is known to be false, for example, because the mutation rate increases with allele length and occasional two-step mutations occur, although it may provide an adequate approximation for some purposes. The SMM can easily be modified, for example, by hypothesizing a bias toward contraction mutations in long alleles, to obtain STR mutation models that do have a stationary distribution [25]. Such models can provide a better fit to observed data than the SMM, and are consistent with the observed between-population homogeneity of allele proportions at many STR loci.

Conclusion

The theory based on likelihood ratios outlined above does not provide a formulaic answer to the problem

of how to convey complex STR profile evidence to a nonscientific court. It does, however, provide a solid theoretical framework for the forensic scientist to think clearly about weight-of-evidence issues, and hence to draw well-informed conclusions about what a rational judge or juror needs to be informed of in order for them to carry out their tasks of evaluating the evidence. For further details of STR interpretation beyond those given here, *see and also* **Statistical Evidence in Court** [2, 10, 26, 27, 28]

Soil: Forensic Analysis

Introduction

Forensic soil science is the science or study of soil that involves the application of soil science, especially studies that involve soil morphology, soil mapping (assisted by existing soil maps and spatially held soil data), mineralogy, chemistry, geophysics, biology, and molecular biology to answer legal questions, problems, or hypotheses. *Soil science* is the term commonly used to study soil as a natural body in the landscape and as a resource to be managed for agricultural production, environmental waste disposal, and construction.

Soils mean different things to different people. Soil scientists (pedologists) view soils as being made up of different size mineral particles (sand, silt, and clay) and organic matter. Soils have complex

biological, chemical, physical, mineralogical, and hydrological properties that are always changing with time. Hence, soil is dynamic, teeming with organisms, and is an integral part of the environment. Agronomists, farmers, and gardeners, on the other hand, see soil as a medium for growing crops, pastures, and plants – primarily in the top 50 cm of the Earth's surface. Engineers regard soil as material to build on and excavate, and are usually concerned primarily with moisture conditions and the capacity for soil to become compacted and support structures. However, some people regard soil as "dirt" or "mud" because it makes them "dirty" when they make contact with it.

Pedology (from the Greek *pedon* = soil), is the soil science discipline concerned primarily with understanding the variety of soils and their distribution, and is most directly concerned with the key questions concerning sampling, descriptions, processes of soil formation including the quality, extent, distribution, spatial variability, and interpretation of soils from microscopic to megascopic scales [1]. This description and interpretation of soils can be used in addressing the questions 'What is the soil like?' and 'Where does it come from?' (i.e., provenance determination) in studies relating to characterizing and locating the sources of soils to make forensic comparisons.

Forensic soil scientists are more specifically concerned with soils that have been disturbed or moved (usually by human activity), sometimes comparing them to natural soils, or matching them with soil databases, to help locate the scene of crimes. Forensic soil scientists usually obtain soil samples from crime scenes and suspected control sites from which soil may have been transported by shoes, a vehicle, or a shovel. Soil properties are diverse and it is this diversity, which may enable forensic soil scientists to use soils with a degree of certainty as evidence in criminal and environmental investigations [2, 3].

Forensic soil science is a relatively new activity that is strongly "method orientated" because it is mostly a technique-driven activity in the multidisciplinary soil areas of pedology, soil survey, soil mineralogy, soil chemistry, soil molecular biology, soil geophysics, and forensic science. There are few reviews of the specific application of one soil science discipline to criminalistics at the time of writing (i.e., apart from a recent series of publications by Fitzpatrick [2], Fitzpatrick *et al.* [3], Dawson *et al.* [4], and Ritz *et al.* [5]). Conversely, there are several wider-ranging and soil-related reviews, which provide comprehensive reviews of (i) "forensic geology" [6–12] and, (ii) "geoforensics", which focuses more on the geoscience techniques such as forensic geophysics, forensic remote sensing and geological trace evidence [13–15], and (iii) archaeology [16].

Soil materials are routinely encountered as evidence by police, crime scene investigators, and forensic staff. However, most forensic and physical evidence laboratories either do not accept or are unable to adequately characterize soil materials. The main reason for this is that the morphological, mineralogical, and spectroscopic analytical knowledge required to examine and interpret such soil evidence needs a large amount of training and expertise that is not yet available in most forensic science facilities. In recent years, soil science technology has advanced dramatically and become very specialized and, for this reason, scientists and police investigation units are not using soil information as much as they did previously (e.g., application mainly of petrographic microscope data). Currently, soil analyses are generally only performed in investigations of serious crime and usually where human DNA analyses or analyses of other more commonly used types of trace evidence were not possible. Consequently, there is an opportunity for the application of soil analysis in the forensic examination of soil from a wider spectrum of routine forensic investigations. This review outlines traditional and new soil methods, as well as systematic approaches for the forensic examination of soils.

Soil as a Powerful Contact Trace

Theory of Transfer of Soil Materials from One Surface to Another as a Result of Contact

The transfer of trace evidence is governed by what has become known as the *Locard Exchange Principle* [17], which states that when two surfaces come into physical contact there is a mutual exchange of trace evidence between them. For example, the exchange can take the form of soil material from a location transferring to the shoes of a person who walked through that location. These types of transfers are referred to as *primary transfers* (e.g., evidence is transferred from the soil surface to the shoe and later recovered from the shoe, such as in the treads of

the sole or within the shoe). Once a trace material has transferred, any subsequent movements of that material, in this case from shoes (e.g., from the shoe to the carpet in a vehicles foot well), are referred to as *secondary transfers*. These secondary transfer materials can also be significant in evaluating the nature and source(s) of contact. Hence, the surface of soils can provide information linking persons to crime scenes. Higher order transfers (tertiary transfers) of trace evidence can also occur, which can present interpretative problems for forensic soil scientists because the ultimate source of trace evidence may be extremely difficult to identify.

Aardahl [18] lists the properties of the ideal trace evidence: (i) it is highly individualistic; (ii) it has a high probability of transfer and retention; (iii) it is nearly invisible; (iv) it can quickly be collected, separated, and concentrated; (v) the merest traces are easily characterized; and (vi) it is able to have computerized database capacity. In this context, glitter (i.e., entirely manmade tiny pieces of Al foil or plastic with vapor-deposited Al layer) has been considered to be the ideal contact trace [19]. Soil materials may be considered as approaching the ideal "contact trace", and the following brief discussion considers how closely they fulfill the criteria of Aardahl.

Soil is Highly Individualistic

Diversity of Natural Soils. It is important to understand and know the different kinds of soils and how they form because this helps in making accurate forensic comparisons. To determine the wide variety of soils that occur in the world, it is necessary to understand soil classification systems used to illustrate this. Soil classifications help to organize knowledge about soils, especially in conducting soil surveys. The two international soil classification systems, which are widely used, are the World Reference Base (WRB) [20] and Soil Taxonomy [21]. Many countries also have national and specialized technical classifications [22]. Soil surveys enable the depiction of soils across a landscape and soil maps are made to show the patterns of soils that exist and provide information on the properties of soils. Soil maps are produced at different scales to depict soils over (i) large areas such as the world, countries, and regions (1 : 100 000 or smaller scale), and (ii) detailed areas such as farms (1 : 10 000 or larger scale). A wide diversity of natural soils exists and each has its own characteristics (e.g., morphology, mineralogy, and organic matter composition). For example, according to the United States Department of Agriculture (USDA), which collects soil data at many different scales, there are over 50 000 different varieties of soil in the United States alone. Parent material, climate, organisms, and the amount of time it takes for these properties to interact vary worldwide.

Anthropogenic Soils. Urban soils is a class of *anthropogenic* or *anthropic soils*, a term used in several soil classification systems [20] to indicate soils that are essentially under strong human influence in urban and suburban areas. They are characterized by a strong spatial heterogeneity, which results from the various inputs of exogenous materials (e.g., compost, minerals, technological compounds, and inert, organic, or toxic wastes) and the mixing of the original (natural) soil material (e.g., parks, gardens, landscaping, and cemeteries). Mine or quarry soils are another class of anthropic soils, which are also strongly influenced soils, but found away from cities. Anthropic soils are characterized by a great ecological heterogeneity, and show special distinctness of soil properties.

These specific soils also contain a large array of historical information, which has been proved very useful in understanding and quantifying soil differences in forensic soil comparisons.

The major question posed is how can soils be used to make accurate forensic comparisons when we know that both natural and anthropic soils are highly complex and that there are thousands upon thousands of different soil types in existence? The following key issues are especially important in forensic soil examination because the diversity of soil strongly depends on topography and climate, together with anthropogenic contaminants:

- Forensic soil examination can be complex because of the strong diversity and heterogeneity of soil samples. However, such diversity, heterogeneity, and complexity enables forensic examiners to distinguish between soil samples, which may appear similar to the untrained observer.
- A major problem in forensic soil examination is the limitation in the discrimination power of the standard and nonstandard procedures and methods.

No standard forensic soil examination method exists. The main reasons for this are that examination of soil is concerned with detection of both (i) naturally occurring soils (e.g., minerals, organic matter, soil animals, and included rock fragments) and (ii) anthropogenic soils that contain manufactured materials such as ions and fragments from different environments whose presence may impart soil with characteristics that will make it unique to a particular location [e.g., material from quarries, asphalt, brick fragments, cinders, objects containing lead from glass (*see* **Examination of Fibers and Textiles**), hydrocarbons, paint chips (*see* **Paint: Interpretation**), and synthetic fertilizers with nitrate, phosphate, and sulfate]. In spite of the increasing impact of human activities on soil and the likelihood that all of Earth's ecosystems have been influenced to some extent by humans, many soils still retain their basic morphology imparted by natural soil-forming processes. These anthropogenic properties make the naturally occurring soils even more individualistic.

Soil is Easy to Characterize: Large and Trace Amounts

Historical Analysis Methods for Forensic Soil Samples: 1856–1904. Soil materials are generally easy to characterize, especially by way of the following published historical examples, which demonstrate how large amounts of soil materials have been characterized using quick morphological and light optical methods to solve crime cases. On a Prussian railroad, in April 1856, a barrel which contained silver coins was found on arrival at its destination to have been emptied and refilled with sand. Prof Ehrenburg of Berlin acquired samples of sand from stations along railway lines and used a light microscope to match the sand to the station from which the sand must have come [22]. This is arguably the very first documented case where a forensic comparison of soils was used to help police solve a crime [2]. Then, in 1887, Sir Arthur Conan Doyle published several fictional cases involving Sherlock Holmes such as "A Study in Scarlet" in Beeton's Christmas Annual of London where Holmes can "Tell at a glance different soils from each other . . . has shown me splashes upon his trousers, and told me by their colour and consistence in what part of London he had received them". In 1891, in "The Five Orange Pips", Holmes observed "chalk-rich soil" on boots. This clearly indicates that Conan Doyle was well aware of the key soil morphological properties (color and consistence) and soil mineralogy (chalk) in forensic soil comparisons. Further, as documented by Murray and Tedrow [9, 10], "October 1904, a forensic scientist in Frankfurt, Germany named George Popp was asked to examine the evidence in a murder case where a seamstress had been strangled in a bean field with her own scarf. George Popp successfully examined soil and dust from clothes for identification to solve this real criminalistic case".

Standard/Traditional Analysis Methods for Forensic Soil Samples. The methods of soil analysis used in forensic science are predicated on the size of the sample and the use to which the analytical results will be put. The aim of forensic soil analysis is to associate a soil sample taken from an item (e.g., shoes, clothing, shovel, or vehicle) by police with a specific location. To achieve this aim, the methods of analyses chosen must be able to discriminate between soil samples from different locations. Importantly, the methods used for comparing the samples must be practical (use of standard methods), inexpensive, accurate, and applicable to small and large samples.

The methodology for describing soils has been developed and refined by soil scientists for more than a century [23]. Soils from crime scenes and control sites can be investigated at least in part with traditional soil survey descriptive approaches/techniques; however, these methods must be properly adapted and new methodology must still be developed [3]. Soil morphological descriptors such as color [24], consistency, structure, texture, segregations/coarse fragments (charcoal, ironstone, or carbonates), and abundance of roots/pores are the most useful properties to aid the identification of soil materials (e.g., [23, 25]) and to assess practical soil conditions (e.g., [26]). These soil morphological descriptions follow strict conventions whereby a standard array of data is described in a sequence, and each term is defined according to both the USDA Field book for describing and sampling soils, Version 2.0 [25] and National standard systems (e.g., Australian Soil and Land Survey Field Handbook by McDonald *et al.* [27].

Soil has a High Probability of Transfer and Retention

In general, soil usually has a strong capacity to transfer and stick, especially the fine fractions in soils

(clay and silt size fractions) and organic matter. The larger quartz particles (e.g., >2-mm size fractions) have poor retention on clothes and shoes and carpets. Fine soil material (e.g., their <50–100-μm fractions) may often only occur in small quantities, as illustrated in a hit-and-run case illustrated by Fitzpatrick *et al.* [3], where a remarkably small amount of fine soil was transferred from a gravelly and stony soil on a river bank (control site) to running shoes (forensic evidence items).

Soil Can Quickly Be Collected, Separated, and Concentrated

Although soil forensic investigations are primarily performed in the laboratory, it should be emphasized that soil analyses typically begins at the crime scene and at the control sites. Hence, this section briefly summarizes the general procedures that will ensure that the collected samples are appropriate for the specific objectives of the forensic soil investigation. Soil samples must be carefully collected and handled at the crime scene or control sites using established approaches and then compared by a soil scientist with forensic science experience to ensure that the soil samples can be useful during an investigation. The size and type of samples to be taken are strongly dependent on the nature of the environment being investigated, especially the type of soil and nature of activity that may have taken place at the scene. For example, if suspect footwear is heavily coated with mud on the uppers and the ground is wet and soft, then the control sample should be collected to a depth of around 0–10 cm [3]. Samples of subaqueous soils or sediments from the bottom of river channels, streams, ponds, lakes, or dams can be obtained by pressing a plastic tube or container into the soft submerged soil/sediment and removing it with a scooping action. In deeper water, subaqueous soils/sediment samples can be taken using specialized sampling devices such as the Russian D-auger. In contrast, if the soil is very hard and dry and only the shoe tread was in contact with the soil, then carefully collect the 0–0.5 cm – or thinner. It is critical to wear clean latex gloves but do not use "talc powder" in the gloves because the layer silicate mineral "talc" will contaminate the soil sample. Always use clean tools (e.g., shovel, trowel, artist's palette knife, which are made of stainless steel). Plastic spades and trowels generally lack the strength required to dig soils, especially for most Australian soil conditions. Artist's palette knives are useful for sampling very thin layer surfaces of samples of mud or dust. Preferably place samples in "rigid plastic containers" – rather than polythene bags or paper bags because the package must keep soil lumps intact. Do not use paper envelopes because they easily tear and leak. If soil is adhering to items of clothing or shoes – first air dry the whole garment and then package whole intact sample and garment. If the soil is wet/moist or adhering in a wet/moist condition to objects (e.g., tires, vehicles, garments, or shovels) first air dry then package. However, as in the case of obvious sequential/chronologically deposited layers of soil being present, first remove the "surface layer" and then air dry. Store dry samples at room temperature and ensure containers are sealed and take appropriate caution when storing and transporting. If biological material is attached, package using clean cardboard box/paper bags because samples are prone to rapid deterioration.

Several standard methods are available for quick separation and concentration of soil materials or particles such as, for example, sieving, magnetic extraction, and heavy mineral separation (e.g., Figure 1).

Soil is Almost Invisible

Although a suspect may be unaware that soil material – especially the fine fractions (e.g., <50 μm) – has been transferred directly to the person (e.g., shoes or clothing) or surroundings (e.g., carpet in a suspect's car), soil materials are easily located and collected when inspecting crime scenes or examining items of physical evidence [2–12]. Traces of soil particles can easily and quickly be located directly using hand lenses or light microscopes. For example, Fitzpatrick *et al.* [3] successfully completed a forensic comparison of small amounts of fine yellow–brown soil adhering to a suspect's shoe with a stony/gravelly black control soil submerged in a river where a hit-and-run offender ran through. Although the black-colored control soil comprised 95% alluvial stone and coarse gravel with only 5% clay and silt, a sufficient amount of fine yellow-brown material (<50 μm) was recovered by sieving. This fine soil material closely resembled the fine soil material that was tightly trapped in grooves and treads in the rubber sole of the suspect's shoe [3]. The control sample under typical viewing conditions by the naked

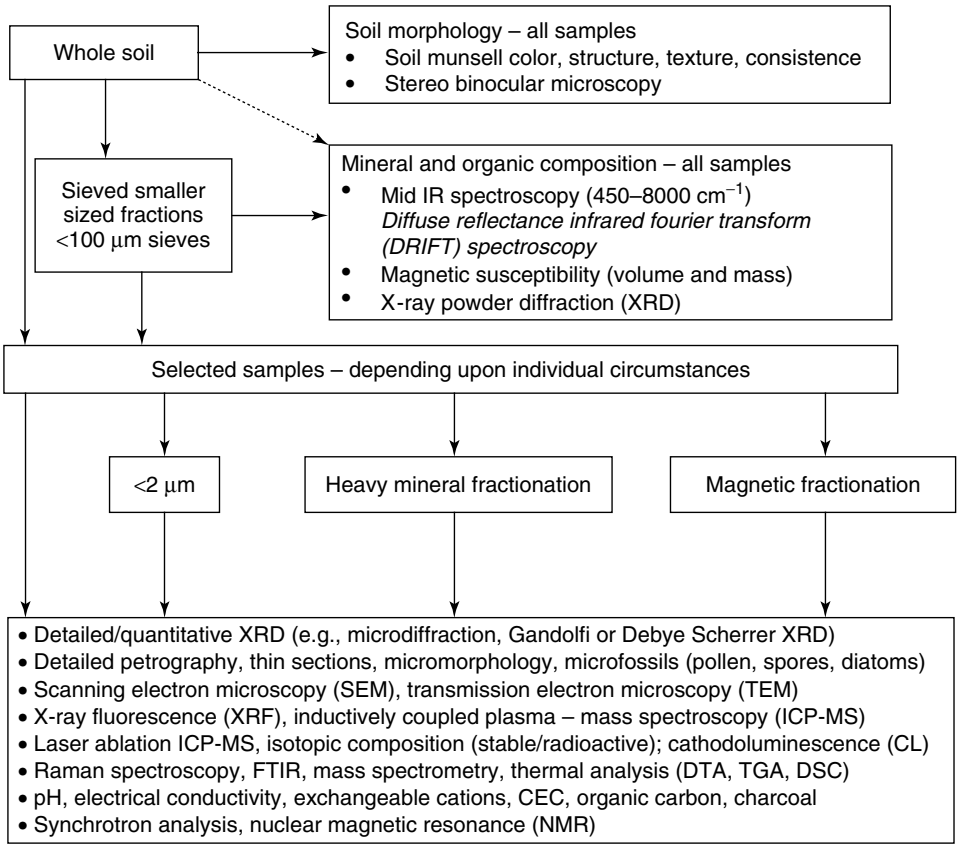

Figure 1 A systematic approach to discriminate soils for forensic soil examinations where FTIR is Fourier transform infrared spectroscopy, DTA is differential thermal analysis, TGA is thermogravimetric analysis, DSC is differential scanning calorimetry, and CEC is cation exchange capacity [3, 28]

eye did not readily observe the yellow-brown color of the fine 5% clay and silt (<50-μm fraction) fractions hidden in the extremely stony/gravelly soil until the sample was sieved and the fine fraction concentrated. This is, for example, often unlike the more obvious bright transfer colors of blood, lipstick smears, and paint chips (*see* **Paint: Interpretation**). Hence, if suspects cannot see fine soil materials adhering to their belongings, especially when they impregnate vehicle carpeting, shoes, or clothing, they will often make little effort to employ a comprehensive cleanup of soil materials.

Computerized Soil Database Capacity

Soil profiles and their horizons usually change across landscapes, and also change with depth in a soil at one location. In fact, soil samples taken at the surface may have entirely different characteristics and appearances from soil dug deeper in the soil profile. One common reason why soil horizons are different at depth is because there is mixing of organic material, in the upper horizons, and weathering and leaching, in the lower horizons.

Erosion, deposition, and other forms of disturbance might also affect the appearance of a soil profile at a particular location. For example, soils on alluvial flats with regular flooding often have clear sedimentary layers. Various soil-forming processes create and destroy layers and it is the balance between these competing processes that will determine how distinct layers are in a given soil. Some of the more common natural processes include the actions of soil fauna (e.g.,

worms, termites), and the depletion and accumulation of constituents including clay, organic matter, and calcium carbonate. In contrast, the main anthropogenic soil-forming processes that destroy layers are excavation (e.g., ploughing and grave digging) and fertilizer applications.

The mapping of the surface and subsurface of both natural and anthropogenic soils provides crucial information as to the origin of a site's specific location, function, land degradation, and management. In Australia, (e.g., [29]) and also in many developed countries in the world, soil data has been encoded into computer-compatible form. Hence, in Australia, for example, a soil map can be produced by downloading information directly from the Internet. The Australian Soil Resources Information System (ASRIS) database has compiled the best publicly available soil information available across Australian agencies into a national database of soil profile data, digital soil, and land resources maps, and climate, terrain, and lithology datasets. Most datasets are thematic grids that cover the intensively used land-use zones in Australia [29]. Hence, the first step when sampling across a region or wider area is to consult these existing/available soil maps of the region of interest in conjunction with or with help from experienced soil scientists. The areas of broadly similar soil type can then be identified as high priority areas for further sampling and comparative analyses – using morphological and analytical information. However, in the absence of obvious features, systematic sampling of the area should be conducted (cross-pattern to fully characterize the soil patterns in the area).

Common and Standardized Techniques Used by Forensic Soil Scientists

Evaluation of Degree of Similarity between Questioned Samples and Control Soil Samples

It is important to first define the word "compare" because no two physical objects can ever, in a theoretical sense, be the same [10]. Similarly, a sample of soil or any other earth material cannot be said, in the absolute sense, to have come from the same single place. However, according to Murray and Tedrow [10], it is possible to establish "with a high degree of probability that a sample was or was not derived from a given place". For example, a portion of the soil (or other earth material) could have been removed to another location during human activity. Pye [11] summarizes different schemes commonly used in the United Kingdom to convey weight of evidence relating to forms of comparisons such as trace or DNA evidence. For example, he has developed "verbal categories" ranging from 0 (no scientific evidence) to 10 (conclusive) – with no statistical significance of the ranks implied. He also states that there is a long history of the use of numerical scales in the context of evidential and legal matters.

Approaches and Methods for Making Comparisons between Soil Samples

Forensic soil scientists must first determine if uncommon and unusual particles, or unusual combinations of particles, occur in the soil samples and must then compare them with similar soil in a known location [2]. To do this properly, the soil must be systematically described and characterized using standard soil testing methods to deduce whether a soil sample can be used as evidence (Figure 1).

Methods for characterizing soils for a forensic comparison involve subdividing methods into three steps: (i) descriptive (morphological), analytical (Figure 1), and spatial information (e.g., mapping).

Soil characterization requires a multidisciplinary approach, which combines descriptive, analytical, and spatial information (e.g., mapping) steps in the following three stages:

Stage 1 – Rapid characterization of composite soil particles in whole soil or bulk samples for screening of samples (Figure 1).
Stage 2 – Detailed characterization and quantification of composite and individual soil particles following sample selection, size fractionation, and detailed mineralogical and organic matter analyses using advanced soil analytical methods (Figure 1).
Stage 3 – Integration and extrapolation of soil information from one scale to next, to build a coherent model of soil information from microscopic observations to the landscape scale (e.g., using existing soil maps or field mapping information). In forensic soil science, a provenance examination or determination, also known as geographic sourcing, has developed to identify the

origin of a sample by placing constraints on the environment from which the sample originated.

Stage1: Initial Characterization of Composite Soil Particles in Whole Samples for Screening

In the initial screening or comparison examination of whole soil samples, soil morphology, low magnification light microscopy, X-ray diffraction (XRD), diffuse reflectance infrared Fourier transform (DRIFT) spectroscopy, and magnetic susceptibility (volume and mass) are used to compare samples *via* bulk morphology, mineralogy, and organic matter characterization.

Soil Morphology – Soil Profiling. Soil morphology is defined as the branch of soil science and pedology that deals with the description, using standard terminology, of *in situ* spatial organization and physical properties of soils regardless of potential land use. Soil morphological interpretation provides a visual, quick, and nondestructive approach to screen and discriminate among many types of forensic soil samples. Morphological soil descriptors are arguably the most common and probably the simplest – and it is for this reason that all samples are characterized first using the four key morphological descriptors of color, consistency, texture, and structure (Figure 1). In many respects, the soil resembles a sandwich with these easily observed characteristics and thickness, which conveys the concept of different soil layers with different properties. In soil samples from crime scenes and control sites in question where soil may have been transported, by vehicle, foot, or shovel, a complete visual description of the soil is essential because it serves as a basis for soil identification, classification [20, 21], correlation, mapping, and interpretation [2, 3].

A checklist of six key macromorphological descriptors has been compiled from standard techniques used in soil science (e.g., [23]) for assessing the soil properties for forensic examinations. Observations of depth changes in various properties are recommended: *viz* consistence, color, texture, structure, segregations/coarse fragments (carbonates and ironstone), and abundance of roots in the different layers or horizons.

The use of petrography is a major and often precise method of studying and screening soils for discrimination in forensics (Figure 1). For example, nearly 50 common minerals (e.g., gypsum), as well as several less-common minerals can easily be seen by the naked eye, but using a hand lens or low power stereo-binocular microscope (**Microscopy: Low Power**) enables the forensic soil scientist to better detect mineral properties (e.g., particle shape and surface texture) and provide more accurate mineral identification. The petrographic microscope (**Microscopy: High Power**) is also commonly available for studying microfossils (pollen grains, grass spores, opal phytoliths, diatoms [11, 16] (*see* **Diatoms**; **Microscopy: Low Power**); and thin sections of soil samples (resin impregnated), minerals, and rocks. Thin sections of soil materials are mounted on a glass slide and viewed with the petrographic microscope under different incident light conditions through its special attachments (e.g., [30]). Where possible, such micromorphological investigations are used to supplement and verify features in macromorphological descriptions. Macromorphological and petrographic descriptors are useful in assessing soil conditions because of the following:

- They involve rapid field and laboratory assessments. Other methods, such as more detailed mineralogy (see below) and geochemistry, are complex and more costly to carry out.
- They can be used to evaluate causes for variations in soil condition induced by weathering (that may range from recent to thousands, to millions, or even billions of years), anthropogenic activities, land management, hydrology, and weather conditions.

Mineral and Organic Matter Identification and Composition. Once a familiarity with the morphology of the materials has been achieved using visual and light microscopic methods, most of the mineralogical and organic matter components in a particular whole or bulk soil sample can be determined using the following three selected methods:

X-ray powder diffraction (XRD) methods. XRD methods are arguably the most significant for both qualitative and quantitative analyses of solid materials in forensic soil science [2, 3, 31]. Extremely small sample quantities (e.g., few to a few tens of milligrams) as well as large quantities can be successfully analyzed using XRD. The critical advantage

of XRD methods in forensic soil science is based on the unique character of the diffraction patterns of crystalline and even poorly crystalline soil minerals. Elements and their oxides, polymorphic forms, and mixed crystals can be distinguished by nondestructive examinations. Part of the comparison involves identification of as many of the crystalline components as possible, either by reference to the International Centre for Diffraction Data (ICDD) Powder Diffraction File [31], or to a local collection of standard reference diffraction patterns, coupled with expert interpretation [2, 3, 31, 32].

Diffuse Reflectance Infrared Fourier Transform (DRIFT) method. The main advantages of DRIFT spectroscopy are that the analysis is nondestructive and can be rapidly applied, and that the mid-infrared portion of the electromagnetic spectrum is sensitive to organic materials, clay minerals, and quartz, due to absorption of infrared light at vibrational frequencies of the molecular functional groups [32–36]. As such, this technique is a powerful qualitative tool, which can then be used semiquantitatively to predict analytes of interest when combined with partial least-squares (PLS) (MIR-PLS) or other chemometric techniques (Stage 2).

A new rapid mid-infrared (MIR) spectroscopic method, coupled with chemometric approaches, specifically PLS (MIR-PLS) modeling has been developed by Janik *et al.* [33, 34] as applied to soils to predict soil physicochemical properties and has been routinely applied to rapidly screen and compare crime scene samples (Figure 1). Principal component analysis (PCA), which models the spectral signatures alone, is also a powerful discriminatory tool, providing an objective method of comparing the mid-infrared spectra of the soil samples being examined when enough samples are available for the technique to be viable.

Mass and Volume Magnetic Susceptibility Methods. Added to the above two rapid methods and techniques are the use of magnetic susceptibility methods, which should also always be used before moving to the more costly detailed methods (Stage 2), which require sample separation (Figure 1). Mineral magnetic techniques are a relatively recent development (post 1971) and have now become a very powerful and widely used research tool to characterize natural materials in landscapes (e.g., [37]).

Stage 2: Detailed Characterization of Composite and Individual Soil Particles

X-ray Diffraction (XRD) Methods. In many soil forensic case investigations, the amount of soil available for analyses (e.g., on clothing or soles shoes) may preclude routine bulk analyses. In such situations, it is best to use an XRD fitted with a system for analysis of extremely small samples (e.g., thin coatings or single particles of the order of 2–10 mg) loaded into thin glass capillaries or deposited onto Si low background holders for XRD analysis [38]. For analysis in a Gandolfi or Debye-Scherrer powder camera, extremely small specimens (e.g., single mineral particles and paint flakes) can be mounted on the end of glass fibers. Consequently, according to Kugler [31], X-ray methods are often the only ones that will permit further differentiation of materials under laboratory conditions. According to Murray [8], "Quantitative XRD could possibly revolutionise forensic soil examination". For example, XRD patterns can also be likened to finger print comparisons between soil samples and how closely they relate to each other [3]. However, what is the significance of the close similarity in XRD patterns to the degree of similarity in terms of mineralogical composition? If the two soil samples, for example, contain only one crystalline component such as quartz (i.e., silicon dioxide), which is very common in soils, the significance of the similarity and its evidential value in terms of comparison criteria will be low. If, however, the two soils contain four or five crystalline mineral components, some of them unusual, then the degree of similarity will be considered to be high [3].

Methods such as XRD, X-ray fluorescence (XRF), and DRIFT spectroscopy, whose results partially overlap, are used. These overlapping results confirm each other and give a secure result to the examination.

Scanning Electron Microscopes (SEM) and Transmission Electron Microscopes (TEM). Scanning electron microscopes (SEM) (*see* **Microscopy: Scanning Electron Microscopy**) and transmission electron microscopes (TEM) are frequently used to examine the morphology and chemical composition (*via* energy dispersive spectroscopy) of particles magnified to over 100 000 times their original size making them very useful for discrimination (e.g., [39–41]).

Soil minerals, fossils, and pollen spores that occur in soils [42] can be described and analyzed in detail by SEM and TEM, and are therefore very useful indicators when studying soil samples (e.g., [11, 16, 39–41]).

Elemental Analysis. The following range of more prevalent instrumental techniques are frequently used to determine the inorganic constituents in soil samples: XRF, atomic absorption spectroscopy (AAS), inductively coupled plasma (ICP) spectrometry, inductively coupled plasma-optical emission spectrometry (ICP-OES) (sometimes called *ICP-AES*), inductively coupled plasma-mass spectrometry (ICP-MS), and neutron activation analysis (NAA) [4–12]. Several geochemical techniques, using isotope ratios and geochemical signatures have been utilized in forensic work (e.g., [43]).

Biological Methods. Fossil pollen grains (*see* **Palynology**) and grass spores are preserved in many soils that are not strongly acidic (<pH 4) or alkaline (>pH 6). These reproductive particles are produced in large amounts by trees, shrubs, and grasses [7–11, 16]. Opal phytoliths (silica-rich) and calcium phytoliths are mineral deposits that form in and between plant cells. Marumo and Yanai [42] used opal phytoliths to differentiate soils with similar mineralogy. As stated earlier, FTIR can be used to characterize soil organic constituents (fats, waxes, proteins, cellulose, hemicellulose, and lignin) in soils [4, 33–36]. Other emerging soil forensic methods such as (i) plant wax markers analysis are summarized in Dawson *et al.* [4], (ii) plant fragment DNA analysis [4], and (iii) microbial fingerprinting using a variety of molecular biological techniques to analyze the diversity in soil microbial communities for forensic soil comparison [4, 44]. Several soil forensic studies have been reported [44, 45] to show that a soil bacterial community DNA profile could be obtained from small samples of soil recovered from potential crime scenes (e.g., shoes or clothing) with the profiles being representative of the site of collection.

Combined Methods. All these techniques and others listed in Figure 1 (e.g., heavy and magnetic mineral separations, routine soil chemical analysis, laser ablation, Raman spectroscopy, thermal analysis, NMR, and synchrotron analysis) in combination achieve reliable, definite, and accurate results, and provide additional information about the mineralogical, chemical, and physical properties of the suspected soil material.

Stage 3: Landform and Soil Mapping

Integration and extrapolation of soil information are necessary because soils from the crime scene and control site may constitute a highly variable continuum. Hence, integration of published soil maps or field mapping information together with other spatially held information, such as (i) terrain analysis Digital Elevation Model (DEM), (ii) regolith, geological, or vegetation maps, and (iii) remote sensing or geophysics data [13–15] are designed to study relationships between soils, landforms, and/or the stratigraphy of parent materials. This information will also ensure (i) better-informed sampling (i.e., pedometric testing of how "similar" soil on a suspect's shoe is to a scene of crime [46]), and (ii) construction of a coherent model of soil information from microscopic observations to the landscape scale (e.g., physical, chemical, or biological mechanistic process models). Decision making in forensic soil science is sometimes guided by mechanistic process models describing processes with physical, chemical, or biological mechanisms [2–15]. Some models use multiple data layers as spatial input. The data required for the analysis are frequently found in and extracted from soil and environmental databases such as geographic information systems (GISs).

Soil, regolith, and geological maps are commonly being used by forensic soil scientists in developing models to predict where sites of particular soil materials are located. An example of this relationship is from the staff in the Centre for Australian Forensic Soil Science (CAFSS) using soil maps and conducting field soil survey investigations to solve a double murder case [47, 48]. Morphological, chemical, physical, and mineralogical properties were used to identify similarities between soil found on a shovel taken from the suspect's vehicle and soil subsequently located in a quarry. Samples were indistinguishable or strongly matched in terms of all comparison criteria used, thus revealing the location of two buried bodies.

Forensic soil examination can be complex because of the diversity and heterogeneity of soil samples. However, such diversity and complexity enables

forensic examiners to distinguish between soils, which may appear to be similar. There is a general lack of expertise in this relatively new area among soil scientists. For research and practical application in this area to grow appreciably, it will need to be considered and taught as an integral part of both soil science and forensic science courses [2, 3]. Finally, an attempt should be made to develop and refine methodologies and approaches to develop a practical "soil forensic manual with soil kit for sampling, describing, and interpreting soils" [3].

Speaker Recognition

Introduction

The global success of mobile telephony provides an opportunity for extensive use of audio recordings to search and establish links between individuals and criminal activities. However, establishing these links through speech applying forensic speaker recognition often remains the last resort for forensic investigation and as evidence in court, in the absence of any other clues. The reason lies in the following difficulties: first, the behavioral component of voice is dominant over the physical component of this biometric modality, preventing the display of highly discriminatory features yet; second, the quality of audio recordings captured in forensic conditions is most of the time far from ideal; and third, the absence of any known underlying model prevents a symbolic description of the speaker-dependent information and limits the study to recognition approaches. To tackle these pitfalls, forensic speaker recognition has been established as a multidisciplinary area of study, predominantly combining phonetics, linguistics, speech signal processing, and forensic statistics.

Speech as a Trace

Speech is a behavior developed by human beings for communication. Speech production is a complex process depending on physiological traits, like the length and shape of the vocal tract and the dynamic configuration of the organs involved in articulation. It also depends on environmental and sociolinguistic factors, like the level of education, the dialectal particularities and the linguistic context. Speech can convey up to six types of information simultaneously (referential, poetic, emotive, conative, phatic, and metalingual). It is an inherently transient phenomenon that can only be imperfectly captured as a signal. A forensic trace involving speech is a storage medium containing an analog or digitally recorded speech signal (*see* **Computers**).

Where the recording consists of a wiretapped telephone call, the trace is generally recorded in uncontrolled conditions, including undesired variations in signal quality due to background noise, transmission channels, and recording devices. Anonymous calls are generally short, from seconds to minutes. Where it is a monologue, it may be a prerecorded message, possibly modified by a filtering or editing procedure. From a lexical point of view, the themes are targeted, e.g., abuse, extortion, obscenity, and/or threats. Results of wiretapping procedures can reach hundreds of hours of recording. Their lexical content is varied but some utterances may refer to internal codes for groups or organizations.

Owing to the absence of highly discriminative features in speech and the uncontrolled recording conditions, individualization of speakers remains a very difficult field of inference of identity in forensic science at the source level, but when solved, inferences at the activity and even at the offense level are most of the time straight.

Forensic Speech Analysis

The speaker-dependent features are spread out over the information conveyed in the different levels of speech communication, but they originate in the two main stages of voice production: the language generation and the speech production. For speaker-recognition purposes, these features can be classified as high- and low-level features. High-level features refer more to the linguistic information of speech i.e., as a behavior and its understanding by human beings while low level features refer more to the speaker's vocal physiology and signal processing by automatic approaches.

The main requirements for the methods applied by human beings and computers for forensic speech

analysis are the independence of the text, the ability to handle minimal length recordings and a superior robustness regarding noise, channels, and variations in recording conditions. Efficient analysis strategies combine both high- and low-level features; many of the high-level features need more speech material than the low-level features for a reliable extraction, but they are generally more robust regarding channel variation. Therefore, the methodology for forensic analysis of human speech should ideally combine expert-based and automatic approaches.

Expert-Based Approaches

Expert knowledge has developed around three main approaches: auditory-perceptual, visual, and phonetic–acoustic.

The auditory-perceptual approach was developed during the first part of the twentieth century. It consists of a detailed auditory analysis of the parameters of the voice such as the pitch, the timbre and the voice quality, the parameters of the speech such as the articulation, the diction, the prosody (speaking rate, pauses, and intonation), any speech defects, and the parameters of the language spoken. It includes linguistic observations of lexical, phonological, morphological, syntactic and idiomatic features, the study of the extent and the variation of the dialect, the accent and the idiolect, and also takes into account paralinguistic features such as breathing patterns. The auditory-perceptual approach does not easily lend itself to validation; it remains a first step in the analysis, but is clearly insufficient if used alone.

The visual approach was developed in the 1960s in the United States under the name of 'voiceprint' technique. It comprises a visual comparison and interpretation of broadband speech spectrograms made by 'experts', most of whom had no scientific education in a speech science or related area. From its conception, the theoretical and logical grounds of the technique were contested. First, the term *voiceprint* is a misleading analogy to the fingerprint and its associated qualities of uniqueness, inalterability, and permanence; none of them apply to the voice and to the speech spectrogram. Second, confusion exists between the degree of reproducibility of the production of spectrograms (analysis) and the high degree of uncertainty associated with the individualization process (interpretation), which can be described as closer to art than science. Since the publication of the National Academy of Science (NAS) report in 1979, some US jurisdictions reject the admissibility of the technique although some still allow it. The Daubert decision (1993), advocating a reliability standard for the admissibility of scientific evidence, clearly militates against the use of this kind of nonvalidated approach, but the US jurisdictions have not adopted a uniform practice in this matter yet [1, 2] (*see* **Expert Opinion: United States**).

The acoustic–phonetic approach was developed during the 1980s. The methodology consists of a set of instrumental measurements of particular acoustic speech parameters present in the segmental and suprasegmental level of the speech. The segmental analysis focuses on the duration and the spectral distribution of energy of the segments, the vowel formant frequencies, their trajectory, and, more recently, their dynamics. The suprasegmental analysis concentrates on the measurements of the long-term features, like the long-term average spectrum of the speech signal, the long-term distribution of formants and different parameters of the fundamental frequency (F_0), as the long-term F_0, the mean F_0, and the deviation of F_0. Once measured, the parameters are interpreted using statistical information on their distributions [3, 4].

Automatic Approaches

Attempts to use computers for forensic speech analysis started in the 1970s, first using semiautomatic methods and from the 1990s using text-independent automatic methods. These automatic methods rely on speech processing, to extract speaker-dependent feature vectors from the speech signal, on pattern recognition to compute comparison scores between feature vectors, and on Bayesian statistics to estimate the evidential value of these comparison scores [5, 6].

State-of-the-art automatic speaker-recognition systems still rely on low-level speaker-dependent features, extracted from the short-time spectral level. The spectrum of the speech signal, analyzed in short-term windows, is directly related to the shape of the vocal tract, which presents speaker-dependent specificities. The spectral envelope is described efficiently using linear predictive coding (LPC) in an all-pole model with 10–16 coefficients. However, as these coefficients are correlated, the cepstrum transform has

been proposed in order to obtain pseudo-orthogonal linear prediction cepstrum coefficients (LPCC). They may also be obtained from a perceptually based mel-filter spectral analysis (mel frequency cepstral coefficients (MFCC)). Other low-level features, which capture the dynamic speech patterns, like delta and even delta–delta features have also been proposed, but LPCC and MFCC are the most widely used low-level features for automatic speaker recognition. Current systems also intend to take advantage from high-level speaker-dependent features, mainly contained in the phonotactics, the prosody, and the idiolect. In phonotactics, speaker-dependent information is embedded in the particular use and realizations of the phones and syllables that presents a highly language-dependent variability. Prosody is the combination of instantaneous energy, intonation, speech rate, and unit duration, which all exhibit speaker specificity. The idiolect contains the information related to the speaker-specific use of a language [7].

Numerous pattern-recognition methods have been developed to model and compare the speaker-dependent spectral features, i.e., vector quantization (VQ), ergodic hidden Markov models (E-HMM), artificial neural networks (ANN) and lately support-vector machines (SVM), but most of the current systems are based on Gaussian mixture models (GMM). GMM is a generative method where a mixture of multidimensional Gaussians model the probability distribution of the speaker-dependent features. Various kinds of score normalization have also been developed using prior information like the handset type or the gender information during the normalization parameter computation to improve the performance of the methods. Forensic systems mainly use a particular class of normalization techniques that rely more on the estimation of the alternative hypothesis used in the Bayesian framework than on a normalization scheme, the world-model and cohort-based normalizations [8].

Until the last decade of the twentieth century, the forensic interpretation of the results given by automatic approaches remained difficult, as solutions concentrated on decision theory and frameworks applied in commercial applications of automatic speaker recognition: speaker verification ($1:1$) or speaker identification ($1:N$ or $1:N+1$).

Nowadays, the evaluation of forensic evidence in speaker individualization cases is based on the latest developments of forensic statistics. The automatic systems not only deliver likelihood ratios but also the accuracy and the calibration of the probabilities inferred by these likelihood ratio values are tested [7, 9].

Forensic Individualization through Speech

Forensic individualization through speech is a question of inference of identity of source. In essence, the answer to the question that is provided by science remains inductive and therefore relative. Nevertheless, the use of a framework based on logic and forensic statistics to interpret the results of forensic speech analysis, allows for the most scientifically correct answer to be reached (*see* **Identification and Individualization**).

With this framework, a practitioner may report logical, robust, and balanced statistics to a court of justice, presenting the evidence according to the prosecution and the defense hypothesis as a likelihood ratio. Moreover, the examiner may combine likelihood ratios evaluated for the auditory-perceptual and acoustic–phonetic approaches based on subjective estimates of the probability of the occurrence of specific features with likelihood ratios estimates of automatic approaches, based on more objective probabilities.

The adoption of this interpretation framework by the practitioners is an ongoing process, but the forensic speaker-recognition community has pioneered from a long time in this matter actively searching for solutions to resolve the logical flaws of an interpretation given in terms of posterior probabilities of common origin for the trace and the source [6, 7, 10].

Validation and Practice

Most of the forensic laboratories still opt for one of the two approaches, even if, in many respects, the expert-based and automatic approaches appear to be complementary. For example, much larger amounts of speech data can be handled automatically than manually, which affects both validation and practice. Validation of automatic methods may be envisaged on a far larger scale than expert-based methods, bringing far more accurate figures for the former than for the second method [11]. Automatic methods are also less dependent on the language spoken, making their validation possible for different languages and

their versatility superior for practical use. In practice, automatic approaches can be used in about one-third of cases, particularly for cases with a large amount of speech material.

Expert-based methods are claimed to be more flexible for cases with qualitative and quantitative limitations and more robust for speech samples with strongly mismatched behavioral and technical conditions, or those containing linguistic or dialectal particularities. Finally, since experts are phoneticians or linguists, the expert-based methods are more easily explained in a court of justice, where they often perceive automatic methods as 'black boxes' [12].

Research and Development

Improvement in forensic speaker recognition requires to study the dependences of the results obtained with the expert-based and automatic approaches, as they appear to be complementary. This, in turn, can only be achieved through the coordination of research and development.

Methods may be developed and implemented to monitor, more carefully, the inevitable subjective components in the expert-based approaches. The development of double-blind approaches for selecting and grouping speech samples in the preanalysis phase of cases may reduce the effect of confirmation bias. It may also increase the calibration of the practitioner regarding the voice, the speech, and the language particularities of the speakers involved in the case. Studies in order to estimate the statistical probabilities of the features used in the expert-based approaches could help the practitioners to improve and calibrate the subjective probabilities they assign to these features based on their training and experience.

The relevance of the features selected may be studied using Bayesian networks and their correlations analyzed with multivariate likelihood ratio approaches. Collaborative exercises and proficiency testing are recognized tools to monitor the expert-based practice, but they encounter two major difficulties in the field of forensic speaker recognition: they are very time consuming and the language dependencies constitute a barrier to their organization at an international level.

The robustness of the automatic approaches to mismatch conditions may also be improved with further development of noise, channel, and recording distortion compensation strategies. Phonetics and linguistics may further contribute to develop more robust and automatic feature extraction and processing of higher level features from speech samples of forensic quality. Knowledge of the language dependency of both approaches, expert based and automatic should also progress, as cases may involve a broad variety of languages.

Species Determination of Osseous Remains

The first question that may come up when dealing with much degraded skeletal remains is whether they are human or not. In fact, at times it is even necessary to verify whether the "remains" are actually composed of osseous or dental material, and not other types of organic or inorganic substance. Small pieces of burnt plastic or other mineral material may resemble bone very closely, and further microscopic or chemical investigations are needed to verify the proper origin. This happens quite frequently with burnt remains, as can be seen from the examples given in Figures 1 and 2.

Once it is determined that the fragment is truly dental or skeletal material, the next step is to verify the species of origin and, usually, whether it is human or not. Investigating authorities need to know whether the fragments belong to a human, for the obvious criminal implications. The facility with which one can determine the origin of such fragments depends on how complete the remains are [1–10]. If the remains, for example, bones or teeth, are voluminous, frequently macroscopic morphological characteristics allow for species identification. Dimensions, shape, and structure are the fundamental parameters. Entire bones, especially if one has experience and an idea of the comparative anatomy of different mammals, are relatively simple to distinguish from human bones, unless some gross malformative pathology is involved. More difficult to interpret are the bones of hands and feet, especially phalanges, quite similar among different animals (for example, man and bear). The articular surfaces of animals are frequently more profoundly beveled and very different

Figure 1 Small fragments (the longest of 8 mm) of presumed bone found in a small metal container (usually used for holy hosts of the catholic ritual) of a young man who had been arrested for attempted murder and was known to be implicated in satanic rites. Investigating authorities wanted to know whether these burnt fragments could be bone, and, if so, if they belonged to the human species

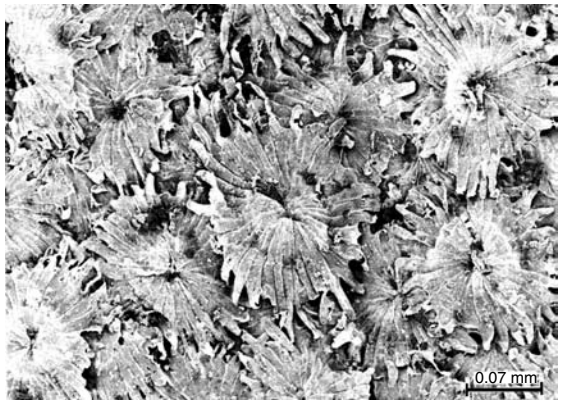

Figure 2 Scanning electron microscopy image of one of the fragments. The material was not of skeletal but of botanical origin; it was an olive gem. The pieces were part of the holy ashes stolen from a church (these are, in fact, produced from burnt olive branches) for satanic ritual purposes, but they did not involve human remains

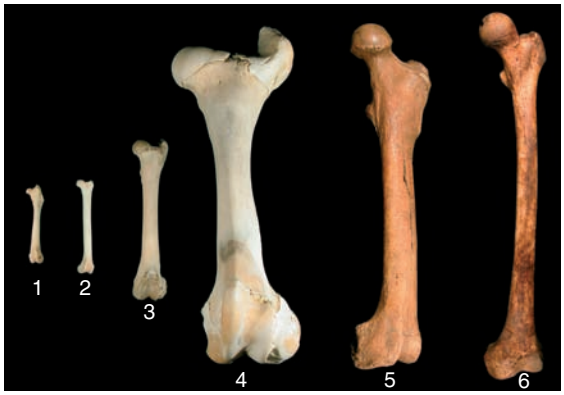

Figure 3 Left femurs of different species. (1) Rabbit (*Oryctolagus cuniculus*); (2) cat (*Felis catus*); (3) goat (*Capra hircus*); (4) cow (*Bos taurus*); (5) bear (*Ursus spelaeus*); (6) man (*Homo sapiens*). One can observe some similarities between man and bear

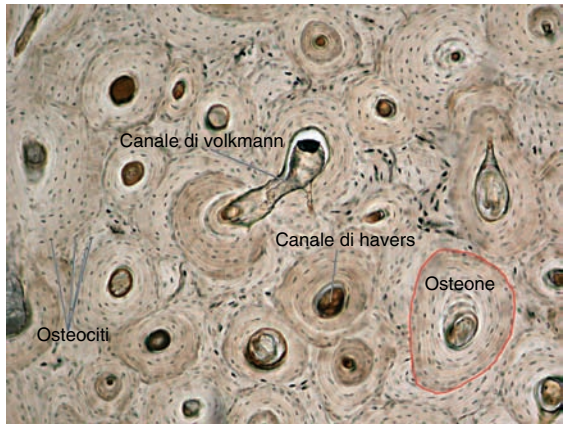

Figure 4 Microscopic structure of bone. Section of undecalcified bone (100×) showing secondary osteons, Haversian canals, and osteocytes

from human ones. Figure 3 shows the comparative morphology between different femurs of commonly found animals.

It is far less easy to determine the species of origin when the material is much more fragmented – for example, with fragments of bone diaphyses or fragments of cranial vault. In some cases, the surface of the bone may have a more coarse texture as opposed to humans or have a different kind of cross section. Cross sections of bird bones, which may apparently seem similar to infant bones, show a very thin cortex with internal lamellae of bone crossing the hollow shaft – infant bones will not have this design. Furthermore, the thickness of the bone cortex is greater in large mammals with respect to the entire diaphyseal diameter. Bones of the cranial vault may also be problematic. Here, the design of vascular sulci may be a good giveaway for human origin, but other areas of the cranium may be more problematic. Fragments of the nasal bone, for example, of small mammals may have a very similar texture to human ones. Even dental fragments can be tricky. The entire tooth is almost never a problem to an expert osteologist; however, fragments of root or crown can be difficult. In particular, fragments of crowns of goat, sheep, and bovine incisors may be similar to those of humans, as pig premolars may also be problematic. It is, therefore, sometimes impossible to perform a diagnosis based merely on macroscopic morphological features. In these cases, one may resort to two other types of methodologies: histological and biomolecular. The choice of one or the other must be performed considering the state of preservation of the fragment. DNA techniques are extremely sensitive; however, they are frequently impaired by severe degradation and calcination. In such cases, microscopic analyses may be a better bet.

Study by transmission light microscopy of thin (100 μm) undecalcified sections (decalcified sections may be used but are more complicated to prepare) prepared simply by grinding the section, which has been fixed onto a slide with resin, down to a thickness of 100–150 μm, allows one to observe microscopic characteristics of the bone, which may help in the diagnosis of species. Bone microscopic structure is made of primary and secondary osteons (Figure 4), fragments of osteons, and lamellar bone, which are in constant remodeling. The fundamental issue for species determination is the design and distribution of the osteons, shape of the single osteons, and their dimensions.

Osteons of the human species are usually distributed irregularly within the bony matrix. A classical means of exclusion is the presence of plexiform bone, i.e., with osteons set in parallel rows. Basically, human bone is nonstratified, vessels run in a longitudinal manner. Furthermore, osteon circumference can be quite important. Some animals have irregularly shaped osteons, with folds along the external circumference. The circumference of human osteons is always neat, regular, and circular (Figures 5–7).

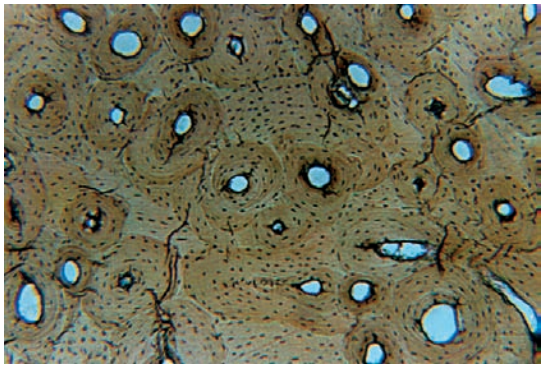

Figure 5 Thin undecalcified section of man (*Homo sapiens*) bone, which shows the typical human osteon design with a random distribution

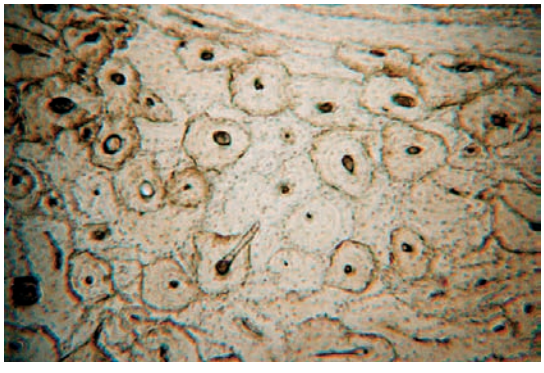

Figure 6 *Felis catus* (cat), which shows smaller Haversian canals with irregular margins of each osteon

However, other mammals have regular osteons also. In this case, it is necessary to perform a metric analysis of the secondary osteon.

Dimensions of the osteon and Haversian canals may be telling. These structures are obviously smaller in small animals and reach maximum dimensions with man. For example, the area of the cross section of a human osteon is usually around $0.039\,\mathrm{mm}^2$; the dog, on the other hand, is $0.018\,\mathrm{mm}^2$. Mammals larger than man do not have significantly larger osteons.

An algorithm including Haversian duct area and lowest and highest diameters, which can indicate human origin of bones, has been devised.

$$D = -3.99 - 0.07(C) + 0.04(D_{\mathrm{m}}) + 0.07(D_{\mathrm{M}}) \quad (1)$$

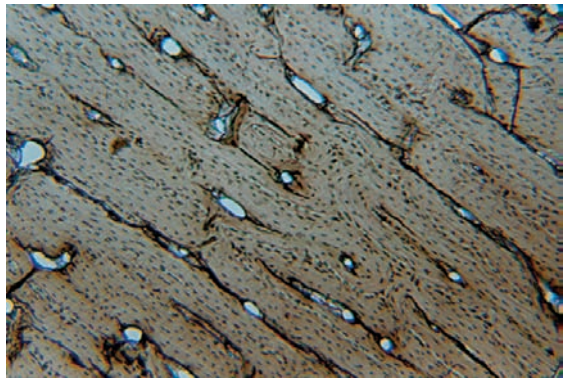

Figure 7 The presence of plexiform bone in horse (*Equus caballus*). Notice the parallel distribution of lamellar bone and osteons

where C is the Haversian canal area; D_{m} is the Haversian canal lowest diameter; D_{M} is the Haversian canal highest diameter. Where D is a positive number a human origin is established with an 80% accuracy; if negative it should be non human. Nevertheless, this method has been tested so far only on long bones; we still ignore variability of osteon characteristics in other bone districts [11].

Similar remarks may be said for the histological structure of teeth. In these cases, however, scanning electron microscopy (SEM) microscopy is the key method, since differences among certain groups of animals can be noticed, especially in enamel prism disposition. Amelogenesis, the process of production of enamel, leaves significant signs in the structure of teeth. Crystallites are organized in 5-μm fibers called *prisms*. Crystallites within and around these prisms change in their orientation. There are three different kinds of pattern they form.

- Pattern 1 has discrete prisms with complete margins and has an oval-to-circular pattern.
- Pattern 2 shows prisms with a horse-shoe section.
- Pattern 3 is similar to pattern 2 but has more of a keyhole appearance.

The latter is typical of humans, but not unique. Therefore, identification of patterns 1 and 2 may reveal a nonhuman origin, but pattern 3 is shared by humans, other primates, and even some lagomorphs (e.g., rabbits and hares). With respect to bone histology, however, dental microscopic features are not preserved in burnt remains.

A final procedure, when others fail, for species identification may be the biomolecular approach. The goal is to be able to extract species-specific biomolecules. Obviously, DNA is the primary choice nowadays, but even though the sensitivity of polymerase chain reaction (PCR) techniques and sequencing has greatly increased, the problems of extraction, contamination, and degradation must not be overlooked. DNA procedures in forensics have been treated in other sections, but a brief comment on other biomolecular techniques is certainly necessary.

Since the 1950s, the notion of species-specific proteins exists and there are innumerous techniques used to this effect. Most are based on the antibody–antigen reaction, which can be used in several kinds of immunoassays such as immunoprecipitation, agglutination, enzyme-linked immunosorbent assays (ELISA), and radio-immunoassay (RIA). The advantage of the search for epitopes or antigens of a protein nature lies in their relative abundance and resistance to degradation. This is true particularly of simple proteins such as albumin. Albumin has been studied in thousands of species in order to reconstruct genealogical trees and is extremely species-specific. Of all seroproteins, albumin seems to be the best adapted, more than collagen, IgG, and hemoglobin for species determination: it is present in higher concentrations in blood and tissues, it is a simple molecule, and is an easy immunogen.

Extraction of species-specific proteins from bone and tooth powder can be obtained by incubation in chelating substances such as ethylenediammine tetracetic acid (EDTA).

Once extracted, several techniques are available. Naturally, there are less-sensitive techniques such as RIA and immunodiffusion, or safer and more sophisticated ones such as ELISA. In practice, the antigen (in this case, a species-specific protein such as albumin) is blocked onto a plastic surface, and a monoclonal antibody to that specific antigen is then used to detect that specific protein via the antigen–antibody reaction (Figure 8). Specificity of the test is an absolute prerequisite. This is guaranteed by assays performed, for example, with the use of monoclonal antibodies, which decreases the risk of false-positive results.

The advent of DNA analysis has certainly slowed down other investigative techniques and research in this area, such as protein analysis or the study of the microscopic structure of bone, all useful tools in verifying whether the fragment is human or not. Such confidence in DNA may be dangerous. In many instances, for example, with charred or very dry bone, DNA may be very difficult to extract. Thus protein analysis or the study of the microscopic structure of the fragment may be useful, and, at times, the only applicable method. However, research in this area is relatively scarce and has stopped at the late 1990s with few exceptions. More research needs to be performed in this area. It is known that proteins are more resistant than DNA to many environmental factors and thus methods for detection of species-specific protein in bone should be encouraged, such as immuno-PCR, a technique that amplifies the sensitivity of immunological ELISA tests by tagging a DNA marker to one of the ELISA reagents and subsequently performing PCR.

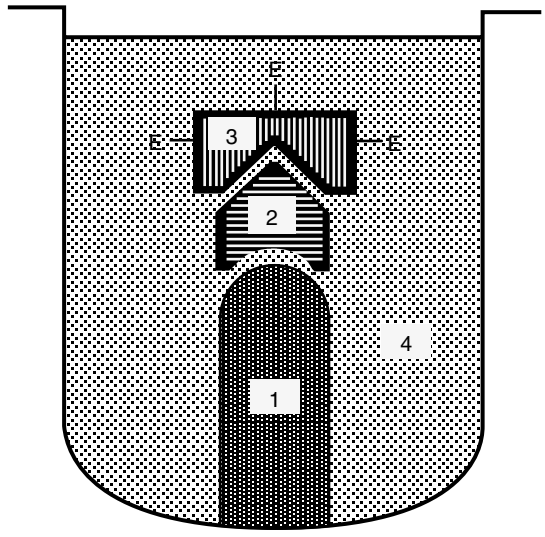

Figure 8 Schematization of an immunoassay (ELISA). In the figure, (1) is the molecule one is looking for, which should be contained in the bone extract, and which has been adsorbed – if present – onto the test plate; (2) is the antibody, which recognizes (1), if present, and "clings" onto it; (3) is a molecule, which is used to link (2) to E, which is a coloring agent that will change from a transparent color to brown or green (4) usually (depending on the enzyme used). This chain sequence that ends with a coloration of the plate proves the presence of a specific molecule in the bone extract

Stalking

The crime of stalking contains three elements: a pattern of unwanted following or harassment; a credible threat; and the induction of fear in the victim. Without victim awareness, there is no crime of stalking. This eliminates the inappropriate application of the term *stalking* to describe violent crimes in which some form of surveillance precedes an attack, such as rape or robbery. Unwanted pursuit and sustained fear are the *sine qua non* of stalking.

Large-scale representative studies of stalking across three continents indicate that 2–13% of males and 8–32% of females will be victimized by a stalker at some point in their adult lives [1]. These figures encompass clinical, forensic, general population, and college samples. Females are the target in 80% of the cases, and half of all stalking cases involve a prior sexual intimate as the perpetrator. The average

duration of stalking is 2 years, but in one large study the modal duration was 1 month [2]. Most stalkers have known their victim in some capacity before the stalking begins. Unfortunately, stalking is a crime that has only received attention in Westernized developed countries, although other areas of the world are beginning to take notice [3].

The most validated typology of stalking is called *RECON* (relationship and context), and identifies four groups of stalkers: those who target prior intimates, prior acquaintances, public figures, and private strangers. This typology was developed utilizing a large nonrandom sample of stalkers ($N = 1005$) in North America, and showed both excellent interrater reliability and discriminate validity [2].

Stalking behavior predictably includes a number of tactics: (i) hyperintimacy – rapidly trying to accelerate intimacy, which induces fear or anxiety in the victim; (ii) proximity/surveillance – watching or following the victim; (iii) invasion – violating the privacy of the victim; (iv) proxy pursuit – using third parties to follow the victim; (v) intimidation or harassment – threatening or psychologically manipulating the victim; (vi) coercion/constraint – forcefully restricting the behavior of the victim; and (vii) aggression – being violent toward self, the victim, third parties, or property [1].

One-third of stalkers will be physically violent toward their victim during the course of their pursuit [1]. The frequency of violence substantially increases when the stalker is a prior sexual intimate of the victim, and exceeds 50%. This is a replicated finding in major urban areas on three continents [4], and suggests that sexual intimacy intensifies attraction, attachment, and emotional reactivity when a bond is threatened.

The nature of the violence in such cases is *affective*, characterized by heightened autonomic arousal, anger or fear, the presence of a threat (usually fear of abandonment), and a lack of planning. It is impulsive, reactive, and immediate. Such violence contrasts with the nature of violence when a public figure is stalked and attacked, which is typically *predatory*: planned, purposeful, and emotionless. These two modes of violence are psychobiologically distinctive in mammals, including humans [5]. Risk of homicide in all stalking cases involving prior sexual intimates is estimated to be 0.25% [6], and data suggest that stalking is a risk factor in the prediction of spousal homicide [7].

The prediction of violence research has found a number of variables that are significantly related to stalking violence, including the presence of threats, substance abuse, a prior sexually intimate relationship, personality disorder, a history of violent behavior, and the absence of psychosis [8]. The most advanced work in the prediction of stalking violence has utilized a regression tree approach, which generates subgroups that have different probability estimates of violence through the interaction effects of the predictor variables [9]. The most useful model contains nine variables: age under 30 years, education less than high school, threats toward the victim, prior intimate relationship, revenge motivation, psychotic disorder, personality disorder, substance abuse history, and criminal history [10]. The directionality of some of these variables depends on their interaction with other variables. Such sophisticated models will likely pave the way for actuarial software programs, which will fairly accurately assess the risk of violence over a particular period of time.

The paradox of stalking – an individual is pursued that is continuously rejecting – is best understood as a pathology of attachment. Attachment is a biologically rooted, species-specific behavioral system that is either secure or insecure, and in cases of stalking, the attachment pathology is insecure and often *preoccupied*. Numerous studies have tested and confirmed this hypothesis [11]. Kienlen found in a small sample of imprisoned stalkers that the majority had lost a primary caretaker in childhood and had also suffered a major loss within a year prior to the onset of stalking. These two findings suggest both predisposing and precipitating events that may contribute to the onset of stalking [12].

Adult stalkers are typically males in their fourth decade of life with prior psychiatric, drug abuse, and criminal histories. They have both a major mental illness and a personality disorder [13], often necessitating a psychiatric and psychological evaluation to discern the best approach to treatment and risk management. Psychosis occurs in a minority of stalkers, but is more likely among stalkers of strangers. Questions remain concerning the psychopathology of college students who engage in "obsessional relational intrusion," a subcriminal form of stalking [14].

Stalkers are preoccupied with thoughts of their object of pursuit. If an obsession is functionally defined as an abnormal frequency of preoccupation with an object, substantial data indicate that

obsessional thinking is the most common cognitive trait of the stalker [15]. The content of the stalker's conscious thoughts varies from case to case, but thinking is generally characterized by paradox and contradiction. Examples include the juxtaposition of statements that both idealize and devalue the victim; the wish for complete freedom for the victim alongside demands for complete control; or statements of rage commingled with yearnings for love and affection.

The preoccupations and contradictions that characterize the stalker's thinking may be unconsciously rooted in "narcissistic linking fantasies," recurrent thoughts of a special and unique relationship with the love object [16]. Such fantasies are normal in the initial stages of romance or infatuation, yet in the case of stalking, they are met with rejection when acted upon, and they usher in emotions of intense humiliation and rage that the stalker will express toward the victim. In normal men and women, romantic rejection often triggers feelings of grief, anger, and sadness, and the search for a new love object. When pathological narcissism predominates, such as one sees among stalkers, the intensity of their fury is a measure of their degree of ego deflation, and the pursuit begins.

The two most prominent emotions among stalkers are anger and jealousy [17]. Such feelings are often consciously felt and acknowledged by the stalker, but often defend against other more vulnerable feelings outside his awareness, such as shame, loneliness, isolation, and social inadequacy. Anger often fuels the pursuit of the victim, and may be further motivated by envy to damage or destroy that which cannot be possessed, or a wish to inflict pain upon the one who has inflicted pain, the primitive impulse of *lex talionis*, an eye for an eye. Anger can also repair narcissistic wounds through a fantasized sense of omnipotent control over the victim. Victim surveys have noted that the most common perceived motivation of the stalker is a desire to control [18].

Jealousy is a complex emotion and is defined interpersonally as competition for the love of the object. Pathological or morbid jealousy may be apparent in some stalkers and may reach delusional proportions, sometimes seen in cases of celebrity stalking [19]. Jealousy also may motivate behavior to dominate and isolate the victim, and has predicted stalking in one study [20].

The psychological defenses used to manage such intense emotions include minimization, denial, projection of blame, and projective identification [21]. Defenses serve to protect the stalker's inflated sense of self, but at a price. He remains vulnerable when confronted by his behavior, which paradoxically can escalate his rage. He inhabits an intrapsychic world populated by his own persecutory objects, but his sense of being persecuted can be confirmed by third parties, such as a husband, an attorney, or a police officer, who are trying to stop his incessant pursuit.

Although most stalkers are male, 15–20% are female. Female stalkers are less likely to have a history of violent criminality or substance abuse, and less likely to stalk a stranger. They are more likely than male stalkers to pursue a professional contact and to pursue a victim of the same gender. Threat and assault rates, on average, are the same as men, but women are less likely to threaten and then assault [22]. In one large study of female stalkers [23], the women were in their 30s, single, educated, and intelligent. A minority were prior sexual intimates of the victims, who were slightly older men. Unlike male stalkers, female stalkers are motivated to *establish* intimacy with the victim, whereas their male counterparts are attempting to *maintain* intimacy with their victim [22, 23].

However, the more intimate the relationship had been prior to the stalking, the greater the risk of violence. The most common documented emotion among the women was anger, particularly abandonment rage. The most common personality diagnosis was borderline personality disorder. Pathological narcissism appears to be less frequent among female stalkers, who are more intent on forming a relationship to assuage feelings of loneliness, dependency, and anger.

Victim impact in stalking cases is severe and chronic. More than one-third of stalking victims will incur a psychiatric diagnosis that will persist long after the stalking has ceased [24]. Many victims have their personal and professional lives seriously disrupted. Risk management of stalking cases is long term, difficult, and complex due to the reluctance of law enforcement to prosecute such behavior and the impressive tenacity and intelligence of many stalkers. Effective management encompasses many principles, which have been elucidated elsewhere [25, 26], but generally focuses upon four recommendations:

First, stalking victims often minimize or deny the crime being committed against them for weeks or months. It is imperative that any unwanted pursuit that induces fear should be recognized as a serious problem, if not a criminal activity, and be treated as such.

Second, stalking victims often attempt to resolve the problem alone. It is imperative that professional help be sought, including contact with both law enforcement and mental health. Stalkers are typically psychiatrically impaired, and efforts to dissuade a stalker often involve simultaneous police and psychiatric interventions.

Third, stalking victims often destroy evidence. It is imperative that all evidence of unwanted pursuit, including notes, letters, e-mails, objects, gifts, audio and video recordings, text messages, and other means of communication be kept in a safe place for eventual prosecution. Stalking laws often require the establishment of a *continuity of purpose* by the stalker, and such evidence is critical in proving a case.

And fourth, stalking victims often decide to initiate contact with the stalker to reason with him. It is imperative that all contact with the stalker be avoided, especially contact initiated by the victim. If the victim attempts to meet with the stalker, it will positively reinforce the stalker's behavior, and increase the frequency of pursuit [23]. One cannot reason with someone who is behaving unreasonably and, in many cases, dangerously.

Statistical Evidence in Court

When a criminalist testifies about an evidentiary "match" in a trial, there is usually much discussion of the criminalist's qualifications, methods, and conclusions. These are important matters. However, an issue that receives far less attention is the wording that the criminalist uses to describe that match. This is an important omission because research shows that even very subtle modifications of the forensic scientist's words can be the difference between a guilty verdict and an acquittal in a close case [1].

The first section of this article examines the different ways that a forensic science match may be characterized at trial. The emphasis is on statistical characterizations because these are more likely to convey information about the probative value of a match than more qualitative characterizations. The importance of error rates is noted and various common but erroneous match characterizations are also identified. The second section examines the issue of how jurors view and use statistical forensic science evidence. This section shows that jurors struggle to understand statistical evidence and that their judgments are heavily influenced by the particular ways in which this evidence is communicated. The third section is a brief concluding section. This section counsels forensic scientists to take care to avoid mischaracterizing the strength of match evidence and to be up front with fact finders about the assumptions that lie behind the statistics that they offer.

Statistical Characterizations of a Match

Many criminalists are accustomed to testifying that, in their expert opinion, a particular item of physical evidence came from a particular source. Such testimony, if it is believed, could be dispositive in a host of criminal cases. For example, if a forensic scientist testifies that the ransom note was written by Mr Smith, or that the bite mark on the victim's wrist was created by Mr Smith's upper incisors, factfinders will probably believe that Mr Smith was involved in the crime. However, such source identifications are generally inappropriate.[a] Instead, forensic scientists may offer qualitative or quantitative reports that describe their findings.

Qualitative Descriptions

When a forensic scientist cannot find any distinguishing characteristics between an evidentiary marking and a potential source, he may describe the correspondence as an "association", a "consistency", an "inclusion", or a "match". These words are synonyms and they do not by themselves provide any indication of evidentiary strength. When a forensic scientist does not find an association between a marking and a potential source, the relationship is commonly classified as exclusion (e.g., this hammer is excluded as a potential source of this indentation). If the forensic scientist is unable to determine whether particular characteristics are or are not shared between a marking and a potential source, he may describe the correspondence as inconclusive.

Quantitative Descriptions

Qualitative descriptions of a match may be misunderstood. For example, some fact finders may not

realize that an impression that is "consistent with" a particular shoe may also be consistent with the other, unmentioned, shoes. In order to give fact finders a better sense of the probative value of a match, witnesses should provide information about how rare the identifiable characteristics are in the potential source population.[b]

Exclusion Probability. The exclusion probability conveys more information about the probative value of a match. The exclusion probability is the proportion of potential sources (i.e., people or objects) in a reference population[c] that can be excluded as a source of the forensic science marking. Alternatively, one may think of the exclusion probability as the chance that a randomly selected element of the reference population will not match the forensic science marking. Like all the probabilities, exclusion probabilities range from 0 to 1. Larger exclusion probabilities reflect greater probative value than the smaller exclusion probabilities because large values indicate that matches are less likely to be the result of mere chance. In most forensic science work, exclusion probabilities are relatively high (98, 99.86%, etc.).

Inclusion Probabilities: 1 – Exclusion Probability = RMP = Frequency. The inclusion probability (or profile frequency) is, simply, 1 – the exclusion probability. The inclusion probability identifies the proportion of the potential source population that might be the source of a marking. In DNA typing, the inclusion probability is commonly described as the random match probability (RMP). The RMP identifies the frequency of a genetic profile in a reference population. Alternatively, the RMP is the probability that a randomly selected person in a population would happen to match the genetic profile of the forensic science evidence. Lower RMPs (i.e., low inclusion probabilities) indicate that the match is unlikely to be coincidental.

It is important to bear in mind that exclusion and inclusion probabilities do not, by themselves, capture the probative value of a match report. They do not, for example, account for the possibility of error, fraud, or misinterpretation. If any of these possibilities are substantially more likely than the chance of a coincidental match, then the chance of these events, rather than the probabilities described above, controls the probative value of a reported match. This point is elaborated in the section "Error Rates Matter".

Likelihood Ratios. Some scholars have argued that likelihood ratios are also an appropriate way of describing the value of a match for some forensic techniques, such as DNA typing [2, 3]. A likelihood ratio is the ratio of the probability that an item of evidence E would arise if hypothesis H was true to the probability that this same item of evidence would arise if alternative hypothesis $\overline{H}$ was true. In symbols,

$$LR = \frac{P(E|H)}{P(E|\overline{H})} \tag{1}$$

In theory, larger likelihood ratios values convey stronger evidentiary matches than smaller ones.

Despite their theoretical appeal, likelihood ratios often suffer from several significant practical shortcomings. First, there is no such thing as "the" likelihood ratio [4–7]. The value of a likelihood ratio depends critically on the choices one makes for describing the hypothesis H. Meester and Sjerps [7] give an example where there are two evidentiary stains (one on a pillow and the other on a sheet) and the suspect matches the pillow stain. The likelihood ratio in this example depends crucially on whether hypothesis H is "the suspect is one of the crime stain donors", or "the suspect is the donor of the pillow stain". Even in simpler one-stain situations, the value of the likelihood ratio will depend on which of the several hypotheses are used. For example, Koehler [6] showed that the hypotheses "Simpson is the source of the blood", "Simpson had contact with the crime scene", and "Simpson is guilty of the crime" would produce different likelihood ratio values.

Furthermore, most forensic likelihood ratios implicitly assume a zero laboratory error rate.[d] Even if error rates are small, they will often be larger – and perhaps substantially larger – than the RMP. In such cases, an upper bound on the probative value of the reported match is provided by the laboratory rate rather than by the RMP. Thus, computations that assume a zero laboratory error rate may yield a likelihood ratio of, say, 1 000 000 000 : 1 (depending on the frequency of the relevant profile), whereas computations on the identical evidence that incorporate a false-positive error rate[e] of, say, 0.001 will yield a likelihood ratio closer to 1000 : 1.

Error Rates Matter

All of the statistical characterizations of matching evidence discussed above are legitimate ways to describe forensic science evidence. However, as this discussion shows, each characterization is predicated on assumptions. Failure to reveal those assumptions in written reports or testimony is unscientific and potentially misleading.

In the previous section, it is noted that most forensic likelihood ratios implicitly assume a laboratory error rate of zero. Similarly, exclusion probabilities, RMPs, and their equivalent representations generally do not take account of the possibility of that a reported match may not be a true match. This is important because one cannot represent the probative value of a reported forensic science match without taking the error rate into account. Indeed, the false-positive error rate may be so important that the probative value of a match report is controlled almost entirely by this number rather than by the RMP [8, 9]. This point has not been disputed. What is more controversial, however, is how one goes about estimating the chance that a particular analyst committed a false-positive error in a particular instance.

One of the most vexing aspects of any discussion of forensic science error rates is that, although everyone knows that errors sometimes occur, no one really knows the rate of error in ordinary case work. This knowledge gap exists because there is rarely any ground truth against which to compare a criminalist's opinion. Some researchers have argued that proficiency test data can provide an indication of the rates at which errors occur. According to these data, error rates in the forensic sciences are sometimes surprisingly high [10].

However, some forensic science scholars counter that these estimated error rates should be disregarded. One popular argument is that error rates computed from historical data overstate the risk of error because they do not take into account the corrective steps that laboratories and analysts take to ensure that those errors do not happen again. A second argument is that general error rates do not take into account the procedures used in a specific case to guard against the possibility of error.

These two arguments contain elements of truth (error rates are imperfect), but they do not support the claim that data-based error rate estimates are irrelevant. Instead, these arguments suggest that historical error rates alone may not provide a reliable estimate of the chance of an error in a particular case. Regarding the first argument, if factors that produced false-positive errors were corrected, then we would expect to see dramatic declines in the rate of errors across forensic science subfields each year. However, not only is such evidence lacking but also misidentification rates in some fields do not even show a clear pattern of improvement [10]. Regarding the second argument, no one would suggest that the specific and unusual measures that a laboratories or analysts take to reduce the risk of error should be ignored. Where such data exist, they should be used to modify general error rate estimates [6]. But care must be taken to ensure that these more specific considerations are not used selectively, and that they are, in fact, distinctive and diagnostic. After all, nearly every laboratory and analyst follows a detailed protocol designed to reduce the risk of error, and the success of these protocols is largely reflected in the general error rate estimates.

Erroneous Characterizations

In recent years, forensic scientists have come under fire for exaggerating the strength of the evidence they provide at trial. In light of the underlying probative force of this type of evidence, it may seem surprising that some forensic scientists make unjustifiable claims about the strength of their evidence. However, some of the exaggerations appear to spring more from ignorance of the statistical character of forensic science evidence than from an intentional desire to mislead jurors. Below, a series of faulty characterizations of forensic science evidence that tend to exaggerate the strength of reported matches is identified.

Individualization Exaggerations. Forensic scientists often claim object individualization as both a goal and an achievement [11]. That is, they commonly claim to have identified the one and only possible source of a marking to the exclusion of all other possible sources in the world. However, there is little scientific basis for such claims, their frequency in textbooks and courtrooms notwithstanding. The fact is that criminalists cannot know that a marking is unique to a particular source, particularly when they have only examined a small fraction of possible sources. As a rule, source certainty statements are inappropriate and only obfuscate the probabilistic nature of the forensic science enterprise.

Prosecutor's Fallacy. The so-called prosecutor's fallacy [12] is the most well-known erroneous match characterization. The prosecutor's fallacy is committed when one equates the RMP with the probability that a matching defendant is not guilty. It is a fallacy to characterize the match frequency this way because probabilities of guilt and innocence require consideration of *all* evidence, including prior odds of guilt or innocence.[f] If RMPs alone could reveal probabilities of innocence or guilt, there would be no need to consider alibis, eyewitness testimony, or evidence implicating other suspects.

Source Probability Error. A more common error, albeit one that is rarely acknowledged, is the source probability error [13]. This error occurs when one equates the RMP with the probability that the defendant is not the source of the forensic evidence. Just as one cannot identify the probability of guilt or innocence without detailed consideration of the nonforensic evidence, one cannot identify the probability that a potential person or object is the source of a stain or marking based on forensic science evidence alone. One also needs to know, for example, how many others could have been the source of the forensic evidence *prior to* the discovery that the suspect matches. This fact may come as a surprise to forensic scientists who routinely provide source probability estimates in court and are aware of others who do the same. However, the pervasiveness of this error does not make it any less fallacious than its more easily understood cousin, the prosecutor's fallacy.

P (Another Match) Error. The P (another match) error also finds its way into the courtroom with a disturbing degree of regularity (see [13]). This error occurs when one equates the RMP with the probability that there exists another person who matches the defendant's DNA profile. But a moment's reflection reveals why these two probabilities are not identical. If the RMP = 1 in 1 000 000, then hundreds of other people in a country the size of the United States (300 000 000) would match. Consequently, one could not obtain an RMP of 1 in 1 000 000 and conclude that the chances are just 1 in 1 000 000 that there exists another person who would match. In contrary, it is a near certainty that *many* other people match this profile.

The Numerical Conversion Error. Finally, the numerical conversion error occurs when experts describe the significance of the RMP in terms of the number of people who would have to be tested before one should expect another match to occur [13]. This computation is straightforward, though it is not, as some forensic scientists have testified, X in an RMP of one in X. A conclusion that 1 in every 1 000 000 randomly selected people match is *not* equivalent to a conclusion that 1 000 000 people would need to be tested before another match might be expected. The number is smaller; in this case, it is 693 147.[g]

Most of the errors identified above tend to exaggerate rather than minimize the strength of statistical forensic science evidence. Such exaggeration, though, is hardly necessary because statistical forensic science evidence can be quite compelling when presented accurately.

How Do Jurors Think About and Use Match Statistics?

Even when a forensic scientist studiously avoids exaggerating or otherwise mischaracterizing the strength of an evidentiary match, there is still a danger that jurors will misunderstand the technical evidence that they hear. Some misunderstandings arise because jurors have preconceived ideas about the strength of match evidence or because they oversimplify the evidence in an effort to understand it. Strictly speaking, such misunderstandings are not the fault of the forensic scientist. However, forensic scientists should know something about the psychology of how people process statistical evidence. Such knowledge could help forensic scientists prepare written reports and testify in ways that are geared to help jurors appreciate the probative value of the evidence.

The Mock Jury Study

How can we know how much jurors value forensic science evidence? After all, cases that involve scientific evidence are usually complex affairs, and it may be impossible to determine posttrial exactly how jurors valued any particular item of evidence. Verdicts provide only a very gross measure of how impressed jurors were with the totality of evidence in a case. Posttrial interviews with individual jurors may provide additional insight, although research shows that people have limited insight into factors that affect their judgments and choices [14].

A better method for assessing how jurors use statistical evidence is the mock jury study. Mock jury studies are controlled behavioral experiments that test causal relationships between predictor variables (e.g., different types of jury instructions) and outcome variables (e.g., jurors' verdicts). In the typical experiment, jury-eligible subjects assume the role of jurors and watch a videotape (or read a description) of a trial or part of a trial. Jurors are randomly assigned to groups that differ only in terms of the predictor variables of interest. For example, one version of the videotaped trial might include testimony from an expert who commits The prosecutor's fallacy, whereas another version might not. A well-run mock jury study enables researchers to isolate the direction and magnitude of various influences on jurors' judgments and verdicts.

The obvious and central disadvantage of the mock jury study is its artificiality. Mock jury studies often use students rather than real jurors, use written case summaries rather than videotaped or live testimony, or collect verdicts from individuals rather than from juries that have deliberated to unanimity. It is only natural to question the usefulness of data derived from such research.

Nevertheless, there is good reason to believe that mock jury studies provide a window into the minds of actual jurors. Studies that have compared student jurors to actual jurors generally report similar patterns of decisions Casper and Benedict [15, p. 78] found no difference in the verdict patterns displayed by college students and jurors selected from the Cook County jury roll in Illinois Bornstein [16] reviewed dozens of mock jury studies and concluded that "[There is] strong evidence that factors at trial affect students and non-students in the same way" [16, p. 80]. Bornstein [16] also reported that it makes little difference whether mock jury studies employ written summaries, transcripts, audiotape, or videotape: "[R]esearch on the trial medium tends not to find many differences." (p. 82, 84). Of course, even if we accept that different types of mock jury studies yield similar results, it is possible that some of the conclusions reached in those studies may not hold when the stakes are real. But as Hastie [17] has observed, "there are so many converging results concerning juror behavior from laboratories and from surveys of actual jurors that most of the conclusions from the studies reported are surely accurate descriptions of juror behavior in real trials." (p. 28). In short, although mock jury studies are imperfect representations of actual trials, they may provide insight into how jurors think and respond at trial.

The Results of Behavioral Experiments

Defense Attorney Fallacy. Thompson and Schumann [12] coined the phrase "the defense attorney fallacy" to describe the erroneous belief that nonunique match evidence is not probative. For example, suppose that a partial DNA profile from an evidentiary sample occurs with a frequency of 1 in 1000 and that the suspect population includes 30 000 adult males in a city. In this scenario, the defense attorney fallacy would occur if one argued that a DNA match on a particular suspect is worthless because approximately 30 adult males in the city would match. This argument is fallacious because it fails to distinguish between probative evidence and dispositive evidence. Non-unique evidence may be highly probative if the size of the inclusion group is small relative to that of the exclusion group. In our example, the partial DNA match is highly probative because 99.9% of people who were not the source would have been excluded, yet the defendant happens to be a member of the very small group of non-excluded people. Holding aside error rate considerations, the discovery of this match means that a juror should believe that the defendant is now about 1000 times more likely to be the source of the DNA evidence than he was prior to the discovery of the match.

Several studies have shown that significant minorities of jurors are susceptible to this fallacy [12, 18], particularly when it is explicitly offered as an argument by a defense attorney Hans *et al.* [19] found that fully 40% of mock jurors agreed with the statement "The mtDNA evidence in this case is completely irrelevant because a substantial number of other people could also be the source of the hairs." (p. 17).

Conditional Probability Confusion. Mock jury studies have also demonstrated that jurors are prone to inverting conditional probabilities [20]. These inversion errors can lead to source probability errors and prosecutor's fallacies. In Bayesian terms, inversion errors sometimes lead jurors to confuse likelihood ratio components with posterior odds components Koehler [5] showed that mock jurors do not distinguish between likelihood ratio statements (e.g., "It is approximately 1000 times more likely we would

see this DNA match if the defendant is the source of the semen than if the defendant is not the source of the semen".) and posterior odds ratio statements (e.g., "Given that we see this DNA match, it is approximately 1000 times more likely that the defendant is the source of the semen than that he is not the source of the semen".). This finding supports other research that shows that most people verbally confuse likelihood ratios with posteriors in nonlegal contexts [21], and that expert witnesses frequently describe likelihood ratios as posterior probabilities [13].

The confusion between likelihood ratios and posteriors in the forensic context is important because it creates the mistaken impression that match evidence alone can identify the probability that a suspect committed a crime or is the source of trace evidence. But in light of the linguistically subtle differences between likelihoods and posteriors, it is hard to prevent this particular error. In June, 1995, Court TV commentator Dan Abrams noted that likelihood ratios were discussed so frequently during various legal motions and arguments in the O. J. Simpson trial that it was important to explain to the viewing public what exactly a likelihood ratio is. Abrams then committed an inversion fallacy when he explained that a likelihood ratio refers to how likely one hypothesis is true *versus* how likely a competing hypothesis is true.

Failure to Appreciate the Role of Error Rates. Jurors have a hard time understanding how to combine error rates with RMPs. This is a serious problem because the probative value of a reported match is determined almost exclusively by the false-positive error rate in cases where the RMP is very small Koehler *et al.* [8] were the first to examine how mock jurors intuitively combined error rates and RMPs. They found that jurors simply ignored error rates (e.g., 1 in 1000 and 2 in 100) when the RMP was very small (e.g., 1 in 1 000 000 000) Schklar and Diamond [22] (hypothesis 2) found that jurors who received separate estimates for the RMP and error rate were significantly more likely to return a guilty verdict than were jurors who received a single statistic that properly aggregated these two statistics for them. Instruction on how to combine the RMP and error rate had little impact [18, 22]. This result suggests that it is no simple matter to get jurors to appreciate the role that error rates play in the interpretation of match reports.

Reasoning by Exemplars. People tend to overweight low-probability events [23]. This phenomenon partially explains why people buy insurance and lottery tickets even though both purchases have negative expected values. RMPs are almost always low-probability events and sometimes they are extremely low-probability events. One might therefore expect that jurors will tend to assign too much weight to the remote possibility of a coincidental match and thereby underweight a reported DNA match. Research generally supports this position. Most studies that have looked at this issue find that jurors attach less weight to statistical match evidence than the evidence would seem to deserve (for reviews, see [19, 20]). However, caution is needed here. Although people tend to overweight low-probability events, *extremely* low-probability events may be *underweighted* if people view those probabilities as negligible.

Research shows that the weight that jurors assign to very low RMPs depends critically on how those probabilities are presented. When RMPs are presented in ways that make it easy for jurors to imagine others who might match the profile, then a reported DNA match seems less impressive and jurors give less weight to the match evidence. But when RMPs are presented in ways that make it hard to think about others who might match, jurors give significantly more weight to the match evidence.

In one study [1], jurors who were told "The probability that Mr. Clinton would match the semen stain if he were not its source is 0.1%", assigned higher probabilities to the hypothesis that Mr Clinton was the source of the stain than did jurors who were told "1 in 1000 people in Washington, DC, who are not the source would also match the semen stain". Although the RMP is identical in the two cases, the latter description makes it easier to imagine examples of others who would also match. These imagined examples weaken the perceived strength of the match evidence. In another study [24], jurors who heard a DNA RMP described as "0.1 in 100" were more likely to believe that the person who matched the evidence was its source than were jurors who heard this same RMP described as "2 in 2000". Whereas the fractional numerator in the former format conveys a sense that others are unlikely to match, the latter format encourages people to think about a second matchee.

How Should a Forensic Scientist Communicate Match Statistics?

This article examined the various ways in which forensic scientists characterize a forensic science match and how jurors are likely to interpret match statistics. Whereas some ways of characterizing a match are more informative than the others from a strictly mathematical standpoint, it is unclear whether untrained lay jurors understand the meaning of those characterizations. So what should a forensic scientist do?

He should begin by educating himself about the foundational principles of probability and statistics. Science, after all, is a probabilistic enterprise and scientists speak the language of statistics. The forensic scientist should pay particular attention to Bayes theorem (odds form) in his studies. Once he understands the difference between prior probabilities, likelihood ratios, and posterior odds ratios, the forensic scientist will be less likely to commit many of thestatistical misstatements discussed in the first section. He will understand why he should abandon traditional source identity claims in favor of carefully worded probabilistic claims. And he will be able to explain to jurors why his science does not enable him to identify the probability that this bullet came from this gun or that this toolmark was produced by this hammer.[h]

He will also be in a better position to correct and explain the misstatements implicit in the questions that attorneys and judges ask of him. For example, when an attorney attempts to confirm a 1 in 1 000 000 RMP by asking "In other words, you're saying that there is only one chance in a million that the blood could be of anyone other than the defendant's, correct?" the forensic scientist should not agree. Instead, he should explain why this statement mischaracterizes the RMP. In the context of rapid-fire courtroom exchanges, this may be a challenge. But the forensic scientist, like any scientist, is duty-bound to correct misstatements of his conclusions and to educate those who use his data to make important decisions.

In addition to avoiding and correcting misstatements, the forensic scientist should disclose all relevant assumptions. For example, he should note that the RMP requires assumption of independence across characteristics, and that most of the forensic probabilities implicitly assume a zero error rate.

The forensic scientist should also be sensitive to the underlying psychology associated with how people think about statistical evidence, in general, and very small probabilities in particular. After all, the primary purpose of forensic science testimony at trial is to convey probative information to the legal fact finder. If that information is conveyed in ways that make it hard for the trier of fact to understand, then adjustments are needed. One possibility is to place some of the burden on jurors by suggesting that they receive training to help them understand scientific and statistical evidence [25]. However, the practical realities are such that, for now, those who offer technical testimony must find simple and clear ways to explain their evidence, erring on the side of caution and conservatism.

An undesirable side effect of scientific conservatism is that recipients of the scientific message may give insufficient weight to the message. Scientific evidence that is accompanied by cautions about what the evidence does not represent, and cautions about the assumptions and limits of the accompanying statistics may discourage some fact finders from attaching sufficient weight to the evidence. In the case of forensic match evidence, jurors may be disappointed to learn, for example, that a handwriting match does not necessarily mean that the matchee authored the questioned document. When jurors realize that the match merely places the matchee in a small group of people who might have authored the document, they may see the evidence as weak or irrelevant because the forensic scientist was not able to individualize the handwriting. Indeed, as noted earlier, 40% of mock jurors in one recent study said they believed that statistical mtDNA evidence was "completely irrelevant" because more than one person could match [19]. Such results indicate that jurors need substantial help understanding how to value forensic science evidence. Assuming that jurors remain untrained, the forensic scientist will need to provide that help. On the one hand, he must identify critical assumptions and avoid overstating his conclusions. On the other hand, he must teach jurors that a reported match can be powerful evidence of identity even when uniqueness and error-free methods cannot be assumed. In the end, the forensic scientist should be truthful, candid, clear, helpful and, above all else, scientific.

End Notes

[a.] A source identification may be appropriate in rare cases in which all the potential sources of a marking are available for examination and only one of those potential sources matches the target marking.

[b.] The phrase *potential source population* here in much the same way as others uses "suspect population" in cases that include human genetic material. The former phrase applies to a broader array of forensic cases (e.g., cases involving toolmarks) and does not attempt to make the forensic scientist the arbiter of which possible human sources should and should not be included in the groups of potential perpetrators. After all, some people may be members of the source population (e.g., they might be the source of the blood), but they might not be members of the suspect population (e.g., if they were in prison at the time the crime occurred).

[c.] Ideally, the reference population should be the potential source population. In practice, data for this population may be hard to construct. If so, then convenient alternatives such as the general population or an ethnic grouping within the general population are commonly used. The extent to which these alternative reference groups are adequate varies from case to case.

[d.] If the evidence E is described as "a true match", then there is no place for considerations of error in the likelihood ratio because E equates the *report* of a match with a true match. For this reason, it is more appropriate to describe E as "a reported match".

[e.] Discussions of "errors" in forensic science sometimes get bogged down by concerns about what exactly is meant by an error. For purposes of this paper, the words "error" and "error rate" are used as synonyms for false-positive error and false-positive error rate, respectively. A false-positive error arises when an analyst affirmatively claims that two markings match when, in fact, they do not share a common source.

[f.] In Bayesian terms,

$$\frac{P(\textit{suspect is guilty} \mid \textit{evidence})}{P(\textit{suspect is not guilty} \mid \textit{evidence})} = \frac{P(\textit{suspect is guilty})}{P(\textit{suspect is not guilty})} \times \frac{P(\textit{evidence} \mid \textit{suspect is guilty})}{P(\textit{evidence} \mid \textit{suspect is not guilty})}$$

Even if we simplify this formula by assuming that $P(\textit{evidence} \mid \textit{suspect is not guilty}) = \text{RMP}$, we may not conclude that $\text{RMP} = P(\textit{suspect is not guilty} \mid \textit{evidence})$ The latter conditional probability also depends on the prior probability that the suspect is guilty (i.e., the probability that the suspect is guilty based on nonforensic considerations).

[g.] In order to estimate the number of people who would need to be tested before there would be more than a 50% chance to find a match on a profile common to one in X people, one must compute the smallest N that makes this equation true: $(1 - 1/X)N < 0.50$. For computational simplicity, one may solve for N, where $N = [\ln(.50)]/[\ln(1 - 1/X)]$.

[h.] These are posterior probabilities and therefore inaccessible to the forensic scientist absent an estimate of the prior probabilities. Estimates of prior probabilities are matters for the legal fact finder rather than the expert witness [26].

Stockholm Syndrome

Incidents of Stockholm Syndrome in the Media

Stockholm syndrome, also referred to as the *phenomenon of survival identification* or *hostage identification syndrome*, is a concept that has been extensively covered by the media and seen in several highly publicized cases of hostage rescue [1]. The term *Stockholm syndrome* was first used to describe the experiences of victims of a bank robbery that occurred at the Sveriges Kreditbank, bank in Stockholm, Sweden on August 23, 1973. Four bank employees were held hostage by bank robbers for 131 h. Following their release, the hostages relayed to reporters feelings that seemed opposite of what was expected. They described fearing the police more than the bank robbers. In fact, they felt grateful for the generosity of the hostage takers in giving them back

their lives [2]. The psychological term, *Stockholm syndrome*, came about as a way to explain the positive feelings the hostages had for their captors and the way they identified with their political goals, if not the means they chose to achieve them.

The syndrome gained additional media attention following Patty Hearst's kidnapping and subsequent bank robbery and trial. Patricia Hearst, granddaughter of media mogul, William Randolph Hearst, was a 19-year-old undergraduate student in California when she was kidnapped by the Symbionese Liberation Army (SLA) on February 4, 1974. Her kidnapping was described by the SLA in a communiqué as an "arrest and protective custody; and if resistance execution" of the hostage to draw attention to their cause of ending racial and economic discrimination and opposing capitalism [3]. Fifty-nine days after her capture Patty Hearst sent a tape to a radio station indicating that she had chosen to join the SLA and "fight for my freedom and the freedom of all oppressed people" [4]. She went on to join the organization and participate in a bank robbery and other illegal activities only to be arrested on September 18, 1975. Her actions were defended by many as the result of the stress of her being held against her will and fearing for her life. Nonetheless, she was convicted.

Role of the Hostage-taker's Intentions

There are different scenarios in which hostage taking can occur. Whether a hostage is taken intentionally, or as part of another crime "gone wrong", plays a role in the way a victim identifies with their captor. Intentional hostage taking is frequently undertaken as a means of drawing attention to a political or social cause. It is often a tactic employed by individuals who believe they lack power and have no other way to draw attention or get their demands met. In these situations it is possible for those taken captive to begin to understand the desperation their captors have been feeling, and to mistake their own feelings of fear and helplessness with the experiences of the cause for which the hostage-taker is fighting.

Other times, hostage taking is not planned but an accident of a primary crime such as a robbery which has gone wrong. In this scenario, when a criminal feels trapped by law enforcement, he may react by taking hostages without fully thinking through the consequences of this action. The situation then worsens and may involve a dangerous stand-off that compounds the original offense with a kidnapping charge. The criminal finds himself in an unexpected situation with his own freedom on the line much like that of the hostages he has taken. The hostage-taker may blame the police for forcing him into taking hostages and make statements alleging that he would allow the hostages to go free if only the police would give in to his demands. In this way, the hostages and hostage-taker may feel they are together in a situation not of their own making and begin to form a bond and share negative feelings toward the police.

Theories Regarding the Formation of Stockholm Syndrome

The term *Stockholm syndrome* has evolved into a catch-all to describe the different psychological explanations for why some captives feel no ill will toward their captors but form a bond with the person who took away their freedom. This unconscious reaction to the stress of being held hostage is a way for the individual to both deal with the fear of the situation as well as try to adapt in order to stay alive [5]. The Stockholm syndrome has been described as a combination of feelings on the part of the hostage which includes positive feelings toward the captor and negative feelings toward authority as well as reciprocal positive feelings toward the hostage on the part of the captor [6]. In a study of the effects of kidnapping in Italy, 50% of the victims described some form of positive bond with at least one of the kidnappers [7]. The following is a discussion of some of the more prominent psychological explanations for the Stockholm syndrome.

Denial

Most explanations for the formation of the Stockholm syndrome are based on the idea that the victim uses defense mechanisms to deal with the terror of the situation [8]. The concept of defense mechanism is rooted in Sigmund Freud's theory that the ego, or the part of a person's psyche that attempts to maintain balance between one's instinctual drives and external reality, attempts to control anxiety by employing coping strategies, defense mechanisms, to reduce it [9]. In hostage situations, the hostage

quickly realizes that they are completely at the mercy of another person. They are psychologically reduced to an early stage of development where they are reliant on another person for their very life, much like an infant.

This promotes the use of the more basic coping strategies. One of the most basic defense mechanisms is that of denial in which a person deals with an anxiety-provoking situation by denying its reality. Kidnapping victims may try to convince themselves that the situation is not real and use distracting techniques such as busy work to avoid being confronted with the reality of the situation [2]. It is only after these strategies fail, and the victim must accept their predicament, that the Stockholm Syndrome begins.

Identification with the Aggressor

One of the most commonly cited psychological reasons for the Stockholm syndrome is a psychological phenomenon first identified by Sigmund Freud's daughter, Anna Freud, who expanded on her concepts of defense mechanisms and introduced the concept of "identification with the aggressor". She described this to occur when an individual experiences fear of an aggressive person and subconsciously deals with this uncomfortable emotion by putting himself in the same category, and thereby identifying the aggressor [10]. This theory helps to explain why captives who have no reason to feel anything but anger toward their captors begin to feel an unexpected allegiance to them.

Learned Helplessness

Hostage-takers may alternate between violence toward the hostage and moments of unexpected sympathy and kindness. This inconsistent pattern of interaction could result in the hostages developing learned helplessness. When a person feels they have no ability to control the outcome of a situation (i.e., become helpless), they begin to give up hope [11]. As the pattern of their captors' responses varies without an obvious reason, the victims realize they have little power to affect the situation and stop trying.

They become increasingly dependent on the person they perceive to have control over the situation and feel grateful to the hostage-taker for providing for their basic needs such as food and shelter. Even the smallest act of kindness coming from someone who has previously been indifferent or cruel carries great weight. Patty Hearst herself described "once they don't kill you, you start to think they're nice. They get nicer every day that they don't kill you" [12].

Factors Contributing to the Development of Stockholm Syndrome

Different variables on the part of both hostage and hostage-taker play a role in the formation of the Stockholm syndrome. According to Thomas Strentz [2] one of the factors which promotes the formation of the Stockholm syndrome is the amount of exposure the hostages and their keepers have to one another. The more time a hostage and hostage-taker are together the greater the likelihood that they will begin to see the other as a person, rather than political tools or faceless captors. This effect, however, is negated if the victim is being abused or if the victim and hostage-taker do not share a common language. Other factors which increase the chance that the Stockholm syndrome will develop include the degree to which the captive depends on his keeper for survival as well as the intensity and duration of the experience [5].

Factors which make the formation of Stockholm syndrome less likely include physical abuse by the captors, intentional emotional distancing on the part of the captors [5], and a strong sense of self and purpose on the part of the victim. Giebels *et al.* interviewed 11 kidnapping victims and found that all but 3 developed positive feelings toward their captors. The three who did not develop positive feelings were all physically abused [13]. Turner [14] added that cultural value systems, pre-existing stereotypes, and the intellectual sophistication of the individual also play a role in Stockholm syndrome's development.

Stockholm Syndrome in Cases of Spousal Abuse

While Stockholm syndrome began as a way to explain the reactions of hostages to their captors, it has also been applied to other situations in which one person exerts power over the other and controls the weaker person's freedom. Domestic abuse is such a situation. Some victims of domestic abuse choose not only to stay with their abusive husbands, but also idealize them and blame themselves for the abuse [15]. In such a situation the victims "deny both their terror and the captor's abuse and *bond* to the kind side of their captor" [16]. This seemingly

contradictory reaction is theorized to share many of the same psychological underpinnings as the Stockholm syndrome including identification with the aggressor and denial. This prolonged psychologically traumatic experience can result in a woman seeing her abusive husband as all powerful and that she has no hope for escape from him (*see* **Battered Spouse Syndrome**).

The Stockholm Syndrome in Legal Proceedings

The combination of positive feelings toward one's captors and a mistrust of authorities that is found with the Stockholm syndrome can have an effect on law enforcement efforts and legal prosecution of hostage-takers. The Stockholm syndrome can drive captives to interfere with police negotiations to end the hostage situation by not giving accurate information or refusing to cooperate [17]. Another consequence of the Stockholm syndrome is the reluctance that a victim may feel to testify against their captors [18]. The feelings of gratitude the victims have for being allowed to live and returned to freedom can lead them to believe they should protect the hostage-taker in return.

The Stockholm syndrome will, therefore, likely continue to be a topic of fascination and media attention. Although there is no single universally accepted explanation for its formation, the primary theories involve the use of defense mechanisms as ways to shield the individual from facing the full force of the trauma. As more victims are willing to discuss their experiences, the understanding of the complex psychological reaction and the role it plays in hostage negotiations will grow.

Substance Abuse

Substance abuse is defined in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) primarily by social consequences resulting from substance use [1] (*contrast* **Addictions**). Substance abuse is generally recognized as being less severe than substance dependence, and an individual cannot be diagnosed with both disorders concurrently. The International Classification of Diseases (ICD) categorizes a broad range of morbidity and mortality causes [2, 3]. Currently in its 10th edition, the ICD is published by the World Health Organization. Substance dependence and harmful use are the ICD-10 classifications used to diagnose substance use disorders. Harmful use is defined as use resulting in health problems; social consequences can be included as well.

The association between crime and substance abuse is multifaceted. Criminal activity related to drug use can be a result of the illegal nature of most substances of abuse [4–6]. Since the business of buying and selling illicit drugs is not regulated, some people resort to crime to resolve disputes or gain access to drugs. Alternately, individuals might offend for the same reasons they use substances (e.g., sensation seeking, attempts to alleviate symptoms of mental health disorders), but the behaviors are not directly related to one another. In addition, some substances can cause physiological changes leading to aggression, which may be manifested criminally.

According to the US Department of Justice, nearly one-third of US inmates committed offenses while they were under the influence of a substance, and between 14 and 19% are incarcerated for crimes related to substances [6]. Among US jail inmates in 2002, 23% met criteria for substance abuse and not substance dependence. Substance abuse without dependence was most common in men and those under the age of 25, whereas substance dependence was most common in women and inmates between ages 35 and 44. Offenders with substance

abuse diagnoses were less likely than those with substance dependence to participate in substance abuse treatment programs before, during, and after incarceration. However, the Department of Justice [6] warns that caution must be used in the interpretation of any data reporting the relationship between substance abuse and crime for the following reasons:

- Crime is rarely caused by one isolated factor but is the culmination of a number of biopsychosocial characteristics and events.
- Studies reporting that offenses are related to drugs may be defining this relationship differently from one another. Calling a crime drug-related could refer to involvement of drugs in any fashion, or the definition may be more stricter, such as requiring the offender to be intoxicated at the time of the offense.
- Many studies rely on self-report, which could be inaccurate because of factors including exaggeration, poor memory, or reluctance to admit experience with substances.

In recognition of the common overlap between substance abuse and involvement with the legal system, the Substance Abuse and Mental Health Services Administration (SAMHSA) released a Treatment Improvement Protocol designed to guide professionals working with offenders who abuse substances [7]. In this protocol the conflicting goals of substance abuse treatment (which typically aims to rehabilitate) and the criminal justice system (which is largely punitive in nature) are addressed. SAMHSA discusses considerations substance abuse treatment professionals may not be accustomed to making, such as assessing psychopathy and navigating complex confidentiality laws dictating what must be communicated to probation officers.

In some cases, a drug use history is associated with greater rates of criminal activity even when crimes are committed while the offender is not under the influence of substances [8, 9]. For example, a sample of patients with functional psychosis who had received mental health services in the United Kingdom participated in a study examining their substance use histories and criminal activities [8]. Individuals who had ever used illicit substances in their lives and those whose general alcohol consumption reached at least "occasional intoxication" were significantly more likely to have committed a nonsubstance misuse-related offense. This study also found that offending commonly precedes substance abuse. These results provide evidence that criminal offenses in substances abusers have a complex etiology and cannot be completely explained by altered mental status because of intoxication during criminal activity. In another study similar results were found and the authors posited that relationships between substance use and criminal offenses might be representative of one underlying behavior pattern (e.g., antisocial or deviant behavior) rather than two exclusive elements in a cause and effect relationship (e.g., drug use causes crime) [9].

Substance abuse can complicate the process of litigation. For example, with individuals involved in court proceedings who claim mild traumatic brain injuries have resulted in significant problems, difficulties may be due to substance abuse rather than brain injury [10]. Forensic neuropsychological assessment indicating cognitive deficits in people with brain injuries can show similar deficits in substance abusers, rendering such assessment tools unreliable in differentiating between cognitive impairments caused by mild traumatic brain injury and those resulting from drug abuse (*see* **Head Injury: Neuropsychological Assessment**; **Neuropsychological Assessment**).

Adolescents

Adolescents are at risk for developing maladaptive behavior patterns that can involve illegal activity, including substance abuse (*see* **Juvenile Justice: Adolescent Development**). Several studies have examined these behaviors in youth. A five-year study that followed 80 adolescent substance abusers on probation into young adulthood found both alcohol use and marijuana use in young adulthood were associated with greater involvement in criminal behavior [11]. Further, with increased substance use, the frequency of criminal behavior was higher as well. Another study evaluated 1122 adolescents receiving substance abuse treatment throughout the US to identify patterns in their behavior prior to entering treatment [12]. The majority of youths already had a history of involvement in the criminal justice system, aside from charges related to substance use and possession. Many were ordered to treatment or chose treatment as an alternative to more restrictive consequences of their criminal behavior. Another study

of adolescents in treatment found that while male adolescents had more days of parole or probation upon treatment entry, female adolescents had more severe substance abuse and mental health symptoms at intake [13]. Involvement with the juvenile justice system may not be a reliable indicant of criminal activity, such as illicit substance use, for both male and female adolescents.

Mental Health Disorders

In offenders with substance abuse disorders, the presence of other mental health disorders can lead to additional difficulties. Bipolar disorder is an example of a mental health disorder that can relate to increased rates of criminality in people with substance use disorders. In a study investigating criminal histories of individuals with rapid-cycling bipolar disorder who abused substances, differences between men and women were assessed [14]. Of 132 participants, the majority (68%) had been charged with legal offenses, with a significantly higher percentage of men charged compared to women (78 and 53%, respectively). These rates were compared to a sample of 33 people with rapid-cycling bipolar disorder and similar demographic characteristics who did not have a comorbid substance abuse disorder. Legal charges occurred at significantly lower rates in the comparison group (8% of men and 17% of women).

A study evaluating bipolar arrestees with a history of psychiatric treatment housed in a jail's psychiatric system compared inmates ($n = 66$) with inpatient bipolar patients who had no arrest history ($n = 54$) [15]. Most inmates were manic and psychotic when they were arrested, and most had recently left inpatient psychiatric treatment. Arrestees had significantly greater rates of substance abuse (76%) than hospital patients (19%). This study suggests further treatment (e.g., aftercare) to help manage psychiatric and substance abuse symptoms may be particularly important in similar populations. Another investigation of comorbid mental health disorders found high rates of criminality and substance abuse in patients with schizophrenia. At a psychiatric clinic in Sweden, assessment of patients with schizophrenia found that nearly half reported a substance abuse history [16]. Rates of criminal history were significantly higher for participants who abused substances (50% *vs.* 11%).

Substance Abuse and Aggression

Violence and substance abuse can be associated for varying reasons [4, 5] (*see* **Aggression**). At times people use violent behavior as a way of gaining the resources necessary to use drugs, or violence can be a result of arguments related to the drug trade that cannot be resolved through legal means because of the illicit nature of the product around which the conflict is centered. Further, as with the relationship between substance abuse and criminal offending in general, both behaviors may be caused by a third factor that leads individuals to act out in a deviant manner. Additionally, some substances can cause physiological changes that lead to aggression. While there are individual differences in how people respond to substances, the potential for alcohol to elicit violence has been demonstrated through a number of pathways [17]. Alcohol intoxication changes the processes of intrinsic reward and punishment systems as well as natural physiological responses to stress and threatening situations. Higher order cognitive functions also are affected and it can lead to impairment in self monitoring, risk appraisal, planning, and motivation [18]. Mixed results have been found in investigations of the relationship between aggression and drugs other than alcohol; a consensus has not been reached in many cases [4].

A study examining female perpetrators of violence found victims to be primarily men who were strangers or acquaintances, and the most common reason for violence was reported to be engaging in a quarrel while drinking [19]. Most women were under the influence of alcohol or drugs when they committed the crimes. In addition, the majority of participants had a history of drug and/or alcohol abuse. The lack of victimization as a motive for violent behavior was speculated as being related to the cultural and political environment in Finland, where the study was conducted, which promoted gender equality.

The role of substance abuse in domestic violence offenses has been examined. In a comparison of men and women arrested for domestic violence, while men had greater numbers of prior arrests, participants of both genders were equally likely to have been using substances when they were arrested [20]. Sexual offending has been shown to relate to substance abuse in many cases as well. For example, an assessment of sexual offenders found that substance abuse predicted higher numbers of sexual assault victims [21].

Treatment

Views regarding substance abuse treatment for offenders have varied over time, and the ideal balance between treatment and punishment within the criminal justice system is still debated [22]. However, even contingents that have historically doubted the usefulness of providing treatment to substance abusing offenders have recognized the scientific evidence showing reduced relapse to substance abuse and recidivism following treatment [23].

Treatment options available to offenders range from brief motivational interviews to more lengthy participation in therapeutic communities (see [24] for a review). Motivational interviewing (MI) is a brief intervention that helps people to explore the pros and cons of changing harmful substance abuse behavior [25]. MI is a therapeutic method that can be particularly useful for offenders whose substance abuse is related to the reason for their incarceration [26]. Legal problems experienced as a result of substance abuse can be highlighted as one of the consequences resulting from abusing alcohol or drugs. In a study investigating the effectiveness of MI for offenders charged with crimes related to alcohol use, results showed that most participants (55 of 63) reported positive changes in their drinking behaviors six months after the MI intervention. Offenders remarked that they were surprised about the nonconfrontational nature of the brief intervention as well as the nonjudgmental style of the counselors.

Therapeutic communities are a form of long-term residential treatment focusing on the holistic needs of residents by using their interactions with other residents and staff as a key component of therapy (see [27] for a description). This type of intensive treatment is best suited to offenders with severe substance use disorders and maladaptive behavior patterns, such as antisocial behaviors. Drug courts are another form of treatment that can be used to promote rehabilitation in offenders charged with substance-related crimes (*see* **Mental Health Courts**). In this modality, the judge serves as a case manager of sorts who helps the offender become involved in therapeutic programs and activities [28]. Meditation is an additional method through which substance abuse can be treated, and assessment of offenders who participated in a meditation-based intervention has shown promising results including decreases in substance use, consequences of substance use, and psychiatric symptoms [29, 30].

Conclusion

Alcohol and drug abuse are disorders that can be related to forensic science because of acute physiological effects, the illegality of possession and use of many substances, as well as the potential for underlying disorders or behavior patterns of which substance abuse and criminality may be symptoms. Data indicate differences between inmate populations who abuse substances and those with substance dependence disorders [31], suggesting that diverse strategies must be used in working with these populations. Special consideration is warranted with other groups as well, such as adolescents, individuals with mental health disorders comorbid with substance abuse, and violent offenders. Several treatment options exist that can be used to achieve the desirable outcomes of reducing rates of substance abuse and recidivism.

Suicide (Behavior)

Introduction

Homicide–suicide is the occurrence of suicide preceded by homicide within a short period of time; typically 24 h. It is an event that occurs rarely at a rate of approximately 0.2 per 100 000 individuals [1]. This incidence rate has remained stable over time and is relatively consistent across nations [2]. In the United States, homicide–suicide accounts for approximately 1200–1300 deaths annually as compared with approximately 16 000 annual murders and 30 000 suicides [3–5]. During 2005, over 10 homicide– suicides occurred every week [3].

The infrequent incidence of homicide–suicide renders it a difficult subject for empirical examination. As a result of the limited research focusing on homicide–suicide, there remains some inconsistency in the language used to describe it. The terms *murder–suicide, extended suicide*, and *dyadic death* are also used to describe the unusual phenomenon [6].

In most homicide–suicide events, the perpetrator is a male (95% of US cases) and the victim is female (85% of US cases). In more than half of all homicide–suicide cases, a jealous male murders a wife or girlfriend who has expressed a desire to divorce or separate from him. Although there is usually one perpetrator and one victim, there may be multiple victims [2]. Firearms were the method used in approximately 95% of the homicide–suicides reported between January 1 and June 30, 2001 [3].

Although homicide–suicide is a psychological phenomenon distinct from either homicide or suicide, it may be more similar to suicide than homicide. Similar to individuals who complete suicide, perpetrators of homicide–suicide are more likely to suffer from depression, feel hopeless, and have prior severe suicide attempts. Unlike individuals who commit homicide, perpetrators of homicide–suicide do not typically have histories of violence or impulsivity [2].

There are four types of homicide–suicide: spousal homicide–suicide, filicide–suicide, familicide–suicide, and extrafamilial homicide–suicide. Spousal homicide–suicide is further divided into jealous type and declining health type. Comprising more than half of all homicide–suicide cases, spousal homicide–suicide jealous type is the most common type of homicide–suicide while spousal homicide– suicide declining health type is less common. In the typical spousal homicide–suicide declining health type scenario an older male murders his physically ill spouse before committing suicide. Often, the older male has experienced feelings of hopelessness and depression [2].

Filicide–Suicide

Filicide–suicide is a specific type of homicide–suicide wherein a parent commits suicide after killing his or her child(ren) [7]. Sixty percent of children under the age of five who die by homicide are killed by a parent [8]. Parents kill their children for five reasons: altruism, acute psychoticism, accident, because the child is unwanted, or as an act of revenge against a spouse. Parents who are acutely psychotic or who have an altruistic motive for killing their child are more likely to also kill themselves than parents who murder a child by accident, because the child is unwanted, or for revenge against a spouse. Most filicide–suicides (70%) are of the altruistic type; a "mercy" killing in which a parent murders his or her child(ren) as a means of removing the child(ren) from real or imaged danger or suffering. Fathers commit filicide–suicide twice as often as mothers [9]. Often, parents use the same means to kill themselves as they used to kill their children. Guns are the most common method.

Familicide–suicide

Familicide–suicide is an event during which a parent kills his or her children and spouse (and sometimes pets and other relatives) prior to committing suicide [2]. Familicide–suicide is less common than filicide–suicide [7]. Older men who suffer from depression are most likely to commit familicide–suicide [2].

Extrafamilial homicide–suicide

Extrafamilial homicide–suicide is an event during which an individual who perceives to have been treated unjustly murders those individuals he or she believes to be responsible prior to committing suicide. Although extrafamilial homicide–suicide is most often portrayed in the media, it is the least common type of homicide–suicide [2].

Physiological Aspects of Drug Distribution in Sweat

Theoretical Background

Sweat secretion is an important mechanism for maintaining a constant core body temperature [1]. Following sympathetic nerve stimulation, sweat is excreted onto the surface of the skin and evaporated to release body heat. Sweat is secreted from two types of sweat glands, eccrine and apocrine glands (Figures 1 and 2). These glands originate deep within the skin dermis and terminate in excretory ducts emptying onto the

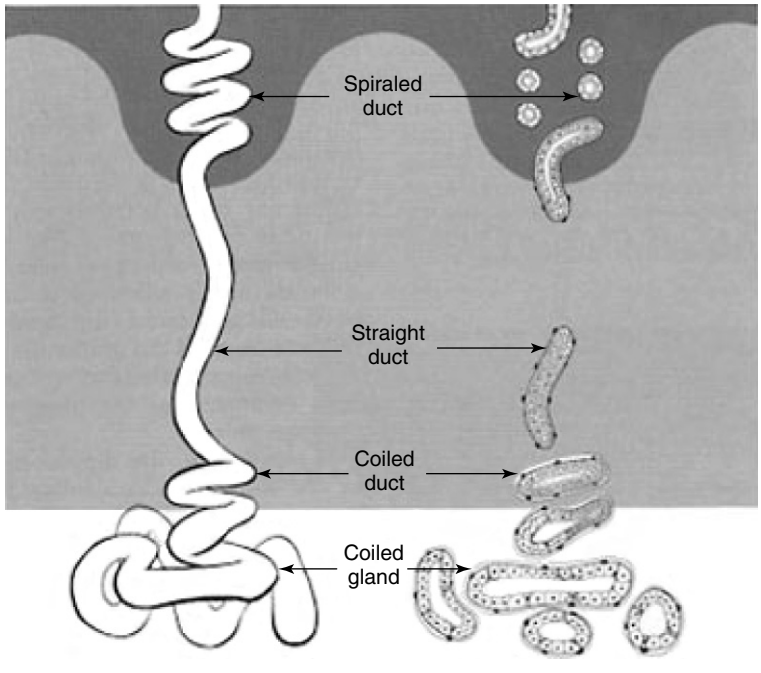

Figure 1 The eccrine gland: eccrine units consist of three portions: (a) the acrosyringium or intraepidermal spiraled duct; (b) the coiled and straight intradermal duct; and (c) the secretory-coiled gland

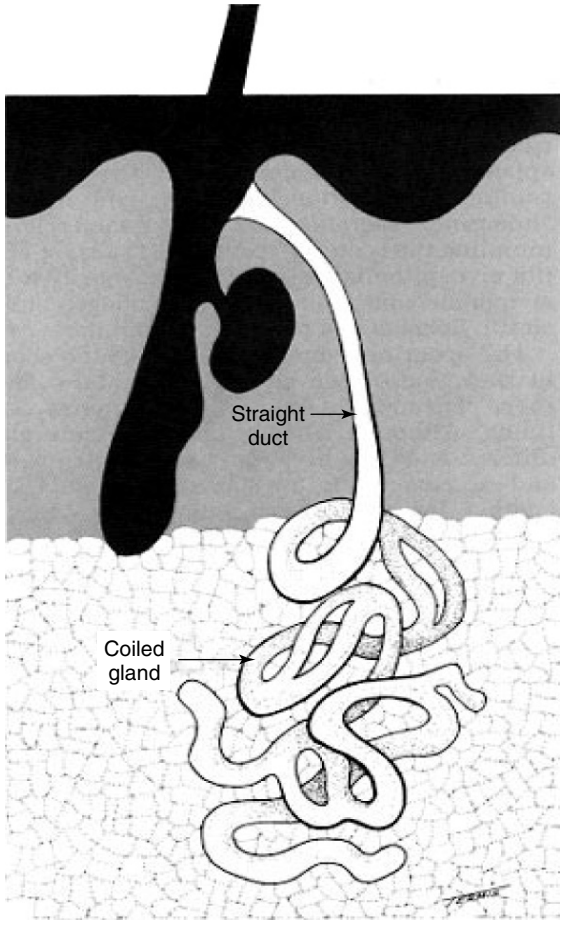

Figure 2 The apocrine unit: apocrine units consist of a secretory-coiled gland and a straight duct that traverses the dermis and empties into the isthmus (uppermost portion) of a hair follicle

skin or the developing hair follicles. Eccrine glands are located on most skin surfaces (not necessarily close to hair follicles), with the highest density on the palm of the hand, the sole of the foot, and on the forehead. These glands are innervated by sympathetic nerves. An odorless, sterile, aqueous hypotonic solution of weak acid pH is produced, derived from plasma by passive filtration. Water is the primary constituent approximately 99%, and sodium chloride is the most concentrated solute. Amino acids, biogenic amines, and vitamins are present only in trace amounts. The pH (4–6) is strongly associated with the amount of lactic acid excreted [2]. Apocrine glands are larger glands located in the shaft of the hair follicles from the armpit, genitalia, and anus. These glands are controlled by a cholinergic innervation but can be also stimulated by adrenergic agents. They secrete a more viscous, cloudy, yellow-white liquid, which is primarily sterile and odorless, rich in cholesterol (75%), triglycerides, and fatty acids (20%) [3].

Sweat also contains albumin, gamma globulins, waste products, trace elements, drugs, and many other substances found in blood.

The rate of sweating is highly dependent upon environmental temperature. Above 31 °C, humans begin to sweat and may excrete as much as $3\,l\,h^{-1}$ over short periods of time [4]. The average sweat pH of resting individuals was reported to be 5.82. Following exercise, the pH was found to increase with the increase in flow rate and was reported to be between 6.1 and 6.7. Approximately, 50% of sweat is generated by the trunk of the body, 25% from the legs, and the remaining 25% from the head and the upper extremities [4].

Multiple mechanisms including passive diffusion and transdermal migration have been suggested for the incorporation of drugs into sweat [5, 6]. Passive diffusion of drugs from blood to sweat is favored for lipid-soluble substances. As distinct from urine, where only drug metabolites are usually present, and from hair, where mainly parent drugs are incorporated, both parent drugs and their metabolites can be detected in sweat, similar to blood. Nonionized basic drugs diffuse into sweat and become ionized as a result of the lower pH of this biological fluid. Basic substances may accumulate in sweat as compared to blood due to the difference in pH between the two matrices. Some drugs may migrate across the dermal and epidermal layers into the stratum corneum. It has to be reminded that drugs are not only excreted by sweat glands but also by sebaceous glands or transdermal liquid transport. Sebaceous glands are associated with hair follicles and they are particularly abundant on the scalp and the forehead. They produce a viscous, yellow-white liquid oily sebum that consists of triglycerides (60%) and wax esters (23%). Excreted sweat and sebum cannot be examined separately. They form an emulsion on the skin surface, which facilitates intercellular diffusion along the cell membrane and a transcellular diffusion and transportation by the keratinocytes [3, 7].

Sweat testing is relatively noninvasive, and identification of drug in sweat may serve as a means

of monitoring recent drug use with a window of detection that can be somewhat wider than that provided by urine testing [8]. Although the use of sweat for drug testing has been hampered by difficulties in sample recovery and sensitivity of analytical methods [9], there are some distinct advantages in using this matrix:

1. Matrix collection is noninvasive.
2. Rapid qualitative on-site tests may be applied to this matrix.
3. Sweat testing can provide a means to obtain information on recent drug use and a cumulative estimate of drug exposure over a period of several weeks, depending on the device applied for collection.
4. The process of sample adulteration is quite difficult.

The disadvantages include the following:

1. Collected volume is generally small (from few μL in normal conditions to 1 – 5 mL when sweating is induced by physical exercise.
2. Production of a quantitative result in drug testing is difficult, since the volume of sweat collected is not measurable when traditional collections systems (cotton wipes, sweat patches) are used.
3. Possibility of environmental contamination should be taken into account.

Collection Devices for Sweat

One of the major difficulties associated with sweat has been its collection and the measurement of the volume excreted in a defined time period. The amount of sweat excreted considerably varies among individuals and even within a single person, and is dependent upon their daily activities, emotional state, and environment.

Systematic collection of specimens is difficult because of the unequal distribution of sweat glands. Indeed, because of regional differences in sweat gland density, the site of sweat collection has a striking impact on the collected quantity of drugs. Furthermore, since apocrine sweat glands are always proximal to sebaceous glands, mixed secretions of sweat and sebum, which are incorrectly referred to as sweat, are generally collected. Furthermore, different perspiration rates and volumes of sweat between individuals could also explain the large intersubject variability in sweat excretion of drugs as shown in controlled administration studies with 3,4 methylenedioxymethamphetamine (MDMA), codeine, and cocaine [10–12].

Sweat can be collected noninvasively by absorption with gauze, cotton wipes, or filter paper, or by collection of liquid sweat in rubber gloves or plastic body bags [8, 13, 14]. To increase sweat production and uptake, physical exercise is required during collection and pads are saturated with sodium chloride solution.

Thermal [15–17] or pharmacological stimulations using pilocarpine [18] have been proposed to secrete large amounts of sweat. In particular, pilocarpine stimulation has been used as a test for the diagnosis of cystic fibrosis via the determination of chloride [8]. In recent years, a sophisticated device "Macroduct® sweat stimulation by pilocarpine iontophoresis and sweat collection system" (Wescor Biomedical, Logan, UT, United States) has been developed and successfully applied in clinical studies using sweat testing in the diagnosis of cystic fibrosis [19] and drug testing at a pilot scale [20]. A modified model of the above-reported apparatus, the "Nanoduct Neonatal Sweat Analysis System®" (Wescor Biomedical, Logan, UT, Unites States) has been designed for the early laboratory diagnosis of cystic fibrosis in neonates [21].

In the 1980s, Phillips reported for the first time the development of an adhesive patch for the long-term collection of sweat (10 days) [22]. This patch was occlusive in design, trapping both the solute and water components, thus permitting the determination of analyte concentration in sweat. A disadvantage of the occlusive patch design was the limited time the patch could be worn because it caused a change in the matrix environment and skin irritation for the wearer [23].

A linear uptake rate of 18 to 47 mg/day of sweat was observed. It was suggested that it might be possible to monitor drug-taking behavior through the use of this patch. This sweat patch was later utilized in the validation of self-reports concerning alcohol use [24].

In the last decade, a new nonocclusive sweat collection device, the PharmChem® Sweat Patch from PharmChem Laboratories (Menlo Park, CA, United States), was developed and successfully applied to sweat testing for drugs of abuse [11, 25–27]. Typically, this type of sweat patch is worn during a

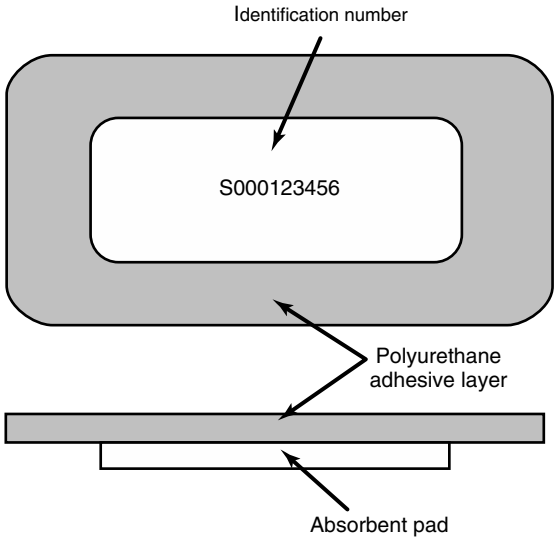

Figure 3 Scheme of PharmChek type patches used for sweat collection

period of one week, but can be also worn for shorter time periods (from several hours to some days) [10, 28].

This patch can be worn for an extended period and concentrates solutes on a collection pad while allowing water to evaporate from the patch. The device consists of an adhesive layer on a thin transparent film of surgical dressing to which a rectangular absorbent pad is attached (Figure 3). Sweat concentrates on the absorbent pad while oxygen, carbon dioxide, and water vapor escape through the transparent film. Larger molecules are excluded by the molecular pore structure of the plastic membrane. The skin must be thoroughly cleaned with isopropyl alcohol prior to affixing the patch to prevent contamination of the patch or interference with the deposition or detection of analytes on the patch. Attempts to remove the patch prematurely or tamper with the device are readily visible to persons trained to remove the sweat patch. Care must be taken not to contaminate the absorbent pad when removing and storing the patch prior to analysis [1].

A potential problem with the PharmChek patch is the absence of a layer between the skin and the absorptive pad to prevent bacterial transfer into the pad and, therefore, the possibility of bacterial growth and drug degradation. Careful preparation of the skin prior to application of the patch should kill or remove bacteria and prevent these problems. Also the absence of substantial moisture in the pad decreases the possibility of bacterial growth [17]. Several patches have been applied (in the back and shoulders) to subjects participating in controlled administration studies to folow the kinetics of drug distribution in sweat. Nevertheless in a situation of sweat testing of illicit drugs in parolees, probationers, or pretrial individuals, a single patch is applied in the forearm of subjects.

Fast Patch devices were developed in the 1990s as an alternative to PharmChek type sweat patches, in order to allow rapid collection of sweat specimens. The Handheld Fast Patch applied to the palm of the hand and the Torso Fast Patch applied to the abdomen or the sides of the trunk were used in controlled trials for cocaine and codeine, but they are no longer commercially available. Both patches employed heat-induced sweat stimulation and a larger cellulose pad for increased drug collection [14].

In Table 1, amounts of recovered substance when applying different sweat collection devices are reported. Cocaine has been used as a model substance to illustrate the performance of collection devices under different experimental conditions (controlled studies vs. field trials).

In this concern, Kidwell *et al.* in conjunction with Jet Propulsion Laboratory developed a system for the monitoring of parolees, probationers, or pretrial individuals. This system both collects sweat and tests it remotely [8]. Such monitoring may be more invasive than that used in the general population because the individuals are under a court order to abstain from drug use. In one embodiment of this device, labeled antibodies are bound to an immobilized drug layer. Drugs in sweat displace a small amount of these antibodies that are then trapped in a superabsorbent polymer layer. An optical system then detects the presence of the label and the readout may be transferred to a remote location using cellular phone technology. The superabsorbent polymer layer facilitates the absorption of substantial amounts of sweat before it becomes saturated, which improves the sensitivity of the device. Two polycarbonate membranes control fluid flow into and out of the sweat badge and improve user comfort. Similar to the polyurethane covering in the PharmChek system, the outer polycarbonate membrane prevents backdiffusion of liquid from the external environment, yet allows evaporation of moisture [8].

Table 1 Concentrations of cocaine in sweat as a function of sample procedure procurement

Sweat collection procedure	Number of subjects	Dose	Concentrations	Reference
PharmChek® Sweat patches	9	3 × 75 mg/kg (every 24 h in 1 week) 3 × 150 mg/kg (every 24 h in 1 week)	First week COC 3.7–197.1 ng/patch; mean(SD) BE 2.6–62.3 ng/patch; mean (SD) EME 3.6–29.2 ng/patch; mean (SD) Second week COC 2.6–59.7 ng/patch; range BE 4.3–162.2 ng/patch; range EME 3.9–41.9 ng/patch; range Third week COC 5.0–13.8 ng/patch; range ND EME 5–6.1 ng/patch; range	Kacinko *et al.* 2005

ND = non detected, COC = cocaine, BE = benzoylecgonine, EME = ecgonine methylester

In none of the collection tools, volume of collected sweat can be known and thus, amount of detected drug has to be considered "per patch" or "per cotton wipe" unless the quantity of drug can be related to either sodium or lactate concentration, both substances excreted relatively constantly in sweat and entrapped in patches and in wipes.

Considering the described devices, two different methodological approaches can be considered for drug testing in sweat [29].

The first is aimed at the detection of recent drugs use (less than 24 h) and involves only collection of sweat at a point in time. A punctual sweat collection coupled to an immunochromatographic test of the sample provides a qualitative result [10, 30, 31], or drugs in sweat collected on a cotton wipe can be extracted and subjected to confirmatory analysis [32]. This approach is mainly oriented to identify individuals who are under the influence of drugs.

The second approach is based on patch technology and allows monitoring of illicit drug use for time windows wider than those provided by urine testing. This is because the patches can be worn for up to one week. Drugs accumulate in the collection device, and little or no drug degradation seems to occur during this time interval [33]. Patch technology is used mainly for the follow-up of drug addicts under treatment to verify abstinence. Both approaches benefit from not being invasive and pose fewer ethical problems for sample collection compared to blood or urine testing.

However, there are several issues that still require a thorough investigation as they may limit the application of sweat testing using patch technology or at least the interpretation of obtained results: (i) environmental skin contamination, (ii) drug absorption/loss through patch membrane, and (iii) drug reabsorption from patches.

Sweat patches are sealed to the skin and are designed to exclude environmental contamination. Nonetheless, an *in vitro* study showed that several drugs of abuse directly applied to the skin of drugfree subjects may persist there for several days [34]. Therefore, cleaning procedures (e.g., by applying a swab impregnated with isopropanol to the skin) are recommended before application of the sweat patch to completely remove drugs deposited on skin. Thus, it might be argued that an environmental contamination prior to patch application is a possible occurrence, especially in the case of drugs of abuse that are usually smoked, such as cocaine or cannabis. Experiments proved that cocaine and its metabolite benzoylecgonine directly applied to the skin are more persistent than delta-9-tetrahydrocannabinol (THC) and 11-nor-delta-9-tetrahydrocannabinol-9-carboxylic acid (THC-COOH), but in any case these substances can remain detectable for up to three days after normal hygiene [34]. For this reason, the recommended procedure is to "clean" the skin with 70% isopropanol swabbing before application of the patch. However, isopropanol, being less polar than water, would neither hydrate the skin layer nor assist in breaking the ionic bonding of the drugs to skin

protein. Therefore, once bound to the skin, drugs could remain for several days owing to ionic bonding, not be removed by "cleansing" with the isopropanol swab, and appear in the patch after sweat- induced transfer, with the occurrence of greater concentrations when sweating is greater.

Hence, studies involving drugfree subjects exposed to heavily contaminated environments with cocaine or cannabis smoke should be performed in order to evaluate the relevance of these observations.

There are some reports suggesting that patch membrane is not only permeable to gases and water vapor but also to drugs to some extent[34, 35]. Drugs of abuse (e.g., cocaine, methamphetamine, heroin) applied on the surface of patch membrane can be absorbed, and drugs excreted in sweat may diffuse through the membrane to the outer environment. These findings suggest that membranes are more permeable than expected, although the rate of substance able to diffuse to the outer side is lower than 15% for the drugs studied [34, 35].

Finally, several studies suggest that there is a time-dependent loss of drugs during patch wearing over time. The loss of drugs of abuse from skin patches limits one of the goals of sweat patch testing: cumulative drug detection. Drugs may not persist inside the patch for two reasons: (i) they may be degraded by enzymes present in sweat, bacteria inside the patch, or the humid environment or (ii) they may equilibrate with the skin, passing from the patch back into the skin, eventually through the skin into the body, and be distributed and eliminated.

The reabsorption back to the skin has been recently hypothesized for two basic drugs, cocaine and MDMA [10, 35].

In both cases, the amount of drug spiked in the patches and applied to the back of volunteers declined over time, showing an inflexion in the kinetics at 24 and 10 h postadministration. Interestingly, in case of MDMA, a higher reduction of drug concentration in the 10 h postapplication patch was observed in a volunteer exercising in the gymnasium. It is known that temperature and physical exercise can change sweat flow and pH. It is known that a rise in body temperature or physical exercise could increase sweat flow producing an increase in sweat pH and the volume of sweat in contact with the patch, thereby facilitating drug transfer to the skin [34]. Indeed, in the above-reported study, the subject with a likely higher percentage of skin reabsorption participated in gymnasium exercise session during the experiment. This observation may be of relevance considering the consumption patterns of drugs such as cannabis cocaine or MDMA (parties, overcrowded, with high ambient temperature and physical exercise associated to dancing). Nevertheless, the impact of this observation in sweat testing performed under 'normal' conditions (i.e., seven days wearing patch) is unclear, as well as the rate of reabsorption for different drugs of abuse, especially in case of neutral or acidic drugs, poorly excreted through skin. Nevertheless, it is concluded that the final amount of a drug collected in the patch is the result of a more dynamic process (excretion vs. reabsorption) than expected. In this sense, chronic heavy users would be eventually detected, whereas this may not be the case for recreational users, giving rise to false-negative results.

Skin environmental contamination and drug reabsorption from patches that may lead to false-positive and false-negative results in the interpretation of analytical findings have to be considered, and experimental studies addressing these issues should be performed before drug testing in sweat may be considered routine.

Analytical Approaches

On-site Testing versus Instrumented Immunoassays

Drugwipe from Securetec (Ottobrunn, Germany) is the only non-instrument-based on-site immunochemical assay available for drug testing in sweat. It was designed for the detection of traces of illegal drug residues in body surfaces and liquid media. Different devices can be used for the detection of each class of drugs of abuse (opiates, cannabis, cocaine, amphetamines), although devices combining more than one drug class are also available. A pink color appearing in the test window should be compared with the color-check triangle on the Drugwipe cover. Sweat is collected with the wiping pad of the test kit moistened with 20 ml tap water. The other part of the detection element is an adsorbent pad, which had to be dipped into tap water to initiate the immunochromatographic reaction. In the presence of drug, the detection field of Drugwipe changes its color from white to pink, depending on the amount of drug collected. According to the manufacturer, the coloration of the whole test window is not necessary, but a line

on the edge could be sufficient to qualify a positive result. Coloration remains stable for at least 1 h. Results are classified as positive or negative either by qualitative observation of an analyst or by applying a reading device known as Drugread. Limits of detection of this device are in the nanogram range and vary from 10 ng for methamphetamine, methylenedioxymethamphetamine (MDMA, "ecstasy"), and cocaine, to 25 ng for opiates and 100 ng for cannabis. Drugwipe has been applied in different settings for the detection of MDMA, amphetamines, cocaine, opiates [10, 30–32, 36, 37]. While performance of Drugwipe when monitoring psychostimulants consumption is adequate, this is not the case for other drug classes like cannabinoids, where sensitivity is not adequate for the purpose of drug testing.

Different immunoassays including radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA) have been used for the detection of drugs in sweat [10, 12, 25–27, 38–41]. They differ from the current methods used for drug testing in urine since they are usually directed at the detection of the parent drugs and more lipophilic metabolites excreted in sweat, and they have an increased sensitivity because of the lower concentrations of drugs in this biological matrix or the lower amount of collected matrix. The most popular immunoassay used for drug screening in sweat has been microplate ELISA marketed by STC Diagnostics (Bethlehem, PA). This ELISA technique is a solid-phase competitive immunoassay involving horseradish peroxidase labeled with a drug derivative. The sample (or a calibrator or control) is allowed to incubate for 30 min with the labeled enzyme. After competition to bind to an antibody linked to the surface of the well where reaction takes place, wells are washed with water, a substrate (3,3′,5,5′-tetramethylbenzidine) is added, and the color produced after 30 min incubation is measured at 450 and 630 nm. Absorbance is inversely proportional to the amount of drug present in sweat. These ELISA techniques were originally designed for the detection of drugs in plasma and some modifications were needed for sweat testing. The main modification is the need for extraction of drugs from the patch/skin swab. Typically, cellulose is extracted with an elution buffer (e.g., 2.5 ml methanol/acetate buffer 0.2 M pH 5.0, 75 : 25) [25, 40]. The composition of the elution buffer may vary among authors depending on the drug targeted [27, 42], and a further solid-phase extraction (SPE) of the buffer extract has been also used to improve the performance of ELISA [10]. After shaking cellulose for 30 min with the elution buffer an aliquot of the eluate is analyzed by immunoassay. It has been suggested that, after collection of sweat, the patches should be stored at $-20\,^{\circ}C$ until analysis for an improved recovery of drugs, particularly for delta-9-tetrahydrocannabinol. Indeed, for this drug it has been observed that the recovery from cellulose is not quantitative, as part of the drug is bound to the cellulose [43].

Mass Spectrometry Coupled to Chromatographic Techniques

As stated earlier, there are no available on-site tests for sweat testing with the sufficient sensitivity to detect drugs at concentrations typically found in this matrix (i.e., cannabinoids) [31]. Therefore, samples are analyzed by laboratories after a preliminary screening by ELISA tests and further confirmation by mass spectrometry coupled to chromatographic techniques or directly by the later analytical techniques. Drugs from patches or skin swab have to be eluted by procedures previously discussed for the analysis of sweat by immunoassays. The eluate is further subjected to solid-phase extraction following procedures very similar to those applied in the analysis of drugs in urine or oral fluid with a specific requirement of increased sensitivity [44]. These sensitivity requirements have been defined by the United States Substance Abuse and Mental Health Services Administration (SAMHSA) mandatory guidelines for workplace drug testing programs when sweat is used as biological matrix for drug testing [45]. Cutoff concentrations for reporting positive findings are defined in terms of concentration per 2.5 ml of eluate. Some authors postulate that results should be reported as concentration per patch or skin swab [46].

Sweat Testing (Patch Technology) in Substance Abuse Treatment Programs as an Alternative to Urinalysis or Oral Fluid Testing

Sweat testing (patch technology) has been postulated as an alternative to urine testing in treatment and probation programs. Some of the advantages include a wider detection window, easier sample collection, and reduced opportunities for sample tampering. As an example, an added value in methadone

maintenance programs is the increased ability of detecting heroin and/or 6-acetylmorphine in sweat when compared to urine due to specific distribution patterns affecting both matrices, and was discussed previously [27]. This fact helps the differentiation between heroin misuse and other sources of opiates like therapeutic codeine prescription or the consumption of poppy seeds of dietary origin [27]. Overall, most studies agree that there is an advantage in sweat testing over urine testing, in particular, when urinalysis is performed twice or less weekly for monitoring opiate consumption [27, 47–50]. In a study comparing sweat testing (patch worn once in a week) and urine testing (thrice weekly) in a methadone maintenance program, results obtained for opiates by ELISA (sweat) and enzyme multiplied immunoassay technique (EMIT) (urine, enzyme multiplied immunoassay) were compared. Taking EMIT results as a reference for the comparison, an apparent rate of 13.5% of false-negative results and 7.9% of false-positive results was attributed to ELISA results in sweat. The sensitivity, specificity, and efficiency of sweat patch results to urine results for opiates were 68.6, 86.1, and 78.6%, respectively [27]. The clinical sensitivity and specificity for detecting drug use by analyzing sweat collected from human subjects following known doses of codeine (0, 30, and 60 mg orally) or heroin (20 mg intravenously) were 76 and 100%, respectively in an study promoted by sweat patch providers [26].

Some of the limitations of the sweat testing approach are the lack of correlation between drug exposure and patch concentrations and the subsequent qualitative nature of results, lack of analysis automation, and lack of controlled studies (except for cocaine and codeine) providing references for the interpretation of results [51, 52]. Further limitations lie on the potential of generating false-positive results because drug release from adipose tissue diffuse to skin in former heavy users once drug consumption is discontinued as it has been postulated in case reports [53] or environmental contamination [54]. A typical example is the possibility of methadone monitoring in sweat (including its chiral analysis) but because of the lack of correlation between doses and drug concentrations, this detection is just limited to demonstrate drug exposure [30].

Sweat patch technology testing has also been applied to monitor cocaine use in treatment programs and clinical trials. In the same study where 44 methadone maintenance patients were monitored for opiates misuse, cocaine consumption was also controlled by sweat testing [39]. ELISA techniques were used for the analysis of cocaine in sweat and results compared to those obtained by GC/MS in the same matrix and with EMIT results in urine. Cocaine was detected by GC/MS in 99% of presumptive findings by ELISA. The sensitivity, specificity and efficiency of ELISA when compared to GC/MS were 93.6, 91.3, and 93.2% respectively. When comparing sweat ELISA with urinary results by EMIT these figures were 97.6, 60.5, and 77.7%. Overall these results supported the use of sweat patch technology for monitoring cocaine use, confirming previous studies where cocaine was administered in a controlled setting [12]. In the context of a clinical trial in cocaine-dependent patients, sweat patches were compared with urine testing and participants' self-report of drug misuse [55]. Patches were worn weekly or per-visit and urine was controlled thrice weekly. There was a good correlation (0.96) between quantitative measurements in sweat patches (weekly vs. per-visit) and between sweat patches and urine analysis of benzoylecgonine (0.76 and 0.73 respectively). The per-visit sweat patch provided cocaine use data in 80.5% in study days ($n = 70$) while urinalysis and weekly sweat patch provided 77.4 and 76.1% respectively. The authors of this study concluded that sweat patch could be an alternative to urine testing as an outcome measure in cocaine clinical trials and that cost incurred in drug testing in sweat compared favorably with that in urinalysis.

Sweat Testing (Wipe Approach) in the Identification of DUID

Sweat could be a matrix of interest for monitoring drivers presumed to be under the influence of drugs (DUID), particularly if rapid drug tests would be available for on-site testing at the roadside [56]. Some studies already show that a combined approach of drug testing in different matrices (oral fluid, sweat and urine) can confirm approximately 98% of policemen suspicions at the roadside concerning drug use by drivers [57].

Two approaches have been used for monitoring drug use in sweat among impaired drivers presumed to be under its influence (DUID). In the first approach, sweat has been obtained with cosmetic pads moistened with isopropanol from forehead

wipes. Alternatively a noninstrumented immunoassay (Drugwipe, Securetec) has been applied for on-site testing after applying a collection pad included in the analytical device to the skin of subjects (e.g., forehead, neck, or back). Overall the skin swab approach provides results similar to oral fluid or urine drug testing but after collection the sample needs to be transferred to analytical laboratories for drug testing [31, 32, 42]. The most favorable situation for police officers that prefer sweat collection over other biological matrices would be the availability of on-site drug tests for sweat at the roadside. Nevertheless, available analytical devices lack the sufficient low sensitivity to detect drugs at concentrations present in this fluid, in particular for cannabinoids and benzodiazepines [42]. The best correlations between on-site Drugwipe results and plasma findings after applying chromatographic techniques in a series of 180 drivers who failed the field sobriety tests at police roadblocks are observed for basic drugs like psychostimulants (95% for amphetamines), and a poorer performance is observed for cocaine and opiates (76 and 75% respectively) [32].

RAFAEL DE LA TORRE AND SIMONA PICHINI

Symptoms *see* Psychopathology: Terms and Trends

Syndromes: Psychological

In medicine, the term *syndrome* is used to describe a group of signs and symptoms that collectively characterize or indicate a particular disease or abnormal condition: the sum of signs associated with any pathological process. For example, cardio-auditory syndrome [1] consists of the combination of sensorineural deafness and prolongation of the part of the standard electrocardiogram known as the *QT interval*. While there is no obvious connection between these two seemingly unrelated symptoms, research has determined that their co-occurrence is associated with other systemic characteristics that suggest a common etiology. An inherited autosomal recessive condition, the cluster is a distinct biodynamic entity and not simply a coincidental co-occurrence. Knowledge of the syndrome, moreover, is important because it alerts a clinician detecting a hearing problem to rule out the possibility of an associated heart condition that, if left undetected and untreated, may be fatal. The concept of syndromes takes on additional significance in medical–legal conditions such as "shaken baby syndrome" [2].

In the behavioral sciences, although underlying relationships between disparate symptoms is certainly known to exist, their fundamental biodynamic processes are not yet fully understood [3]. Mental health professionals, therefore, seldom use the term *syndrome*, preferring instead "disorder", which is unequivocally descriptive yet implies no specific etiology. In medicine, the disorder first described by Tourette is understood well enough to be classified as a syndrome, yet the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*), consistent with its accepted nomenclature, is only beginning to discuss the possibility of changing the condition's name from its more conservative label of "Tourette's disorder" [4].

The use of the official and scientific-sounding term *syndrome* as a description of behavioral science concepts developed specifically for use in the courts has and continues to create widespread concern not only in the United States [5] but also worldwide [6]. This has created extensive debate as to whether syndrome evidence meets admissibility standards as well as social and policy questions related to the use of behavioral concepts in ways that may influence the relationships between gender and racial groups. These issues can be best considered in the context of the evolution of syndrome evidence, and the legal conventions that have emerged to deal with its abuse.

Syndromes and Behavioral Evidence

American trial law is unique in that it does not rely simply on whether a defendant did or did not do a particular deed, but looks beyond the obvious facts to motive, intent, and circumstance. State law typically considers mental state broadly as a question of fact to be answered by the jury at trial. Courts in some jurisdictions may therefore grant a *presumption* of sanity and requisite mental circumstances, but if a

defendant asserts a defense based on mental criteria, the burden of proof may shift to the prosecution to disprove the facts of the defense's assertion (*see* **Behavioral Science Evidence**).

All of this makes for subtle procedural distinctions, and it is therefore not surprising that jurors and also judges and lawyers can find the issues confusing. Such a misadventure occurred in the 1988 *Mulica* case [7]. No one disputed that John Mulica had made off with and squandered more than $200 000 of someone else's money. The problem confronting his defense was finding a way to keep John out of jail. The "compulsive gambler defense" had been tried before in other jurisdictions and by the late 1980s had been thoroughly discredited [8]. Posttraumatic stress disorder (PTSD) had only recently been defined and, amidst continuing debate, incorporated into the then-current *Diagnostic and Statistical Manual* [9] (*see* **Posttraumatic Stress Disorder**; **Malingering: Forensic Evaluations**).

The defense asserted PTSD, and the jury had little trouble sorting out the facts of the case, but everyone became confused when the jurors were about to start their deliberation and the judge explained the law. The jury could have accepted that John was a compulsive gambler, but that particular mental state would have gained the defendant nothing in the way of leniency. The judge then asked the jury to base its ruling on PTSD, but when the jury convicted and appeared to reject that argument, the defense contended that it should be able to assert a different theory.

The appellate courts agreed, holding that the prosecution is not relieved of its burden of disproving a defendant's mental incapacity simply because a defendant pursues a focused trial strategy centered on a diagnosis that the jury rejects. The decision was not intended to issue a fishing license for the murky waters of diminished responsibility, but to warn prosecutors to shut all of the doors to these "novel" defenses the first time around. Nevertheless, the prospect of a potential "mini" mental status defense – a defense that could get a defendant out from under a criminal charge without meeting all of the formal requirements and probable confinement reinstated as a part of the actual insanity defense – was too great a temptation for defense attorneys to ignore (*see* **Insanity: Defense**; **Temporary Insanity**).

There is little doubt that stress can change lives. As international traumatic stress expert Bessel van der Kolk said, summarizing a career of research, "overwhelming social experience can become indelibly etched in people's memories and set up a cascade of disturbances that can permanently alter their capacity to regulate their biological systems" [10]. Stress, however, is a fact of life. The same events can have very different impacts on different people, and people can and do recover from extraordinary experiences and never turn to these experiences as justifications for failing to observe reasonable standards of human conduct.

Perpetrators as Victims

For centuries, men killed and were set free by juries who applied the "Unwritten Law" that men are justified in taking out their anger against an unfaithful spouse or her lover. The fact that even more women acted on the same anger and benefited from unwritten social mores did little to change the fact that other women without a convenient excuse for murder endured desperately unhappy marriages. In the late 1970s, psychologist Lenore Walker was called in as an expert witness at several trials of women who had killed their husbands. To help explain the common threads of these cases, Walker came up with a theory of "learned helplessness". A husband may beat his wife for overcooking an egg, or for undercooking it; for turning on the TV or for turning it off; for talking or for keeping still. Eventually, she finds that there is no connection between what she does and what happens to her. Why go on trying?

Learned helplessness is, of course, not unique to women; but it did seem to fit the stories reported by many women who had murdered their mates. Walker's book, *The Battered Woman* [11], struck a resonant cord in the feminist movement, and became well known to lawyers representing women charged with the murder of their mates.

For seven years, Ernest Kelly drank and beat his wife Gladys. She would move out, he would promise to change, and she would return to him. Their rows were ongoing, but usually took place out of public view; but on May 24, 1980, as the typically drunk Ernie and his bride of seven years walked down the street, Gladys stabbed him to death. According to prosecution testimony, Gladys started a scuffle. Quickly separated and restrained by passersby, Gladys shouted that she would kill her

husband. Breaking away, she chased after him, pulled a pair of scissors from her pocketbook, and took his life.

The defense tried unsuccessfully to introduce expert testimony on battered woman's syndrome, but the Supreme Court of New Jersey, in an opinion that draws extensively from Walker's work, overturned the conviction, holding that the research on battered woman's syndrome was "sufficiently reliable" to meet the standards for "scientific testimony" [12].

Battered woman's syndrome, and psychological syndromes in general, would remain a subject of controversy in the criminal law for the remainder of the decade [13, 14].

Human behavior in the context of the law, however, is not only subject to all of the vagaries inherent in mental health, but is compounded by the obvious vested interests of parties to litigation in which not only vast sums of money but freedom and life itself are often at stake. To what extent is it appropriate to lend the imprimatur of "science" to opinions about human behavior and motivation in the context of a criminal trial? Was the judge at Gladys Kelly's trial correct in believing that such testimony was little more than an attempt to "explain and justify" as opposed to sharing scientific findings beyond the experience of the jury?

There can be no clear, bright line between the point at which behavioral science ends and advocacy begins. Inherent in American justice is an acceptance that justice requires consideration of both actions and intent. In a secular culture, our source of guidance in that gray zone, which forms the buffer between worthy and unworthy intent, has fallen, by default, to the behavioral professionals [15]. However, responsibility for acting appropriately on that guidance, like the responsibility for distinguishing good from evil, is one which cannot be delegated [16].

While it is the jury that must define justice, it is the courts that must define the rules of evidence. This was the duty confronted by the Supreme Court of Ohio in *State v Koss*, [17] and either course open to that court brought with it a potential for hindering the administration of justice. At the heart of *Koss*, however, was not a simple act of murder but the seemingly inexplicable behavior of the woman accused of the crime. Where Gladys Kelly simply stabbed her husband, Brenda Koss spent the next day following a routine that seemed inconsistent with her alleged conduct. In the years following *Kelly*, the battered woman's movement had grown increasingly sophisticated [18].

In the process, social psychologist Angela Browne made an observation that the *Koss* court found directly on point. "A history of physical abuse alone does not justify the killing of the abuser," she wrote. "Having been physically assaulted by the abuser in the past is pertinent to such cases only as it contributes to the defendant's state of mind at the time the killing occurred" [19].

The significance of the "syndrome", thus suggested, was *not* to offer a legal excuse for murder. If in fact expert testimony could help the jury make sense of Brenda Koss's unusual behavior in the hours after the crime, then there should be no reason why the jury need be denied its benefit. Obviously, the defense attorney could argue the theory to the jury, but lawyers are not behavioral scientists and are not generally subject to cross-examination. Let the jury hear the theory, the Supreme Court of Ohio concluded in its landmark *Koss* decision that proved a turning point for judicial acceptance of syndrome testimony nationally – the jury will be free to make of it what they may.

Once opened, however, the door to mental health "exotica" proved difficult to monitor. Within a year, the courts were flooded with expert witnesses of dubious distinction hawking plausible theories as implausible defenses. A new definition of syndrome had been created specifically for trial law: A syndrome (legal variety) = (i) socially unacceptable behavior + (ii) a sympathetic antecedent combined with (iii) a behavioral dynamic explanation [20].

In 1985, Lisa Becker Grimshaw arranged for two male friends to waylay her husband in a wooded area where he was bludgeoned to death with baseball bats. She used the battered woman defense and was convicted of the lesser charge of manslaughter. By the early 1990s, however, when the case reached appeal, even the highest courts in the nation were growing impatient with "expert" witnesses, and the Supreme Judicial Court of Massachusetts concluded that the prosecutor's use of the term *hired gun* to describe Lenore Walker, while "to be disapproved of", was not a reversible error in this case since the characterization did not create a "substantial risk of miscarriage of justice" [21].

Syndromes became *the* behavioral science tool of the defense. The conduct that most frequently placed defendants in need of legal refuge, not surprisingly,

centered on primal forces of sex, drugs, greed, and ambition. In the late 1980s, with the arrival of widespread cocaine abuse and particularly crack cocaine, also known as *freebase* or *rock cocaine*, the justice system and society itself was confronted by a tidal wave of crime and health problems. Cocaine abuse by pregnant women ranged from 1% to over 10% in urban areas, with resulting birth defects that will affect the health and functioning of their children throughout their lives.

Many drug abusers have preexisting psychiatric conditions. Others develop symptoms as the consequences of abuse begin to take their toll. By the early 1990s, courts were faced with the potential of countless defendants claiming lack of responsibility for the consequences of events, which the defendants themselves had set in motion. *Commonwealth v. Herd* [22] was a turning point in the resolution of that issue. Reginald Herd had been using cocaine when he beat his girlfriend's three-year-old son to death with 277 blows of an electric cord. He pleaded lack of criminal responsibility, but a noteworthy appellate decision provided the first clear guidelines on the role of drugs in diminished capacity. While *Herd* does not preclude a defense of legal insanity by drug abusers, it does preclude a diminished responsibility defense for symptoms produced by drug abuse, even by a person who begins or continues drug use knowing that it will or may arouse symptoms of a preexisting mental disease or defect.

By the late 1980s, PTSD, first officially created in large part not only in response to patient demands for an officially recognized diagnosis that would fit their symptoms but also in response to shifting attitudes to Vietnam veterans, had become in the words of many mental health and legal professionals the "black hole" of litigation [23]. The diagnosis remains controversial, and many experts would prefer to see it eliminated or at least replaced with something more objective [24–27]. Everyone does agree, however, that no other diagnosis in American psychiatry has had as profound an influence on civil and criminal law.

Charles Delaney and his estranged wife were in the midst of an ongoing disagreement over child custody when he strangled her with a garrote. The grave that he had dug two days earlier hardly suggested that the crime was spontaneous and unpremeditated. Yet like many other veterans, when charged with his crime, Delaney blamed his conduct on the trauma of military service and arrived at trial prepared to impress the jury with war stories.

Just as physicians make it a practice to be among the first to read each month's issue of the *Reader's Digest* medical column to be prepared for the expected symptoms of the month, psychiatrists had learned to follow the current films. Movies like *The Deer Hunter* and *The Burning Bed* – in themselves valuable contributions to a nation's awareness of the unseen scars of trauma and abuse – made excellent guidebooks for anyone searching for excuses to avoid criminal conviction [28]. Military veterans themselves have been among the most active and successful at routing out false claims of military stress "syndrome", which they rightly consider an affront to every serviceman who has returned to civilian life and managed to avoid taking out their frustrations on innocent bystanders.

Delaney claimed, among other defenses, that he had recovered bodies from the October 1983 bombing of the Beirut Marine Barracks. His commanding officer, however, had no knowledge of such an experience, and recalled that the tank mechanic had spent most of his Lebanon tour in a hotel and had never been exposed to combat or even hostile fire. A psychiatrist who examined Delaney prior to trial noted that Delaney brought attention to a twitch, similar to that seen in movies about traumatized veterans, which Delaney affected on initial interview but that vanished when the defendant was alone. Suspecting that he was being led to a self-serving diagnosis, the psychiatrist asked Delaney if he had the nightmare that occurred every night in PTSD victims. Delaney said that he did, but was unable to describe their content and observers were unable to note any indications of actual sleep disturbance.

Delaney was appealed all the way to the highest court in the state, and although each review devoted careful attention to assuring that all of his due process rights had been fully protected, Charles Delaney's murder conviction was upheld [29].

By the time Norma Roman came up with her multiple personality disorder (MPD) defense in the early 1990s, arguing that while one of her personalities may have been caught dealing drugs but her "core" personality was law abiding, the diagnosis itself had begun to wear thin. The courts found that at least one of the "personalities" had criminal intent, and upheld her conviction [30].

No one had ever heard of "multiple personalities" until the 1950s when Chris Sizemore presented with the symptoms that became the basis for the celebrated book and 1957 Academy Award *tour de force* movie *The Three Faces of Eve* starring Joanne Woodward as a woman with separate identities and personalities. Patients, well coached in their performance by *Eve* and its imitators, soon learned to oblige their doctors with similar manifestations, and suddenly America had an epidemic of "split personalities". It was not until the 1980s that clinicians responsible for treating patients at public institutions began to compare notes and discovered that none of them had ever seen a case of MPD. The condition, it seems, had been restricted largely to private patients who had the time, money, and imagination to keep up with the popular arts (*see* **Deception: Truth Serum** for a discussion of the condition that succeeded MPD).

Chris Sizemore, in the meantime, had gone on to become a celebrity and dynamic lecturer. MPD enjoyed a brief vogue as a criminal defense, but the lawyers soon figured out that whichever of their client's personality had done the dastardly deed, they would all hang by the same neck and therefore that particular courtroom charade really was not worth the effort [31].

In a sense, the concept of multiple personalities actually had some validity, and anticipated, by decades, the discovery of the dispersed operation of the human mind [32]. It was the notion that each of the dispersed components would have their own names, wardrobes, and identities that was pure fabrication; or at best, an analogized externalization of an inventive but marginally integrated personality. Chris Sizemore became as active as anyone in correcting the false impression that "multiple personalities" could exculpate a criminal defendant.

Only rarely has a court accorded any significance to a criminal defense plea based on multiple personalities, which makes the 1993 decision in *United States v. Denny-Shaffer* [33] worthy of note. A New Mexico delivery nurse, 37-year-old Bridget Denny-Shaffer, had a history of depression, abusive relationships, and two failed marriages when her pregnancy by a boyfriend ended in miscarriage. Wearing the uniform and false credentials of a medical student, she later walked into the nursery of another hospital, examined several of the babies, selected one of the infants, and walked away with the child undetected. Arriving at the home of her boyfriend in visible (yet false) pregnancy, she spent the night and the next day when the boyfriend returned home from work Bridget greeted him from a blood soaked bed, held out the missing infant, and said "This is your little one."

Thrown out by the boyfriend, Denny-Shaffer and the infant began a cross-country odyssey that ended in an Federal Bureau of Investigation (FBI) stop and a federal conviction for interstate transport of a child unlawfully kidnapped. Her counsel had chosen to assert a multiple personality defense that crumbled in the realization that the diagnosis was being discontinued and in any case one that could not protect her under the post-Hinckley federal insanity guidelines. A sad and sympathetic figure by any definition, her case was taken up by the US Court of Appeals that reversed the conviction and sent the case back for retrial. The decision, however, had little to do with psychiatry and a great deal to do with justice.

Even in early England, with its formalistic legal codes that offered prosecutors little discretionary authority, justice often prevailed despite the law. At a time when the "gentlemen" of the jury were truly gentlemen in the sense of rank and privilege, the early English courts would often look the other way and allow a jury to hand down decisions contrary to law [34]. Known as *jury nullification* in the legal vernacular, America's reconceptualization of justice administration made the practice largely unnecessary. In fact, America's obsession with fairness has led it from justice by judicial discretion being denounced as too prejudicial to this group or that, followed by its replacement with mandatory sentencing guidelines, which are then denounced as too inflexible to serve the interests of justice – a cyclical gyration with often paradoxical consequences [35].

In the case of Denny-Shaffer, the Court of Appeals concluded that a jury could not do any worse by Bridget than what she had already endured, and asked the trial court to reconsider the "jury's right to determine credibility, to weigh evidence, and to draw justifiable inferences". In short, with all due respect to the insanity guidelines, perhaps this was one best left to the common sense of a jury.

No one has yet tried to palm off a bogus syndrome defense under *Denny-Shaffer*, but the case has come to represent a small milestone for juror discretion. Perhaps this reflects, in part, a measure of faith in the axiom that anyone who is able to consider a mitigating defense before committing a crime is unlikely to see that defense accepted by an actual

jury. Less visible to the public, however, was an equally insidious potential for behavioral forensic abuse by the prosecution.

Effect as Proof of Cause

Generally, we think of legal "syndromes" as a tool of the defense. In reality, they have been used to support anything and everything that may be of help to either side.

In *State v. Allewalt* [36], prosecutors sought to convict a 17-year-old of the rape of his girl friend's mother despite testimony by both the defendant and the girlfriend that the mother had initiated the encounter. In this case, the prosecution reached out for expert behavioral syndrome testimony; not simply in an effort to bolster the credibility of and sympathy for the mother, but to use that credibility and sympathy to convict the defendant. As with so many legal "syndromes", the scientific credibility of the testimony drew upon PTSD. Although there have been endless court battles over the admissibility of testimony on everything from "battered spouse syndrome" (**Battered Spouse Syndrome**) and "Vietnam survivor syndrome" to "rape trauma syndrome" [37] and "child sexual abuse accommodation syndrome" (**Child Sexual Abuse Accommodation**) [38], all draw their scientific credibility not from any legal "syndrome" but from the *Diagnostic and Statistical Manual of Mental Disorder*'s inclusion of PTSD as a recognized diagnostic entity.

The PTSD diagnosis, however, was never intended to support litigation. PTSD was included in the *DSM* upon the insistence of *clinicians* who had been confronted by people with symptoms of often-unknown etiology. Often these individuals had difficulty being taken seriously because family, friends, and officials doubted whether they had experienced anything at all which would justify all the fuss. People know, from their real-life experiences, that secondary gain is a powerful motivation. The world is filled with unhappy, vindictive, or envious folks who want recognition, support, and an explanation for their emotions. While this is by no means the explanation of all or even most requests for emotional help, much of the work of behavioral therapy is an investment of human effort in search of a meaning for the events of daily life.

Every day, people have disputes in which it is impossible to sort out the true facts and establish who is right and who is wrong. That is why we have courts. Courts settle disputes by considering all of the evidence and taking a side – this is how we *define* justice.

Clinicians have traditionally been uninterested in objective truth or official blame. Clinicians confront people with problems, and it is their job to address those problems. If a person seeks help for an emotional issue, it really does not matter *how* that issue arose. Since everybody faces disputes every day, and most of these disputes are resolved in one way or the other, everyone by that definition is wrong half of the time. At best, most people learn to compromise and accommodate; nevertheless, most still have some positions on which they are reluctant to go against what they consider right. Others are unhappy because of an entire host of problems that most observers would consider to be of their own making. Others always try to do the right thing yet have exceptionally bad luck. Still others are unhappy because they got what they thought they wanted but are having difficulty living with the price.

Psychotherapists recognized that quibbling over blame would not help – that prolonging dispute, by itself, would just make matters worse. Therefore, they learned to be *nonjudgmental*: to accept what the patient said and move on from there. Some therapists even took a further step and tried to teach the world to take people at their word. Others, quite correctly, pointed out that regardless of fault, stress can cause people to do strange things. Blame is often just a further complication. In a great many cases, however, people can and do have mixed feelings, and these conflicting emotions contribute to distress as much if not more than being a completely blameless victim of uncontrollable forces.

PTSD, as a *DSM* diagnosis, was ultimately accepted simply as a name for powerful emotions, and a diagnostic label through which these emotions can be explored in the context of an environmental explanation. It has four criteria. Three of these relate to emotions: persistent reexperience; the avoiding of people, places, and feelings; and increased arousal. The fourth, placed first on the list, is a past confrontation with a threat that generated intense fear, helplessness, or horror. The diagnosis *assumes* that the environmental trigger is the *cause* of the emotions because the person in treatment *reports* reexperiencing and avoiding things that are related to that experience.

It is significant to consider that the association of experiences and powerful emotions predates the inclusion of this diagnosis in the psychiatric lexicon. In fact, recognition of the association predates Freud and the birth of modern psychodynamic insights. Prior to Freud, professionals who dealt with emotional issues were quick to assume very simplistic relationships between objective events and subsequent emotions – what behaviorists termed *stimulus and response*. Even Freud's early work is filled with just such assumptions. However, as Freud and those who followed progressed in their research, they came to the realization that few causal links are all that simple. The basic defense mechanisms are, in fact, explanations as to just why simple assumptions are generally wrong.

Yet such discredited assumptions are implicit in the acceptance of PTSD as a diagnostic entity. To make the diagnosis of PTSD is to say that there *was* a traumatic event and that the event *caused* the response. This is why PTSD encountered so much resistance in the professional community, and why it took so long for it to be included in the *DSM*. In the end, it was included because the clinicians mustered greater political power than the researchers and scholars. The clinicians wanted to be able to meet a market, and activists who wanted to be able to assert that identifiable life problems were the obvious source of common emotional conditions were a major force in developing the *DSM*.

The original logic behind the legal acceptance of behavioral "syndromes" was grounded in solid psychodynamic theory. People who have been through traumas do inexplicable things. They may be slow to report victimization, fail to take obvious defensive measures, and even maintain a seemingly pleasant relationship with their victimizer. People, who must nevertheless unravel the truth of criminal assertions, including juries, need to understand this. The original purpose of expert testimony was to provide that knowledge.

By testifying that a person has PTSD, however, an expert *by definition* appears to be testifying to the *truth* of the alleged charge. That expert, moreover, lends full weight and authority not only of their personal presence and qualifications but also of all the mental health professions as well. This conclusion is hard to avoid in any such testimony, and is further complicated in *Allewalt* by the psychiatrist's *explicit* statement of the causal conclusion.

In a case like *Allewalt*, there is no way of ever knowing whose story is correct. Both accounts may be completely accurate from the point of view of the person recounting the events. Alternatively, for all we know, the psychiatrist may have gotten it right [39]. At best, Bill Allewalt cannot be commended for his judgment or restraint. Nevertheless, there is another way to look at the facts. Clearly, the deed was done, and clearly, the mom was very unhappy afterwards. Many of her symptoms, however, were consistent with behavior she had been exhibiting for at least three months before. Her testimony also includes references to the fact that following her encounter with young Allewalt she wondered if neighbors, friends, and acquaintances thought she was "cheap", or if she was "dressing cheap", or if they were looking at her out of the windows when she came out of her home. She was no longer comfortable around young men, and was withdrawing into herself.

She was a woman, married for 16 years, and dealing with the reality of living alone. She had been thrown into daily close contact with a healthy young man who was living with her daughter. It does not take a psychiatrist to come up with dozens of alternative scenarios; each more or less favorable to one side or the other. Most jurors could come up with an even longer list. This is the point in fact, and why it is so helpful to be able to call upon a credible "expert" to cast one's own preferred spin to a jury.

Allewalt is still law in Maryland (although its reasoning has been rejected elsewhere) [40], and was cited as precedent in one case that made it all the way to the US Supreme Court [41]. However, one lone voice on the seven man court which decided *Allewalt* had an interesting suggestion. "I agree," the Judge said, "that testimony explaining posttraumatic stress disorder (PTSD) is admissible ... [but] I do not agree that opinion testimony should be received on the question of whether the complainant actually suffered PTSD" [42]. The remainder of the court dismissed the observation as irrelevant to the question placed before it, but the following year the state of Washington took a broader view:

> The courts which have admitted rape trauma syndrome testimony believe it sufficient that the myriad of symptoms encompassed therein are 'generally accepted to be a common reaction to sexual assault.' We find, however, that this is not the relevant question. The issue is not whether rape victims may display certain symptoms; the issue is whether the

> presence of various symptoms, denominated together as 'rape trauma syndrome', is a scientifically reliable method admissible in evidence and probative of the issue of whether an alleged victim was raped. The literature on the subject demonstrates that it is not [43].

Perhaps the most serious problem with syndromes is that in their propensity to depict victims, they create indelible images of alleged perpetrators. This is illustrated vividly in the *Banks* case in which an offender profile was misused to convict Sgt. Russell Banks (*see* **Profiles: Psychological and Behavioral**). The problem came to world attention through the "recovered memory" cases in which dissociative disorders were cited as proof not only that a crime had taken place but also to identify and convict perpetrators who were simply inferred from the nature of the "syndrome" (*see* **Deception: Truth Serum**). Any syndrome or behavioral concept that is advanced to not only describe an effect but also establish a cause must be viewed with special concern.

Evidentiary Standards

Behavioral dynamics are integral to human conduct, and in jurisdictions including the United States they are inextricably linked to the tasks confronting the triers of fact (*see* **Behavioral Science Evidence**). In recent years, judges have become increasingly familiar with behavioral science evidence and expert testimony [44], although their understanding and application of the discipline continues to be questioned [45].

In any trial in which behavioral dynamics have a bearing upon the questions that must be addressed by the trier of fact, the court cannot assert that the topic is irrelevant. If behavioral science evidence or expert testimony is proffered, its admission can only be excluded to the extent that it is cloaked in any inappropriate imprimatur of science or proposes to address issues that are beyond the appropriate scope of the relevant issues of fact. Usually, the question becomes one of credibility rather than admissibility. The court, and opposing parties, must nevertheless assure that scientific standards are upheld, and that the evidence is kept within appropriate boundaries.

Research on actual judicial practice confirms that the courts are admitting behavioral science evidence, and that the unique properties of that evidence are not in themselves viewed as grounds for their prohibition under *Daubert* or other emerging evidentiary standards [46].

Syndromes and Public Policy

In medical malpractice cases, for example, the facts in dispute are generally of sufficient complexity and beyond the daily experience of the court that the law may *require* that expert testimony be introduced to explain the issues and to help frame the questions that the jury must answer. In this unique role, the expert is allowed to speak from general experience and knowledge, and to apply that expertise to facts in dispute even though the expert may have little or no direct knowledge of the facts in the specific case. Between direct testimony and in cross-examination by opposing counsel, it is assumed that the jury will have the opportunity to weigh the expert's opinion and the extent to which that opinion should be relied upon in deciding the case.

In legal cases that involve human behavior, however, it is more difficult to define the appropriate role of the expert. While most nonphysician jurors can easily see how an expert can help them understand a medical issue, most human behavior is not considered beyond the expertise of the general public. People deal with behavior, their own and that of the people around them, every day. Knowledge of the appropriate standards for human behavior – the distinction between right and wrong – is something everyone is taught and then tests against the realities of life from the day they are born.

To understand that abused women may chose to freely remain with their abuser rather than take steps to change their situation is not the same as concluding that this common behavior justifies the subsequent murder of the abuser. To cite the statistics that young black men frequently kill other human beings does make it any more likely that a jury will then conclude that this justifies a dispensation for future black murders – even if you dress up the argument as "Black Rage Syndrome".

The core of the scientific evidence concerning battered women, and black offenders, and virtually every other identified special population which comes before the courts, is that people can and do assess their options; and that often people see their options

as far more limited than they may well be in actuality. This is the "learned helplessness", which Lenore Walker saw in the battered women who went on to kill their abusers, and a similar inability to see more reasonable solutions to common problems has influenced both the characterization of defendant populations and the rationale for sharing this insight with the triers of fact who must determine their fate.

Radical activists, on the other hand, responding to their own agendas, have extended this logic to conclude that all injustice could be eliminated if only the courts would always take their side in any dispute. When there are no witnesses, and we come down to the word of one person against another, we always assume that the woman is right, or the racial minority is right, or that whoever the special interest group represents must be and always will be right.

One problem with this advocacy logic is that it does not stop at simply accepting scientific observations noted in some members of a given population, but elevates these observations to the stature of an inevitable truism. This has the paradoxical consequence of turning members of minority groups into apologists for the very negative stereotypes that most members of that minority group abhor.

Women's legal syndromes, therefore, have come to paint women as indecisive clinging predators who mean no when they say yes, who cannot be trusted to make up their own mind, and who are unable to take responsibility for their own actions and decisions [47]. It has taken decades for lawyers to correct stereotypes created by Lenore Walker and her "battered woman" syndrome; laying a foundation under law for women to save their marriages or have them end in something other than murder or perpetual entrapment [48, 49].

Minority syndromes have similarly painted blacks as violent and impulsive [50, 51], Hispanics as playing by their own rules [52], white men as unable to tolerate the normal vicissitudes of daily life [53], and most foreigners as unable to live in our land of opportunity without welfare and our toleration of their behaviors, which we would consider unacceptable in our own offspring [54].

The American judicial system does not condone and will actively oppose any attempt to use the courts as a forum in which to propagate stereotypes about the relative worth of one group as opposed to another. The justice system, however, does share with all of the responsible institutions in our society a stake in providing citizens with a maximum opportunity to fully understand their options and obligations, and in helping people to make informed choices with which they are both willing and able to abide. This is a desire, however, which the justice system must always balance against its unique duty to preserve, for each responsible American, the ability to make free choices and to live with the fruits of those decisions, both good and bad.

If a dispute involves issues that are truly beyond the experience of a jury, for example the conduct of a person held hostage for a prolonged period, the jury is much more likely to defer to professional expertise. Furthermore, if expert testimony is reasonably consistent with the natural instincts of the jury, they are more likely to accord weight to the testimony and perhaps modify their judgment accordingly. A case in point is the trail of newspaper heiress Patricia Hearst for her part in the April 15, 1974 armed robbery of the Hibernia Bank in San Francisco. Hearst had been taken captive by the radical Symbionese Liberation Army, but later joined her captors as a gun-wielding member of their gang. At trial, experts testified that such behavior was not uncommon among hostages who come to depend upon and identify with their oppressors (*see* **Stockholm Syndrome**).

Captive or "Stockholm" syndrome testimony was novel at the time [55], and led to a major battle between experts as to its applicability. In the end, however, the jury convicted Hearst; not necessarily because they failed to believe the experts who testified that allying with captors was a fairly common phenomenon, or even because they believed that being a hostage was sufficiently within their own experience so that behavioral expertise was unnecessary, but because it was their judgment that regardless of how common the behavior may be it should not excuse or justify armed robbery.

The courts have grown increasingly wary of the use of any legal "syndrome", ascribed to a complainant in a criminal trial, to support an inference that the accused is, in fact, guilty of the crime [56]. On the other hand, courts continue to recognize that expert testimony as to how victims of the *type* of crime alleged by the prosecution typically conduct themselves can assist the trier of fact when such testimony does *not* carry with it any opinion as to whether the complainant is telling the truth about

either the crime itself or an alleged offender [57]. In addition, expert testimony is generally held to be admissible when it is used to refute suggestions that a prosecution witness may be unreliable due to behaviors that can be better appreciated by the trier of fact when placed in context by expert testimony [58].

Use of complainant syndromes, however, is a two-edged sword. Not only are prosecution experts open to attack under cross-examination and their testimony potentially turned to the benefit of the defense but the defense can also introduce their own experts who may characterize the complainant to the advantage of the defendant. Georgia, for example, experienced a spate of cases in which accused child molesters sought to introduce expert testimony on the "Lying child syndrome" in hope of discrediting complainants [59]. The "syndrome" detailed the propensity of a child to relate and to repeat untruthful statements about a person who is an authority figure in their life in order to manipulate that child's environment to advantage. The courts, which characterized the phenomenon as not "unique as a mysterious area of human response", said, thanks but no thanks – we know about that one and if the jury doesn't, it can figure it out for itself.

Conclusions

After a decade of debate and publicity, the legal status of the most advanced behavioral science contributions to the criminal justice process remain wedded to fundamental concepts that would be easily recognized by the twelfth century jurist Henry de Bracton were he with us today. In order for syndrome evidence to be admissible, the physical, emotional, or mental condition addressed by the evidence must be presented in a manner that meets the scientific requirements for legal evidence [60]. Expert testimony concerning a trait of an accused may only be used as evidence that the accused possesses such a trait. It must be left to the jury to determine whether and how such a trait may influence its view of the facts of the case [61]. Although the term *syndrome* may appear to give behavioral evidence an aura of scientific respectability, such labels themselves do nothing to enhance the stature of the substantive underlying observations. In fact, if anything, good science and credible observation are more readily accepted without them [62].

Temporary Insanity

Insanity is a legal, not medical, term (*see* **Insanity: Defense**). Although the term has wide popular usage as a way of referring to any type of mental illness, it carries no specific medical meaning. Broadly speaking, psychiatric illness consists of symptoms that cause impairment of cognition and/or mood. An illness is diagnosed when a practitioner can match groups of signs and symptoms to a particular diagnostic label. In psychiatry, these diagnostic labels are included in various standardized handbooks. In the United States, it is the Diagnostic and Statistical Manual-IV-TR (DSM-IV-TR) and in Europe, it is the International Classification of Diseases-9 (ICD-9). A psychiatrist using the DSM-IV-TR would therefore put a patient's symptoms of visual hallucinations (e.g., hearing voices) and delusions (e.g., paranoia) under the diagnosis of schizophrenia, provided the symptoms have been present for at least six months and cause the patient distress and/or functional impairment. The term "insanity" describes neither a symptom nor a diagnosis recognized in either handbook.

Insanity is a legal construct used to justify a defendant's lack of criminal responsibility for an act. To prove that a crime has occurred, a prosecutor must show the presence of both *actus reus* (the "forbidden act") and *mens rea* (criminal intent). In asserting an insanity plea, a defendant acknowledges *actus reus,* but denies the presence of *mens rea*, by reason of mental disease or defect. Although the defendant may have committed the illegal act, they did not do so with criminal intent, and therefore are not punished with conviction or imprisonment.

History of the Insanity Plea

Since the time of Aristotle [1], society has agreed that the mentally ill should not be punished for acts caused by illness or ignorance. This general concept was

more explicitly stated in the trial of *Rex v. Arnold*, with the resulting "wild beast" test of insanity: a man would be exempted from punishment if he was "totally deprived of his understanding and memory and doth not know what he is doing, no more than an infant, than a brute, or a wild beast" [2].

M'Naghten

The "wild beast" test was used until the 1843 trial of Daniel M'Naghten, a Scottish woodcutter who shot and killed Lord Peel, secretary of the British Prime Minister, in the belief that the Prime Minister was conspiring against him. Medical experts testified (based on their observation of M'Naghten, not examination) that he was insane, and he was acquitted. The public was outraged. At the direction of Queen Victoria, the Law Lords established the following standard of insanity, commonly known as the M'Naghten test: sanity would be presumed unless the defense proved "that at the time of the committing of the act, the party accused was laboring under such defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing, or if he did know it, that he did not know he was doing what was wrong" [3]. This rule became the standard for insanity in the United States and Britain and is still used in 25 states [4].

Durham or "Product" Rule

Critics of M'Naghten stated that this cognitive test was too limiting; it would not include persons who knew right from wrong, but were unable to apply this knowledge rationally. The 1954 trial of *Durham v. United States* liberalized the M'Naghten rule by establishing the "product test": a defendant is not criminally responsible "if his unlawful act was the product of mental disease or defect".[a] This rule, however, was soon felt to be too broad. Moreover, it allowed testifying psychiatrists to go beyond expressing an opinion and reach conclusions that many felt should be left to the trier of fact.

Irresistible Impulse

Some states added a volitional component to the cognitive M'Naghten test: "irresistible impulse". This test, which was first used successfully in the 1840 trial *Regina v. Oxford*, stated that regardless of knowledge of right and wrong, a defendant could not be held criminally responsible if mental illness caused them to lack ability to conform their conduct to the law. "If some controlling disease was . . . the acting power within him which he could not resist, then he will not be responsible" [5].

Model Penal Code

In 1972, the American Law Institute (ALI) developed a new test for insanity as part of the Model Penal Code. This test included both the cognitive M'Naghten test, and the volitional irresistible impulse test, by stating a defendant is not criminally responsible if they "lack substantial capacity either to appreciate the criminality of his conduct or to conform his conduct to the requirement of law." This broad "substantial capacity" test is at present used by 19 US states [4].

Insanity Defense Reform Act

Insanity as a defense came under sharp criticism in the United States after John Hinckley was found not guilty by reason of insanity (NGRI) in the 1981 attempted assassination of President Ronald Reagan. The public was outraged and many demanded the abolition of the insanity defense altogether. In 1984, the federal insanity defense act was established, and placed the burden of proof on the defendant to prove, by clear and convincing evidence, that "at the time of the commission of the acts constituting the offense, the defendant, as a result of a severe mental disease or defect, was unable to appreciate the nature and quality or the wrongfulness of his acts." This Act is used in all the federal courts and branches of the US military [4].

Since then, various states have abolished the insanity defense. Others have limited the defense to the cognitive, and not volitional, test. Others have placed the burden of proof away from the prosecution and on the defense.

Temporary Insanity

Definition

The insanity plea has long been controversial. The defendant admits to commission of an illegal act, but

seeks to excuse their behavior by reason of mental illness. Especially in the case of a violent crime, the public seeks punishment and perceives that a criminal may be literally "getting away with murder". When John Hinckley was found NGRI, the public was outraged. After shooting President Reagan and Press Secretary James Brady, it did not seem fair to many that Mr Hinckley was hospitalized instead of imprisoned. Although he required hospitalization for treatment of his ongoing mental illness, he was technically acquitted of his crime. Studies show that most persons acquitted by reason of mental illness spend more time institutionalized in a hospital than they would have in a prison if found guilty and sentenced, yet the public perceives that such institutionalization is easier than prison, and not just.

The public has even greater difficulty accepting an insanity plea in the case of a defendant who is no longer insane and does not require any type of institutionalization. This is the case in temporary insanity: the defendant was insane at the time of the act, and is now sane. A defendant found to be not criminally responsible under such a plea is subject to release into the community without psychiatric hospitalization or treatment. Imagine the American public's outrage if John Hinckley had been acquitted of his crime by reason of insanity, and then released into the community. Despite this controversy, the plea of temporary insanity has continued to be used, with a variety of outcomes.

Permanent Insanity Versus Temporary Insanity

At present, some argue that law should not distinguish temporary insanity from chronic insanity. If a defendant is found to be not criminally responsible at the time of the act due to insanity, "it makes no difference whether the period of insanity lasted several months or merely a number of hours" [6], so long as the insanity was "fixed and stable for a reasonable duration" [4].

Some psychiatric illnesses can be temporary in nature. For example, a person under extreme stress might experience transient hallucinations or delusions. Moreover, even chronic psychiatric illnesses can wax and wane in symptom severity. A person with chronic schizophrenia may suffer an exacerbation of psychosis and temporarily experience hallucinations or paranoia.

Of course, the difficulty with such temporary illnesses or exacerbations is proof. Since a psychiatric exam is typically necessary to establish a diagnosis of mental illness, a psychiatrist should examine the defendant as soon as possible.

Historical Use of the Temporary Insanity Plea

United States: Congressman Daniel Sickles. The temporary insanity defense was first used in the United States by Congressman Daniel Sickles of New York in 1859. Sickles, a public figure known for personal scandals, learned that Phillip Key (son of American composer Francis Scott Key) was having an affair with his wife. A few days later, Sickles murdered Key in the middle of the day, in a park across from the White House. At the highly publicized trial, Sickle's team of attorneys evoked a plea of temporary insanity brought on by a "brainstorm" and "uncontrollable frenzy." The all-male jury sympathized with Sickle's rage at being cuckolded and voted to acquit. Many authors consider this verdict to be less a statement on the concept of temporary insanity than a reflection of the morals of the nineteenth century. Jurors told reporters, "In the absence of any adequate punishment by law for adultery, the man who violates the honor and desolates the home of his neighbor, does so at the peril of his life, and if he falls into the outraged husband's hands, deserves his doom" [7].

Ireland: Mary Rielly. In 1887, 30-year-old Mary Rielly was a widow with four children to support. In April, she was employed by the family of Michael Dillon, a 35-year-old man with fever, to act as nurse. According to the Royal Irish Constabulary police report, early in the morning of April 23, members of the Dillon household awoke to find Michael Dillon "lying dead on a fire which had been lit in the centre of the floor", with Mary Rielly "in a state of wild excitement, throwing burning coals upon him". Ms Rielly was arrested, found "temporarily insane from excessive drinking", and institutionalized at Dundrum Lunatic Prison in Dublin [8].

Like the case of Congressman Sickles, the case of Mary Rielly is an interesting comment on society in Ireland in the nineteenth century, explored in detail in Prior's article, "Roasting a Man Alive: the Case of Mary Rielly, Criminal Lunatic". At the time, few women were convicted of murder. Of

those who were, the majority were found guilty of infanticide. Society assumed that this action could only stem from the hormonal irregularities of women in the postpartum, and therefore such women were put in asylums for the insane rather than prisons.

Mary Rielly, who had apparently killed a grown man, was unique. Although she did not have a known history of alcohol abuse, most people involved with her case assumed that her actions stemmed from delusions caused by "demon whiskey." At the time of her arrest and trial, her manner was violent and bizarre, and she did not vigorously or coherently defend herself. Moreover, it appeared that some measure of whiskey was missing from the premises. Almost everyone, including the court, concluded that Mary had been drunk. This conclusion was further bolstered by two facts: first, murder as a result of drink was not uncommon and second, the medical literature of the day described the ability of alcohol to cause "transient frenzy" and delusional ideas. Society, in an effort to make sense of an unusual situation – a women committing murder other than postpartum infanticide – was quick to attribute the incident to alcohol.

What did Mary say of the event? Mary did not recall many details of the night, as she was exhausted from having cared for Mr Dillon night and day for over a week. An 1890 report by doctors at Dundrum to the Inspector of Lunatics noted Mary "states, as she has always done" that Mr Dillon was sick and restless, "and must have got out of bed and fallen on the fire", while the exhausted Mary was in a "state of profound slumber by his bedside." When she awoke, she was indeed in a "transient frenzy" and she attempted to put out the fire and remove coals from under Mr Dillon. The official postmortem examination offered support to her version, noting that Mr Dillon had been "very seriously ill" and had likely died from shock resulting from one initial burn to the scalp, such as might occur if a person fell onto a coal fire.

In 1891, after four years of being locked up as a criminal lunatic, Mary was judged to have regained her sanity and released on condition she emigrate to the United States. In the end, it is unknown whether she was truly "temporarily insane", or whether she was a victim of the legal system and political climate of the time.

Current Use of Temporary Insanity

Examples of mental illnesses that are severe enough to interfere with *mens rea* at the time of the crime, and then spontaneously remit, are sparse, but exist. Examples include acute stress disorder and shared psychotic disorder (or folie a deux). Acute stress disorder can occur from situations such as wife battering. In some jurisdictions, premenstrual syndrome (PMS) has been accepted as a means of reducing criminal responsibility for a defendant. In contrast, some conditions currently classified as mental illnesses – notably, substance abuse, or dependence – has not been accepted as a successful insanity defense in most jurisdictions. Likewise, conditions not currently classified as mental or medical disorders (such as homosexual panic) have not been successful insanity defenses.

Shared Psychotic Disorder. In this disorder, a delusion develops in an individual or individuals who are in a close relationship with a person who already has established a similar delusion. Joshi *et al.* published a recent account of a shared psychotic disorder among three sisters (folie a trois). In this case, two sisters without prior psycohsis developed religious delusions that mimicked those of their schizophrenic sister. The sisters, after a period of becoming increasingly enmeshed, broke into a home they believed was theirs by divine decree, and vigorously assaulted both the homeowners and officers who attempted to stop them. In jail, the sisters were initially housed together, and their delusions continued. Upon separation from their schizophrenic sister, however, the delusions of the two sisters spontaneously resolved. After a four-month hospitalization mandated by South Carolina law, the sisters were discharged to the community without incident [4].

In this situation, although the two non-schizophrenic sisters did not suffer from chronic mental illness, their extreme closeness to each other, and to their schizophrenic sister, produced a temporary delusion. At the time the sisters committed the actus rhea, therefore, they lacked *mens rea*. Specifically, they believed their actions were ordained by god, and therefore were not criminal or wrong. That the sister's delusions were temporary does not change the fact that their actions stemmed from mental illness, and therefore did not constitute a crime.

Premenstrual Syndrome (PMS). Although the defense of PMS to support claims of temporary insanity has not been particularly successful in courts, it has been successfully used to support diminished capacity [9]. In diminished capacity, a charge of murder is reduced to manslaughter on the grounds that the defendant was mentally impaired at the time of the crime, and is therefore not wholly responsible for his or her actions. This is illustrated in several landmark cases that occurred in these countries in the 1980s.

In the United Kingdom, cases involving barmaid Smith (nee Craddock) received wide media attention. In 1980, Craddock, a barmaid with a long criminal history of theft, arson, and assault was charged with murdering a coworker. Investigation of her violent behavior revealed it had a cyclical nature: PMS turned her into a "raging animal each month". On the basis of this defense, in *R v Craddock*, she was found guilty of manslaughter based on a plea of diminished responsibility. She was sentenced to probation and court-ordered progesterone treatment. As long as she remained on progesterone, she did not commit acts of violence. In 1981, her progesterone dose was lowered, and shortly thereafter Ms Smith threw a brick through a window, attempted suicide, wrote a threatening letter to a police officer, and was found hiding outside of the police station with a concealed weapon. In *R v Smith*, she was again sentenced to probation and court-ordered progesterone [10].

In another UK trial, *R v. English*, the defendant had no prior criminal record, but still successfully used the defense of PMS to reduce responsibility. After a fight with her lover, she got in her car, and ran him over. A medical expert testified that her "extreme" PMS, coupled with the fact that she had not eaten for 9 h prior to the event, produced "exceptional circumstances" that resulted in diminished responsibility. In Canada, several women accused of theft were sentenced to probation and psychiatric care due to the mitigating factor of PMS.

Although lawyers have continued to present PMS as a defense to criminal charges, reaction by the courts and public is mixed. The courts have most often rejected that PMS is a strong enough factor in a crime to completely eliminate *mens rea*, but have accepted that PMS can diminish capacity and therefore criminal responsibility. Many argue that this approach is inconsistent: if the mental condition of PMS can diminish capacity, why is it not a valid defense for temporary insanity? The public's reaction is similarly controversial. While a woman suffering from a genuine mental disorder should not be held guilty of a crime if no criminal intent existed, the "excuse" of PMS should not be used to stigmatize women.

Intoxication. The use of drugs or alcohol can significantly and transiently alter a person's mental status (*see* **Alcohol: Behavioral and Medical Effects**; **Substance Abuse**). Drugs, in particular, can cause hallucinations and delusions that mirror a state of psychosis. Traditionally, however, courts have not accepted such intoxication as grounds for diminished or absent criminal responsibility under the insanity defense, based on the fact that the intoxication was voluntary. In addition, a person who is intoxicated "is not insane, for insanity requires a 'disease of the mind' or a mental disease or defect; this requirement is one that 'mere drunkenness' cannot satisfy." An intoxicated person is therefore presumed sane; and a sane person cannot plead insanity [11].

Homosexual Panic. In 1998 in the United States, Aaron McKinney was convicted of the brutal murder of student Matthew Shepherd. Shepherd, a homosexual young man, was beaten to death by a group of men who included McKinney. McKinney's attorneys tried to argue a "gay panic defense", stating that Shepherd made a pass at McKinney, causing him to fly into murderous rage. The court rejected the defense, on the grounds that it was in essence a plea of temporary insanity under the irresistible impulse test, which is not allowed in the state of Wyoming. In addition, the court stated that "homosexual rage panic" did not have precedent in psychiatry, and would "mislead and confuse the jury" [12] (*see* **Homosexual Panic**).

Wife Battering. In a sensational United States 1993 case, Virginia the wife Lorena Bobbitt cut off her sleeping husband's penis with a kitchen knife and flung it into the woods. She explained that her husband John had repeatedly raped and abused her. The state brought criminal charges against Mr Bobbit, but he was found not guilty in criminal trial. In 1994, Ms Bobbitt faced criminal charges of malicious wounding and was ultimately found not guilty based on the jury's conclusion that she was temporarily insane from stress over her husband's battering. Ms Bobbitt was sent to a psychiatric

hospital for treatment and released after 45 days [13] (*see* **Battered Spouse Syndrome**; **Battered Woman's Reality**).

Temporary Insanity and the Media

Pleas of temporary insanity increased after the movie *Taxi Driver*, and, more recently, *The Matrix*. In the latter film, characters live not in reality, but in a computerized version of it called "the matrix". After the movie, defendants in several countries claimed they were not responsible for their actions because they also believed they were living in "the matrix". In Canada, Tonda Lynn Ansley was found NGRI of murdering her landlady. She reported that she committed the crime because she believed her landlady was part of a computerized conspiracy to brainwash and kill her. In the United States, a California man was similarly found NGRI of murdering his landlady because he had believed she caused him to be drawn into "the matrix". In Virginia, the attorneys of Joshua Cooke, who murdered his parents, stated he did so believing he was living in "the matrix" [14].

Such cases increase the controversy of the temporary insanity defense. Proponents argue that psychotic persons often center their delusions on real-world events. For example, a schizophrenic man might be paranoid if he is being watched by police, if an officer lives next door. The same man might similarly develop delusions about a popular movie, especially if that movie focuses on conspiracy and danger. Alternately, opponents of the insanity defense argue that criminals are smart, and use popular movies as an excuse to avoid responsibility for their actions.

In summary, temporary insanity, like insanity itself, is a defense that is frequently mired in controversy. The most successful use of this defense occurs in the context of a previously established mental illness (such as an exacerbation of an underlying disorder), or a new but recognized illness (such as folie a deux). Even in such cases, however, public perception and contemporaneous politics play a role in affecting the decision of the court.

Therapeutic Jurisprudence

A New Idea

In 1990, David Wexler published an anthology entitled *Therapeutic Jurisprudence: The Law as a Therapeutic Agent* [1], highlighting the potential for the fields of law and mental health care to become more streamlined. He supported the use of the law as another tool in the arsenal of treatment options available for the mentally ill. Wexler emphasized the notion that any outcome in the justice system has the potential to act in either a therapeutic or nontherapeutic way, and he encouraged revisions to the system that could yield in therapeutic results. Since this time, many authors, including Wexler, have continued to expand on this idea.

Therapeutic Jurisprudence

Therapeutic jurisprudence "is the study of the role of the law as a therapeutic agent" [1]. Any legal decision and the participants in the process can have either a positive or a negative impact on the individual involved. Participants who are aware of the potential psychological ramifications of their actions may be able to avoid unintended consequences. Attorneys must value not only their clients' legal rights but also their psychological well being. The concept of therapeutic jurisprudence is most often referenced in the context of mental illness but is applicable to many other types of law as well, such as domestic violence and family law [2].

Early writings on the topic stress four main areas where the application of therapeutic jurisprudence could be further studied. The first area concerns the psychological dysfunction that the law can cause. This could refer specifically to such unintended consequences as diminished self-esteem or negative thoughts of hopelessness, helplessness, and worthlessness. The second involves investigating potential therapeutic aspects of legal rules. For example, this could include sentencing patients to a treatment facility rather than a prison. The third area entails examining the therapeutic aspect of legal procedures; individuals may reclaim some control in their lives

by taking responsibility for their wrongdoing. The fourth calls for the examination of the therapeutic aspects of judicial and legal roles. For example, attorneys may be encouraged to more vigorously represent their clients in civil commitment hearings [3]. Many authors have expanded on these ideas and offered creative solutions.

While it is important to consider the potential therapeutic advantages of legal outcomes, it is emphasized that these benefits should not stand in the way of appropriate adjudication of court cases. Therapeutic jurisprudence is but one of the many elements to consider when determining the resolution of legal matters. Ultimately, mental health laws can serve to both protect the civil liberties and assist in meeting the therapeutic needs of the mentally ill [4].

The Development of Therapeutic Jurisprudence

In the first half of the twentieth century, American psychiatric practice was governed by the theory of paternalism, in which the physician provided the treatment that he believed was in the patient's best interest. Patients could be committed to long term facilities based on the recommendation of a physician alone in some cases. Procedures were performed and medications were given without necessarily obtaining the patient's consent [5]. In the later half of the century, in conjunction with factors including deinstitutionalization and a national focus on civil liberties, the rights of the mentally ill were closely examined [6].

With the subsequent development of a rights driven approach to mental health law, Wexler contended that the field became too regimented, ignoring the uniqueness of each individual [7]. That the theory of therapeutic jurisprudence is not limited to a rights orientation allows for a less biased analysis of whether changes in the legal system actually produce their intended outcome [8]. While recognizing the importance of these rights, others favoring therapeutic jurisprudence proposed that, if these rights have antitherapeutic consequences, perhaps they are of secondary importance to an appropriate therapeutic outcome [9, 10]. This different perspective may create the ability to reconceptualize the field of mental health law [11]; instead of changing the laws themselves, the way that the law is practiced could be reformed [12].

Though therapeutic jurisprudence may initially appear paternalistic, proponents believe that there are many applications with outcomes that foster self-determination, and it is these results that are felt to be more therapeutic than rules dictating the fate of the individual [4, 13]. Winick, a legal scholar with many publications on therapeutic jurisprudence, noted that his work "is animated by the insight that such paternalism is often antitherapeutic, and that legal protection for individual autonomy can have positive therapeutic value" [14].

Applications of Therapeutic Jurisprudence

Wexler identified "psycholegal soft spots", which he defined as areas where the opportunity arises for the law to intervene in a therapeutic way [15]. Specialized courts, civil commitment, mandatory treatment, and informed consent are processes that can each lend themselves to the application of therapeutic jurisprudence.

Specialized Courts

One of the clearest examples that incorporate the tenets of therapeutic jurisprudence is the existence of specialized courts (*see* **Mental Health Courts**). Participants in the proceedings of specialized courts are provided specific training pertinent to their area of practice. The overall purpose of these courts is to shift away from the traditionally adversarial legal process in order to address the underlying causes of crime.

Drugs courts were developed in the 1980s following a tremendous rise in drug-related cases. In these courts, addiction treatment may be viewed as an option for decreasing recidivism when used in lieu of punishment. The power of the law allows for supervision to support offenders' participation in and completion of substance use treatment programs. The court's involvement in the process assists in clearly defining expectations and affirming offenders' agreements to take part in the program. The law also provides the ability to sanction offenders when requirements are not fulfilled. Finally, the court offers offenders the opportunity to begin taking personal responsibility for their addictions by making choices concerning their treatment [13].

The first mental health court (*see* **Mental Health Courts**) was established in the United States in 1997,

and since that time, others have been developed nationally [16, 17] and internationally [18]. These courts serve to better utilize therapeutic opportunities created through legal interventions. In addition to many of the tenets of drug courts, mental health courts can

1. expedite case processing for early identification of individual treatment needs;
2. encourage participation of the individual and his or her family; and
3. employ a liaison to facilitate interactions between the individual, their family, the court and mental health services [13].

Other examples of specialized courts include domestic violence courts, family courts, and community focused courts [13]. While they do not necessarily deal directly with addiction or mental illness, the principles of therapeutic jurisprudence are still evident in their focus on providing appropriately specialized services to those individuals processed through their dockets.

The existence of specialized courts is evidence that, rather than merely being applied by individual judges or attorneys, the principles of therapeutic jurisprudence are being utilized on a systemic level. There are, however, some notable drawbacks in maintaining these specialized courts. It may be difficult to define the spectrum of the courts' practice in order to effectively process the maximum number of cases. It is important that the courts maintain their specialization without overly narrowing their focus such that there are not enough cases to warrant a separate court. Professionals practicing in these courts may suffer burnout due to overexposure to the increased psychological and social complexity of their caseload. In addition, some practitioners may be unwilling to participate due to perception of less prestigious cases and fewer opportunities for professional advancement [19].

Civil Commitment

A number of authors have examined the issue of civil commitment (*see* for example, **Civil Commitment**) in relation to the principles of therapeutic jurisprudence. Though there has been significant change over the last several decades, some still feel that civil commitment hearings exist only as a formality [20]. Given their clients' diagnoses of mental illness, attorneys may advocate less vigorously for their rights, instead of feeling that they should do what they deem to be in the best interest of their clients [21, 22]. This may cause the hearing to become a nonadversarial event, in which the judge simply "rubber stamps" the opinion of the expert without giving fair consideration to the patient's opposing position [20, 23]. Such a scenario could demoralize and discourage patients, who may anticipate active participation in what they assume will be fair and balanced proceedings. Subsequently, patients may lose confidence in the legal system, their attorneys, judges, and mental health care providers [24, 25]. This may ultimately lead to increased difficulties with hospitalizations and treatment compliance in the future [8].

According to the principles of therapeutic jurisprudence, civil commitment hearings offer an opportunity for the court to intervene in a therapeutic manner. Those involved may use this occasion to explain to the patient the meaning and process of civil commitment, including the benefits and repercussions that can be associated with it. In particular, this may include the potential improvement in symptoms or increased likelihood of safety that could be associated with an extended hospitalization. On the other hand, patients should also be aware of the potential stigma associated with civil commitment. Collectively, this knowledge may assist the patients in making good choices, encourage them to advocate for themselves and decrease their concerns about the proceedings. If patients feel that their concerns have at least been recognized, they may be more willing to accept the decision, even if they feel that it is unfavorable to them [20].

The release of a patient from civil commitment also creates a situation in which the theory of therapeutic jurisprudence may apply. According to Wexler, this offers an opportunity for the law to intercede, smoothing the transition between life within the confines of the hospital and what awaits outside. This could be achieved through such measures as outpatient civil commitment. The therapeutic goals of this easier transition would include less psychological stress on the individual and ultimately the decreased likelihood of recommitment [15].

Mandatory Treatment

When a mentally ill individual no longer requires an inpatient setting but will most likely decompensate

in the community, the court can intervene in the form of outpatient civil commitment. Alternatively, when a hospitalized patient refuses medications, and for example, appears to be a threat to themselves or others, after being petitioned the court may require the patient to accept the proposed treatment regimen.

Given that medication compliance can be made mandatory, there exists a high likelihood that individuals may feel coerced, which could undermine the effectiveness of the treatment [26]. Feelings of coercion may be minimized by acting out of concern for the individual, being respectful, fair, and honest, and providing a forum for the individual to express concerns [27]. The experience may also be improved for individuals if they are offered some degree of decision making ability, such as choosing between medications [28].

Informed Consent

Informed consent requires explaining to a patient the nature and purpose of treatment as well as its risks, benefits and alternatives [29]. Failure to do so may be a violation of tort law [30]. In addition to protecting oneself from malpractice, advocates of therapeutic jurisprudence believe that the process of informed consent can be used to strengthen the therapeutic alliance between care providers and patients [28]. Defining goals and negotiating about different treatment options allows patients to take ownership of their own health care. Inherent in the process of informed consent is offering the option of no treatment. Recognizing and discussing this right to refuse treatment (*see* **Treatment, Right to Refuse: Mental Health**) may also assist in enhancing the therapeutic relationship between care providers and patients [31].

Therapeutic Jurisprudence and the Future

Therapeutic jurisprudence is a young field that continues to evolve as more investigators apply its tenets to areas in which law and psychiatry overlap. Given the variety of people with input into judicial proceedings, the future of research in this field requires interdisciplinary collaboration, including participation from judges, attorneys, parole officers, law enforcement, social workers, and mental health care providers.

Preventative Law

While the judges may practice therapeutic jurisprudence in their courtrooms by taking advantage of therapeutic moments as they arise, Wexler proposed that the future lies in preventative law [32]. This concept, espoused by Stolle in the context of elder law [33], highlights the importance of "legal checkups" to identify "soft spots" in order to minimize potential legal problems [34]. When combined with therapeutic jurisprudence, these practices would aid in the identification of legal issues that may generate anxiety, distress, depression, or resentment. Subsequent to the recognition of these scenarios, lawyers may implement solutions to lessen these effects. Wexler provided the example of an estate planning attorney who assists clients with the potential emotional repercussions of choosing to leave someone out of their will.

Advance Directives

Another potential future oriented application of therapeutic jurisprudence involves the creation of mental health care advance directives. When patients are competent, lawyers and mental health care providers may suggest to them that they consider drafting a document that describes their wishes should they become incompetent. These advance directives empower patients and provide clinicians with some insight into patients' desires concerning their treatment [35].

Conclusion

Advocates of therapeutic jurisprudence note that, with continued collaboration between the fields of law and mental health care, each would become more familiar and comfortable with the workings of the other. This may serve to streamline the efforts of both and create better therapeutic outcomes for patients by opening up more options for treatment and encouraging better usage of the modalities already in existence. According to its proponents, this becomes evident when the tenets of therapeutic jurisprudence are applied to situations such as specialized courts, civil commitment, mandatory treatment and informed consent. Future applications of therapeutic jurisprudence seem to exist in prevention of unanticipated and distressing legal consequences.

Threat Assessment: School

Rationale for Threat Assessment in Schools

Threat assessment (*see* **Threat Assessment: Workplace**) became an important school safety practice in the United States following a series of highly publicized school shootings in the late 1990s. These tragic events stimulated the perception that violence was rampant in American schools. In response, both the U.S. Secret Service [1] and Federal Bureau of Investigation (FBI) [2] conducted studies of school shootings and observed that the student perpetrators were often victims of bullying who had become angry and depressed, and were influenced by a variety of social, familial, and psychological factors. However, the studies concluded that, because similar characteristics are found in so many students, it would not be possible to develop a profile or checklist that could be used to pinpoint the small number of truly violent students among them. As a result, both the FBI and Secret Service cautioned schools against a profiling approach.

Nevertheless, the FBI and Secret Service did point out that almost all of these students communicated their intentions to attack through threats and warnings to their peers. Had these threats been reported to authorities and investigated, the shootings might have been prevented. In its study, the FBI identified a number of potential school shootings that were prevented because students reported a threat to authorities that was investigated and determined to be serious. On the basis of these observations, the FBI and Secret Service both recommended that schools adopt a threat assessment approach [2, 3].

School threat assessment is a form of risk assessment designed to prevent targeted violence, i.e., incidents in which an identified individual targets a particular victim prior to attack [4]. In the case of school shootings, there may be multiple targeted victims or the general school population that are subject to attack. Threat assessment was developed by the Secret Service as a means of evaluating the risk posed by individuals who communicated threats to public figures [5], but was soon applied to broader contexts such as workplace violence (*see* **Threat Assessment: Workplace**).

Threat assessment begins when an individual is identified as having made a threat, which is defined broadly as any expression of intent to harm someone, including indirect or ambiguous threats. Threat assessment is concerned with determining whether the individual who has "made" a threat actually "poses" a threat [1]. An individual is more likely to pose a threat if he or she has engaged in planning or preparation to carry out the threat, such as obtaining weapons, making detailed plans, rehearsing an

attack, recruiting accomplices, or inviting others to observe the attack. It follows that a threat assessment is focused on behaviors that are linked to carrying out a threat, as distinguished from broader characteristics such as the individual's personality or demographic background.

Threat assessment can be distinguished from another form of risk assessment: criminal profiling [2, 4]. Profiling originated as a means of identifying the likely perpetrator of a crime by examining crime scene evidence – which is a retrospective process, but evolved to include prospective attempts to infer the identity of potential perpetrators by matching them to the characteristics of individuals who have committed similar crimes. Prospective profiling is dependent on the existence of a set of defining characteristics of individuals who commit a particular kind of crime. There are two main weaknesses to this procedure that are common to all prediction efforts: the indicators must be sensitive enough to detect all or nearly all perpetrators and they must be sufficiently specific that they do not identify innocent individuals as perpetrators [6] (*see* **Serial Homicide**; **Profiles: Psychological and Behavioral**). The FBI and Secret Service concluded that the common characteristics of students who engaged in rampage school shootings lacked both sensitivity and specificity, i.e., there was no characteristic or set of characteristics that were common to all offenders and the most promising characteristics that they shared were not specific to offenders.

The weakness of profiling can be observed in the checklist of warning signs that the US Department of Education included in its 1998 publication, "Early warning, timely response: A guide to safe schools" [7]. Among the 16 warning signs are items such as "history of discipline problems", "drug use and alcohol use", and "feelings of being picked on and persecuted", and "excessive feelings of rejection" that could be found among many adolescents. Similarly, the National School Safety Center [8] developed a 20-item "checklist of characteristics of youth who have caused school-associated violent deaths" that included items such as "has been previously truant, suspended, or expelled from school", "has little or no supervision from parents or a caring adult", and "tends to blame others for difficulties she or he causes". Because the base rate of severe violence is low, checklists like these will produce large numbers of false-positive identifications of students who are not violent [6]. As the authors of the federal warning signs report cautioned, "Unfortunately, there is a real danger that early warning signs will be misinterpreted" [7], p. 7.

Perceptions of Risk

Forensic consultants must be aware of the influence of public perceptions of risk on school policies and administrative decision-making. In response to the school shootings of the 1990s, school administrators began to impose zero tolerance sanctions on students for seemingly minor transgressions such as bringing a plastic knife to school in a lunchbox, pointing a finger like a gun, and shooting a paper clip with a rubber band [9]. The public response reflected a similar fear of school violence: a Gallup poll conducted after the 1999 Columbine shooting found that two-thirds of Americans believed that a similar incident could occur at schools in their community [10]. Ironically, in the year of the Columbine shooting, 17 students were killed at school, but over 2500 young people (ages 5–19) were murdered outside of school, and more than 9700 were killed in accidents [11].

Heightened fears often follow a highly publicized school shooting and generate new calls for security measures. For example, after a man invaded a one-room Pennsylvania Amish school and killed five girls in 2006, there were renewed recommendations to arm teachers with guns [12] and a call to issue Kevlar-coated textbooks to students for use as bullet shields [13]. A Fort Worth suburban school division hired a former military officer to train students to make a mass attack and attempt to subdue an armed gunman [14]. After the 2007 shooting at Virginia Tech, colleges across the country began to implement new safety and security measures [15].

Public fears may be encouraged by media speculations about "new trends". The Pennsylvania Amish school shooting generated news reports of "a new trend of adults killing children in schools" [16] and "a pattern in rural school shootings" with "girls as targets" [17]. Pseudo-trends can be generated by random patterns in the large numbers of violent acts that occur each day in the United States. In a nation of 300 million people, there are approximately 30 000 shooting fatalities (suicide, homicide, and accident) each year [18], which means an average of 82 fatalities every day.

In making recommendations to school officials and legal authorities, forensic consultants may need to correct misperceptions of the risk of violence at school. Student-perpetrated homicides are rare events in the nation's 119 000 schools. There were 103 such cases during the 12 school years from 1992–1993 to 2003–2004, which means an average of 8.58 incidents per year [7]. This rate will mean that the public could hear about a fatal school shooting by a student approximately once a month throughout the school year, fueling the perception that such events are commonplace. Although even one school homicide is too many, an event that affects an average of 8.58 schools out of 119 000 means that the average school can expect a student-perpetrated homicide about once every 13 870 years (119 000 divided by 8.58). These figures are estimates that will vary over time, but illustrate the very low base rate of student-perpetrated school homicides.

After the Virginia Tech shooting in 2007, there was a public perception that colleges were dangerous places, too. According to the latest available data from the US Department of Education [19], there were 95 murders on college campuses in the six years from 1999 to 2004, an average of 16 per year. Since there are approximately 4200 colleges in the United States, this means that an average college can expect to experience a murder on campus about once every 265 years. If we include all 2808 murders that occurred in the surrounding community – off campus as well as on campus – the rate is much higher: about once every 9 years. This is a reflection of the much higher rate of violence in the general community.

Although there are limitations to any single source of information about violent crime, the evidence from multiple sources is consistent in indicating an overall decline in youth violence in communities and schools from the early 1990s to recent years.

- According to FBI arrest statistics, juvenile homicide declined more than 80% from 1993 (3284 arrests) to 2006 (956 arrests; [20]).
- Homicides on the grounds of primary and secondary schools during the school day dropped from 42 during the 1992–1993 school year to 11 during the 2006–2007 school year [21].
- Serious violent crimes, as measured by victim reports on the National Crime Victimization Survey dropped from 13 per 1000 students in 1994 to 5 per 1000 in 2005 [22].
- According to the Youth Risk Behavior Surveys administered nationally to over 10 000 students each year, there have been declines of 21% in physical fighting and 48% in weapon carrying at school from 1993 to 2003 [23].

The attention given to school homicides can overshadow the more pervasive problems with fighting, bullying, and other forms of aggressive behavior at school. According to data compiled by the National Center for Education Statistics [22], during the 2005–2006 school year, 78% of public schools reported at least one violent crime at their school. In 2005, 8% of high school students reported being threatened or injured with a weapon in the previous 12 months, and 28% of students, ages 12–18, reported being bullied at school in the previous six months.

Schools authorities take disciplinary action in response to student aggression, and frequently make referrals for risk assessments of those students. According to the national School Survey on Crime and Safety [22], nearly half (48%) of all public schools took serious disciplinary action against one or more students during the 2005–2006 school year. This included suspensions of 5 days or more (74%), expulsions without services (5%), and transfers to special schools (20%).

The Virginia Model for Student Threat Assessment

Many school systems have developed in-house methods for conducting risk assessments, such as the Dallas Threat of Violence Risk Assessment [24], which uses a checklist of 19 risk factors to classify a student as low, medium, or high risk. There are also several guidebooks on school security that advocate principles of threat assessment [25, 26]. Researchers at the University of Virginia developed and field-tested a comprehensive set of threat assessment guidelines [27] derived from the recommendations of the FBI [2] and Secret Service reports [3]. The Virginia model conceptualizes threat assessment as a process involving threat management and risk reduction rather than the more traditional prediction of violence [28]. The threat assessment team attempts to understand why a student has made a threat in order to address the underlying conflict or problem that triggered it. This

model places an emphasis on determining the seriousness of the threat in order to avoid the complementary errors of overreacting to threats that are not serious as well as failing to take decisive action in the face of a serious threat.

According to the Virginia model, each school has a threat assessment team led by the principal or assistant principal and staffed by representatives from mental health and law enforcement. Teams follow a seven-step decision tree. The initial stages of a threat assessment are typically handled by the team leader (principal), and many cases can be readily resolved. In more complex or ambiguous cases, the team leader brings in additional team members for more extensive assessment. The seven steps are reviewed briefly as follows:

Step 1. The leader of the threat assessment team interviews the student who made the threat and witnesses using a standard set of questions. The focus is not only on determining what the student said or did but also the context in which the threat was made and what the student intended by making the threat.

Step 2. The team determines whether the threat is "transient" or "substantive". Transient threats can be readily identified as expressions of anger or frustration (or perhaps inappropriate attempts at humor) that dissipate quickly when the student reflects on the meaning of what he or she has said. In contrast, substantive threats represent a sustained intent to harm someone beyond the immediate incident. If there is doubt whether a threat is transient or substantive, the threat is regarded as substantive. One way to identify a threat as substantive is to look for certain characteristics derived from the FBI report [2] that suggest that the threat is likely to be serious:

- the threat includes plausible details, such as a specific victim, time, place, and method of assault;
- the threat has been repeated over time or communicated to multiple persons;
- the threat is reported as a plan, or planning has taken place;
- the student has accomplices, or has attempted to recruit accomplices;
- the student has invited an audience of peers to watch the threatened event; and
- there is physical evidence of intent to carry out the threat, such as a weapon or bomb materials.

Step 3. A transient threat identified at step 2 can be resolved without engaging a comprehensive evaluation. The student may make an explanation and apologize to those affected by the threat, or take other action to make amends for his or her behavior. There may be a reprimand or other disciplinary consequence if the behavior was disruptive or violated the school's discipline code. If a transient threat was sparked by an argument or conflict, the principal can involve other team members in helping to address or resolve the problem.

Step 4. If the threat is not transient, a substantive threat is determined to be "serious" or "very serious", based on the intended severity of injury. A "serious" threat is a threat to assault, strike, or beat someone up. A "very serious" threat is a threat to kill, sexually assault, or severely injure someone.

Step 5. In the case of a serious substantive threat, the team takes actions to protect potential victims. Protective actions depend on the circumstances of the threat, as well as how soon and where the threat might be carried out. Immediate protective actions include cautioning the student about the consequences of carrying out the threat and contacting the student's parents. The team also has the responsibility of notifying the intended victim of the threat.

Step 6. Very serious substantive threats require the most extensive action by the team. In addition to any immediate action to assure that the threat is not carried out, the student is suspended from school, pending a complete assessment of the threat and determination of the most appropriate school placement. The team conducts a more comprehensive safety evaluation, which includes both a mental health assessment conducted by the school psychologist or another suitably trained mental health professional and a law enforcement investigation conducted by the school resource officer.

Step 7. The team integrates findings from the safety evaluation into a written safety plan, which is designed both to protect potential victims and to address the student's educational needs. At this point, the principal decides whether the student can return to school or should be placed in an alternative setting. If the student is permitted to return to school, the plan describes the conditions that must be met and the procedures in place to monitor the student when he or she returns.

This threat assessment procedure was field-tested in 35 schools for one school year [9, 29, 30]. The 35 threat assessment teams responded to a total of 188 threats. The most common threat was a threat to hit or beat up someone (77 cases, 41%). There were also 27 threats to kill, 24 threats to shoot, and 18 threats to cut or stab. There were 32 cases in which the threat was vague or nonspecific (e.g., "I'm going to get you"), and 10 miscellaneous threats, such as to set a fire or detonate a bomb. All types of threats were seen at all school levels, although threats to kill or shoot occurred more frequently in elementary school than in middle and high school combined.

The majority (70%) of threats were easily resolved as transient threats. Of the remaining 30% that were substantive threats, 22% (42 cases) were "serious" substantive threats to fight or assault someone, and 8% (15 cases) were "very serious" substantive threats to kill or severely injure someone. A threat assessment approach gives school authorities flexibility in choosing the disciplinary consequences for students who make threats. Under a zero tolerance policy, many students would have been expelled for making threats to kill or injure someone. Using threat assessment guidelines, only three of the 188 threat cases resulted in expulsion. Half of the students who made threats (94 cases) were given a short-term suspension, either an in-school suspension or a suspension outside of school. The modal suspension (32 cases) was one day, with a range of 1–10 days. Only six students were arrested; three students had made a false bomb threat, two students had assaulted a school staff member, and the final case involved a student found with a knife.

At the end of the school year, principals were interviewed to obtain follow-up information on each of their cases. In three cases, the principal was not sure whether a student's threat to hit another student was carried out, but in all other cases, the principals reported that the threat was not carried out. When asked to assess the student's overall behavior after the threat, the principals rated 43% of the students as demonstrating improved behavior during the remainder of the school year, 39% as about the same, and only 18% as worse in their behavior.

Limitations to Threat Assessment

There is a need for randomized controlled studies examining the effects of threat assessment (and other risk assessment procedures) on school safety and student outcomes. Research on threat assessment is limited in part because school systems are understandably reluctant to engage in experimental procedures about a highly sensitive issue.

Another limitation is that threat assessment is designed for persons identified as making threats, so it is critically important that students (as well as parents and teachers) be encouraged to report threats. Many students are reluctant to report threats because they regard it as a form of "snitching" or they fear that they will become victims of retaliation. Accordingly, schools are advised to teach students to distinguish snitching for personal gain from seeking help to prevent someone from being hurt, and to offer anonymous as well as direct means of reporting threats.

Because threat assessment is concerned with targeted violence, it is not a useful approach for preventing less specific forms of violence. To prevent instrumental crimes such as robbery, schools must rely primarily on security measures and close supervision of students. To prevent fighting and bullying, there are a variety of effective school-based programs ranging from individual counseling to schoolwide systems of positive behavior support [9, 31–33]. A meta-analysis of 249 controlled studies confirmed the effectiveness of school-based interventions for aggressive and disruptive behavior [34].

DEWEY G. CORNELL

Threat Assessment: Workplace

History

The concept of assessing the validity or meaning of threatening communications must be as old as threats themselves, but the effort to develop a scientific approach to threat assessment is a more recent phenomenon. Threat assessment arose in the second half of the twentieth century as an effort to evaluate the risk posed by individuals who were communicating threats to others and, where the person making the threat had not been identified, to narrow the search for the identification of that person. Threat assessment could not have emerged as a field of endeavor without the emergence in the nineteenth century of psychiatry, psychology, criminology, professional policing, and professional security – the professional disciples from which threat assessment practice continues to draw with greater or lesser fidelity depending on the credentials, training, and experience of those who undertake such work.

Early pioneers whose work forms the basis of interest in what would become known as *threat assessment* are as follows:

- Brussel, a psychiatrist, whose analysis of the anonymous writings and deeds of the "Mad Bomber" in 1956–1957 helped the law enforcement officials to predict his behavior, identify the offender, and arrest him, preventing further bombings [1].
- Macdonald, a psychiatrist, whose monograph on mental patients civilly committed to a mental hospital after making homicidal threats was the first empirical study of death threats [2].
- Miron, a psycholinguist, whose work first achieved national attention in the Patricia Hearst case through the successful analysis, on behalf of the Federal Bureau of Investigation (FBI), of transcripts of seven tape recordings sent by the Symbionese Liberation Army [3, 4].
- De Becker, a private security specialist, was the first to recognize the need to preserve threatening and other unusual communications directed to public figures in the private sector and to urge the government to fund scientific research of such communications [5].
- Park Dietz, a forensic psychiatrist and criminologist, whose interdisciplinary team conducted the first scientific study of threatening and other inappropriate communications to public figures on behalf of the National Institute of Justice [6–8].
- Threat Assessment Group, Inc., of Newport Beach, CA, founded in 1987, which was the first organization specializing in the prevention of workplace violence and the assessment of threats on behalf of employers.

The US Secret Service, the Federal Bureau of Investigation, the US Capitol Police, the US Marshall's Service, the Central Intelligence Agency, and other federal, state, and local law enforcement agencies have developed varying internal capacities to monitor threats communicated to their protectees and to others within their jurisdiction. The primary responsibilities of these public entities are dictated by law and by agency policy, but from time to time representatives of these organizations assess threats on behalf of employers in the private sector, and the federal agencies are often called upon by the local law enforcement agencies seeking guidance on what to tell employers. Because law enforcement must neutrally enforce the law – even where doing so carries risk to one or more of the concerned parties – and because law enforcement has no legal duty to prevent crime or to protect the public, much less any particular employer or employee, the guidance and actions of law enforcement do not always work to

the benefit of the employer. Examples of such problems, from the standpoint of employers, are urging victims of domestic violence to leave their abusers and obtain restraining orders, worsening the odds of an attack at the workplace; interviews of threatening employees by uniformed officers in the presence of their coworkers, families, or neighbors, thus adding stress to the threatening employee and possibly compromising the identity of the informant; or, in some of the more egregious cases, reacting with excessive force to the unfounded rumor that a threat has been made.

In part, not only because of these issues but also because employers value privacy, immediacy, and control, the needs of employers for threat assessment services are today served primarily by small, private businesses that offer fee-for-service consultation. These businesses vary greatly in approach, philosophy, credentials, qualifications, technique, experience, and emphasis, and the consumer has little guidance available to select among them. Private investigators, security consultants, retired police officers, psychologists, psychiatrists, psycholinguists, people with diploma mill credentials, and others with no relevant expertise whatsoever, all offer threat assessment services to the unwary consumer.

Varying Meanings of "Threat Assessment"

The concepts of "threat assessment" and even "threat" are used inconsistently, in part, because many writers use "threat" as a synonym for "danger" or "risk", whereas others use "threat" to refer only to communications that contain some verbal reference to the possibility of interpersonal violence. Moreover, the term *threat assessment* has been used in the corporate security community to describe certain activities that might be more precisely described under other names, which are as follows:

1. *Vulnerability assessment* consists of efforts to determine the vulnerability of various sites, industries, procedures, or equipment to criminal action or other disruptive events. Thus, for example, some security and law enforcement professionals use the term *threat assessment* to refer (i) surveys of which of a corporation's multiple plants are most vulnerable to labor disputes, natural disaster, or other challenges, (ii) evaluations of the vulnerable points in an executive's itinerary, or (iii) studies of the vulnerabilities in an overall security plan.
2. *Intelligence collection and analysis* is actually the development and analysis of information about potential adversaries. Many corporations find it useful – and some find it critical – to develop and analyze intelligence about potentially disruptive or destructive elements (such as terrorist groups, animal rights activists, environmentalists, hackers, or corporate spies). Corporate espionage has proved an enormous drain on the US economy that is beginning to receive the attention it deserves from businesses of all sizes [9] and the FBI's Counterintelligence Domain Program.
3. *Emergency triage* is the rapid determination of the severity of an urgent situation. For example, Cadwell [10] used the terms *threat analysis* and *determination of threat level* to refer to procedures whereby the guards at a nuclear facility decide how to respond to various types of alarm signals that have been activated. Tactical and self-defense instructors sometimes use the term *threat assessment* to describe the process of deciding whether to shoot or not to shoot at an assailant or the process of deciding the sequence in which to shoot multiple assailants. In the information technology community, "threats" refer to various hazards to networks and computers, and the procedures for triaging these threats is sometimes referred to as *threat assessment*.

In the mental health community and elsewhere, there is also confusion between the concepts of "threat assessment" and "violence risk assessment". Traditionally, *violence risk assessment* referred to a mental health professional's evaluation of an individual for the purpose of assessing future violence risk (*see* **Dangerousness: Risk of**; **Bomb Scene Management**). Although psychiatrists and psychologists have long endeavored to evaluate the risk of future violence among those they examine, in recent decades, some have begun to refer to this process as *threat assessment* if the person was referred for evaluation after uttering a threat. Mental health professionals commonly rely on a face-to-face examination as one of their primary assessment tools, so many assume that this is a necessary or desirable component of a violence risk assessment.

Likewise, attorneys and employers unfamiliar with the advances of recent decades may assume that the way to determine whether an employee will become violent is to have the employee examined by a mental health professional as part of a disability evaluation or fitness for duty evaluation. The employer expects to receive a report that provides a valid indication of violence risk, perhaps with recommendations for treatment or other interventions that might reduce the risk. The results of this approach are often disappointing to the employer, who does not realize what information is needed to conduct such an assessment, what information may be shared with the evaluee, or the limits of the mental health disciplines or the particular provider.

Of potentially greater importance is the observation that such evaluations often prolong the employment relationship unnecessarily and may worsen the risks of litigation or violence. In many instances, an equally valid determination of violence and other risks is possible without an interview of the subject, thereby avoiding these hazards.

In practice, many violence risk assessments are conducted by mental health professionals and others without conducting a face-to-face examination or interview of the person whose behavior is of concern. The practice of *indirect assessment* has its roots in such techniques as psychological and psychiatric autopsy (*see* **Psychological Autopsy**), the forensic evaluation of mental state at some time in the past (e.g., testamentary competence or criminal insanity), profiling or criminal behavior analysis by law enforcement, psychobiography, and personality assessment of foreign leaders by intelligence agencies (*see* **Profiles: Psychological and Behavioral**). All these applications of indirect assessment draw on whatever information can be developed about the subject of the analysis and the context of his behavior, which may include personal writings; voice mail messages; videotaped statements or interviews; employment, military, business, criminal, correctional, medical, mental health, and other records; interviews with third parties; published descriptions; historical documents; and other sources of information. The depth of an analyst's experience with such assignments may contribute greatly to the value of an indirect assessment of threats in the workplace.

In reference to interpersonal communications, the term *threat* is most often used to mean an expression of an intention to harm, but this common meaning is the source of great mischief. "Threat assessment" can only have maximal value if applied to a much broader class of inappropriate communications and behaviors than the subset of communications that include a clearly articulated intent to harm. Threat assessment is best conceptualized as the analysis of communicative behavior for four specific purposes:

- *Identification*: the specific identity and location of the author of the communication.
- *Description*: the characteristics and motives of the communicator.
- *Prediction*: the probable future behavior of the communicator.
- *Prevention*: the options available for minimizing the risks of adverse outcomes.

Threatening and other inappropriate communications pose dilemmas to their recipients and to those responsible for protecting the recipients. These messages may be an end in themselves or may be warnings of future harm. In threat assessment, the analyst attempts to draw specific inferences concerning the author of a communication from an examination of the text of messages and all other available data, to make predictions about the subject; and on the basis of these inferences and predictions, to suggest options to reduce the risk of harmful outcomes. Violence is not the only harmful outcome of concern to thoughtful employers, who do not limit their use of threat assessment to articulated threats to behave violently.

An annual survey of *Fortune 1000* corporate security directors has identified a variety of "security threats" of recurrent concern to large US employers. These include workplace violence prevention, business continuity planning, information security, employee selection, employee theft, property crime, terrorism, fraud, and other issues. The priority of these and other concerns varies from year to year, but in 2008 workplace violence prevention was ranked first, as it was from 1999 to 2003 [11].

Threatening Communications in the Workplace

Within the United States, in all large workplaces and in all industries, the primary types of naturally occurring threatening communications are as follows:

- verbal threats (direct, indirect or veiled, or contingent);

- threatening behavior (e.g., a raised fist, a threatening stance, or an outright battery);
- frightening behavior (e.g., stalking, harassment, vandalism, throwing objects, or a psychotic rant); and
- other inappropriate communications or behavior.

Contrary to popular belief, obvious and direct verbal threats are not the most significant warnings of future harm. Other kinds of communications, interactions, and misconduct may carry far more significance than mere verbal promises to harm another, yet clear spoken threats to harm another are more likely to be reported, investigated, and acted upon than the myriad other ways in which those who will become violent signal this risk. Indeed, in some contexts (e.g., letters to celebrities and politicians), the presence of a threat is unrelated to risk or a significant indicator of risk reduction [6].

Moreover, the threatened action is not always interpersonal violence. Other commonly threatened actions include harming someone's reputation or career (e.g., by making false accusations, exposing infidelity or other indiscretions, conveying unfavorable information to management, assigning undesirable shifts or tasks); damaging production or property (e.g., labor strikes, sabotage, and vandalism); damaging the company as a whole (e.g., litigation, unfavorable publicity, and complaints to regulatory authorities); or causing both casualties and economic damage (e.g., arson or bomb threats, threats to tamper with food or drugs, and threats to create nuclear disasters).

In US workplaces today, a majority of injurious assaults and overt verbal threats are reported to management, at least in nonunion environments. In many union environments, the tradition of "shop talk" tolerates large numbers of threats used in daily discourse, making it more difficult to recognize those that violate cultural norms, and there is often great reluctance to inform management of any misconduct. In both union and nonunion environments, a majority of threats that are neither injurious nor obvious goes unreported until the subject does something more serious; at which time old and undocumented stories emerge about past misdeeds for which the employee should have been counseled or disciplined. This is particularly true for misconduct that bears no obvious relationship to violence risk, and which employees may only recognize and report when properly and frequently trained and reminded.

Kidnappings, telephonic bomb threats, aggravated assaults, brandishing of weapons, sexual assaults, threats to use weapons of mass destruction, and extortionate death threats are typically and properly reported to law enforcement. These relatively uncommon events comprise less than 5% of the threats reported to large corporate security departments.

The behaviors constituting 95% or more of workplace threats are either misdemeanor offenses (e.g., terroristic threats, harassment, stalking, disorderly conduct, or trespass) or not crimes at all but merely violations of the rules of the company or of common civility, making it impossible for law enforcement to provide definitive interventions. Many small businesses, lacking access to professional security staff or consultants, turn to the local police department for guidance, where they encounter a highly variable response, ranging from no response at all, to helpful guidance, to action or guidance that worsens the risk of violence. Others turn for guidance to their employment lawyer, who may or may not be sensitive to the risks inherent in these situations when using discipline, restraining orders and similar injunctions, or fitness for duty evaluations.

Threats in the workplace may be communicated by any medium, but in settings other than call centers, the entertainment industry, or the offices of government leaders and other public figures, the majority is communicated in person. In one large manufacturing company keeping good data on reported threats, 67% were communicated through direct, in-person contact, 21% by telephone, 9% through a third party, and 3% in writing.

As one might expect, males threaten other males and females more often than females threaten others. Offender/victim relationships vary by industry, depending in part on the frequency of customer contact and the sex ratio of employees. For example, retailers and banks experience a higher prevalence of customer/employee and intimate partner/employee threats than manufacturers.

A large proportion of the more serious cases handled by large corporations arises from intimate partner violence, a jealous member of a love triangle, or frustrated romantic pursuit. The offender in these cases is often not an employee, but rather an intimate partner of the victim or a customer. Cases with these origins span the full range of verbal abuse,

harassment, intimidation, stalking, overt threats to harm, and attacks of all kinds.

Another large share of cases arises internally, most often involving not only peers threatening each other but also involving threats from employees to supervisors, from supervisors to employees, and from former employees to others. Although epidemiologists and other researchers sometimes label these events as "disputes" in efforts to classify the incidents, that is not often an accurate characterization of what occurred, nor is "dispute resolution" the ideal response in many cases. Most often, an employee reacted in a highly inappropriate manner to a perceived slight, indignity, or frustration. In some cases, there was objective provocation in the form of bullying, baiting, or gruff management to which the employee reacted inappropriately. In others, the perceived provocation was an innocuous event or comment that was misperceived by someone impaired by a personality disorder, another mental disorder, intoxication, or mounting life stressors.

Threat Assessment and Workplace Violence Prevention

Employers undertaking development of a comprehensive program of workplace violence prevention require threat assessment as one part of a larger program that includes

- policies regarding violence, threats, misconduct, weapons, intimate partner violence, and bomb threats;
- a system for reporting, investigating, assessing, and managing all threats, misconduct, and inappropriate behavior;
- access controls;
- a security plan and procedures;
- preemployment screening procedures;
- a drug-free workplace program;
- an employee assistance program;
- critical incident response procedures; and
- training of all employees in their roles in each of the above.

Threats and other inappropriate behaviors and communications must be brought to the attention of those who are capable of properly investigating, assessing, and managing them. The first effort to achieve this occurred in the 1980s after one large employer experienced two mass murders. The affected company implemented a policy in which all threatening employees would be referred to the medical director's office for a fitness for duty evaluation. The company did not then realize that fitness for duty evaluations does not necessarily lead to valid assessments of risk, that the causes of workplace threats are usually not medical, and that other approaches lead to a higher rate of successful outcomes. Unfortunately, this outmoded and ineffective approach has been incorporated into the policies of a number of government agencies and government-regulated industries, such as the nuclear power industry.

Over the past 20 years, a majority of *Fortune 1000* companies has implemented many of the components of a comprehensive program, but there remain many that have not yet devoted resources to appropriate training of employees, supervisors, managers, human resources, and others who ultimately manage threats and other misconduct. Moreover, all of the same problems arise in smaller companies, yet few businesses outside of the *Fortune 1000* have succeeded in developing comprehensive programs.

Employers have used three main approaches to incorporate threat assessment services into their workplace violence prevention programs as follows:

- **Completely internal**

A few large employers have undertaken to develop an internal capacity to assess threats of all kinds, usually by having some members of the security or loss prevention department attend various courses, workshops, and professional meetings. Some of the incentives for this approach are short-term cost containment, reducing the risk of confidentiality breaches, maintaining independence, and perhaps a bid for job security for those with these responsibilities. Problems with this approach include the low odds that sufficient expertise exists internally in all of the relevant disciplines (particularly expertise in indirect assessment and, now that there are so few internal employee assistance programs, expertise in psychopathology and personality) and the fact that this approach keeps all of the liability risk internal, too. In the event that litigation ensues, it would be difficult to defend the failure to consult a highly credentialed expert.

- **Internal with external support**

The most common approach for the largest US employers is to develop internal procedures for

screening and managing most cases, using an outside vendor to provide training for an internal, cross-disciplinary management team; training materials for various audiences in the company; and consultation in selected high-risk, complicated, or unusual cases. This is the model developed collaboratively by 3M Company and Threat Assessment Group, Inc., during the 1990s, and it has been widely benchmarked, implemented, and imitated.

- **Completely outsourced**

Many employers seek guidance from an external vendor whenever they become aware of behavior they regard as threatening. This is particularly common among those with fewer than 10 000 employees or those who do not have internal security or human resources professionals. If an appropriate vendor is selected, which is not a simple task in the current market, the employer may receive excellent guidance at a reasonable cost. Unless coupled with appropriate internal policies and training, however, this approach tends to insure that many threats are missed entirely and that most that receive attention do so at a late stage in the escalation of risk.

Although public attention focuses largely on the highly publicized shooting incidents that capture the headlines from time to time, the problem of workplace violence is much broader, encompassing events such as verbal abuse, bullying, harassment, fears related to intimate partner violence, and threats that occur at a rate in excess of 10% of employees per year. Many large employers have taken important steps to reduce the productivity losses that routinely accompany these events. Nevertheless, even in the United States which has been a leader in addressing these problems, there is a long way to go before maximum benefit can be achieved. Much of the world has yet to even address the challenges or systematically consider solutions.

Time of Death Determinations

General Considerations

Estimation of the time since death is a practical task in daily forensic casework. Research on estimating the time since death should always bear this practical task in mind. However, a great number of articles on "estimating the time since death" just describe the time dependence of an analyte or parameter postmortem without being of any value in practice [1–3].

The main principle of determination of the time since death is a calculation of a measurable parameter along a time-dependent curve back to the starting point, the time of death. The characteristics of the curve (e.g., the slope) and the starting point are influenced by internal and external, antemortem and postmortem conditions (Figure 1). Since the initial value and the slope are influenced by so many factors, e.g., the ambient temperature or local temperature at the site of measurement and the estimation of the time since death can only suggest a range and not a precise and accurate point in time.

The current parameters used for estimating the time since death are completely different in nature [3, 4]:

- e.g., body cooling and postmortem lividity are predominantly physical processes;
- rigor mortis and supravital reagibility of skeletal muscle are physicochemical processes;
- putrefaction is mainly based on bacterial processes;
- chemical methods to estimate the time since death are based on metabolic processes, autolysis and diffusion according to the concentration gradient.

The methods used for estimating the time since death are not only different in nature but their scientific value, the underlying scientific background,

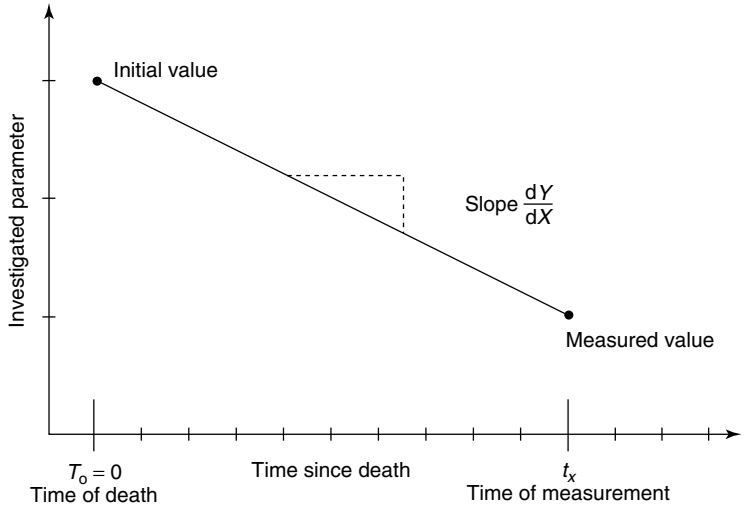

Figure 1 Main principle of the determination of the time since death (calculation from a measured value along a curve back to the initial value)

and the amount of validation of a method differ widely.

- While for some methods of estimating the time since death extensive quantitative measurements with mathematical description of a time change have been carried out taking into account the influencing factors quantitatively and clear data on the precision of estimating the time since death with proof of the precision on independent case material (example: body cooling) are available, other methods are based on a subjective grading of the postmortem change; for further methods, time estimations are based just on empiric data (empiric knowledge, no controlled longitudinal, or cross-sectional studies) instead of statistically evaluated reference values.
- The range of validity of different methods of estimating the time since death concerning experimental background, study type, influencing factors, and statistical evaluation have to be kept in mind in casework. Of highest evidential value are the methods that can show.
- Longitudinal studies on well-characterized reference samples.
- Mathematical description of postmortem changes.
- Clear data on precision of death time estimation.
- Precision of death time estimation proved on independent control sample.
- Field studies on the applicability of the method in practice.

These should replace the other, less reliable, methods of estimating the time since death.

Objectives of Death Time Estimation

Methods of estimating the time since death use two different approaches:

- which premortal changes, either physiological or pathological, can be detected on the body and allow together with investigations by the police conclusions on the time since death (survival time); and
- which postmortem changes allow a conclusion on the time since death.

The first approach comprises methods like wound age estimation or death time estimation from gastric content, normally only very rough estimations are possible.

The second approach is the more important one and comprises the spectrum of methods of death time estimation based on progressive postmortem changes. These are usually used at the scene of crime. However, if time of death and time of assault are not identical, it is necessary to combine both the approaches in order to get an impression of how long an injury was survived and in which interval death occurred after the assault.

The police may use further criminalistic or scene markers that have of course of no scientific background like

- date of last mail or newspapers;
- when was the individual last seen alive by neighbors; and time and date of an opened TV guide.

The medical estimation of the time since death at the scene of crime may have different purposes.

- To give the police a preliminary idea of the time of the assault. However, the time since death will give information on the time of assault only in those instances with a short survival period. This has to be checked on the autopsy findings.
- To check whether the time since death is consistent or inconsistent with the alibi of the suspect.

Only in rare cases timing of death plays a major role at court as the only evidence for or against the guilt of a suspect.

The estimation of the time since death should of course be as precise as possible but even more important is a reliable result. A very precise but unreliable result may mislead police investigations for a considerable time.

Practical Application of Different Methods for Estimating the Time Since Death

As no single method has been shown to produce a precise and accurate result, practitioners generally use a combination of methods to derive an opinion. From all the methods of estimating the time since death, the nomogram method by Henssge based on the body cooling after death is the most intensively investigated, most precise and reliable procedure.[a] Therefore, it should be used in all the cases if

requirements are met and it should be used as the leading method [1–3, 5–19]. However, even in the most favorable case the resulting time since death comprises an interval of ±2.8 h about the mean value. By combining the temperature method with other methods of estimating the time since death efforts should be made to narrow down this range of at least ±2.8 h further.

Methods that can be combined with the nomogram method as a compound method are time-dependent criteria of rigor mortis (beginning, maximum, and reestablishment) [20, 21] and hypostasis (beginning, confluence, maximum, disappearance on thumb pressure, and complete/incomplete shifting) [20, 21], electrical excitability of facial muscles (musculus orbicularis oculi with six degrees, musculus orbicularis oris) [3, 22], mechanical excitability of skeletal muscle (idiomuscular pad) [3, 23], pharmacological excitability of the iris [22]. The issue is how to use the data of these time-dependent classical signs of death with supravital reactions?

The mean values for any criterion of these classical methods do not represent the time interval, in which a positive reaction occurs. For reliable estimations derived from these criteria only the upper or lower limits of these criteria should be used (Figure 2). In Figure 2 mean values, 95% limits of confidence (electrical excitability of orbicularis occuli muscle), or variation (lividity, mechanical excitability, rigor, and chemical excitability) of the different criteria are arranged chronologically over the time since death (x-axis) according to the increasing mean values. As can be seen, the mean value does not really truly represent the time interval in which a positive reaction occurs; a positive reaction may occur at any point between the upper and lower limits of confidence (right and left end of the bar). Therefore, for reliable estimations derived from these criteria only the upper or lower limits of confidence of these criteria should be used.

For casework, the data of the described signs of death and supravital reactions were together with the time of death estimation based on the nomogram rearranged into a special chart which facilitates the choice of the subsequent helpful criteria in an actual case (Figure 3).

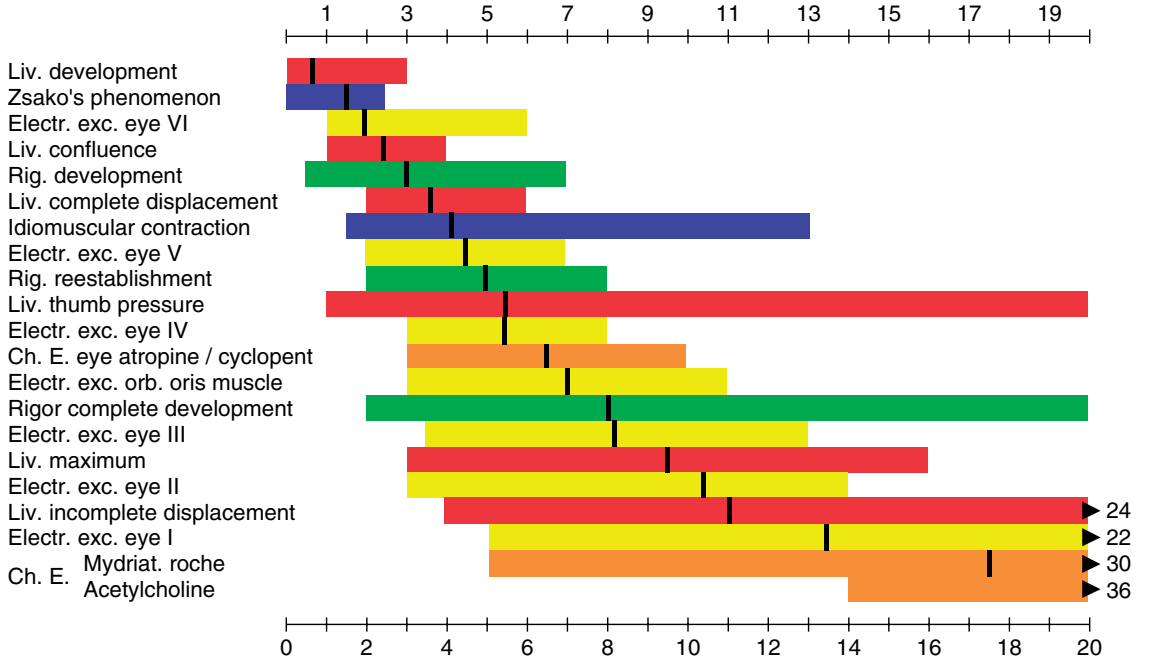

Figure 2 Mean values (black bars) and variations of different time of death dependent criteria. Red, lividity; blue, mechanical excitability of skeletal muscle; yellow, electrical excitability; green, rigor mortis; and orange, pharmacological excitability

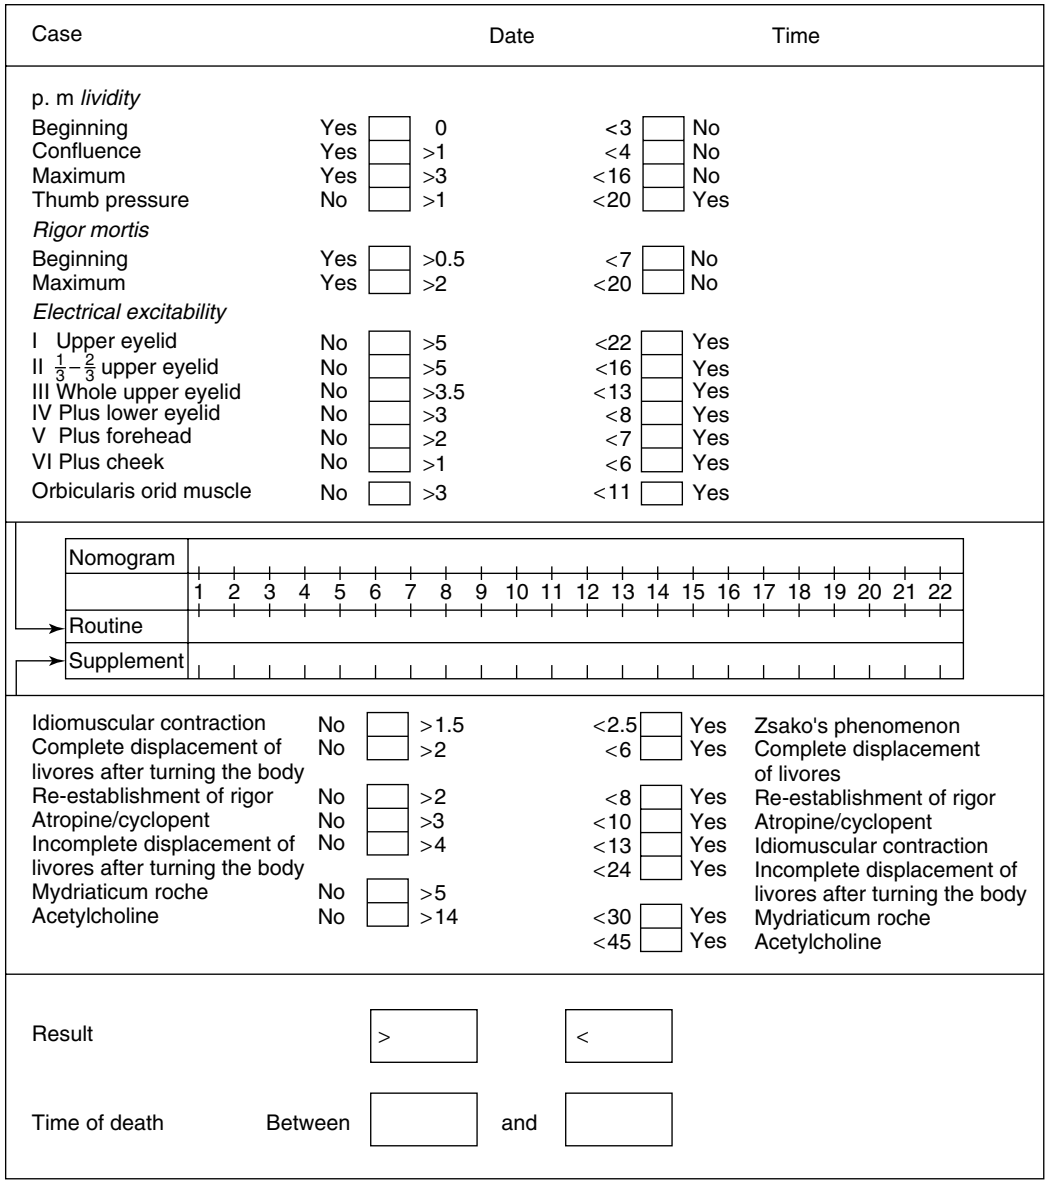

Figure 3 Integrating chart for casework at a scene of crime

In casework, the examination begins with estimating the time since death by the nomogram method after taking temperatures and choosing the appropriate corrective factor. Dependent on the range given by the nomogram method specifically those criteria are examined which are suitable to narrow down the lower and upper margin given by the temperature method. Using this chart at the scene of death will minimize the risk of error, and the inspection and examination of the body should be efficient concerning the time of death estimation.

In Figure 4, a practical example is given. At the scene of crime, the examination began with the measurement of the rectal temperature. Using the nomogram, the estimated time of death was between 4.5 h (lower limit) and 10.1 h (upper limit). The

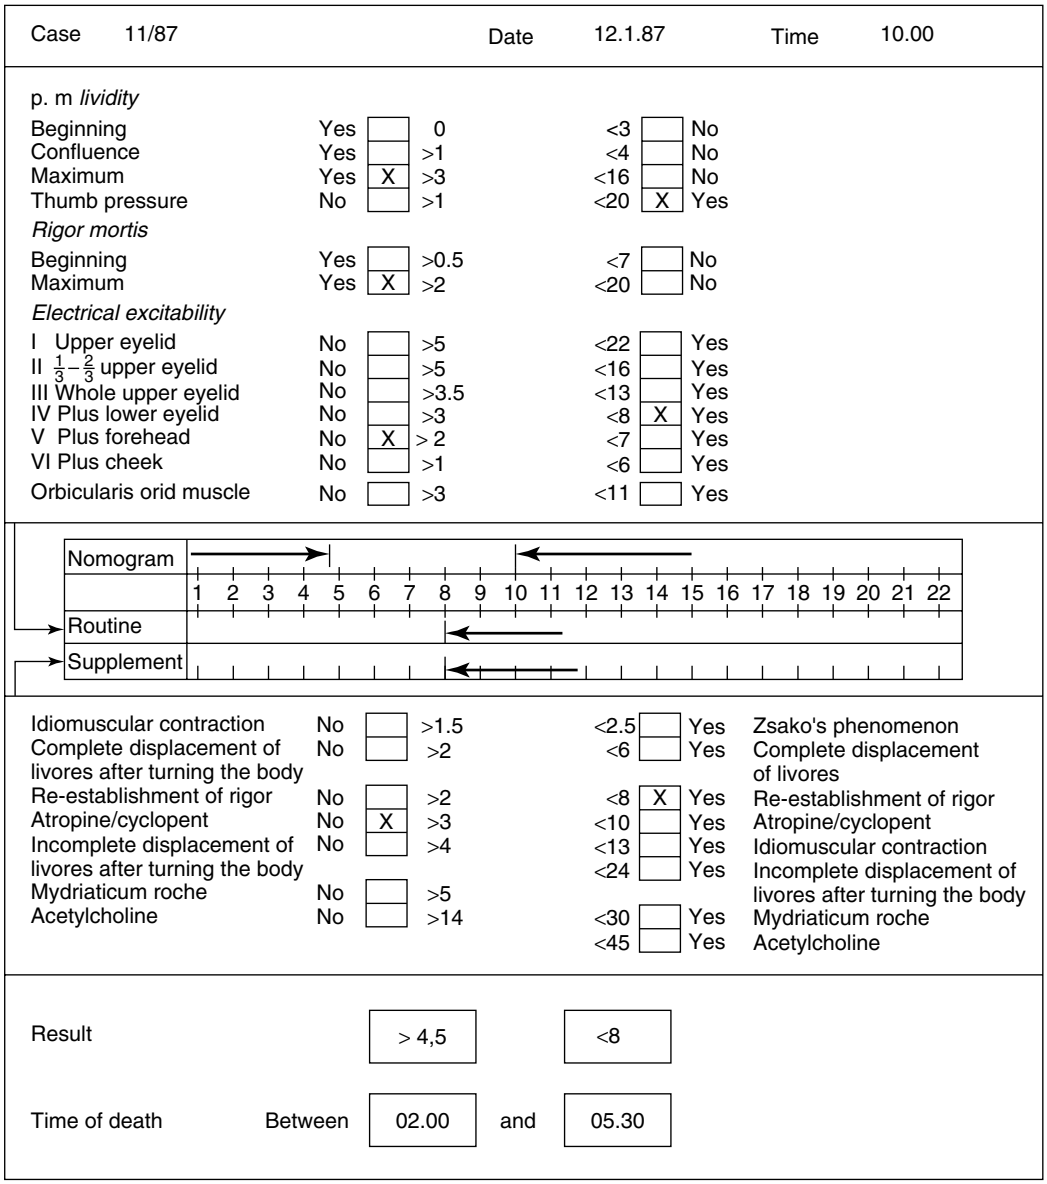

Figure 4 Integrating chart for casework at a scene of crime with an example

lower limit can be confirmed or improved only by a criterion with a higher value than 4.5 h; the upper limit can be reduced only by a criterion with a lower value than 10.1 h. The electrical excitability of facial muscles showed a positive reaction according to degree IV, which means time since death was below 8 h. Furthermore, rigor mortis reestablished after breaking can also only be observed in time intervals up to 8-h postmortem. Therefore, the upper limit of death time estimation (10.1 h) could be reduced to 8 h.

In cases in which temperature methods must not be used alone with this chart (e.g., hypothermia, fire in building where the bodies were found) valuable information on the time since death can still be obtained (Figure 5). In the case of Figure 5,

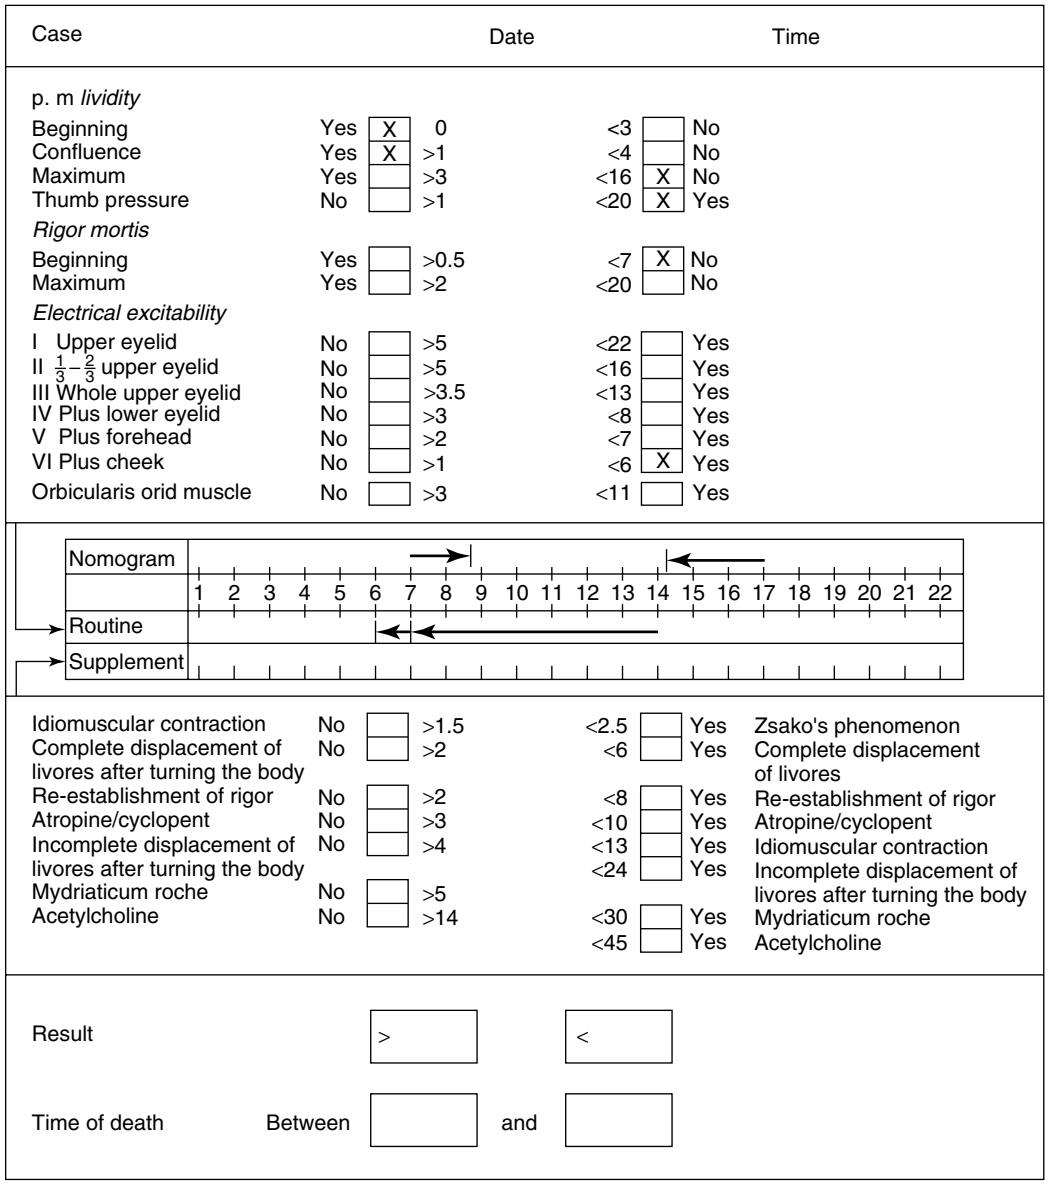

Figure 5 Integrating chart with contradictory results of death time estimation based on body cooling (nomogram), rigor mortis and electrical excitability (case of fatal hypothermia)

the temperature-based nomogram method revealed a death time estimation from 8.8 to 14.3 h based on the rectal temperature of 26.6 °C, ambient temperature 10 °C and body weight of 72 kg. Rigor mortis had not yet established and electrical excitability showed a full reaction (degree VI) resulting in a death time estimation of less than 7 or 6 h, respectively. These results were mutually exclusive. Autopsy revealed hypothermia as the cause of death and this decrease of body temperature during life simulated a long time since death. Therefore, the body temperature must not be used in cases of fatal hypothermia for estimating the time since death, but the other parameters give reliable results.

Our own experiences using electrical excitability besides the nomogram method revealed already that, especially, in the time interval from 3- to 8-h postmortem the combination of both the methods results in a more precise and accurate death time estimation than using one method alone (Figure 6) [24]. Disparate results between the death time estimation derived from the degree of electrical excitability and nomogram may be a hint of special circumstances in the case (for instance hypothermia).

A recent field study on the compound method on 72 consecutive cases over a long postmortem interval revealed that in 49 cases the limits of the period since death estimated by the temperature method were improved by the nontemperature methods [18]. The degree of electrical excitability was the most valuable additional method, but the classical signs may improve the nomogram result as well. Even if the temperature result is not improved but just confirmed this may increase the confidence of the investigator on the time since death, because the conclusion is based on independent methods.

Further Methods

Potassium in Vitreous Humor

Although there is a vast literature on chemical methods for estimating the time since death they do not play any role in practice.

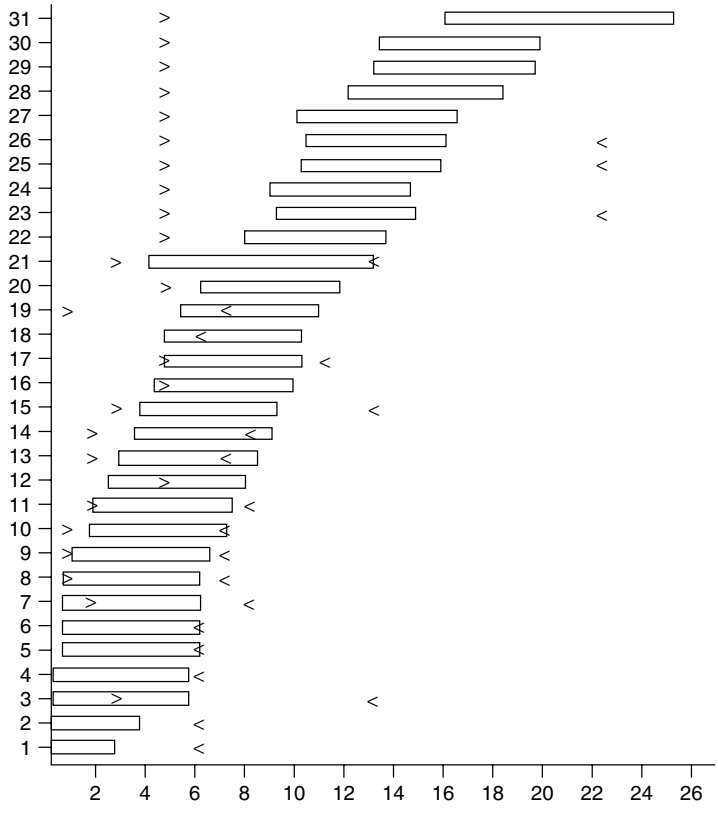

Figure 6 Combined application of the temperature-based nomogram and the electrical excitability for determining the time since death. On the *y*-axis, case numbers. Boxes, death time estimation by the nomogram method (lower and upper 95% limits of confidence). ><, death time estimation based on the degree of electrical excitability. For instance, degree III positive (case 15) not only provides the information that the time since death is below 13 h postmortem but also means degree IV negative; therefore, the time since death is >3 h postmortem. Especially, during the time period from 3–8 h postmortem, combining electrical excitability with the nomogram method allows more precise death time estimation than using one method alone. The real time since death was always within the calculated time since death

After the original description of the postmortem increase of vitreous potassium with very narrow 95% limits of confidence of death time estimation authors found a much wider range, especially when cases with abnormal electrolytes prior to death were included and different statistical parameters of the regression line were described [3, 25–31]. The literature on vitreous potassium has recently been reviewed again [29, 32, 33].

Factors that govern the postmortem rise of vitreous potassium are temperature, chronic illness, and urea retention. Beside temperature rise and scatter of vitreous potassium are determined by the state of health or chronic illness preceding death. Potassium values from individuals dying after chronic illness are much more erratic than those derived from individuals dying of acute trauma. Our own investigations revealed that urea nitrogen is a very suitable indicator of disturbed homeostasis of electrolyte metabolism and depending on the urea values, the corresponding reference sample and formula can be chosen to extrapolate time since death with different 95% limits of confidence (Table 1). In an entire sample including clinical and forensic pathology cases the 95% limits of confidence were ±34 h. By eliminating cases with urea values $>100\,\mathrm{mg\,dl^{-1}}$ and in a second step additionally cases with a terminal episode >6 h, the 95% limits of confidence could be reduced to ±22 and ±20 h. Other factors which are of importance for estimating the time since death by vitreous potassium are of course new methods, e.g., capillary zone electrophoresis or the methodology of pretreatment of vitreous humor before biochemical analysis (e.g., centrifugation, homogenization using enzymes like hyaluronidase, etc.). Statistical aspects for death time estimation have also recently been reviewed [3, 31, 32].

Gastric Contents and Time Since Death

The gastric content alone allows only a rough estimation of the interval between last meal and death. State of digestion and the distribution of the last meal in stomach and upper intestine have long been proposed as a method to estimate the time since death. For the estimation of the time since death the volume of the stomach content compared to the volume of the last meal and transportation distance into the small intestine must be known. Even if the volume of the last meal is not known the type of the meal (breakfast, lunch, and dinner) may allow rough estimations of the daytime when death occurred. Gastric emptying has been studied and quantified in the last decades using different methods (radiological, intubation-aspiration, radioisotopes, ultrasound, absorption-kinetics of orally administered solutes, and ferromagnetic traces) [2, 35, 36], review in [33, 37]. Liquids leave the stomach much faster than solids. While gastric emptying follows obviously for liquids an exponential function for solids show a linear emptying pattern. The following gastric emptying times are given in the literature: 1–3 h for a light small volume meal; 3–5 h for a medium sized meal; and 5–8 h for a large meal. However, it must be kept in mind that different anatomical and functional disorders cause delayed or rapid gastric emptying [33] (Table 2). According to Horowitz and Pounder [35] only the solid compartments of a mixed solid and

Table 1 Precision of time of death estimation using vitreous potassium in different random samples[(a),(b)]

	Urea as inner standard

liquid meal should be considered and the weight of the stomach content should be compared with an estimated weight of the last meal and reference made to the known 50% emptying times for the solid components of meals of various sizes.

Tröger *et al.* [37] compared the gastric content (volume) found at autopsy to time and volume of last meal on an autopsy collective of 47 cases (sudden and unexpected death, exclusion of brain tumors, operations of gastrointestinal tract, intoxication, and alcoholization). Gastric contents in percentage of the volume of the last meal was plotted against the survival time. Only a gastric content with a weight over 10 g was considered. Regression line and 90 and 98% confidence limits were calculated (Figure 7). From this graph, the following conclusions can be derived: if at autopsy 50% of the volume of the last meal is found the last food intake was about 3–4 h prior to death with 98% confidence limits not shorter than 1 and not longer than 10 h.

If 90% of the last meal is found in the stomach the last ingestion took place probably within the last hour prior to death with 98% limits of confidence of not more than 3–4 h.

However, conditions for a delayed and rapid gastric emptying have to be kept in mind (Table 2).

Table 2 Etiology of delayed and rapid gastric emptying[(a)]

Transient delayed gastric emptying
Postoperative illness
Acute viral gastroenteritis
Hyperglycemia
Drugs: morphine, anticholinergics, levodopa, beta-adrenergic agonists, and nicotine
Stress: labyrinthine stimulation, cold, pain, and pectin supplementation
Chronic gastric stasis
Diabetes mellitus
Postsurgical – truncal vagotomy with pyleroplasty and antrectomy
Gastro-oesophageal reflux
Anorexia nervosa
Progressive systemic sclerosis
Chronic idiopathic intestinal pseudo-obstruction
Amyloidosis
Myotonia dystrophica
Familial dysautonomia
Dermatomyositis
Tachygastria
Paraplegia
Idiopathic myocardial infarction
Acute abdomen
Laparotomia
Physiological: liquids, acid, lipids, and left-side position
Rapid gastric emptying
After gastric surgery
Vagotomy
Antrectomy/subtotal gastrectomy
Zollinger–Ellison syndrome
Duodenal ulcer disease
Reserpine
Physiological: liquids and hunger

[(a)] Modified according to Horowitz and Pounder [35] and Tröger *et al.* [37]

Putrefaction

Putrefaction is a bacterial process predominantly influenced by environmental factors, mainly ambient temperature, but by underlying diseases and body proportions as well; advanced stages of putrefaction may be seen within a few hours after death, which are in moderate or cold climates not seen after weeks. Even in relatively constant ambient temperatures the progression of putrefaction varies considerably (Table 3). Recent H-magnetic resonance spectroscopic investigations on metabolites emerging during decomposition of brain tissue have already offered promising results that even decomposition may be used as reliable method of estimating the time since death. However, these longitudinal studies on postmortem changes are still on an experimental level and decomposition under different ambient temperatures has to be studied. A weak point may be that decomposition has been studied in isolated brains and skulls; thus, an invasion of bacteria from the gastrointestinal tract is not possible. There is no sound approach to use the stages of putrefaction as shown in Table 3 for estimating the time since death while the body is lying in air. For bodies recovered from water, a quite good and reliable method for estimating the minimum and maximum water time has been developed based on putrefactive changes, which are visible at external examination or at the dissection of the body [37]. This is mainly due to the fact that water temperature is relatively constant over a longer period of time and during day and night, while air temperature differs not only from day to night but from one day to the other. Morphological findings that are taken into consideration for the estimation of duration of immersion in immersed bodies are as follows:

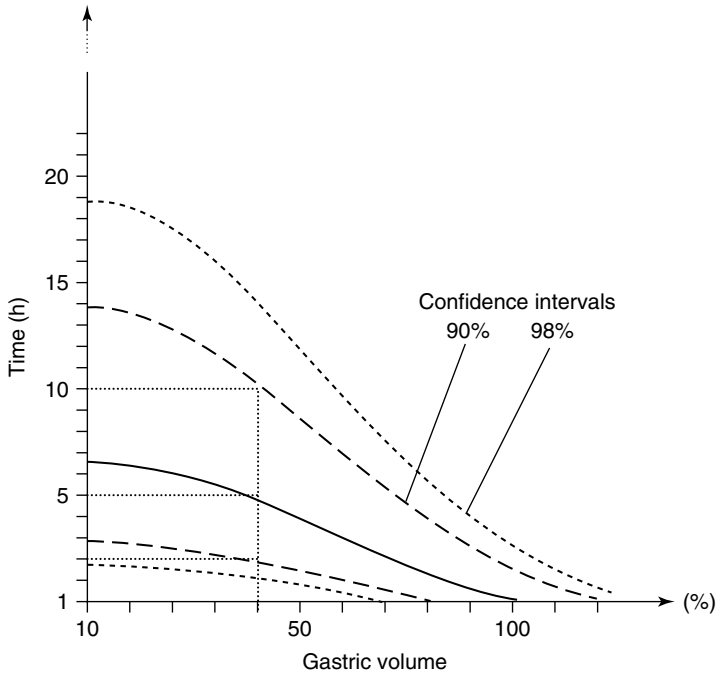

Figure 7 Relation between gastric volume and a mixed meal in percentage of ingested volume and time after ingestion with regression line, 90 and 98% limits of confidence (from Tröger *et al.* [37])

Table 3 Progression of putrefaction of bodies in air temperatures of about 20 °C[(a)]

After 1–2 days
Green discoloration of abdominal wall, softening, and decreased tension of eyeballs
After 3–5 days
Dark-green discoloration of great parts of the abdominal wall
Some patchy green discoloration of the skin, of other body regions
Body fluid leaking out from mouth and nostrils
After 8–12 days
Whole body surface dark green
Face, neck, and thoracic wall partly reddish green
Bloating of abdomen, scrotum, and face
Fingernails still fixed
Hair loose, begins to peel
After 4–20 days
Whole body green or reddish brown
Bloating of the whole body
Blisters, partly filled with putrefactive fluid, partly burst with desiccation of the dermis
Eyes (iris, pupil, and sclera) discolored red brown
Fingernails peeling

3. marbling
4. bloating of face, scrotum, and subcutaneous tissue
5. discoloration of skin (green, black, and reddish)
6. loss of epidermis
7. loss of hairs
8. hands
   (a) washerwomen's skin
   (b) loosening of nails
   (c) peeling of skin
   (d) loss of nails
9. feet
   (a) washerwomen's skin
   (b) loosening of nails
   (c) peeling of skin
   (d) loss of nail.

Table 4 Chart to estimate the minimum time interval of immersion[a]

	Month	January	February	March	April	May	June	July	August	September	October	November	December
Ø	Median water temperature (°C)	3.5°	3.9°	5.8°	9.9°	13.0°	17.4°	18.6°	18.6°	17.3°	13.2°	8.8	4.7°
1.	Marbling	32	25	16 (23)	9–10	4–5	2	1–2	2	3	4–5	10	17
2.	Distension of tissues by gas	35	25	16 (23)	10	4–5	2–3	2	3	3–4	7	10	17
3.	Discoloration of the body	35	25	16 (23)	(14)	4–5	2	2	3	3–4	7	10	17
4.	Peeling of the epidermis	35	25	16 (23)	(16)	4–5	3	2	3	3–4	7	10	17
5.	Hair lost	35	25	16 (23)	10–12	4–5	2–3	2–3	3	3–4	7	10	17
6.	Hands: beginning of wrinkling	(1)	(1)	(12 h)			(6 h)			2 h		2 h	(1)
7.	Nails become loose	Over 35	28–30 (40)	23	16	5	2–3	3	3	3–4	11	17	28
8.	Peeling of skin in glove form	35	30–32 (45)	23	16	10	3	3	3–4	4	7	20	28
9.	Nails lost	Over 53	45	30 (40)	21	14	8	3	4	10	Over 11	20	Over 35

10.	Feet: beginning of wrinkling	(1)	(1)	(12 h)	(1)		(6 h)	0.30 h		2 h		2 h	(1)
11.	Nails become loose	Over 53	40	26 (35)	17	10	5	3	4	8	12	17	28
12.	Peeling of skin	Over 53	60	35	16	10	5	3	5–6	8–9	Over 11 (14)	20	28
13.	Nails lost	Over 53	Over 60	53	Over 35	Over 28	Over 10	3	Over 10	Over 10	Over 11	Over 20	Over 35
14.	Transsudate in pleural cavity[b]	35	25 (40)	18 (35)	10	5	3–4	3	3	11	5	Over 20	
15.	Heart without blood	Over 39	32–34 (40)	23	14–15	9	4	3	3	5	11	20	28
16.	Brain liquefied	35	30 (40)	(23)	14–16	5	3–4	3	3	6	10	17	28

[a] First line: month; second line: median water temperature for the month; left column: signs of putrefaction and Maceration; following columns: minimal time interval in days. If, e.g., in July marbling, distension of tissues by gas, discoloration of the body, peeling of the epidermis, loosening of finger and feet nails, peeling of the skin of hands and feet, and a liquefied brain are observed, the minimum time interval of immersion would be about 2–3 days
Minimum time of duration of immension. Data in () indicates maximum time
[b] >500 ml in adults

Internal findings

1. volume of transudate in pleural cavity
2. heart without blood
3. liquefaction of brain.

The warmer the water the sooner a definite stage of putrefaction is achieved. From the mean water temperature for each month and the stages of decomposition, the German forensic pathologist Reh [37] developed a chart with the minimum time intervals of immersion. Considering all the 16 parameters for estimating the minimum time of immersion the following chart can be used (Table 4). On the left side the useful criteria, in the first line the months, in the second line the mean water temperature, and in the following line the minimum time interval in days.

As many criteria as possible should be used for estimating the minimum time interval since death. With more than only one or two criteria the result will become more reliable. For estimating the minimum time interval, the mean water temperature that is nearest to the actual water temperature at the time of recovery should be used. With this chart not only the minimum time interval of immersion but also the maximal interval can be estimated, by considering those criteria that have not yet developed. If in June marbling, bloating and discoloration of the body have developed, the nails are loose but not lost, it may be concluded that the interval of immersion is over three days but below eight days. Our personal experience with this chart is quite good since it is much better than the old rules of thumb because it takes the actual temperature for the progression of putrefaction into consideration [32].

End Notes

[a.] This method is described in detail in **Death: Time of**.

Tire Impressions

Introduction

Locard's exchange principle contends that every contact, no matter how slight, will leave a trace. Thus when two objects come into contact with one another, trace materials are exchanged between the two materials. This principle can be applied to a variety of objects at a crime scene. In this article, we will look at the implications on tire marks in particular. These marks can potentially be significant because vehicles play and important role in 75% of all major crimes in today's society [6]. Tire marks are found in cases involving the movement of suspects away from the crime scene and/or a change of vehicle and/or in cases that occur far from housing areas. Tire marks have been used in may cases to either implicate or more importantly exonerate suspects related to crime scenes. Tire marks mostly occur when a vehicle proceeds to drive over a pliable surface like mud, sand, snow, dirt roads, etc. These marks are called tri-dimensional marks.

Bi-dimensional marks, usually occurring on smooth surfaces, are often found in a garage or shed and are often incomplete, following the path of the vehicle on a pool of oil, paint, or blood [7, 8]. They can be composed of a variety of materials as the tire passes through the material and then deposits it on the smooth surface as a two dimensional mark [9].

The way in which tire marks are looked for, detected, protected, recovered, examined, and interpreted are very similar to the forensic examination of shoemarks.

Scene Investigation

As with any forensic evidence, tire mark examination starts at the crime scene. For an investigator it is extremely important to process and document the marks thoroughly. Sketches, photographs, and casts should be obtained in order to reconstruct events and place the vehicle in context of the crime that took place. It is important to determine the direction the car was moving in as well as differentiating between the rear and front wheels and to take note of the required measurements [7, 8]. Nothing should be overlooked and all mark evidence should be treated as valuable pieces of information [10].

When entering a crime scene and in particular surrounding areas, great caution should be taken in order to detect and protect such marks because they are extremely fragile. They should be recorded photographically immediately after they have been discovered using different light sources in order to maximize contrast. They should then be lifted using gelatin lifters by experience technicians. When processing a crime scene many vehicles are active around the scene and it is thus of utmost importance to know which marks are known and which marks are under further investigation [11].

The lifting of the mark is a critical part of processing the evidence. Because marks may be found in a variety of mediums and thus different media holding the mark together, different recovery methods may be used. It is very important that a trained technician makes the decision as to what method will be used to make an accurate lift [4]. Many of the lifting methods and theories can be taught but a large amount of information can only be obtained by hands on experience. Many new methods for lifting is available in the literature. Wilson proposed using expandable polyurethane foam for producing 3-D test prints of tires in question [12]. Buck *et al.* demonstrated that the non destructive method of 3-D optical surface scanning by GOM ATOS 2 system, delivers more detailed results and higher accuracy than the conventional casting techniques [13]. The most commonly used method for casting is still using dental stone. This particular method is discussed in detail by Bodziak and Hammer [14] (Figures 1 and 2).

The tire evidence is mostly used for comparison purposes. The comparison is made between an evidentiary tire imprint and a tire of known source [7, 8]. They are also valuable in obtaining information regarding the sequence of events at the crime scene. Information regarding the vehicle and the actions of that particular vehicle at the scene can be obtained. As a wheel rolls forward, a layer of ground on which the wheel is moving is compacted. As the wheel moves

Figure 2 Cast of tire mark using dental stone [15] [Reproduced with permission from Ref. 15. © Canadian Society of Forensic Science.]

forward, this dirt is then lifted in the direction the wheel is going [16]. The use of physics and logical thinking helps in establishing the direction the vehicle was moving. For example, as a vehicle moves through water, the tracks will slowly diminish in the direction the vehicle is moving.

Examination and Value of Tire Marks

Tire marks are very important as the tire contains elemental pattern features that enable manufacture and acquired characteristics to be identified. Of particular interest are " sipes" that distinguish design elements. Sipes are very small raised areas located on the design elements [11]. The design of these components is very important when studying a suspect's tire mark.

The elemental tread patterns illustrated in Figure 3 are very important manufacture (class) characteristics that could enable the investigating officer to determine what type of tire created the mark. Tire marks can lead to the identification of a brand name and possibly the model of the tire [7, 8]. It is possible to obtain a highly detailed three-dimensional representation of the tire by casting the tire mark. This will demonstrate the dimensions, design and wear of the tire. If the quality of the tire mark is high, many manufacture and even acquired characteristics (some of which can be truly individual) will be visible [17]. Manufacture characteristics enable us to link the tire mark to a certain model produced by a certain manufacturer.

The investigative value of tire marks has been clearly stated in [17]: "The ultimate goal of tire track investigation is the identification of the vehicle producing the track. If sufficient tire track information is present, careful and accurate measurements can yield both the manufacturer and the production year of the suspects vehicle."

Over the years many different databases have been created to help identify the brand of tire that a particular tire mark originated from. These include *Tread Design Guide* by Tire Guides, Inc. and *Who Makes It and Where released* on CD-Rom by Pearl Communications. This particular CD contains 18 000 photographs of tires and information regarding the manufacturers [4]. Another very useful tool is a database created by the Michigan State Police and the Royal Canadian Mounted Police [11].

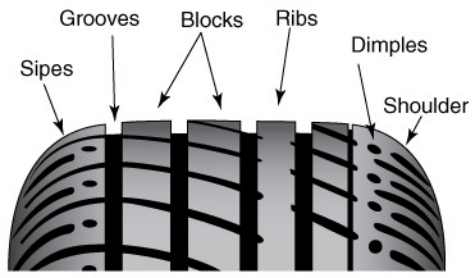

Figure 3 Elemental patterns visible on a tire [18] [Reproduced from Ref. 18. © Elsevier, 2003.]

(c) 2011 John Wiley & Sons, Inc. All Rights Reserved.

Acquired characteristics are those that are randomly produced during the life of the tire, and, in their totality, they enable the investigator to link a tire mark to a particular tire [11]. The terms manufacture and acquired characteristics are increasingly used instead of respectively class and individual characteristics to reflect the actual source of these characteristics and also to depict their identifying value in a more accurate manner (some acquired features, e.g., wear pattern, may be very valuable in the identification process without being truly individual).

Overall, the identification process and scientific underlying theories are similar to those presented in the series of article about shoemarks:

- The tire mark under investigation and the test tire print or cast present manufacture characteristics that are indistinguishable from each other and there are insufficient acquired characteristics to reach a definite conclusion regarding the identification. In this case, the mark could have been left from a particular tire (i.e., nonexclusion).
- The tire mark under investigation and the test tire print or cast present manufacture and acquired characteristics that are indistinguishable from each other. Depending on the quality of the mark and on the quantity and randomness of the acquired features, it may be possible to conclude that the particular tire did leave the mark found at the scene (i.e., identification). In some cases, a qualified opinion may be given, where the value of the mark will depend on its quality and on the rarity of the tread pattern, construction and/or size of the tire, combined with the presence, or not, as well as the number of random acquired features.
- The tire mark under investigation and the test tire print or cast present at least one meaningful (or unexplainable) difference and the mark could not have been left from a particular tire (i.e., exclusion). In this case, it is important to determine that the highlighted difference or differences cannot be due to differences in the life history of the mark compared to that of the suspected tire (e.g., major cut acquired by a tire after it had left an evidential mark).

Tire Tracks

The tracks that tires make are also of considerable value to an investigator. A standard tire track is composed of at least one set of tracks from the same vehicle. They have the potential to show many details of a particular vehicle that a single tire mark cannot. The advantage of tire tracks lies in their ability to give the investigator information about the vehicle itself by displaying the dimensions between the tracks.

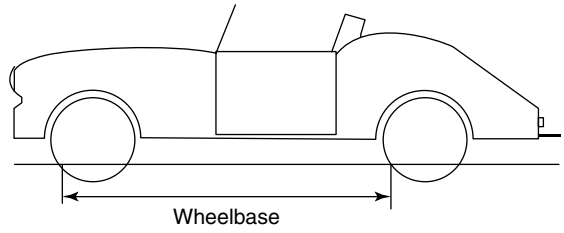

Figure 4 Wheelbase of a vehicle [7, 8] [Reproduced from Ref. 7. © Taylor and Francis Group, 2005.]

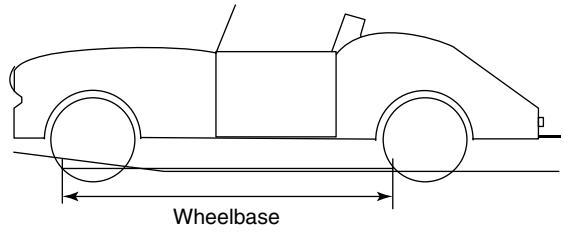

Figure 5 Wheelbase of a vehicle [7, 8] [Reproduced from Ref. 7. © Taylor and Francis Group, 2005.]

Tire marks have the ability to give the investigator critical information regarding the actual tire that left the mark while the tire tracks give the investigator critical information regarding the vehicle that left the tracks. A skilled tire technician can use information obtained through the study of tire tracks to determine the vehicle's turning radius, track width, size type and wheelbase [11] (Figures 4 and 5).

The total length and the relative position of the mark in relation to the rest of the crime scene are also important. Multiple marks can enable the investigator to reconstruct events and draw a conclusion as to the direction the car moved [7, 8] (Figure 6).

Skid Marks

Another extremely important mark that involves tires is a skid mark. These marks offer valuable

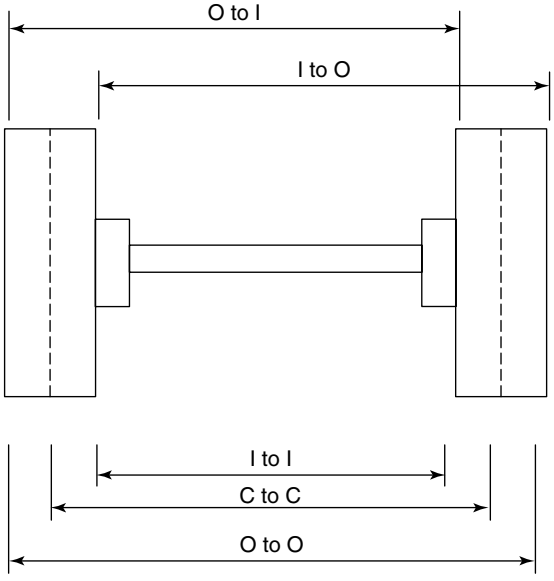

Figure 6 Different methods of obtaining tire track stance [7, 8]. I, inside; O, outside; and C, center [Reproduced from Ref. 7. © Taylor and Francis Group, 2005.]

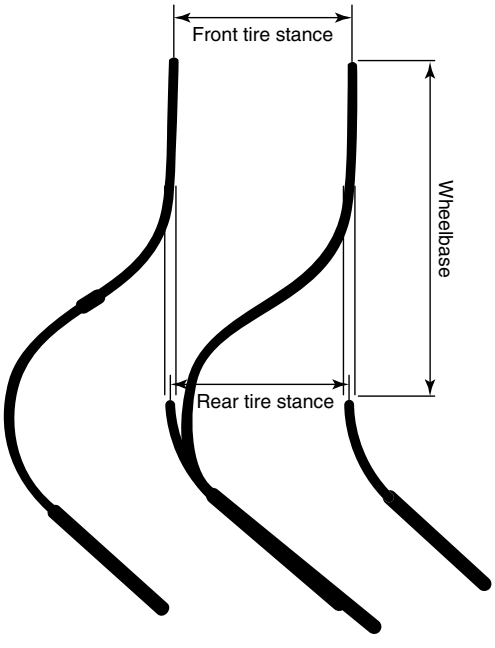

Figure 7 One method for obtaining wheelbase and tire track stance measurements [7, 8] [Reproduced from Ref. 7. © Taylor and Francis Group, 2005.]

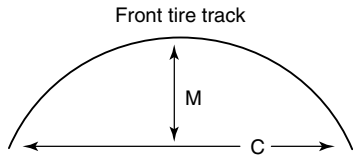

Figure 8 Measurement of turning diameter [4] [Reproduced with permission from Ref. 4. © Perason Education Ltd, 2007.]

information regarding speed and direction of travel. These marks are routinely analyzed at hit and runs as well as homicides and burglaries [6]. At the moment these marks do not offer much information regarding the vehicle but is more useful in reconstructing the event. Research however has been conducted into the analysis of tires and tire traces using chemical analysis; e.g., fourier transform infrared spectroscopy (FTIR) and pyrolysis- gas ghromatography mass spectrometry (Py-GC/MS) [2, 14, 19]. It is important to obtain particular information by using the skid marks. For example, circumference of the tire, tread width and turning diameter [4]. If one knows both the tread and the width, the manufacturers can determine the size of the tire [17]. The turning diameter can also be determined.

The chord (C) is measured followed by the distance from the centre of the chord to the closest point on the art [4].

Skid marks are also commonly used in vehicular accident reconstruction because their size and shape assist the investigators to estimate the vehicle speed and forces of acceleration or deceleration [17] (Figures 7 and 8).

Toolmarks

Introduction

Toolmarks examinations are performed by most of the forensic science institutes. Such examinations are closely related to the following subjects: mechanical properties and wear characteristics of condensed matter, manufacturing methods of materials, tools, and machines [1].

Samples of Toolmarks Examinations

Surface marks on various materials are the main objects of toolmarks examinations. They occur as striation and impression marks. Different manufacturing processes of materials result in characteristic volume structures inside the materials, and especially in specific characteristics of the surface of the engineering materials. Examples of surface marks are structures produced by grinding, turning, milling, electro-discharge erosion, laser-beam machining, casting, powder metallurgy, extrusion, and foam molding [1, 2].

Examination Processes

A goal of toolmark examinations is the identification of a questioned sample to the exclusion of all other samples. However, this goal is often not achieved at all or at least not in the form of a clear evidence (then formulated as a "probability statement" in the expertise opinion). Sometimes merely class characteristics can be determined (determination of the type of a tool). In other cases, the determination of the manufacturer, the origin, the use or the function of the questioned sample is desired, or a damage analysis is requested [3]. Table 1 gives a survey of the types of examinations of mechanically induced surfaces (toolmarks).

In general, the sequence of the examination process is as follows:

1. Inspection of the marks and the tool
   (a) Visual inspection of the questioned surface.
   (b) Surface imaging of the working surface of the questioned tool using light microscopy or scanning electron microscopy (SEM) and a subsequent classification of the surface topography into class and identifying characteristics.
2. Verification of the relationship between the marks and the questioned tool.
   Verification of a possible relationship between the marks and the tool by conducting tests with the tool in question under defined conditions; examinations using the comparison microscope or the scanning electron comparison microscope, if necessary, also with the aid of image analysis methods.
3. Reporting the results
   (a) Writing a report of the results (conclusions) of the forensic tests (examinations): expert opinion (court statement).

Table 1 Types of examinations of toolmarks

	Comparative examination of test and evidence marks	
Examination of a single questioned sample	Pattern fit (physical match)	Striated/impression marks (pattern transfer)
Interpretation of surface structures: manufacturing processes, fracture mechanisms, kind of toolmarks *Microstructures*: class and identifying characteristics	Fractures or cracks in condensed matter (brittle, ductile materials), which can be joined unambiguously or with some probability	*Striated marks*: screwdrivers, milling machines, etc. *Impression marks*: punches, etc. *Aim*: establish a link with a specific source (tool)

(b) Considering of at least two hypotheses in the expert opinion:
- The evidence mark was produced by the working surface of the questioned tool (hypothesis).
- The evidence mark was not produced by the working surface of the questioned tool (alternative hypothesis).

(c) Using a "multisteps expert opinion scale" (conclusion scale) including a guideline for the evaluation of the different steps (levels).

Individual Characteristics of the Working Surface of a Tool

Saying a toolmark is caused by a tool may sound trivial. Among the tools submitted to a forensic laboratory are pliers, screwdrivers, hammers, chisels, coining dies, tablet press machines, and cameras. To link a toolmark with a seized tool, however, only a small part of the tool, the working surface, is relevant. The specific type of tool is therefore of only minor importance for forensic examinations. To evaluate the evidence toolmarks and the test marks, the condition of the tool's working surface is the decisive factor.

Technical and Natural Surfaces

The working surface of a tool is a technical surface, originating from technical processes designed by man. In contrast to this, there are natural surfaces formed without the influence of man. Examples of the latter are the surface of a natural stone or a crystal, a shell, a peppercorn, or the bark or leaf of a tree. The state of such surfaces changes permanently. Water, air, wind, and dust as well as temperature influences change their appearance and destroy them gradually, even without the influence of man. As scanning electron micrographs prove, natural surfaces both exhibit very regular and extremely irregular shapes.

Within the scope of technology, "bodies" with a well-defined geometry surface – such as plane or curved surfaces – are produced. However, "surface" in the technical sense has another meaning than the term *surface* in the mathematical sense. It shall be explained using the following example. For a technician the "cylindrical surface of a workpiece" means a more or less rough body with form errors, while the mathematical term *cylindrical surface* merely evokes the idea of a form which can be exactly defined with respect to its geometry and which does not even have to exist in a physical sense.

Random Parameters of a Technical Surface due to the Manufacturing Process

Many materials would have undergone a long manufacturing process before they are in the semifinished stage and they can then be given their final form. Sometimes the original surface of such a semifinished product remains unchanged during the final working stages. In this case, it must already have the geometric characteristics required of the finished product. However, usually an additional forming or cutting cycle is necessary, which is frequently followed by a surface finishing process. All these surfaces that were produced by technical means and that also serve a technical purpose are referred as *technical surfaces*.

Technical surfaces are the surfaces of machines and equipment parts, tools, and facilities that are subjected to certain mechanical, chemical, thermal, or other stresses that finally lead to wear, corrosion, or other types of destruction. In addition, such surfaces may undergo chemical and physical changes, already at the moment of their formation, which may even affect deep structural layers, even if such changes will hardly be visible on, for example, a freshly lathe-cut workpiece. Thus, technical surfaces differ from natural surfaces only in that they are formed under the laws of nature under conditions that are not or only rarely found in nature.

A manufacturing method will always result in a specific workpiece surface that is characteristic of the respective method. Given the wide range of variations, even in one manufacturing method, it is obvious how unforeseeable and manifold the resulting surface condition may be. The generation of the surface profile – especially the generation of the geometric texture of the roughness and of the surface character as a result of a vast number of microscopic random parameters forms – the basis for the forensic evaluation of toolmark examinations.

Examples of microscopic random parameters are the statistical variations of local material characteristics of the workpiece of the tool, the chemical composition, the crystalline texture including the structural characteristics (crystal defects and crystal anisotropy), and the mechanical–technical characteristics (hardness, tensile strength, and elongation).

Random parameters attached to the machining process are the dynamic characteristics of the machine tool, type and sequence of motion, speed, normal force, temperature, cutting thickness, rake angle, and chip dimensions.

All these characteristics must be considered as random parameters, because they are subject to instantaneous variations and are thus continuously influencing and changing the surface topology to a varying extent. In addition, stochastic wear mechanisms, which dull the cutting edge, play a decisive role in the generation of the respective surface roughness and character. In general, the term *wear* as used in materials science describes the stresses that are acting on the surface of a condensed matter through the contact and relative motion of a second matter, including the related material losses (small material particles breaking off in a way unforeseeable in time and space, which are permanently causing various changes of the surface contour).

For this reason, measurement and control engineering as part of the engineering sciences describes and analyzes the roughness of technical surfaces as a stochastic (random) process using statistical methods. When calculating statistical degrees of dependency (correlation analyses) of surface profiles with irregular textures (stochastic profiles, e.g., of machined surfaces), the correlation function attains a very small value (tending toward zero). Such a value – obtained on condition that the examined surface profiles were produced by one and the same manufacturing method – characterizes individual structures.

This is confirmed by forensic "recurrence models" of toolmarks, based on probabilistic approaches [4, 5]. The individual character of the surface profiles of the working surfaces of tools is substantiated on materials science and probabilistic grounds. If the patterns of the evidence toolmark and the test mark cannot be differentiated and scientifically founded individualizing characteristics are present, the evidence toolmark can then frequently be unambiguously linked with the tool (working surface) producing the mark to the exclusion of all other tools.

Application of Probability Theory Models on the Comparison of Striations

Since the results of toolmarks examinations are based on "geographic features", efforts have been made to obtain objective criteria as to whether the degree of similarity is sufficient for identification [1, 4, 5]. The mentioned articles study several probability theory models, based on certain assumptions, e.g., the patterns must be generated by random processes.

Very often the relevant forensic information related to the toolmarks is given by the position, intensity, and the shape of the "curve diagram" of the striation. In [1, 4, 5] models are described mainly based on the position information of the striation (model of intervals or linear cells).

Experimental Methods

Toolmark examinations require methods in which exhibits are analyzed, compared, and finally evaluated. The applied techniques are mainly based on microscopic principles. In many cases, the use of reflected oblique lighting (stereo binocular microscope and comparison light microscope) will be the major requirements. In plastic bag cases, the application of incident and transmitted light microscopy is often necessary, sometimes in combination of shadowgraph and Schlieren photography including "crossed polarizing filters".

Comparison Light Microscopy

Light comparison microscopes are the instruments usually used for toolmark examinations [1]. The images obtained with this method are clear and convincing as they allow side-by-side comparison of the evidence toolmark and the test mark. All information gathered in the laboratory must be presented in such manner that nontechnical people at court will be ready to accept concise and detailed information – yet sophisticated presentations ought to be avoided wherever feasible. Comparison light microscopes (Figure 1) are well-established tools in forensic science institutes all over the world, and jurisprudence will readily accept photographic recordings of this kind. It is expected, that the light-optical comparison microscopy will keep its place in the majority of cases in the future. Figures 2 and 3 show images (examination of vehicle license plates [6]; fracture matching of two broken pieces of plastic [3]), received with such kind of instrument.

However, there are many cases where the question whether or not two specimens are of common origin cannot be answered to full satisfaction. Also, photographic recording often leads to difficult problems.

Figure 1 Comparison light microscope "Leica DMR" allowing direct visual comparison of test and evidence marks (oblique and transmitted lighting). The magnification range is between 16 and 500. By using polarization effects, surface reflections can be eliminated and traces on plastic surfaces – such as adhesive tape – which are hardly visible with oblique lighting can be imaged with high contrast. For comparison of transparent objects, transmitted light device gives homogenous illumination. Nowadays, instead of a video camera a digital camera is used. The microscope is connected to an image analysis system to provide higher magnification and a greater amount of contrast

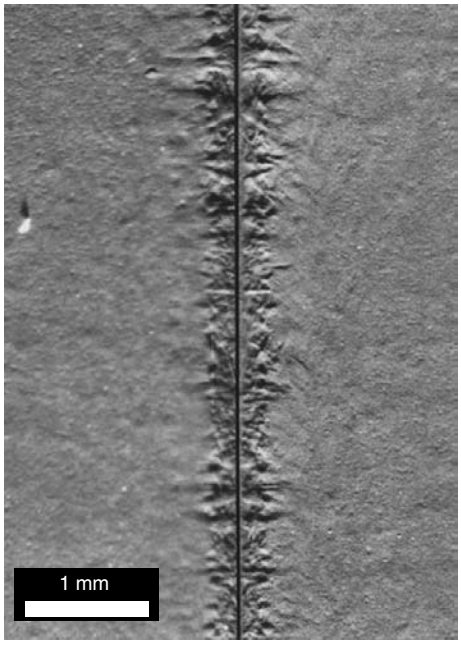

Figure 2 Comparison light microscopy: vehicle plate examination of test and evidence marks. During the embossing process, when the die hits the plate it creates a deformation of the plate of the same shape. If the die bears small defect, it will be reproduced on every plate that was embossed by the particular die. The proper observation of this characteristic and its comparison with the original die may allow for its identification as the source of the impression

Figure 3 Fracture matching (PMMA-plastic; PMMA, polymethyl methacrylate) done with a comparison light microscope showed "a very good match". Some broken pieces were found at the scene of crime (traffic accident). Some parts of the blinker were found at a suspect car. The question was to prove whether pieces of the broken material were attached to another

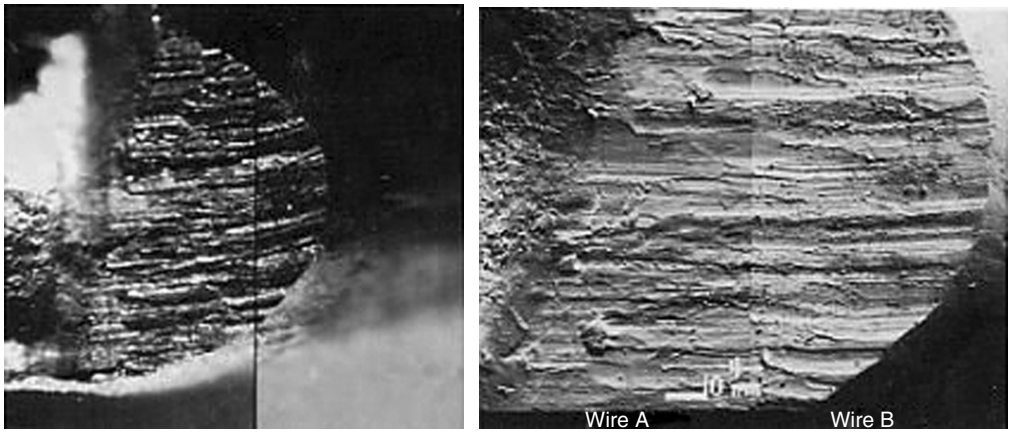

Figure 4 Light microscope (LM) and scanning electron microscope (SEM). The depth of focus and the resolution of the SEM are greater than of the LM. Here are shown the cut surfaces of a copper wire, imaged with a LM (a) and with a SEM (b)

For example, bullets may be severely deformed or their characteristic topography is too faint for recording. Moreover, highly three-dimensional structures or deeply undercut toolmarks are nearly impossible to investigate by light-optical methods. Here, a scanning electron microscope proves to be a very powerful tool, producing images of great clarity with plenty of depth of focus [1, 3] (Figure 4).

Comparison Scanning Electron Microscopy

For objects with a rugged surface or with structures of 1 μm or smaller, the light comparison microscopic method yields only insufficient results. In these cases, a scanning electron microscope with its high depth of focus and high resolution is capable of providing useful images of the structure of the questioned surface [1, 3, 7]. The disadvantage of a single scanning electron microscope is that two specimens which are to be compared cannot be shown at the same time. Instead, each specimen must be mounted and observed individually. After taking micrographs of each one, these images must then be trimmed to size and mounted in such way that comparison is feasible. It is not a simple task to mount two specimens and than record their surface details with similar illumination and at exactly the same magnification. Disregarding the fact that this takes a lot of time, experience also has shown that often important information is simply being overlooked. For the operator, it is a tedious and hard job.

These considerations were brought together, keeping in mind the questions arising in light-optical comparison microscopy. This gave rise to the concept of comparison scanning electron microscopy. Two scanning electron microscopes were electronically interconnected so that the image information from two specimens, mounted in each of the two specimen chambers, could be combined in a variety of presentation modes on a single video screen. Now, the advantages of scanning electron microscopy can be fused together with the above mentioned well established comparison microscopical methods [1, 3, 7, 8]. In Figure 5, a total view of the instrument is shown, and Figures 6–8 show images received with a comparison scanning electron microscope: striation marks of a pair of nippers on two pieces of a copper wire; fracture matching of two broken pieces of a key [3]; and impression marks on Polaroid photographs [9].

Casting Techniques

Casting techniques are used to produce true-to-shape and dimensionally stable reproductions for the examination of surface marks in forensic science. These techniques are used in all cases where an examination of the original surface is impossible or

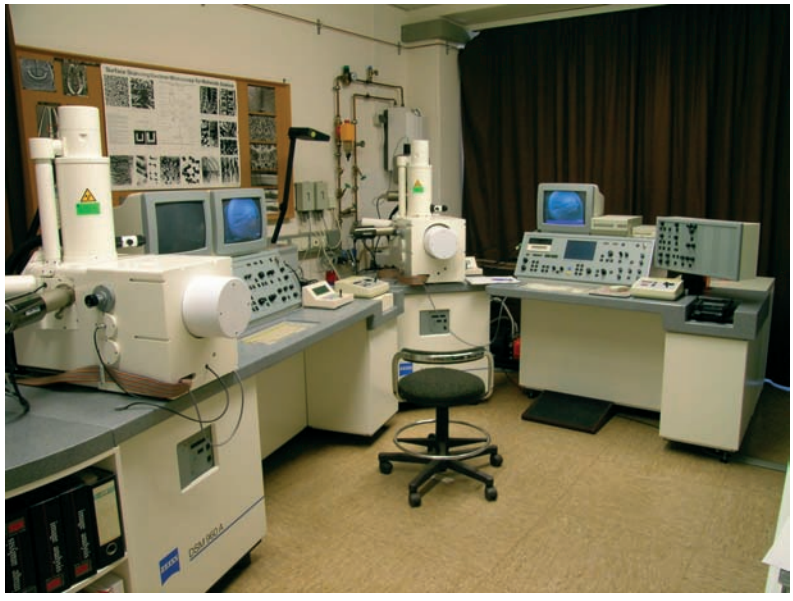

Figure 5 Comparison scanning electron microscope (Zeiss DSM 962/960A). The instrument is equipped with several electron detection systems, which produce special contrast effects and with an EDX-system (EDR 288 W Röntec). A number of interchangeable specimen holders have been designed

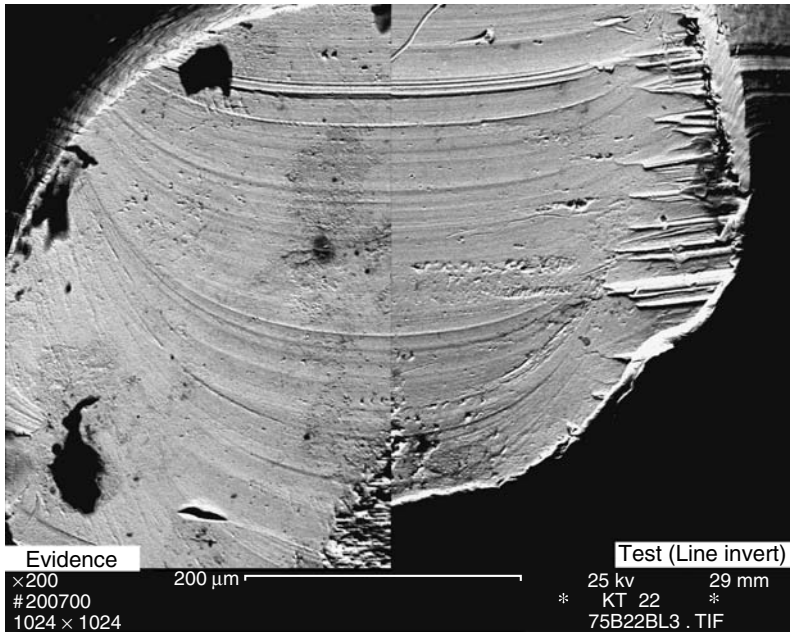

Figure 6 Corresponding striation marks on two cutting surfaces of copper wires produced by the same tool (a pair of nippers); comparison of SEM image

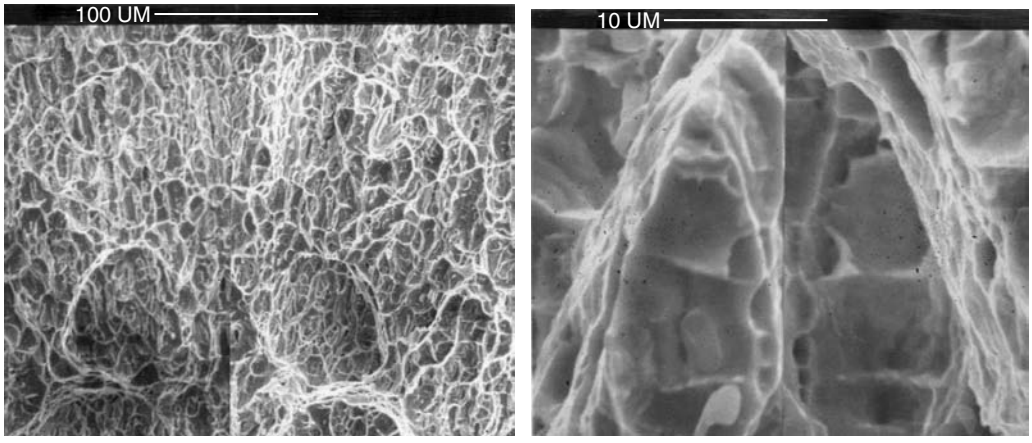

Figure 7 Fracture matching: two broken pieces of a key. The two comparison SEM images were produced with different magnifications. Matching of microstructural surface details of a rupture with ductile features (dimples)

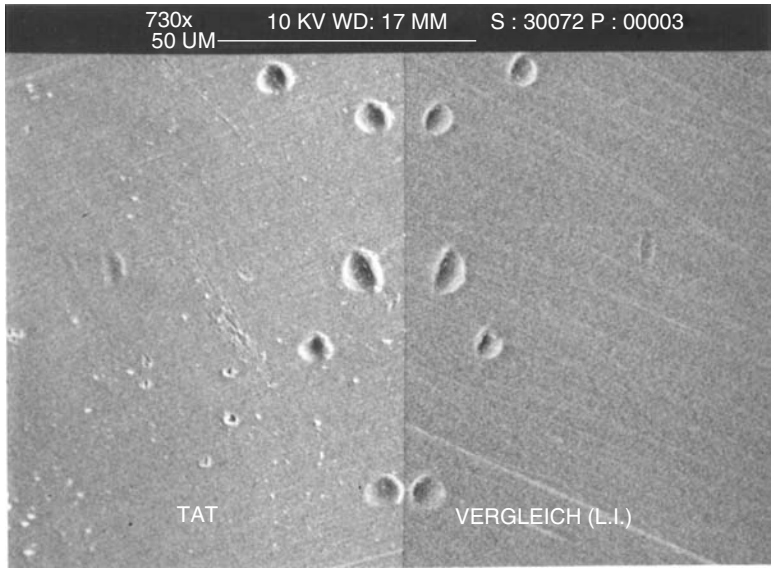

Figure 8 Impression marks on Polaroid photographs. The impressions are made by the steel rollers of the camera. The largest tips of the stalagmitic drops (produced by an electrical-discharge machining process) are pressed in the surfaces of the photographs. The random events of the producing process – shape, size, and location – are in very good agreement to each other. Having all those characteristics in combination, one can say that the recurrence of such pattern constellation would be extremely rare (identifying characteristics). In the report of the result of this kind of forensic test you would write: It was determined that the known impressions in the Polaroid pictures were produced by the questioned camera

where they can simplify or improve examination and documentation. They are also used for collecting and archiving marks, if the original piece of evidence does not lend itself to these purposes. In the field of firearm and tool marks castings are made of

- highly reflecting (shiny) objects to improve the photographic documentation of evidence and
- areas bearing marks that are difficult to examine.

The ability to produce castings of complex three-dimensional structures can be of tremendous

importance for proficiency tests or for additional forensic comparative examinations at other laboratories.

Castings materials used in forensic science and, especially, for light microscope and scanning electron microscope examinations should have the following properties [1]:

- reproduction of the finest details;
- no or only slight shrinkage;
- no inherent structure;
- chemical neutrality toward the surface to be cast;
- easy release from the surface to be cast;
- opacity and high reflectivity;
- high contrast for microscopic examinations;
- high-dimensional stability combined with sufficient elasticity;
- low or no propensity for the formation of bubbles;
- variable processing and curing times;
- low heat buildup during curing;
- freedom from tack; and
- long-term storage suitability.

When introducing a new material for making single and/or double castings, first you have to check the material if the required properties are fulfilled. The reproduction of fine details with no dimensional change is a property of special importance. Therefore, this property of manufactured castings should be tested by using a calibration standard and measured by means of a laser profilometer and a comparison scanning electron microscope. A summary of some results of different casting materials is given in [1]. For making "mass-produced" castings by means of "nontime-consuming techniques" special casting devices were developed [10].

Aspects to the Expert Opinions

A question arising frequently is whether the agreement between two surface profiles found by examination is sufficient to establish a doubtless, unambiguous "physical match", or an unambiguous link with one and the same source of the mark (working surface of the questioned tool). Would another event be able to produce the same surface structures? This problem can be scientifically discussed with the aid of probabilistic methods (Bayes theorem, likelihood ratio (LR), errors of type I and type II, and occurrence models). To estimate an error of type II in the sense of a "recurrence quantity", there are probabilistic models, which assume that the characteristic features used in the calculation can be attributed to random processes. The following discussion describes a concept for the forensic examination of marks based on probabilistic methods [1, 11]. Another section of this encyclopedia provides a thorough coverage of probabilities and statistics in forensic science.

Probabilistic Causality Concept

The question frequently asked by the requesting agency (police, public prosecutor's office, and court) is whether or to what degree of probability a seized tool has caused the toolmark at the scene of crime. Before this question is answered here, some related aspects shall be discussed first.

We are used to think in categories of cause and effect. We note that it starts to rain and expect the road to become wet. We burn dry leaves and expect smoke to rise. We hit a coconut with a stone and the coconut breaks (sometimes). Speaking in general terms: by observing an event C we conclude that a second event E will follow, i.e., a cause C results in an effect E (principle of causality). There is a relationship (a correlation) between C and E.

In mathematical terms, the correlation of two events may also be expressed as a conditional probability $P(E/C)$, put into words: the probability P of the event E in the presence of C. Examples: P(wet road/rain); P(smoke/fire); P(nut broken/hit on the nut); P(toolmark/tool); P(shoeprint/shoe); or – in general, – P(effect/cause) = $P(E/C)$ [direct causal relation]. These examples prove that the conditional probability may be interpreted as the "probability concept of causality". The examples mentioned represent "directly causal" probabilities.

Reverse Causality when Examining the Toolmarks in the Laboratory

We will now look at a scene of crime, where the working surface C of a tool produced a toolmark E : $P(E/C)$. Subsequently, the toolmark E is preserved. A tool is seized from a suspect. The examination request to the forensic laboratory may state: "What is the probability that the toolmark E at the scene of crime was produced by the working surface C of the seized tool?" This question put to the expert deals with "conclusions" or "posteriors", i.e.,

the conclusion from "effect E" to "cause C", i.e., $P(C/E)$. The expert shall, so to speak, draw a backward (retrograde, retrocausal) conclusion from a present effect E to a cause C: The conditioned and the conditioning event are reversed ("reverse causality"), i.e., we have a "retrocausal probability".

Application of Bayes Theorem to Retrocausal and Directly Causal Probabilities

A mathematical formula for the interrelationship between retrocausal and directly causal probabilities is provided by Bayes theorem. For the application of Bayes theorem within the framework of forensic expert opinions, the very elegant "odds form" of Bayes' rule is often used [1, 11–14]:

$$\frac{p(C/E)}{p(\overline{C}/E)} = LR \cdot \frac{p(C)}{p(\overline{C})} \qquad (1)$$

where $LR = P(E/C)/P(E/\overline{C})$.

The left-hand side of the equation is known as the *posterior odds*; the last quotient of the right-hand side as the *prior odds*. The factor that converts prior odds to posterior odds is the *LR*. The *LR* characterizes in a brief form the result of the forensic science examination. If the *LR* has a value greater than one, it lends support to the hypothesis C, and a value less than one lends support to the alternative hypothesis $\overline{C}$.

For toolmark examinations, the "posterior odds" can be interpreted as follows: What is the probability of a toolmark E having been produced by the recovered tool C or a different tool (tool $\overline{C}$)? To make a statement on this, both the "prior odds" and the "likelihood ratio" must be known [15]. Some forensic experts say that it is the role of the forensic scientist to evaluate the LR, and it is the role of the judge and jury to assess the prior odds and posterior odds [13]. However, the experience of many forensic scientists in court is that the judge wants an answer from the forensic expert to questions like:

> *"What is the probability that the submitted tool made the tool mark?"*

That means that the forensic scientist has to present to the court a posterior probability in addition to a likelihood ratio. Therefore, the expert has to make an estimation of the prior probability in order to be able to apply Bayes rule. For the estimation of the posterior probability, an estimation of the LR and an estimation of the prior probabilities are necessary.

This demand was also made during a Marks Conference about "Interpreting Evidence" in Berlin in 2003 by a Supreme Judge. The Supreme Judge requires the expert to make a scientific assumption of the prior probability. Arguments for this requirement are that only the forensic expert has knowledge on scientific or technical details that are needed to estimate a scientific prior probability. In cases of "lack of information" the expert can proceed – as a "pragmatic way" and not as an absolute role – according to the "principle of maximum entropy" in information theory [15] with prior odds equal 1.

If assumptions of the prior probabilities are made, it is important that this happens in a transparent way. The expert has to name explicitly the value for the prior probability. He/she should also be able to explain why he/she has chosen this value and what information led him/her to his choice.

Further on, he/she should name the value of the LR. Thus the judge has the opinion of modifying the expert's opinion and of repeating his/her calculation by using a different value for the prior probability. Sometimes it is worthwhile for the expert to make up a table relating different prior probabilities (up to four values) to posterior probabilities by considering the same value for the LR [14].

Quality Management

Quality management (QM) in forensic science laboratories encompasses everything from the equipment maintenance to training of the staff and to proficiency testing. The aim of QM is to maintain the integrity and accuracy of all laboratory testing systems over time. A guideline for QM programs is the EN 17025, formerly EN 45001 [1]. This international standard is used by various national accreditation bodies. An accreditation to the standard EN 17025 has an international recognition. A thorough discussion of QM in forensic science can be seen in **Accreditation: Organizational**.

The EN 17025 was originally meant for testing laboratories. Testing laboratories are laboratories that perform repetitive tests (such as "drinking water laboratories") and the test results are data with a well-defined precision (such as the concentration of

sodium in water). This type of testing is called *objective testing*.

According to this definition, a forensic laboratory is only a testing laboratory for a part of its activities, because laboratories usually do not end their reports with the above-mentioned data from laboratory analysis. The result of most of the reports is a concluding statement (conclusion). This part of the job is very important and gives a forensic laboratory its surplus value.

So, it appears that a forensic laboratory cannot be accredited according to EN 17025, because it does not fit within the definition of a testing laboratory. However, there are two reasons for fitting the definition of a testing laboratory [1]. In practice, the definition of a testing laboratory is interpreted widely and second a special standard for forensic laboratories, the "ILAC-G 19: Guidelines for Forensic Science Laboratories" (International Laboratory Accreditation Cooperation (ILAC)) was issued.

According to ILAC-G 19, the definition of an "objective test" is as follows: a test which having been documented and validated is under control so that it can be demonstrated that all appropriately trained staff will obtain the same results within defined limits. These defined limits relate to expressions of degrees of probability as well as numerical values: for example, "The result of the tool mark examination is more probable if the suspected tool generated the mark on the box than if another tool did generate it." Furthermore, according to ILAC-G 19, an objective test will be controlled by: documentation of the test, validation of the test, training of staff, and maintenance of the equipment. An objective test will obtain by a provision of guidance for interpretation and by checking of the results by an independent checker. Visual inspection, qualitative examinations, and computer simulations are included in the definition of an objective test.

Does the tool mark examination satisfy this definition of an objective test? It is obvious that the general aspects for tool mark examination do not differ much from other types of forensic examination. Graphically speaking, a tool mark expert can be considered as a black box with an input of questioned tool marks and test tool marks to compare and an output of a limited number of possible statements. If it can be demonstrated that several tool mark experts examined the same case and all these experts obtained the same conclusion with not more than one step difference on a conclusion scale, then there is an objective test within the scope of this definition. Before any statement (court statement, written report) leaves the laboratory, the examination must be peer reviewed. The checker may not actually rework the whole case but he/she is shown all the relevant materials that have been used for the examination.

Harmonized Conclusion Scale for Marks

The way experts express their opinions may differ depending on the country, jurisdiction, or simply their education and training. Over the last 10 years, in Europe, the situation moved toward some harmonization. During an European Network of Forensic Science Institutes (ENFSI) Expert Working Group (EWG) Marks Conference in Stockholm in 1999 a "Scale Committee" was established. It was agreed that the goal of the Committee would be to harmonize all the conclusions for the European examiners in many countries. Therefore, at the end of this project a "Conclusion Scale for Interpreting Findings in Proficiency Tests of the EWG Marks" should be reached, enabling practitioners to understand what was meant by conclusions formed by examiners across Europe.

The project had many parts: discussions about interpreting evidence, guidelines for interpreting patterns, discussion with a judge of the Superior Court in Berlin. This project produced many discussions, often controversial discussions in the "Bayesian community". The proposed harmonized conclusion scale is arguably a step toward a more practical use of a probabilistic framework to express opinions of identity of source in forensic marks examination. All the members of the Conclusion Scale Committee reached an agreement of a "six-step scale", considering two mutually exclusive hypotheses, such as: "the unknown mark was produced by the known object" and "the unknown mark was produced by another object but the known object" (see Table 2).

The harmonized conclusion scale of the EWG marks is an official ENFSI document, approved by the ENFSI "Quality and Competence Committee" [16]. A similar project was simultaneously carried out by an expert team in Germany [17]. The main result of this project was a six-step conclusion scale too.

Table 2 Conclusion scale of the ENFSI EWG Marks: assumed prior odds $P(C)/P(\overline{C}) = 1$

Step	Likelihood ratio	Probability (posterior)
1	Identification	Identification
2	Very strong support for (C)	Very probably (C)
3	Moderate support	Probably
4	Inconclusive (support for neither (C) nor ($\overline{C}$)	Inconclusive
5	Strong support for ($\overline{C}$)	Likely ($\overline{C}$)
6	Elimination	Elimination

Toxicology: Analysis

Introduction

The choice of which postmortem specimens to be used for toxicology examinations in a death investigation is at least partly historical. Prior to the development of spectrophotometric- and

chromatographic-based assays, testing relied on bulk distillation of a specimen such as the brain (for alcohol and other volatiles), or laborious extraction and isolation techniques for plant-derived drugs such as alkaloids, where the best specimen was stomach contents or one of the large organs such as the liver or lungs [1–4]. However, the development of instrumental analytical techniques allowed the use of smaller sample volumes and simpler extraction and isolation methods. Around this time, and especially after the development of pharmacokinetic theories and therapeutic drug monitoring, postmortem blood (in place of serum or plasma) became the specimen of choice for postmortem toxicology testing. This is because, in theory, blood is the specimen that best reflects the drug concentration at the site(s) of action of the drug or substance (i.e., the most easily accessible fluid that circulates closest to the site of action – the target receptors).

However, because postmortem blood is usually not a homogeneous fluid and because postmortem blood drug concentrations may change upward or downward after death, other specimens are often analyzed. Hence, a thorough postmortem toxicological investigation may involve multiple tissues or fluids. No single postmortem specimen should be relied upon for toxicological interpretation in all circumstances.

Specimens

Postmortem Blood

Blood is the most common postmortem specimen that is collected. It can be drawn from various locations in the body, generally without any form of dissection. It is usually liquid, typically with small clots that are easily avoided or drawn through a large-bore needle. Larger clots may exist in the major pulmonary vessels or the major chambers of the heart. Blood can be collected from the major vessels during external examination of the body or during the autopsy (dissection). It is good practice to collect blood from a peripheral site such as the femoral vein and a central site such as one of the cardiac or adjacent vessels. The larger volumes available from the central vessels (e.g., 30–80 ml) should be used to screen for the presence of drugs and toxicants, whereas the smaller volumes available from peripheral vessels (e.g., 3–10 ml) should be used for drug quantification. A list of suggested postmortem specimens and uses is given in Table 1.

Wherever the blood is obtained, it should be taken from a discrete vessel and not by a "blind stick" into the chest cavity in the hope of hitting one of the cardiac vessels or chambers. A "blind stick" carries the significant risk of collecting pooled blood or other fluid from the pleural or chest cavity, rather than from an intact vessel. The consequence may be a grossly elevated concentration of alcohol or drug if the stomach has been ruptured or lungs punctured [5].

Collection and sometimes measurement of drug concentrations in blood collected from two different sources (e.g., peripheral and central) is important because postmortem blood is rarely entirely homogenous and may contain vastly different concentrations for some drugs. This can be because of incomplete distribution of a drug prior to death or redistribution of a drug after death. Although this is not necessarily critical for a potent toxin such as strychnine, which ought not to be present at any concentration, it can affect interpretation of drugs the deceased person was prescribed or known to be taking.

The distinction between peripheral and central blood is critical from the perspective of interpretation, but not absolute. In other words, blood from these sources should not be regarded as separate and unvarying. For example, "central" blood can contain vastly different concentrations of certain drugs subject to postmortem redistribution depending on whether the blood actually comes from the aorta, inferior vena cava (IVC) or the pulmonary vein or aorta, or a combination [6]. Similarly, a large volume of blood drawn from an unligated femoral vein may be contaminated with blood from the iliac vein and IVC, carrying an increased risk of being contaminated with "central" blood subject to postmortem redistribution.

Ideally, the vessel from which the blood is drawn from should be ligated (i.e., tied off) to prevent blood being drawn from another part of the body [7]. For example, if a needle is inserted into the femoral vein, drawing a large volume (e.g., 30–80 ml) may result in much of that blood siphoning down from the IVC and other central vessels that are subject to postmortem redistribution. Applying a tourniquet above, the point of collection from the femoral vein is an alternate method of minimizing the siphoning of blood from central vessels.

Table 1 List of postmortem specimens, suggested amount, and uses for toxicological analysis

Specimen	Amount	Use
Central blood	20–50 ml	General drug screening and quantitation, including volatiles
Peripheral blood	5–10 ml	Drug/toxicant quantitation, including volatiles
Vitreous humor	3–6 ml	Quantitation of ethanol and other volatile, glucose, electrolytes (except potassium), quantitation of specific drugs
Liver	20–100 g	Secondary specimen for drug screening in the case of insufficient blood; additional specimen for drug quantitation to assist interpretation
Gastric fluid	All available	Quantitation of drugs
Lungs	Whole lung (tied off)	Sometimes useful for the detection of acutely inhaled gases if the death is very sudden, with little opportunity to exhale the inspired gas
Brain	20–100 g	Sometimes useful for the detection and measurement of drugs and/or metabolites that are more stable in brain than in blood (e.g., heroin/6-acetylmorphine; cocaine)
Spleen	20–100 g	Source of blood, where otherwise not available, for the determination of carboxyhemoglobin (carbon monoxide) or cyanide
Kidney	20–100 g	Sometimes useful for the determination of heavy metals, as these tend to concentrate in renal tissue
Bile	3–10 ml	Useful for the detection of some drugs that concentrate in bile, but where blood levels are very low
Cerebrospinal fluid	2–10 ml	Useful alternate specimen for the measurement of ethanol
Other organ tissues (e.g., lungs, heart, brain, spleen, kidneys, and skeletal muscle)	20–100 g	Usage is similar to that of liver. Tissue from multiple organs sometimes used for the determination of drug distribution in a homicidal poisoning or other potentially difficult cases
Hair	~20–100 hairs, pulled or shave at level of scalp	Can be useful in special cases to help differentiate acute from chronic exposure, e.g., abuse cases, homicidal poisoning, and sexual assault
Bone and nails	1–20 g	Can be used for qualitative determination of drugs where other specimens are not available. Quantitative data useful for arsenic or heavy metals

In special circumstances, an otherwise good specimen may be affected by external factors. For example, intravenous pumps (e.g., patient controlled anesthesia devices) or even simple intravenous lines may continue to run, even for a short time after death, resulting in locally elevated concentrations of the drug being administered – potentially resulting in misinterpretation of a high blood concentration.

The toxicologist should also be wary of specimens labeled as "blood" taken from moderately decomposed bodies. Such specimens may not always be collected from discrete vessels and in fact may be pooled bloody fluid from the chest cavity containing drug concentrations that will be difficult to interpret (*see* **Postmortem Toxicology: Artifacts**).

Urine

Urine is typically a clear fluid, ranging in color from nearly colorless to almost brown, containing

98–99% water. Urine has long been preferred as one of the best fluids for screening for drugs and other toxicants. The reason is the lack of protein and relative lack of lipids that can interfere with (gas chromatography) GC-based screening tests, and since urine contains concentrations of "basic" drugs (e.g., alkaloids) and other substances that can be 10–100 times the corresponding blood concentration. In addition, as a clear fluid, urine is easy to pipette and amenable to automated or semiautomated screening systems such as immunoassay and is easy to use with solid-phase extraction columns. By its nature, urine should be completely homogeneous at the time of collection.

There are, however, disadvantages in using urine as a postmortem specimen. First, there is very little correlation between the concentrations of most drugs in urine and blood. Second, urine is not always available as a specimen, either because of trauma or because of loss of bladder control at the time of or after death. Third, many drugs are so extensively metabolized in the body that little if any of the parent drug is excreted into the urine. That stated, many toxicologists find the detection of known metabolites to be equally useful.

Vitreous Humor

Vitreous humor is a clear colorless, slightly viscous fluid found in the center of the eyeball. Approximately 3 ml can be recovered from each eye. The main use of vitreous fluid is for the measurement of alcohol (ethanol), or more specifically as a fluid that can be used to corroborate postmortem blood alcohol findings. Alcohol can be produced in blood after death due to postmortem fermentation (i.e., due to metabolism of glucose and other substrates in blood contaminated with exogenous microorganisms or those naturally present) [8]. Fermentation in postmortem blood can produce alcohol concentrations approaching or in rare cases considerably exceeding the legal limit for driving of 80–100 mg/100 ml. However, the vitreous fluid in the eye is sterile and therefore not subject to postmortem fermentation [9, 10].

Vitreous humor is also useful for confirming the presence of a hyperglycemic state (abnormally high glucose) and therefore also diabetic ketoacidosis at the time of death. "Normal" glucose concentrations rapidly decrease to almost zero after death due to continued cellular metabolism. Conversely, if blood is collected close to the liver (e.g., from the IVC), glucose concentrations can be erroneously high due to breakdown of glycogen in the liver. Vitreous humor is remote from the liver and therefore not affected by glycogenolysis. Although glucose concentrations are also known to fall in the vitreous humor after death, this decrease in concentration appears to be limited, such that in a severely hyperglycemic individual, vitreous humor concentrations of glucose will invariably remain high after death. If the person is also in a state of ketosis, vitreous acetone concentrations will also be elevated [11, 12].

In addition to glucose, vitreous biochemistry (e.g., urea and creatinine) and electrolytes (e.g., sodium and chloride) are sometimes measured [12]. Elevated concentrations of these substances, particularly urea and creatinine, can indicate renal insufficiency or failure at the time of death. Elevated sodium and chloride can indicate dehydration of the body. Measurement of potassium is generally not performed because it increases with time after death due to diffusion from surrounding tissue. Although measurement of potassium has been studied as a possible indicator of time since death, the actual increases are too unpredictable to give a reliable estimate in any given case [13].

Vitreous humor is also increasingly being used for the measurement of drugs. Such use was originally limited by the relatively small volume of fluid available in each eye. However, increases in sensitivity of analytical instrumentation and methods now permit a wide range of drugs to be measured. In this respect, the use of vitreous humor as a specimen offers two advantages. First, vitreous humor lacks the enzymes that are in blood, which rapidly hydrolyze certain drugs or metabolites such as cocaine and 6-acetylmorphine (the intermediate and diagnostic metabolite of heroin) [12, 14]. Second, the specimen is relatively protected from postmortem redistribution and diffusion; it is relatively remote from the major organs such as liver, lungs, stomach, and heart. Measurement of digoxin in vitreous humor is a classical example [15]. However, for some drugs postmortem redistribution from the brain is a possibility.

Besides the relatively small volume of fluid available, the other disadvantage of measuring drug

concentrations in the vitreous is the lack of a comprehensive database. Although the forensic literature contains innumerable articles that report the distribution of drugs in many different tissues and fluids, including vitreous humor, the data are not easy to locate for any specific drug, and even then may only be available for a very small number of cases. Direct interpretation by comparison to blood databases cannot be done because drug distribution into the vitreous humor is often different than for blood. For example, drugs that are highly lipid soluble or strongly protein bound tend to have significantly lower concentrations in vitreous fluid [16].

Liver

Other than the skin, muscle, and fat, the liver is the largest organ in the body, weighing 1.5–2 kg in an adult. It has been used in the past for drug detection and measurement because it was easy to collect and offered a large mass to work with – especially if trying to isolate a pure substance for crystallography or animal studies. Now, however, the main advantage of liver tissue is as a secondary specimen for the measurement of drug concentrations. It is a tissue that is relatively easy to macerate (to form a homogenate). Drug concentrations of many drugs are 10- to 50-fold higher than in blood, enabling easier detection and measurement. Most drug concentrations are also relatively stable in the liver, undergoing relatively little postmortem distribution compared with that in the blood [17, 18]. Measurement of drugs that can undergo extensive postmortem redistribution, such as tricyclic antidepressants, has been well published [19–21].

However, as for many "secondary" tissues, a disadvantage of measuring drug concentrations in liver tissue is that comprehensive databases to assist with interpretation do not exist; notwithstanding that apart from blood (and in the living, serum or plasma), liver is the organ in which drug concentrations have been most reported. The forensic toxicologist should also be aware of the potential problems of analyzing liver tissue that has been collected from the lobe proximal to the stomach. In cases of overdose, or even sometimes recent therapeutic doses, postmortem diffusion from the stomach (across the stomach wall) can occur and may elevate drug concentrations in the adjacent liver tissue [22]. Despite these potential problems, the liver can be a useful secondary specimen that, when properly considered in the context of the case, can provide useful quantitative information.

Bile

Bile is the straw to green-colored fluid that collects in the bile duct with a volume of 5–10 ml. Bile has traditionally been used for the detection and measurement of some opiates – in particular morphine – because of the high concentrations found. Similarly many other drugs that undergo enterohepatic circulation also tend to concentrate in bile fluid. The use of bile has been advocated by some as a useful specimen for postmortem work [23, 24]. It is potentially useful since some drugs concentrate in bile and can be detected in bile for a longer period of time than that in blood, e.g., morphine and colchicine. However, there is not a well-established quantitative relationship between the concentrations of drugs in blood and bile, limiting its use for interpretation. This is not surprising. Most tissues are highly perfused with blood, and therefore drugs are expected to develop and maintain equilibrium between that tissue and blood. As the blood concentration rises, the tissue concentration of the drug in that organ should also rise accordingly (although the absolute concentration of the drug in the tissue may be quite different than that in the blood). However, bile is a fluid that is secreted by the liver over time and stored in the bile duct until required. As for urine, bile fluid is not in constant equilibrium with circulating blood and therefore cannot be a good predictor of blood drug concentration, nor drug concentration at the target organ or receptor. Bile drug concentrations may also be influenced by the liver and in the case of an overdose, by postmortem diffusion from the stomach.

Attempts have been made to use bile as a secondary specimen for the measurement and interpretation of postmortem alcohol [25, 26]. However, although the correlation is reasonable in a fresh cadaver, bile alcohol concentrations will certainly be unreliable where the possibility of postmortem fermentation exists, due to its proximity to the liver and gastrointestinal tract, and the massive source of glycogen and microorganisms, respectively.

Gastric Contents

The nature of gastric contents can vary anywhere from almost clear, sometimes mucous fluid excreted

by the stomach, to barely digested half-macerated food. The measurement of drugs and other toxicants in gastric contents is, or should be, standard practice in the case of suspected oral overdose. Homogenization of the stomach contents prior to sampling for drug measurement, or dissolution in a water-miscible solvent, can be important for quantitative accuracy, especially if unabsorbed medication is present.

It is important to recognize that, unlike for blood and tissue, interpretation of drug residue in the gastric contents should be made on the basis of the *total amount* present (e.g., milligrams or grams in the total volume) and not the concentration (e.g., milligrams per liter). In particular, gastric fluid drug concentrations should never be compared directly with blood concentrations. For example, a very high concentration can result if a person swallows a single, therapeutic dose of a medication on a nearly empty stomach. The same dose will result in a much lower concentration if the same dose of medication was consumed after a meal and a drink. It is the total amount of drug in the stomach that is important – not the concentration.

Obviously, if a drug is consumed recently and orally, its detection in the gastric contents can be expected. However, it should be borne in mind that merely detecting a drug in the gastric contents does not prove an oral route of administration. Any drugs circulating in the blood will, at least in theory, occur at some concentration in the gastric fluid for no other reason than that most drugs are widely distributed to virtually every tissue and fluid in the body. Drugs can therefore enter the stomach by secretion in gastric juice. Some drugs will also enter the stomach through the bile. Drugs that are "basic" (or alkaline) in character, such as alkaloids, may tend to occur in the gastric fluid more than neutral or acidic drugs, because of the low pH of gastric fluid.

For similar reasons, caution should be expressed about drawing conclusions regarding the time of ingestion of a drug from its presence or concentration in the stomach. The origin of low concentrations has already been discussed. "Stomach emptying" is reported to occur within an hour or so. However, stomach emptying is highly variable and is known to be delayed by an unusually large meal. (How many of us have woken up in the middle of the night with a bloated stomach, hours after the meal was consumed?) It is known that irritant substances can delay gastric emptying. In addition, after a drug overdose, some medications can form a semisolid mass in the stomach that persists largely unabsorbed for many hours or even days [27, 28]. Similarly, the presence of "ghost pills" in the stomach has been reported [29]. This occurs because the tablet excipient is poorly digestible, while the more easily dissolvable drug diffuses out and passes into the small intestine, leaving the tablet "shell" behind in the stomach. This typically occurs with slow-release tablets that have a waxy matrix, e.g., slow-release oxycodone, theophylline, and acetylsalicylic acid. Furthermore, some drugs affect gut motility and will therefore delay gastric emptying and the passage of food and drugs through the gut (e.g., opiates, plus drugs with cholinergic action including many antipsychotic medications).

Other Tissues/Fluids

Virtually any tissue can be used for the measurement of drugs, including brain, lungs, kidney, spleen, and muscle. The main consideration is availability, the work entailed in the measurement and ability to interpret the result obtained. For example, in some types of death (severe decomposition; animal activity of a body outside) other than bone, muscle may be the only tissue available. Interpretation of a drug concentration may be difficult, but simple detection and confirmation of the presence of the drug or toxicant may be all that is required (e.g., suicide or poisoning by strychnine).

Brain tissue is frequently used for the measurement of cocaine concentrations because they are typically higher than that in blood, due to greater stability in that organ [30, 31]. Drug concentrations in the brain should not be affected by postmortem redistribution or diffusion. However, for at least some drugs, concentrations may be dependent on the area of the brain the tissue is sampled from [32].

Spleen can be useful for the measurement of carbon monoxide and cyanide because the organ is rich in red blood cells.

Kidney has been classically used for the measurement of heavy metals and there is a good database of "normal" concentrations for this tissue.

Cerebrospinal fluid (CSF) can be used for the same purpose as vitreous humor. However, although the volume of CSF is generally larger than vitreous fluid, it is more difficult to collect and may not always be available.

Injection Sites

Pathologists sometimes submit suspected injection sites for the purpose of determining whether a drug or toxicant was injected. Certainly, if the drug was injected into muscle just before death, the tissue should contain elevated concentrations of that drug. However, the simple detection of a drug at an injection site cannot be used as proof of the route of administration. The reason is that virtually all drugs are widely distributed throughout the body and certainly into all muscle tissue. Therefore, regardless of the route of administration, some drug is expected to be found in muscle. The only way to demonstrate a likely point of injection is to also collect and analyze a similar portion of tissue from the other site of the body and compare the drug concentrations. For intravenous injections, proof of the site of injection may be difficult because the drug will be swept into the general circulation quickly, with little remaining near the injection site.

Hair

Hair has been used for the detection of potential poisons for decades, albeit mostly arsenic and heavy metals. Most drugs and poisons with significant stability will be taken up into the structure of hair as hair growth occurs. Therefore, if external contamination of the hair sample can be excluded, the presence of a toxicant indicates administration when alive. Segmentation and sequential analysis of those segments can be used to differentiate acute from chronic administration (for example, this has been used for arsenic) [33]. This type of analysis has also been useful in corroborating criminal administration of a drug as part of drug-facilitated sexual assault [34]. Analysis of hair is also widely applied to demonstrate illicit drug use. Hair analysis for this purpose has the advantage that it can demonstrate drug use for a much longer period (e.g., weeks or months) than does urine testing (e.g., hours or days). (*see* **Hair: Toxicology**).

Nails and Bone

Although nails and bone are chemically different (nails are cartilage and bone is not), both take up drugs and can be used to demonstrate exposure to drugs and other poisons [35]. The application of analysis of these specimens is limited to the detection of substances that should not be there. Interpretation of quantitative data is difficult or impossible because of the lack of reference values. However, detection of a substance such as strychnine or an unusually high concentration of arsenic or a heavy metal may be sufficient to prove that poisoning has occurred [36, 37].

Other Exhibits

Analysis of drug paraphernalia, such as papers and foils containing powders, residues in syringes, spoons, etc., may provide useful information. For example, heroin is rapidly broken down in the body to morphine via 6-acetylmorphine – neither heroin or 6-acetylmorphine may be detected. Finding heroin in a nearby syringe or spoon, therefore, provides useful corroboration of heroin use in a person where only morphine was found in blood postmortem. Similarly, other drugs may be detected at the higher concentrations often present in the paraphernalia that are analyzed compared with the very low concentrations often present in blood (even in an overdose).

Antemortem/Perimortem Specimens

One of the most difficult problems encountered in postmortem toxicology is the postmortem redistribution of drugs and other changes such as continued metabolism in a delayed death. Therefore, the availability of a blood or serum specimen that was collected close to death (for example, during emergency medical treatment or during resuscitation attempts), or immediately after death, can provide invaluable information for interpretation that cannot be obtained in any other way. The simplest example is the determination of a drug concentration in a blood sample drawn close to the time of death. For drugs subject to postmortem redistribution, an antemortem specimen will provide the most valuable data.

Where a person ingests or injects a potentially fatal overdose, but is found alive and resuscitated, death may eventually occur from complications of the drug intoxication days or even weeks after the initial event (e.g., hypoxic brain damage, pneumonia, and organ failure). In such circumstances, the original drugs would have been completely cleared from the body, leaving no chemical evidence of the original

intoxication. Availability of a blood sample collected soon after the original admission may therefore provide the only evidence of the original intoxication.

Premortem specimens may also provide invaluable information about the ability of the person to metabolize and clear drugs when alive. When alive, some drugs accumulate in the body due to impaired metabolism or excretion and may ultimately cause death [38]. If the drug concentration is high at the time of death, then the toxicologist, pathologist, and medical examiner/coroner have to try and determine whether it was high due to a natural process or acute ingestion. That may still be difficult to determine, but at least the occurrence of elevated drug concentrations due to postmortem redistribution can be ruled out.

Summary

In summary, most drugs and poisons are widely distributed throughout the human body. Therefore, virtually any biological specimen can be used to screen for, identify and measure their presence. The governing fact is usually the availability of a specimen (for example, blood, vitreous, and urine not may be available in a severely decomposed body). Thereafter, the usefulness of analysis of a particular fluid or tissue will be dictated by the ability to interpret the analytical finding and its value in determining the cause and manner of death.

Toxicology: Forensic Applications of

Introduction

The purpose of forensic toxicology is to produce scientifically valid toxicological information for the administration of justice and to improve the legal protection of individuals and society. This goal sets a high standard for sampling, handling, and analyzing evidence; ensuring the chain of custody is intact. Laboratory analysis requires the use of validated chromatographic and spectrometric techniques in order to obtain robust and unambiguous results [1]. This distinguishes forensic toxicology with clinical toxicology, where the use of rapid immunoassay techniques for drug classes is often justified and is sufficient for diagnosis – but is not suitable for legal purposes alone.

The origin of forensic toxicology is related to the work of the Spanish-born French toxicologist and chemist M. J. B. Orfila (1787–1853), later professor at the Paris Faculty of Medicine. He contributed

fundamentally to the scientific basis of toxicology and established the principles on giving expert opinion in the court. In the famous trial of Marie Lafarge, who was suspected for the murder of her husband, Orfila was able to prove, using the Marsh test, that there was arsenic in the body. This made it possible for Lafarge to be found guilty [2]. Since then, the discovery of homicide by poisoning has been the ultimate duty of forensic toxicologists.

In forensic toxicology, suspicion is the driving force and the general unknown is the main challenge. The suspicion arises usually from the background information of the circumstances of the case: what has happened and what is out of the ordinary. In postmortem cases, this kind of information is most often collected from the scene of death and gathered by the police or coroner. Sufficient background information is in every case an essential starting point to a successful laboratory investigation and is needed to widen the analytical scope in the right direction. For instance, if an insulin pen is found at the scene, the body should be assayed at least for insulin; the sudden death of a goldsmith warrants an analysis of cyanide; and aged people are more often prescribed digoxin than younger people.

The first phase of the analytical procedure is usually screening (the initial test) analysis. Depending on the purpose of the investigation, the screening can be comprehensive, as is the case of death investigations, where all possible findings are of interest. It can also be limited, as in drugs and driving cases, where only the drugs that have an effect on driving performance are included. The focus can also be set by agreement, for example, when conducting urine testing for drugs in the workplace (*see also* **Toxicology: Initial Testing**).

The scope of forensic toxicology is vast: it includes investigation of poisonings in humans and animals, screening for alcohol and drug abuse, monitoring pollution of the environment, detecting tampering of pharmaceutical and chemical products, and also uncovering the substances used in a terrorist attack. The wide range of applications explains the multitude of analytical techniques that are required to solve these tasks. Many laboratories have also received certification or accreditation from an authoritative body.

In the analysis of human samples, forensic toxicology answers two key questions: (i) has the person under investigation been exposed to alcohol, drugs, or other xenobiotics and (ii) has he been under the influence of any foreign substances [3]. Exposure to a substance is verified by detecting the presence of a substance in a biological sample, not only in urine but also in blood, breath, hair, oral fluid, sweat, or tissues. The mere presence of the parent substance, e.g., cocaine in the hair, is sometimes not sufficient alone to prove systemic use, but the presence of metabolites may also need to be demonstrated to reliably interpret the finding. In any case, a positive finding does not mean that the person has actually taken the substance by himself, because exposure can take place deliberately or unwittingly.

An accurate measurement of the blood concentration of the substance is a prerequisite for evaluating whether a person is under the influence. With living persons, a representative specimen of venous blood can easily be collected by venepuncture; however, sampling is more challenging with cadavers. Blood from central compartments, such as heart blood, may contain drugs in up to 10 times higher concentrations compared to peripheral blood [4] (*see* **Postmortem Toxicology: Artifacts** for further information).

Considering all the shortcomings in collecting postmortem blood, femoral venous blood represents antemortem blood more closely than does any other blood sample [5]. In some countries, breath testing with evidential breath alcohol analyzers can be used *per se* as evidence of being under the influence of alcohol (*see* **Alcohol: Analysis** for examples and further information).

Forensic toxicology is often associated with a forensic medicine department at universities. Research typically includes development and validation of analytical methods, pharmacokinetics of drugs and poisons, pharmacogenetics, case studies, and epidemiology of poisonings, and social studies such as evaluation of the consequences of drug abuse and research on drug safety.

Postmortem Toxicology

In postmortem forensic toxicology, analytical results are utilized to determine the cause and manner of death. Poisoning can be the underlying cause of death (WHO Ic), which means that poisoning "initiated the train of morbid events leading directly to death", or the immediate cause of death (WHO Ia), defined as a "condition with the symptoms of which the

deceased died". Poisoning can also be a contributing cause of death (WHO II) [6]. It is possible for Ia and Ic to be the same, as in the case of death by alcohol poisoning after heavy drinking if no other cause is operating simultaneously. The substances that frequently cause fatal poisonings include opioids, tricyclic antidepressants, neuroleptics, alcohols, carbon monoxide, and, especially in developing countries, pesticides. In traffic and workplace accidents, the economic consequences can be considerable and the question of culpability has significance from the viewpoint of criminal and civil law. Applications of postmortem toxicological investigations are listed in Table 1.

The question of poisoning arises typically at the scene of death: medicine bottles or packets, pills, tablets, syringes, or needles are found in the vicinity of the body. Alternatively, prescribed drugs are missing or the consumption of drugs has surpassed the amount prescribed. In suicidal poisoning, a suicide note may also be found. External examination of the body can reveal dried drug stains around the mouth or powder around the nose, or needle marks may be detected in the skin. Skin color and lividity can suggest poisoning, for example, in carbon monoxide and cyanide poisoning the lividity is typically reddish. The internal examination, or autopsy, includes opening of the skull and investigation of the brain. On this occasion, an odor suggesting alcohol, cyanide, or other volatiles may be noticed. In the alimentary tract, irritation, corrosive changes, or tablet remains are indicative of oral poisonings. In other organ systems, congestion and edema are typically present in poisonings. The blood can be flowing and appear more reddish than usual. However, these changes are not necessarily pathognomonic and can be caused by nonspecific changes found in sudden death due to asphyxia or exposure to a cold environment.

Table 1 Applications of postmortem forensic toxicological investigation

Autopsy findings or circumstances suggest poisoning
Homicides and other suspicious cases
Suspicion of malpractice
Need to confirm an apparent cause of death
Traffic accident
Occupational or workplace accident
Check of compliance with pharmacotherapy
Obscure death

Another application of postmortem toxicology is a suspicion that the death is due to pharmacotherapy. These include cases related to drug injection given by a member of the nursing staff or that the death has otherwise an obvious temporal connection to a dose of drug. Postmortem toxicology can be used to assess compliance with pharmacotherapy, e.g., the use of anticonvulsant drugs, antidepressants, insulin, oral hypoglycemic drugs, etc.

Sometimes, such as in suicides committed with car exhaust gas, the cause of death is obvious, but the toxicological determination of carboxyhemoglobin (caused by binding carbon monoxide with hemoglobin) is still justified. Currently, this is even more important since new cars are equipped with catalytic converters and the death may be due to suffocation (from depletion of oxygen) instead of carbon monoxide. According to good practice, the diagnosis of obscure or unascertained death (*Mortuus inventus, causa ignota*) as the underlying cause of death can be issued only if a postmortem toxicological investigation has been performed and did not reveal poisoning.

Sudden and unexpected death can also be due to potentially criminal matters such as homicide or negligent medical treatment, and suspected cases ought to be subjected to forensic cause of death investigations, including full forensic toxicology. A striking example of negligence in this respect is the Shipman case. Dr Harold Shipman was a private practicing doctor who was also an active serial killer in 1970–1998 in England. He was convicted for 15 murders by poisoning with diamorphine (heroin) or morphine, but the actual number of victims possibly amounted to at least 218 [7].

Traffic Medicine

Impairment of drivers is the main cause of traffic crashes and accidents. Typical reasons for impairment are the use of alcohol and drugs including in particular drugs of abuse. This is why forensic toxicological investigation is needed for evaluating whether the driver has been under the influence of a substance. According to the legislation of some countries, police must first perform a roadside evaluation of impairment before subjecting the driver to a breath or blood test, whereas in other countries they are allowed to perform random stop checks. Punishable blood–alcohol concentration varies from

zero in Hungary through 20 mg/100 ml (Sweden and Norway) to 50 mg/100 ml (Australia and most European Union countries) and 80 mg/100 ml or higher (United States and Canada). If the driver is able to blow sufficient breath and no other adverse substances are suspected, the presence of alcohol is typically assessed by using an evidential breath analyzer. Otherwise, laboratory determination of blood–alcohol concentration by headspace gas chromatography is performed (*see* **Alcohol: Analysis**; **Alcohol** for further information).

Drugs of abuse are more frequently the cause of impairment in driving. This is why new methods to reveal drug-positive drivers have been developed. Much effort has been focused on oral fluid drug testing, but a present survey of oral fluid testing indicates that the sensitivity of the tests for cannabis and benzodiazepines is still unsatisfactory. However, random drug testing has been used successfully as a deterrence. Positive roadside tests by immunoassay do not authorize the imposition of legal penalties unless a confirmation analysis has been carried out in a forensic laboratory equipped with specific chromatography-mass spectrometry methods.

There are differences in the legislations of different countries regarding how to handle a positive test result. In some countries, such as the United Kingdom, Norway, and Denmark, the law stipulates that a driver's impairment must be proven. Some countries, e.g., Germany, France, Switzerland, Belgium, Sweden, Finland, and many Australian States, apply the so-called zero tolerance, which means that any time a banned drug or its metabolite is detected in a blood sample, violation of the law occurs. In practice, an analytical method has a limit of detection and a limit of quantification, and consequently a cutoff limit is applied. Any result exceeding the cutoff is interpreted as positive and conversely, any result below the cutoff is interpreted as negative. Cutoff limits for different drugs vary between countries, and they have also changed over the years. In some countries, such as France and Finland, the cutoff is equal to the limit of quantification of the laboratory method (*see* **Drug-Impaired Driving** for more information).

Clinical Forensic Toxicology

Clinical forensic toxicology is applied to a multitude of purposes in society, some of which are listed in Table 2. Drugs may precipitate violent behavior, including psychotic effects of amphetamines or disinhibitory effects of alcohol or benzodiazepines, leading to an assault, even homicide. Sampling in such cases may take place in ordinary healthcare units, often under the surveillance of a police officer or other authority, or at a police medical department. Extreme care should be taken to ensure that the appropriate procedures are followed in collection of any specimens.

A current topic in clinical forensic toxicology is drug-facilitated crime, such as drug-facilitated sexual assault, theft, child abuse, or the use of force or coercion to forge legal documents. The substances used in these crimes typically cause anterograde amnesia, have a rapid onset of effects, leave no taste, and can easily be mixed with drinks or food. Drugs used in these cases are short-acting benzodiazepines, other hypnotics such as zopiclone or zolpidem, or psychedelics and empathogenics such as ecstasy, cannabis, or lysergic acid diethylamide (LSD). Other potential substances include γ-hydroxybutyrate (GHB), clonidine, chloral hydrate, scopolamine, tetryzoline, fentanyl, or neuroleptic drugs.

The investigation of drug-facilitated crime is a challenge to the laboratory since typically several hours elapse before the victim seeks help. Collection of both blood and urine is always advisable, and a hair sample may provide some useful additional information. Discriminating between voluntary and involuntary drug use is a major problem and requires consultation between the toxicologist, the police, and the clinician to maximize the interpretation of any

results (*see* **Drug-Facilitated Sexual Assault** for further information).

Workplace Drug Testing

Workplace drug testing started in the United States after some conspicuous accidents in transportation and aviation in the 1980s. As early as 1986, all federal employees working in critical positions concerning safety and security were tested, according to an executive order. Additionally, several private companies began to test employees in risk areas such as transportation and the nuclear industry. As some of these companies were operating overseas, testing programs were extended internationally. In Europe, testing has been in force since the 1990s. The typical drugs tested are included in the Mandatory Guidelines for Federal Workplace Drug Testing Programs of SAMHSA (Substance Abuse and Mental Health Services Administration, USA): amphetamines, cannabis, cocaine, opiates, and phencyclidine. In Australia and Europe, phencyclidine is not routinely tested but benzodiazepines are usually included.

Drug testing is performed in most cases by urine immunoassay. Positive test results are confirmed by a specific technique, such as gas chromatography–mass spectrometry (GC-MS), and the final laboratory result is interpreted by a medical review officer. Thus, possible confounding causes such as cough medicines can be excluded. Cutoff limits for screening and confirmation are consistent among the European Union, United Kingdom, and Australia; however, in the United States cutoffs are higher for amphetamines and opiates [8].

Alternatives to urine samples are oral fluid and hair samples. See the respective articles on these specimens.

Workplace drug testing can be preemployment or random testing, and the practice can be mandatory or voluntary. Ireland and Finland are the first countries to have a special law regulating workplace drug testing. In Finland, an employee has the right to refuse participating in a test, but in such a case the medical review officer cannot make a statement on the suitability of the employee for a given task, which may result in rejection. Although it is easy to understand and accept the rationale behind drug testing at a workplace, in schools, in the armed forces, etc., there is a balance with the individual's civil liberties.

Doping

Doping refers to the unfair use of drugs or methods to enhance performance in sports. The prohibited list was first published in 1963 under the leadership of the International Olympic Committee. Since 2004, the World Anti-Doping Agency (WADA) is responsible for the preparation and publication of the banned substances list. The prohibited substances are divided into three main categories: prohibited in-competition, out-of-competition, and in particular sports. Substances that are prohibited at all times include anabolic agents, hormones and related substances, β-2 agonists, agents with antiestrogenic activity, and diuretics and other masking agents. The prohibited methods include enhancement of oxygen transfer, chemical and physical manipulation, and gene doping. Substances that are prohibited in-competition include stimulants, narcotics, cannabinoids, and glucocorticosteroids. Substances prohibited in certain sports include alcohol and β-blockers. WADA gives laboratories accreditation to perform doping analysis and follows the performance of the laboratories. The accredited laboratories should also comply with the requirements of the international standard, ISO/IEC 17025. It is noteworthy that doping is not only a violation against rules of fair play but also, in some countries, a criminal act. As the list of prohibited substances is extensive, a doping laboratory has to utilize several screening and confirmation methods to cover all common drugs [9]. Some of the substances are also endogenous, e.g., testosterone and erythropoietin, and in these cases special techniques, such as carbon isotope ratio or metabolite ratio determination, are required.

Terrorism

Forensic toxicological expertise is crucial in preventing and investigating terrorist attacks. In a well-known case in Japan, a deviant religious group released the warfare agent sarin. In 1994, in Matsumoto close to 600 inhabitants were suddenly suffering from strange symptoms and seven victims died. The next year in a Tokyo subway, up to 5500 passengers were exposed to sarin and 12 died [10].

In both the cases, the acetylcholine esterase activity of the victims was lowered and sarin was detected. Another tragedy took place in 2002 in Moscow, when Chechen terrorists captured Dubrovka theater with about 800 spectators. On the third day, the Russian special forces attacked the theater and made unconscious both the terrorists and the victims by using aerosol. Rescue forces were delayed and 129 hostages were killed. After the incident, the Russian health minister admitted that the gas was a fentanyl derivative. The symptoms also suggested exposure to an opioid-type knock-out gas or aerosol.

A difficult and unparalleled toxicological case was the poisoning of the ex-Bulgarian citizen Georgi Markov in 1978 in London, when he was assassinated with a pellet containing ricin. During an election campaign in 2004 in Ukraine, the presidential candidate Viktor Yushchenko was suddenly taken seriously ill. Among other symptoms he developed facial eruption, which was finally recognized as chloracne, and the diseased condition was found to be poisoning with dioxin. In the above-mentioned cases of terrorism, the substances used are not on the ordinary analysis repertoire of forensic laboratories, and even all the reference materials required for analysis are not freely available.

The Tylenol tampering incident in 1982 in Chicago, USA, revealed a new pattern of crime: someone had switched Extra Strength Tylenol (acetaminophen) capsules with similar capsules containing cyanide, resulting in the death of seven people. Since then, comparable tampering misdeeds have occurred, and Tylenol itself was again tampered with in 1986. These incidents have promoted the use of tamper resistant packages, protective seals, and labels.

Environmental Toxicology

Pollution has resulted in severe environmental disasters and caused diseases and deaths. Perhaps the worst manmade global problem is air pollution due to gaseous and particle emission. In a classic case, the London smog of 1952, it is known that the excess mortality during the period was 3500–4000 people. Death came typically to the elderly, who were the first to suffer from cardiac or respiratory diseases. In these types of cases, identification of a single victim is a difficult task, as is also the identification of the culprit because of collective responsibility. However, there are many other more local environmental disasters, where individual victims and offenders can be identified. Such cases are cadmium pollution (Itai-itai disease), methylmercury poisoning (Minamata disease), and PCBs (polychlorinated biphenyls)/PCDFs (polychlorinated dibenzofurans) poisoning (Yusho disease), all of which were first discovered in Japan; the dioxin disaster in Seveso, Italy, and the methylisocyanate accident in Bhopal, India.

For legal proceedings, exposure must be verified by toxicological analysis. Certainly pollution of the environment is *per se* a criminal offence, and laboratory results are needed to verify the incident. An exceptional series of poisonings happened in 1996 in Caruaru, Brazil, where a private dialysis center used defectively purified water: 117 out of 136 patients in the treatment became ill and 50 died. The cause of the disaster was an algal hepatotoxin, a microcystin, which was present in the water used in the treatment.

Database Research and Epidemiology

Conventionally, forensic toxicological investigation has been primarily used to resolve individual cases. However, a lot of information that is valuable to society and is otherwise difficult or impossible to obtain can be extracted from casework. To give statistics additional epidemiological value, the size and structure of the target population, sampling procedure, and coverage of analytical processes must be known thoroughly. An example of the possibility of utilizing a cumulative database of individual cases is the statistical approach that is used when compiling the fatal and control concentrations of drugs found in postmortem femoral blood [11]. Generally, prospective studies produce more well-defined information than retrospective since there is better information on the circumstances, the presence of other contributing drugs, and pathology processes (*see also* **Postmortem Toxicology: Interpretation**).

When reporting fatal poisonings within an area, the number of cases related to a particular drug or drug category is usually presented on an annual basis. However, these kinds of statistics do not contribute to the evaluation of drug safety, and a more informative picture of fatal poisonings is obtained if the fatalities are related to drug consumption. A fatal toxicity index, where the number of deaths associated with

a particular drug is divided by the number of prescriptions for the drug, can be used to rank drugs or drug categories [12]. As the number of prescriptions is not always available, the consumption of a drug can be estimated by the quantity of sales using the concept of Defined Daily Dose per 1000 inhabitants per day [13]. This approach can reveal differences in intrinsic toxicities, prescription practices, and abuse potentials of therapeutic drugs. It has been shown that, among antidepressants, the risk of death related to older tricyclic drugs is much higher than with newer selective serotonin reuptake inhibitors, while other newer antidepressantsmoclobemide, mirtazapine, and venlafaxine fall in between.

Toxicology: Initial Testing

Introduction

Toxicological analysis, be it forensic, clinical, environmental, workplace, drug abuse, or doping control, principally involves the detection of chemical substances potentially harmful to living organisms. Chemical analysis is used to detect the presence of these substances, measure their concentrations, and interpret this in relation to their relative toxicity. Paracelsus (1493–1541) said, "All things are poison and nothing is without poison, only the dose permits something not to be poisonous."

Our society is surrounded by a large number of poisons (including chemicals, drugs, pesticides, common household products, etc.), and the task of the toxicologist is a formidable one to attempt to detect as many of these substances as possible in a toxicology screen.

Forensic toxicology requires a number of analytical techniques to exclude the presence of any poisons. For most laboratories, that may be analyzing hundreds or thousands of samples per year, it is not practical to try and cover all of these compounds simultaneously and an appropriate approach is to screen for the common drugs of abuse, prescription and nonprescription drugs in the first instance, and then perform any specific analyses that may be indicated by the case history. In most forensic toxicology laboratories, a drug screen will include a range of immunoassay tests, alcohol analysis (either by direct liquid injection or by headspace gas chromatography), headspace analysis for volatile organic compounds and a broad-based gas chromatography (GC) or high-performance liquid chromatography

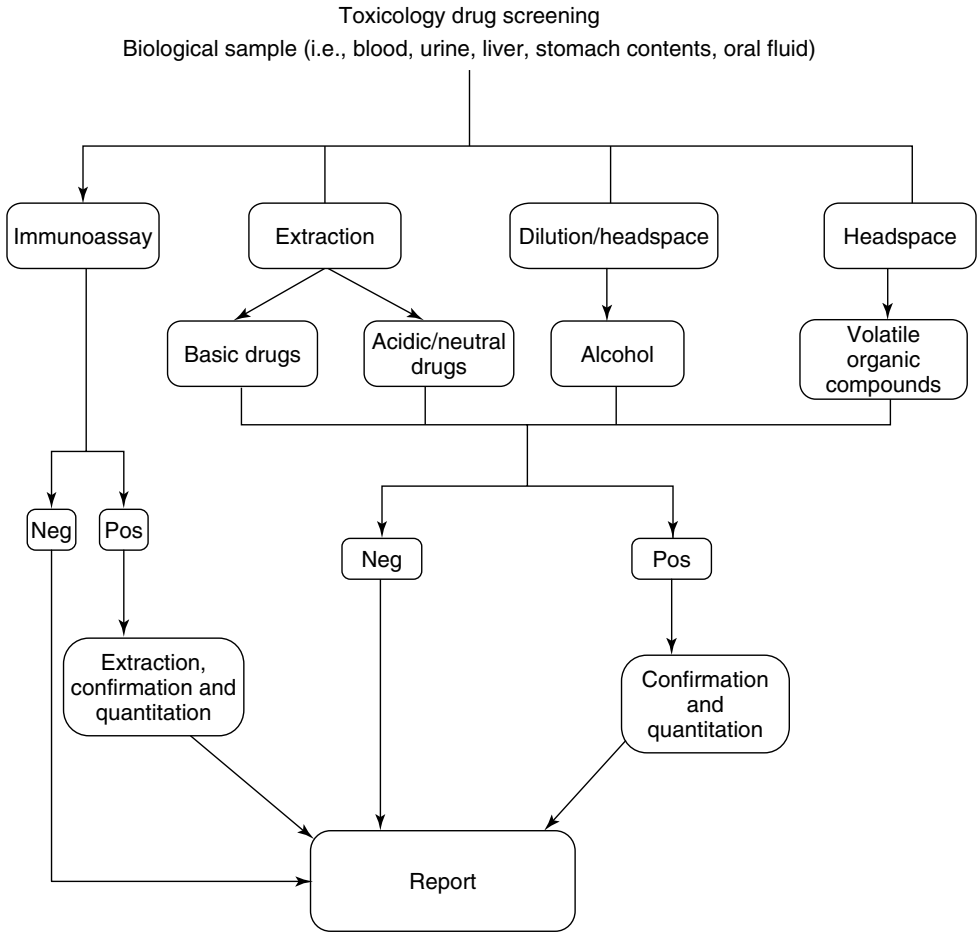

Figure 1 Flowchart showing common screening procedures

(HPLC) procedure (Figure 1). Thin layer chromatography (TLC) may also be used in some laboratories. Nitrogen–phosphorus detectors (NPD) are commonly used in GC screening as the large majority of drugs contain nitrogen, whereas many endogenous compounds (fatty acids, cholesterol, and other lipids) are nonnitrogenous. Electron capture detectors (ECD) have also been used for the screening of halogenated compounds (e.g., many benzodiazepines contain halogens).

Similarly, HPLC systems are often coupled to an ultraviolet (UV) detector or to a photodiode array detector (DAD). With the improvement in technology and the decrease in costs, mass spectrometer (MS) detectors are now increasingly replacing the NPD and ECD in GC systems and UV and DAD in HPLC systems. There are a number of articles in the literature relating to systematic toxicology analysis (STA) [1–4].

Sample Selection

It is important in toxicology that the appropriate sample is selected for screening, as this will have significant relevance for the interpretation of the results. In cases where it is necessary to only show that a subject has used a drug, it would be more suitable to analyze urine or hair as these samples are more likely to show past exposure to a drug. However, if the presence of a drug is necessary to show the involvement of that drug in

some actions of the subject, i.e., cause of death, driving under the influence (DUI), or criminal activity then the best specimens for analysis would be blood or oral fluid. In postmortem cases, it is also preferable to analyze peripheral blood as this is the least likely site to experience any postmortem changes in drug concentrations. Some laboratories may choose to screen blood from the heart, as this will contain higher concentrations of the drug; however, it is important that any further quantitative analysis is carried out on peripheral blood for interpretation purposes. As an example if 11-nor-9-carboxytetrahydrocannabinol (carboxy-THC) was detected in a urine sample from a person suspected of DUI, it could not be used to support the charge of DUI (unless there is other evidence available, e.g., sobriety tests) as this metabolite of tetrahydrocannabinol (THC) can be detected in the urine of frequent users for several weeks after use. It also may be found from exposure to passive smoking. However, determining the concentration of THC in blood can be used to show the recent use of cannabis. A simple guide for sample selection is shown in Table 1.

For selection of specimens in a postmortem environment, (*see* **Toxicology: Analysis**).

Immunoassays

Immunoassay in forensic toxicology is primarily used to screen biological samples for the presence of drugs or drug classes. They offer a rapid and convenient way of screening large numbers of samples from a variety of different matrices (blood, urine, oral fluid, etc.) for a number of drugs and drug classes. A negative immunoassay result avoids the need for more complicated and expensive analytical procedures. They require little or no sample preparation, although some techniques require pretreatment of blood or tissue specimens. Any laboratory can use immunoassay with methods that range from on-site testing for the analysis of a single sample to fully automated systems capable of handling thousands of samples per day.

Immunoassays are based on the interaction of the target compound (antigen) with a corresponding antibody. For drug testing, the immunoassay uses an antibody specific for the nominated drug or drug class and a labeled form of the same drug or of the antibody to produce a measurable signal.

Although immunoassays are extremely useful in screening large numbers of samples, it must be remembered that positive results should always be confirmed by a more specific technique (e.g., gas chromatography–mass spectrometry (GC–MS) or liquid chromatography–mass spectrometry (LC–MS)). Immunoassays will only give an indication of a drug or drug group being present and should only be used for screening purposes and cannot be used as confirmation of the drug or drug group.

The basic immunoassay technique involves the competition of a fixed amount of labeled drug with an aliquot of the sample for the specific binding sites on a fixed quantity of antibody. At equilibrium, the proportion of labeled drug molecules bound is inversely proportional to the number of unlabeled drug molecules (Figure 2).

Immunoassays can be divided into two types.

1. Homogeneous immunoassays

These are assays that do not require the separation of the antibody bound drug from the unbound (free) drug before measurement of the signal. They include assays that rely on optical change (e.g., UV absorption, fluorescence, or luminescence) where there is a difference between the signals from the bound and the unbound labeled drug. Examples of this type of immunoassay are EIA (enzyme immunoassay), CEDIA (cloned enzyme donor immunoassay),

Table 1 Time frame for drugs in different biological specimens

Specimen	Drug(s) present	Time frame	Interpretation
Blood	Parent/metabolites	Hours	Recent use
Oral fluid	Parent drug	Hours	Recent use
Urine	Metabolites	Hours/days	Use
Hair	Parent drug	Months	Use

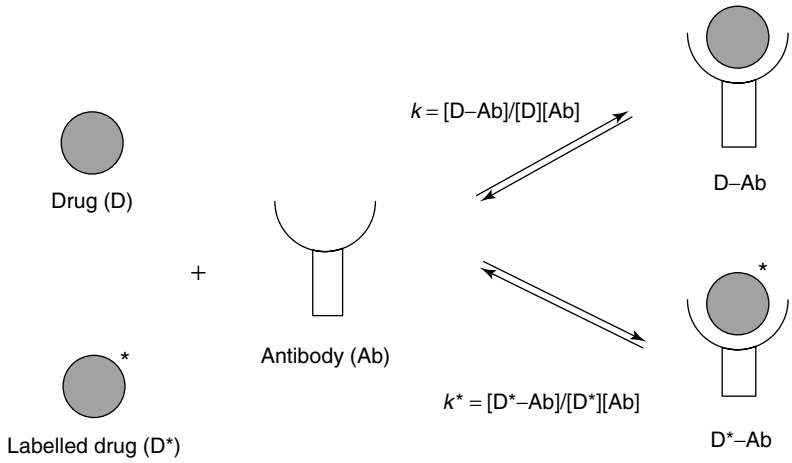

Figure 2 Competitive binding process in immunoassay

FPIA (fluorescence polarization immunoassay), and microparticle methods.

2. Heterogeneous immunoassays

These assays require the separation of the antibody bound drug and the unbound drug before measurement of the signal. This is required as there is no difference in the signals from the antibody-bound and the unbound drugs. Examples of this type of immunoassay are ELISA (enzyme-linked immunosorbent assay), RIA (radioimmunoassay), and chemiluminescence immunoassays.

There are two distinct advantages of the heterogeneous immunoassays over the homogeneous type. First, using a wash step any potential endogenous interfering compounds can be removed, which may be produced by whole blood or highly discolored urine. This also means that there are no preliminary sample extraction steps required. The second advantage is that these assays have lower limits of detection. This is best illustrated by being able to use whole blood in heterogeneous assays, whereas the extraction of the blood sample is often required for homogeneous assays.

Specificity and Cross-reactivity

It is important with any immunoassay technique to determine how the assay responds to other drugs relative to the drug used as a calibrator. The cross-reactivity of the assay is important, as it will determine the suitability of the test. For example, determining the use of *Cannabis* by the analysis of a urine sample requires the immunoassay to have good cross-reactivity with the major urinary metabolite, carboxy-THC. However, by contrast, the assay needs to have good cross-reactivity to THC if the samples to be analyzed are oral fluid or hair, as the relative parent drug concentration is greater than metabolite in these specimens.

There are many immunoassay kits available commercially and specifications as to their sensitivity and specificity should be available for each kit. Table 2 shows cross-reactivity data for an opiate ELISA assay.

Table 2 Typical cross-reactivity of common drugs in an opiate ELISA assay

Analyte	% Cross-reactivity
Morphine	100
Codeine	100
Hydrocodone	93
Morphine-3-glucuronide	90
6-acetylmorphine	88
Dihydrocodeine	85
Diacetylmorphine (heroin)	60
Morphine-6-glucuronide	47
Hydromorphone	6.7
Oxycodone	5.2
Oxymorphone	1.4
Meperidine	<0.1
Imipramine	<0.1

Basic Principles of Immunoassay

All immunoassays use antibodies and the way they are produced determines the performance of the system. Antibodies are immunoglobins (Ig), which are produced by beta-lymphocytes in response to an immunogen. Drug molecules are not large enough to produce an immune response so drug immunogens are made by conjugation of the drug of interest to a large carrier protein (such as bovine sera albumin (BSA)) to form an immunogen, this process is known as *haptenization*. Animals such as rabbits, sheep, or goats are used as hosts for antibody production of polyclonal antisera and mice for the production of monoclonal antibodies. The conjugation is usually via a $-NH_3$ or $-COOH$ group on the drug.

Specificity of the antibodies is determined by the position on the drug molecule at which the protein is conjugated. A good example of this is the morphine molecule.

If the immunogen is produced at the 3-position, the resultant antibody will display cross-reactivity to all metabolites of heroin (diacetylmorphine) and morphine (e.g., morphine-3-glocuronide). It will also cross-react with codeine (3-*O*-methylmorphine). Thus, the antibody produced by the haptenization at the 3-position will produce a broad cross-reacting antibody of all opiates.

If the haptenization occurs at the 6-position then antibodies with greater specificity to morphine relative to codeine and morphine-3-glucuronide would be expected. These antibodies should also display good cross-reactivity with the active metabolite morphine-6-glucuronide and 6-acetylmorphine. Conjugating via the nitrogen following derivitization would produce a more specific assay for morphine (Figure 3).

All antibodies have an affinity constant that is the measure of the strength of the binding between the antigen and the antibody. This binding is reversible, noncovalent, and will reach equilibrium. Antibodies with a higher affinity will bind faster than those with lower and will produce better performance in immunoassays. Polyclonal antisera contain a complex mixture of higher affinity antibodies raised through the immunization process, whereas a monoclonal antibody is a singe entity produced from a single antibody cell with lower affinity.

Enzyme Immunoassay (EIA)

EIAs can be either homogeneous (enzyme multiplied immunoassay technique (EMIT) [5–8]) or heterogenous immunoassays (ELISA [9–12]).

EMIT is a liquid phase assay based on the enzyme activity of a drug-labeled enzyme. The enzyme attached to the labeled drug is glucose-6-phosphate

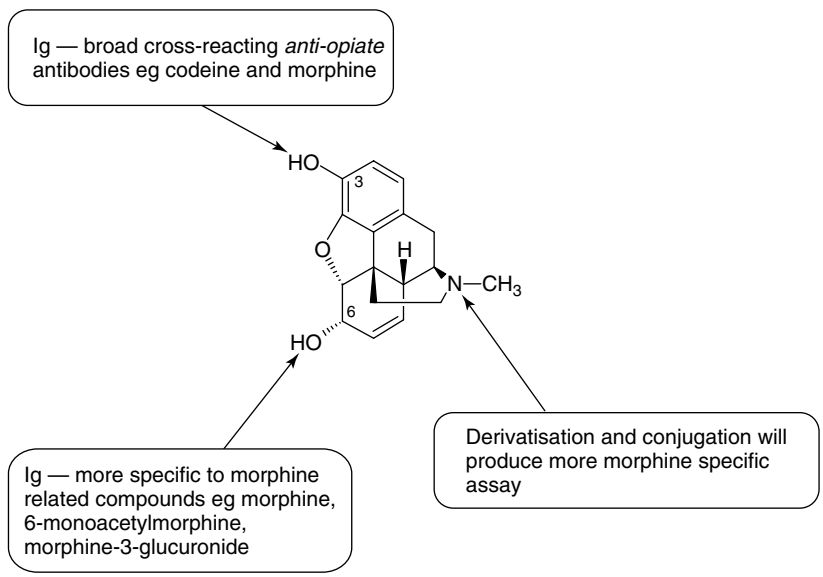

Figure 3 Different antibody binding site on a morphine molecule

dehydrogenase (G6PDH) and antibodies raised against the drug of interest modulate the activity of the enzyme. In the presence of glucose-6-phosphate, the enzyme reduces nicotine adenine dinucleotide (NAD) to NADH and the resulting increase in absorbance is measured spectophotometrically at 340 nm. If the drug of interest is present in the sample, it will compete with the drug-labeled enzyme for binding to the antibody and allow unbound enzyme to become active. This will result in an increase in absorbance at 340 nm. Thus, as the amount of drug in the sample increases then there will be a corresponding increase in enzyme activity and an increase in the rate of NADH production, which will be measured spectrophotometrically by monitoring the λ_{max} at 340 nm.

As EMIT relies upon a color change in the solution, it is not suitable for samples such as blood or highly discolored urine without sample pretreatment. Another limitation of the technique is that, as well as interference for other cross-reacting compounds, any compounds in the matrix that may inhibit the enzyme activity will also affect the result.

ELISA is probably the most commonly used immunoassay in most forensic toxicology laboratories. Commercial ELISA kits are supplied as a dry 96-well microplate with each well precoated with the antidrug antibodies. Table 3 gives a list of common commercial drugs of abuse kits.

ELISA is a heterogeneous, solid phase assay that requires the separation of reagents. There are two techniques available for antigen measurement, competitive immunoassay, and sandwich or double-antibody technique.

The most common ELISA technique is the competitive immunoassay (Figure 4). In antigen competitive assays, the antibody is bound to the well and the sample and labeled antigen are added, the labeled and unlabelled antigen competes for the limited number of antibody binding sites. After an incubation period, an immune complex is formed from the antigen–antibody binding and any unbound antigen is removed by washing. A substrate and chromogen is then added to the immune complex and a reaction between the enzyme and the substrate causes the chromogen to become colored. The more antigen (drug) present in the sample the less color is produced. The reaction is stopped after a preset time by the addition of dilute acid and the color measured at the λ_{max} at 450 nm. ELISA is a more sensitive technique than EMIT and is less subject to matrix effects. It is regularly used to analyze postmortem blood samples.

Radioimmunoassay (RIA)
