Registered office

John Wiley & Sons Ltd, The Atrium, Southern Gate, Chichester, West Sussex, PO19 8SQ, United Kingdom

For details of our global editorial offices, for customer services and for information about how to apply for permission to reuse the copyright material in this book please see our website at www.wiley.com.

Bomb-Pulse Dating, pp. 418–422; Radiocarbon Dating, pp. 2231–2233; Dissociative Disorders, pp. 784–792; Footwear and Foot Impressions: Foot Impressions and Linking Foot to Shoe, pp. 1244–1248; Footwear and Foot Impressions: Overview, pp. 1252–1255; Forged and Counterfeit Documents, pp. 1255–1276, are all US Government works in the public domain and not subject to copyright.

Accreditation: Laboratory, pp. 1–10, is copyright of The American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB) and is used here with their consent.

Juvenile Justice: Adolescent Development, pp. 1608–1612, and Juvenile Justice: Transfer to Adult, pp. 1612–1618, are copyright of the John D. and Catherine T. MacArthur Foundation and are used here with their consent.

Bloodstain Pattern Interpretation, pp. 97–134, is copyright of the author and is used here with his consent.

The right of the authors to be identified as the authors of this work has been asserted in accordance with the Copyright, Designs and Patents Act 1988.

Contents

VOLUME 1

Accreditation: Laboratory 1
Accreditation: Organizational 10
Acid Phosphatase 17
Addictions 18
Adversary Systems of Justice 23
Aggression 24
Aggression: Gender Differences in 36
Airbags 51
Alcohol 58
Alcohol: Analysis 81
Alcohol: Behavioral and Medical Effects 99
Alcohol: Interaction with Other Drugs 108
Alcohol: Use, Abuse, Tolerance, and Dependency 120
Allelic Designation 126
Alterations: Erasures and Obliterations of Documents 128
Amphetamine 134
Amplified Fragment Length Polymorphism 140
Analysis: Computer Network 141
Analysis: Neutron Activation 150
Anthropology 152
Anthropology: Age Determination of Remains 179
Anthropology: Aging the Living 188
Anthropology: Ancestry and Stature Determination 191
Archaeology 199
Arson Investigation: Misconceptions and Mythology 207
Asphyxia 224
Assault: Sexually Motivated 234
Autoerotic Deaths 243
Automated Fingerprint Identification System 249
Automatism as a Defense to Crime 253
Autopsy 256
Autoradiograph 262

Battered Child Syndrome 263
Battered Spouse Syndrome 270
Battered Woman's Reality 272
Bayesian Networks 276
Behavioral Science Evidence 281
Behavioral Toxicology 290
Benzodiazepines 293
Best Evidence Rule 298
Biological Agents 299
Biological Stains 314
Biological Swabs 320
Biometric Devices 321
Blood Grouping 338
Bloodstain Pattern Interpretation 359
Blunt Force Trauma 396
Bomb Scene Management 411
Bomb-Pulse Dating 418
Botany 422

VOLUME 2

Cannabis 431
Capacity Assessment 437
Capacity for Independent Living 444
Capacity to Consent to Medical Treatment 450
Capacity to Stand Trial 456
Capacity to Waive Miranda Rights 463
Cardiac and Natural Causes of Sudden Death 468
Case Assessment and Interpretation 483
Ceiling Principle: DNA 497
Chain of Possession of Tangible Evidence 498

Chemical, Biological, Radiological, and Nuclear Investigations 500
Chemical Warfare Agents 507
Child Sexual Abuse 529
Child Sexual Abuse Accommodation 537
Children: as Defendants 542
Children: as Witnesses 549
Children: Suggestibility of 553
Civil Commitment 556
Civil Law Systems of Justice 561
Cocaine 562
Cofiler/CofilerPlus 569
Compulsion 571
Compulsion Defense 576
Computer Animation and Simulation Evidence 579
Computers 584
Confessions: Evidentiary Reliability of 588
Confirmation Testing: Toxicology 595
Crime Scene Documentation 602
Crime Scene Investigation 614
Crime Scene Management 619
Crime Scene Photography: US Perspective 625
Crime Victims' Decision to Report Crime 643
Criminalization of the Mentally Ill 649
Cross-Examination: Impact on Testimony 656
Cross-Examination of Experts 662

Dangerousness: Risk of 667
Databases 677
Dating: Document 684
Daubert v. Merrell Dow Pharmaceuticals 692
Death: Time of 697
Death Penalty and Age 717
Deception: Detection of 720
Deception: Detection of and Brain Imaging 724
Deception: Truth Serum 728
Delusions 741
Demonstrative Evidence 745
Diatoms 748
Differential Extraction 757
Direct Examination of Experts 758
Disaster Mental Health 760
Disaster Victim Identification 764
Discovery: Depositions 772
Discovery: Discovery Motions 774
Discovery in the United States: Civil Cases 775
Discovery in the United States: Criminal Cases 778
Discovery of Expert Findings 781
Dissociative Disorders 784
DNA 792
DNA: an Overview 800
DNA: Degraded Samples 816
DNA: Sources of 821
DNA Databases and Evidentiary Issues 831
Documents: Authentication of 840
DQα 842
Drug Analysis 844
Drug Profiling 851
Drug Testing: Urine 860
Drug-Facilitated Sexual Assault 868
Drug-Impaired Driving 877
Duty to Warn 885

Earprints: Interpretation of 891
Education and Accreditation in Forensic Science 897
Elder Abuse: Policy 902
Elder Abuse: Risk 912
Elderly in Court 916
Electrical Engineering 920
Entomology 934
Environmental Science 946
Enzymes 954
Error Rates in Forensic Methods 955
Ethics: Codes of Conduct for Expert Witnesses 957
Evidence: Rules of 963
Evidence Collection and Preservation: Casting 963
Evidence Interpretation: a Logical Approach 968
Evil: Illusion of 977
Examination of Fibers and Textiles 985
Expert Opinion: Appeal v. Trial 998
Expert Opinion: United States 1001
Expert Opinion: United Kingdom, Canada, and Australia 1003
Expert Opinion in Court: a Comparison of Approaches 1004

Expert Opinion in Court: Civil Law Jurisdictions (France, Germany, Italy, and Spain) 1007
Expert Witness: Who Is? 1012
Expert Witnesses: Selection and Investigation of Credentials 1013
Explosions: Scene Investigation 1019
Explosion Debris: Laboratory Analysis of 1028
Extraction 1060
Eyewitness: Suggestibility of 1065
Eyewitness Lineups: Identification from 1072
Eyewitness Testimony 1075

VOLUME 3

Facial Comparison 1081
Facial Reconstruction 1086
Falsifiability Theory 1093
Federal Rule of Evidence 702 1095
Fibers 1095
Fire: Chemistry of 1103
Fire: Dynamics and Pattern Production 1112
Fire: Scene Investigation 1122
Fire and Explosion Investigations: Overview 1136
Fire Debris: Laboratory Analysis of 1137
Fire Investigator: Standardization, Accreditation, and Certification 1171
Fire Modeling and Its Application in Fire Investigation 1175
Firearm Discharge Residue: Analysis of 1189
Firearm Examination: Ballistics 1200
Firearms: Bullet and Cartridge Case Identification 1204
Firearms: Identification of Handling of Firearms/Trace Metal Detection 1211
Firearms: Overview 1216
Firearms: Scene Investigation 1219
Firesetting 1225
Footwear and Foot Impressions: Comparison and Identification 1230
Footwear and Foot Impressions: Databases 1240
Footwear and Foot Impressions: Foot Impressions and Linking Foot to Shoe 1244
Footwear and Foot Impressions: Intelligence 1248
Footwear and Foot Impressions: Overview 1252
Forged and Counterfeit Documents 1255
Foundation Testimony 1276
Friction Ridge Examination (Fingerprints): Interpretation of 1277
Friction Ridge Skin: Comparison and Identification 1282
Friction Ridge Skin: Fingerprint Detection and Recovery Techniques 1292
Friction Ridge Skin: Interaction between Fingerprint Detection and DNA/Biological Material 1318
Friction Ridge Skin: Morphogenesis and Overview 1322
Frye v. United States 1331

General Acceptance Test for Novel Expert Evidence 1333
General Electric v. Joiner 1334
Genomics and Behavioral Evidence 1335
Geographical Identification by Viral Genotyping 1342
Glass 1348
Glass Evidence: Bayesian Approach to 1351
GSM Analysis and PDAs 1360
Guardianships of Adults 1371
Gunshot Wounds 1380

Hair: Animal 1403
Hair: Microscopic Analysis 1415
Hair: Toxicology 1427
Hallucinations 1432
Handwriting and Signatures, Comparison of 1436
Handwriting and Signatures, Interpretation of Comparison Results 1451
Hardy-Weinberg Equilibrium 1458
Head Injury: Neuropsychological Assessment 1459
Hearsay Evidence 1465
Histology 1468

Homicide: Multiple (Behavior) 1474
Homosexual Panic 1480
Human Factors: Industrial Incidents 1483
Human Remains and Identity 1495
Hypnosis and Memory 1500
Hypothetical Question 1505

Identification and Individualization 1508
Identification of Human Remains 1511
Identifiler 1518
Image Processing and Analysis 1520
In Limine Motions and Hearings 1528
Injury: Burns, Scalds, and Chemical 1529
Ink Analysis 1541
Ink Comparison and Interpretation 1546
Insanity: Defense 1552
Interpretation: Document Evidence 1557
Interpretation: Legal Perspective 1561
Interpretation: Low Template DNA 1566
Interpretation: Observer Effects 1575
Interpreting Expert Opinions: History of 1579
Interrogation 1586
Interrogative Suggestibility 1590
Intersecting Lines: Documents 1594
Ipse Dixit Testimony 1599

Judicial Notice of Scientific Principles and Facts 1601
Jury Dynamics 1602
Jury Instructions on Expert Testimony 1607
Juvenile Justice: Adolescent Development 1608
Juvenile Justice: Transfer to Adult 1612

Kumho Tire v. Carmichael 1619

Learned Treatises as Evidence 1623
Length Measurement 1624
Light Bulbs and Filaments: Examination of 1632
Low Copy Number DNA 1639
Luminol 1645

VOLUME 4

Malingering: Forensic Evaluations 1657
Malpractice Actions against Experts 1663
Marks or Impressions of Manufactured Items 1668
Mass Grave Investigation 1674
Materials Science 1680
Matrix: DNA 1688
Medical Malpractice 1689
Memory: Reconstructive 1709
Memory: Repressed 1712
Mental Health Courts 1717
Mental Retardation 1724
Mental Retardation: Death Penalty 1730
Mental Status: Examination 1737
Microchemistry 1743
Microsatellites 1749
Microscopy: FTIR 1750
Microscopy: High Power 1758
Microscopy: Light Microscopes 1762
Microscopy: Low Power 1791
Microscopy: Scanning Electron Microscopy 1793
Mini-STRs 1804
Missing Persons and Paternity: DNA 1810
Mitigation Testimony 1818
Mitochondrial DNA: Interpretation 1823
Mitochondrial DNA: Profiling 1833
Mixture Interpretation: DNA 1838

Natural Causes of Sudden Death: Noncardiac 1843
Neuropsychological Assessment 1862
Neuropsychological Assessment: Child 1869
Northwest Juvenile Project 1877
Nuclear Forensics 1883

Odontology 1889
Opioids 1895
Oral Fluid Toxicology 1903

Packaging and Transport 1927
Paint 1931
Paint: Interpretation 1943
Palynology 1954
Paper Analysis 1968
Parental Alienation 1981
Parental Rights and Prerogatives 1984
Parenting: Assessment of Capacity 1989
Particles: Form 2001
Peak Height: DNA 2007

Peer Review as Affecting Opinion Evidence 2009
Pharmacogenomics 2012
Phenotype 2021
Photography: Marks, Impressions, and Documents 2036
Poisons: Detection of Naturally Occurring Poisons 2057
Police Use of Force 2068
Policing and Critical Incident Teams 2071
Polymorphism: Genetic 2075
Postmortem Biochemical Examinations 2076
Postmortem Interval: Anthropology 2089
Postmortem Toxicology: Artifacts 2093
Postmortem Toxicology: Interpretation 2115
Postmortem Toxicology: Laboratory Analysis 2119
Postpartum Psychosis 2136
Posttraumatic Stress Disorder 2141
PowerPlex 2149
Premenstrual Syndrome 2149
Profiles: Psychological and Behavioral 2156
Psychological Autopsy 2161
Psychological Testing 2173
Psychopathology: Terms and Trends 2186
Psychopathy 2193
Psychopathy Checklists 2197
Psychopharmacology 2201
Psychopharmacology: Child and Adolescent 2210

QiaAmp 2219
Quality Systems: Toxicology 2219

VOLUME 5

Radiocarbon Dating 2231
Radiology 2233
Rape Trauma Syndrome 2241
Recollective Accuracy of Traumatic Memories 2243
Reconstruction: Accident 2250
Reconstruction: Three Dimensional 2257
Report Writing for Courts 2268
Risk Assessment 2271
Risk Assessment: Patient and Detainee 2272

Sampling and Estimation of Quantities 2281
Sampling Trace Evidence 2291
Scientific Method Compared to Legal Method 2296
Seizures: Behavioral 2298
Sentencing: Demographic Factors in 2306
Serial Homicide 2311
Serial Number Restoration: Firearm 2324
Sex Determination of Remains 2328
Sex Offenders: Treatment of 2332
Shaken Baby Syndrome 2339
Shooting Distance: Estimation of 2351
Short Tandem Repeats 2354
Short Tandem Repeats: Interpretation 2365
Soil: Forensic Analysis 2377
Speaker Recognition 2389
Species Determination of Osseous Remains 2393
Stalking 2397
Statistical Evidence in Court 2401
Stockholm Syndrome 2409
Substance Abuse 2413
Suicide (Behavior) 2418
Sweat: Toxicology 2420
Syndromes: Psychological 2431

Temporary Insanity 2443
Therapeutic Jurisprudence 2449
Threat Assessment: School 2454
Threat Assessment: Workplace 2460
Time of Death Determinations 2466
Tire Impressions 2480
Toolmarks 2485
Toxicology: Analysis 2495
Toxicology: Forensic Applications of 2503
Toxicology: Initial Testing 2509
Trace Evidence: Transfer, Persistence, and Value 2534
Traffic Fatalities 2541
Training and Certification (in Criminalistics) 2545
Transfer: DNA 2555
Trauma Analysis of Skeletal Remains 2557

Trauma Causation: Analysis of Automotive 2565
Treatment, Mandated: Mental Health 2576
Treatment, Right to: Mental Health 2580
Treatment, Right to Refuse: Mental Health 2584

Ultimate Issue Evidence by Experts 2589
Use of Knowledge-Based Systems in Forensic Science 2590

Variable Number Tandem Repeats 2595
Violence Risk Assessment for Mental Health Professionals 2597
Visitation Rights 2602
Visual Recognition Systems in Identification 2611
Web Resources 2619
Weisgram v. Marley 2627
Whole Genome Amplification 2628
Wildlife 2635
Wood 2640
Wounds: Sharp Injury 2646
Writing Instruments and Printing Devices 2660

Y-Chromosome Short Tandem Repeats 2677

Glossary 2683
Author Index 2701
Subject Index 2707

Foreword

Forensic scientists who are attempting to provide guidance that assists investigators and solves crimes are well aware of the capabilities of the various disciplines in which they toil. Even more importantly, they are also cognizant of what their chosen specialty cannot (yet) accomplish. With a carefully nurtured and expanded knowledge base of the strengths and weaknesses of science, experts are often key to solving perplexing and high-profile cases. Their accomplishments on those occasions draw widespread attention from the media but, even more importantly, these experts also labor quietly on a daily basis to solve the more common cases that represent the bulk of their laboratory efforts and analyses. The consumers of forensic science – be they courts, legislative bodies, or regulatory agencies – rely on the solutions and ideas which these dedicated researchers strive to supply.

In the past few decades, there have been many new discoveries and advances in scientific disciplines, enabling forensic science specialists to apply an ever increasing depth of expertise in carrying out their tasks. Cases are being solved today using techniques that were unheard of twenty, ten, five, or even one year ago. It seems as if every issue of a scientific or technical journal that is published reports new innovations that are progressing from the experimental to the practical. In that environment, the *Wiley Encyclopedia of Forensic Science* is no doubt destined to be recognized as the premiere compendium of knowledge. After all, the entries in its volumes have been compiled by recognized, internationally known, and respected experts in every field.

There is no denying the popularity of television programs such as *CSI*, *Cold Case*, *Forensic Files*, and others. Indeed, there is perhaps no topic of greater interest in today's cyber world than the use of forensics to solve crimes. The small (and not-so-small) screen of the home theater also allows people to view a plethora of movies dealing with scientific ways to demystify complex scenarios. Prominent actors are cast in the white coats of laboratory examiners and interact with other participants in an effort to convince us of their prowess.

Through television, the movies, and an ever growing number of Internet sites, the public receives an abundance of information about how crime laboratory science assists in solving mysteries. The so-called "CSI effect" influences jurors, and even some judges, who have come to expect real life to mirror what they see on television, the movies, or what they read in other media. Unfortunately, not all of the information purveyed via these mediums comports with reality. Expectations are inflated beyond the possible. Even the most accomplished expert cannot solve cases in one hour or less as their television counterparts suggest *they* can!

Expectations in the legal profession, the courts, those who serve on juries, and the public at large demand that those who deal with the judicial system be familiar and are knowledgeable about what is possible and what is perhaps coming in the future. Experts, and anyone else who seeks knowledge about forensics, must not only be familiar with the well-established foundations of scientific proof, but must also stay reliably informed about new developments in the various forensic science disciplines. Here again, the *Wiley Encyclopedia of Forensic Science* serves as a complete, accurate, realistic, and up-to-date resource that will sate the knowledge thirst of experts as well as that of consumers of forensic science.

The framework for this five-volume Wiley encyclopedia was designed and compiled by its two Editors-in-Chief, Allan Jamieson of the United Kingdom and Andre Moenssens of the United States, both pre-eminent authorities in forensic science and its practical and legal applications. They are intimately familiar with the formidable strengths of forensic evidence as well as its perhaps less-known weaknesses. In their daunting task to seek a balance reporting on topics from A to Z, all of which straddle different levels of achievement, the Editors-in-Chief were ably assisted by a selection of knowledgeable subject-specialist topic editors and hundreds of contributors from all over the world. The cooperation and efforts of these many leaders in the scientific enterprise ensures that information dispensed in each discipline is reliable, relevant to real-life problems, and useful to a broad audience.

There are over 370 articles written by more than 330 contributors. These articles reference the myriad subjects of forensic science and embrace the physical, biological, behavioral, as well as comparative sciences. Laboratory management and case investigative techniques, laboratory support mechanisms, quality control programs, and discussions on the modern trends in interpreting the confidence level accorded test results by reference to statistical likelihood ratios are also dealt with.

Concerns about the desired exactness of science, and the inexactness of the law, also required that precedent-setting court decisions and discussions of legal principles that impact on a forensic expert's performance be explained and analyzed in these volumes. Issues of examiner education, training, and accreditation in various disciplines, as well as the ethical requirements governing scientists' professional behavior and the problem of expert witness malpractice have not been neglected.

For the layperson, the Encyclopedia provides authoritative answers to most questions about specific forensic problems. For the practitioners in specific fields, it reminds them of the basic fundamentals in their own discipline while it also informs them of the totality of knowledge in other fields so as to better understand the system as a whole and its interrelated complexities. References to published data and source materials appended to most articles allow interested persons to study areas of special concern in greater depth. Truly a collection of useful information on most of what is known as "forensic science", the Encyclopedia provides ready answers for everyone who is either involved or simply interested in forensic science.

In assessing how well John Wiley & Sons and all those associated with the production and publication of these volumes have achieved their objectives, there is no doubt the verdict and judgment will be favorable.

The Honorable Haskell M. Pitluck
Past President, American Academy of Forensic Science
Retired Circuit Judge, State of Illinois
April 2009

Preface

Forensic science is a broad label. It covers the entire complement of human industry and experience at the point where they interface with legal and legislative processes. This interaction may involve civil as well as criminal concerns and often takes the form of expert testimony offered to answer questions posed by a variety of human institutions. In the exercise of that function, the opinions of experts may vary widely in probative value, weight, and persuasiveness. But forensic science also serves therapeutic and human aspects apart from problem solving, and is often a crucial component in the formulation of policy and the passage of regulatory endeavors destined to insure the health and safety of populations.

The advent of DNA profiling has heralded a revolution in forensic science that goes well beyond forensic biology. The techniques and principles used in evaluating forensic scientific evidence are being closely examined at this moment in the light of the work in DNA as an individualization process – considered somewhat as a Holy Grail for forensic science. The ability to develop population databases, based on the easy numerical nature of DNA profiles, enabled the introduction of other approaches to the evaluation of evidence. The scientific rigor of some aspects of this process has posed difficult-to-answer questions for those forensic disciplines that emerged primarily from experience-based endeavors but which, through use, had become accepted in criminal justice systems. The debate as to the response within many of these specialties is ongoing.

This state of events has brought us to an era of unprecedented development and debate, as well as a measure of uncertainty, in some forensic science functions. Several disciplines are now broadly divided into "old school" and "new school" practitioners. It is not easy to predict which school will emerge as the dominant thinking in these disciplines, but it is almost certain that the future will see more scientifically robust techniques of evidence evaluation gaining widespread acceptance.

Many of the entries in this work may represent the seeds of that future. The existence of these competing schools inevitably creates differences of opinion regarding the science. The constant and varied evolution of science means that the state of the art in one discipline (in instrumentation, analytical accuracy, or evaluation) may be very different from the state of the art in another.

Although science may be regarded as international, law is not. Jurisdictional differences also inevitably create differences in the practice of forensic science. We have encouraged authors to be candid, but to represent those differences in their writing, and occasionally different authors will discuss the same or similar topics while offering a slightly different approach. We regard this as healthy and a natural part of the scientific discourse. As such, the debate is encouraged. However, the consequence is that the views expressed within articles are not necessarily the definitive or final word on any topic, nor do they necessarily represent the view of any other author or of the Editors-in-Chief.

In bringing together such a large and varied selection of experts in one major work, we were cognizant that imposing a "house style" would be close to impossible. Our limit seemed to be the adoption of American-English spelling and a single reference style. Inevitably, our

workload and a variety of deeply ingrained localized or national approaches will have allowed some departures from the standard to slip through the editorial net. We hope that this does not detract from the content. We did not enforce any particular writing style and the varied entries reflect that.

One thing that all of our authors had to be aware of was that this is a very unusual major technical reference work in that we aimed to inform an audience that includes people who are not forensic science professionals and who may simply be interested in selected topics discussed in these volumes, such as writers, reporters, educators, but who may have only a sketchy knowledge of the core principles or language of science. The work also purports to inform the legal profession, the judiciary, and paralegals. With these different audiences in mind, we have attempted to maintain sufficient depth to provide a valuable reference source for practitioners and academics as well. Only use will establish the degree to which we have been successful in achieving those disparate aims.

The complexity of providing information to a wide potential readership, composed of such a variety of interested parties, placed important choices on the editors in terms of its coverage. No one source can serve all of humanity, and thus the editors sometimes had to make painful judgments on what to include and what to pass over. Sometimes the choices on what to include were dictated in part by the availability of experts willing to share their professional experience with our readers. At other times, choices related simply to the fact that the dividing line between science and pseudoscience required a decision as to whether conclusions reached in a particular field provided sufficient guarantees of trustworthiness and reliability. This in no way can be taken to mean that the lack of appearance here invalidates any particular discipline, nor for that matter that inclusion validates it! Whatever the choice, the editors acted in their best judgment and will remain vigilant so as to select, for later inclusions, those emerging fields currently perhaps on the fringes of forensic science that increase their underlying knowledge-based data and gain a modicum of acceptance in the broader forensic science profession.

No work of this nature is perfect. This will not prevent us from striving to improve it online and in subsequent editions. We welcome feedback on any aspect of this work, including topics that, almost certainly, we have missed in our attempts to be all-inclusive.

We are only part of a very large and skilled team including our Editorial Board and the team at Wiley. Our heartfelt thanks go to all of them and in advance to you, the reader, for your feedback which will assist us to provide better resources for your future work.

Allan Jamieson and Andre Moenssens

The International System of Units (SI)

There are many different units of measure for most physical parameters such as length, mass, and temperature. The scientific community have agreed on a single system called the SI (Systeme Internationale) as the accepted international system of such units. SI units are either base or derived. Base units are fundamental and not reducible. Table 1 lists the main base units of interest in the discipline of materials science and engineering.

Derived units are expressed in terms of the base units, using mathematical signs for multiplication and division. For example, the SI units for density are kilogram per cubic meter (kg/m^3). For some derived units, special names and symbols exist; for example, N is used to denote the Newton, the unit of force, which is equivalent to 1 kg-m/s^2. Although many use the '/' notation (e.g. m/s) the system uses a superscript or exponent (to the power of) notation where a negative symbol replaces the '/'. For example, m/s becomes ms^{-1}, and m/s^2 becomes ms^{-2}. Table 2 contains a number of important derived units.

It is sometimes necessary, or convenient, to form names and symbols that are decimal multiples of SI units. Only one prefix is used when a multiple of an SI unit is formed, which should be in the numerator. These prefixes and their approved symbols are given in Table 3. Symbols for the main units are used in this book, SI or otherwise. Some disciplines retain other nomenclatures by practice or convention, although these are departures from the main scientific recommendations.

Table 1 The SI base units

Quantity	SI unit	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Amount of substance	mole	mol

Table 2 Some of the SI derived units (including examples of the superscript notation)

Quantity	Name	Formula	Special symbol
Area	square meter	m^2	–
Volume	cubic meter	m^3	–
Velocity	meter per second	m/s (ms^{-1})	–
Density	kilogram per cubic meter	kg/m^3	–
Concentration	moles per cubic meter	mol/m^3	–
Force	newton	$kg{\cdot}m/s^2$ ($kg{\cdot}ms^{-2}$)	N
Energy	joule	$kg{\cdot}m^2/s^2$, Nm	J
Pressure/Stress	pascal	kg/ms^2, N/m^2	Pa
Strain	–	m/m	–
Power, radiant flux	watt	$kg{\cdot}m^2/s^3$, J/s	W
Viscosity	pascal-second	kg/ms	Pa-s
Frequency (a periodic phenomenon)	hertz	1/s (s^{-1})	Hz
Electric charge	coulomb	A·s	C
Electric potential	volt	$kg{\cdot}m^2/s^2C$	V
Capacitance	farad	$s^2C/kg{\cdot}m^2$	F
Electric resistance	ohm	$kg{\cdot}m^2/sC^2$	Ω
Magnetic flux	weber	$kg{\cdot}m^2/sC$	Wb
Magnetic flux density	tesla	kg/sC, Wb/m^2	(T)

Table 3 SI multiple and submultiple prefixes

Factors by which multiplied	Prefix	Symbol
10^{12}	tera	T
10^9	giga	G
10^6	mega	M
10^3	kilo	k
10^{-2}	centi[(a)]	c
10^{-3}	milli	m
10^{-6}	micro	μ
10^{-9}	nano	n
10^{-12}	pico	p

[(a)] Avoided when possible.

Guide to Legal Citations

What is the Correct Form?

There are many systems for citing sources

When a publication such as this Encyclopedia is to accommodate technical contributions from authorities across the world, there is benefit in uniformity in the form that source references are printed. Thus, for scientific publications, we decided that the Vancouver style would be adopted. For the most part, that format is followed throughout these volumes.

It was more difficult to decide on the format for legal authorities and sources, because there is no single system of citing court cases, statutes, and other law publications. What exists is a conglomeration of conventions that are not always followed by various courts even within the same country. Local custom of reporting legal sources often supersedes what was prescribed as the "official" system in a jurisdiction.

Of course, that is only of limited help. In the United Kingdom, for instance, with no less than a dozen different courts that, at one time or another, publish or have published case reports (e.g., Appeal Cases (second and third series), Chancery Division, Criminal Appeal Reports, Queen's Bench, House of Lords, and other specialty courts), whatever convention exists is not always enlightening when one is confronted with a citation of a court. It is not easy for individuals who are not solicitors, barristers, or trained in law to locate where a particular case report may be found.

The confusion is even greater in the United States where there are 50 different states, each printing their case reports in official and/or unofficial reporter systems. In addition, the federal court system publishes cases decided by the United States Supreme Court (in three different reporter systems), by eleven Circuit Courts of Appeal and the District of Columbia (in two different publication forms), and by numerous United States District Court opinions. Then there is also a multitude of reports for specialized courts or federal agencies.

To seek to impart uniformity in citation form, editors from the Universities of Harvard, Columbia, Yale, and Pennsylvania Law Reviews have devised what is known as *The Bluebook – A Uniform System of Citation*. It is referred to as the *Bluebook*. The latest edition of the tome is the Eighteenth Edition, published in 2007. It comprises 415 pages. Unfortunately, the *Bluebook* has not imparted uniformity in citation form.

First, each of the *Bluebook's* editions advocated using conventions that were later partially modified in successive editions. Furthermore, the *Bluebook* is used essentially by law review journals published by law schools, but courts and other legal writers as well as publishers pay only scant attention to it and report cases in varying ways that they deem rational.

Clearly, then, some leeway must be accorded to authors in these volumes in the way they report case law, statutes, and other legal collections, since there is no one accepted way that might be said to be generally accepted as the "correct" format. In the face of these considerations we decided, as a matter of convenience, that legal sources would be cited in the form that was customary in the jurisdiction where the source originated.

It is more important, then, to understand the purpose that references serve. The purpose of a citation is so that the complete opinion of the court or other legal authority can be readily retrieved. Sadly, the convention whereby decisions of courts are cited makes sense only to legally trained individuals or to persons who work within a relatively closed environment.

Basic requirement of an informative citation form

An adequate citation of a reported opinion of a court is supposed to contain the following: (i) the name (or "style") of the case, (ii) the reporter system wherein the opinion has been published, (iii) the court that decided the case, and (iv) the year of decision. This is the preferred order in which court cases are cited in the United States and in many other countries, though the four elements of an informative citation are not always listed in the same order.

In the United Kingdom, for instance, the preferred form is to start with (i) the case name, (ii) the year of decision in parentheses, and thereafter (iii) the volume number (if available), (iv) the reporting system, (v) the page, (vi) the deciding court if that information is not otherwise clearly indicated by the reporting system, and (vii) the jurisdiction where the case was decided, if that information is not evident from the context or the citation. It is also preferred that cases be cited from official Law Reports rather than from ancillary sources. The Official Reports consist of the Appeal Courts (A.C.), Queen's Bench (Q.B.), Chancery (Ch.), Family (Fam.), and Probate (P) Reports. When citing decisions of the House of Lords, the Privy Council, or other sources that may report appeals from more than one jurisdiction, the jurisdiction from which the appeal was taken should be indicated parenthetically.

Most forensic scientists may be familiar with the way court opinions are published in their own country, but may not understand where and how foreign legal sources may be found. If, for research purposes, it becomes necessary for them to retrieve a complete court opinion or a statute for which the researcher possesses a citation, help in locating the full text referenced may be obtained from law-trained individuals. Major court systems also maintain libraries staffed by knowledgeable librarians. Legal libraries staffed with helpful librarians are further maintained in most law colleges and by many large legal firms.

Because a single uniform system for referencing legal authorities is lacking, some variations may be noted in the citation form used by authors of contributions. With the guidance offered here, the individual who is not legally trained will hopefully be able to decipher the meaning of legal references encountered throughout this Encyclopedia.

Accreditation: Laboratory

Crime laboratory accreditation has been one of the most powerful forces in improving the efficacy of forensic science services in the twenty-first century. Effective quality assurance programs are the linchpins for good forensic science, reliable techniques to apply the science, and trustworthy expert opinion testimony [1]. Encouraged by judicial opinions [2], mandated by four state legislatures [3], and implemented by crime laboratory directors [4], accreditation programs have brought needed regulation to a critical segment of our criminal justice system.

Introduction

The quality of scientific analyses conducted in crime laboratories varied widely throughout the United States before a program for crime laboratory accreditation was available. There were no generally accepted, published standards and no governmental regulations governing quality assurance in American crime laboratories [5]. A national proficiency testing research project during the mid-1970s [6], conducted by the Forensic Sciences Foundation (FSF) and funded with a grant from the National Institute of Law Enforcement and Criminal Justice Law Enforcement Assistance Administration (LEAA), brought public attention to proficiency problems and other inadequacies in some of America's crime laboratories [7]. An analysis of the results of the LEAA-funded project revealed "that some crime laboratories were experiencing serious problems in the examination and interpretation of several types of test specimens" [8] (*see* **Error Rates in Forensic Methods**; **Interpretation: Observer Effects**).

Some of the concerns cited by critics and commentators about unregulated crime laboratories included the following: (i) lack of written protocols for testing; (ii) lack of proficiency testing; (iii) level of education

and competency of examiners; (iv) uninformative nature, and in some cases the nonexistence, of laboratory reports and case files; (v) lack of review of examination results; (vi) experts testifying beyond the scope of their expertise or the science; (vii) questions about the integrity of evidence in the laboratories; (viii) questionable validity and reliability of scientific theories and methodologies used in the laboratories; and (ix) lack of oversight to remediate problems identified in laboratories [9, 10].

Crime laboratory directors and professional organizations [11], as well as legal commentators [12–14], recognized the need for the regulation of crime laboratories and the implementation of universally recognized quality assurance programs [15]. Crime laboratory accreditation programs help implement and oversee quality assurance programs that resolve the types of deficiencies mentioned above and improve the quality of the laboratory and the science performed in the laboratory [16].

That is not to say, however, that the absence of accreditation means a particular crime laboratory does not perform quality work. There are many unaccredited laboratories that have rigorous quality assurance programs ensuring valid and reliable scientific results [17]. Nor does accreditation guarantee that every examiner from an accredited laboratory will always perform up to appropriate standards. Accreditation is a safeguard that helps ensure that the laboratory provides accurate and valid results [18].

Since the LEAA-funded proficiency testing project, several forensic science laboratory accreditation programs have been developed. The American Board of Forensic Toxicology (ABFT) accredits toxicology laboratories, having 24 laboratories accredited under its program [19]. The National Association of Medical Examiners (NAME) established a voluntary accreditation program and has accredited 54 medicolegal death investigative offices [20]. Forensic Quality Services-International (FQS-I) provides accreditation to forensic science testing laboratories in the United States and has accredited 53 crime laboratories and other forensic science laboratories since 2001. It also provides accreditation to Identification Sections and Crime Scene Units within police departments [21]. The National Forensic Science Technology Center (NFSTC) conducts external DNA audits of publicly funded laboratories desiring to receive federal funding and entry into the National DNA Identification System (NDIS). The NFSTC is funded by a Cooperative Agreement with the National Institute of Justice, Office of Science and Technology [22] (*see* **Databases**).

By far the oldest, most prolific accreditation program, and the most widely recognized by courts, legislatures and the crime laboratory community, is the American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB®) [23]. ASCLD/LAB came into existence through the work of the "Committee on Evaluation and Standards," which was one of the first committees appointed by the ASCLD. The committee was appointed largely because of deficiencies in crime laboratories, which were revealed by the LEAA proficiency testing program. The committee was charged to develop a program which sets standards of operation and a process for evaluation of crime laboratories. ASCLD/LAB received its first accreditation applications in early 1982 and accredited seven Illinois State Police laboratories.

By the fall of 1984, ASCLD/LAB had accredited 30 crime laboratories and had achieved a predetermined minimum size to become an independent not-for-profit organization, which was then incorporated in the state of Missouri. Since its inception, ASCLD/LAB has accredited more than 342 public and private crime laboratories at every governmental level, including international laboratories and the major federal law enforcement and military crime laboratories in the United States [24]. As of September 2008, the 342 laboratories holding current ASCLD/LAB accreditation included 178 state laboratories representing 48 states, 109 local government laboratories, 22 federal laboratories, 22 private laboratories, and 11 international (non-United States) laboratories. ASCLD/LAB maintains two programs, ASCLD/LAB-Legacy® and ASCLD/LAB-*International*®. The former is the original program under which accreditation is based upon requirements created, adopted and maintained by the ASCLD/LAB Delegate Assembly. The Legacy program is being phased out. The International program, implemented in April 2004, is based on the requirements of the International Organization for Standardization (ISO) and supplemental requirements such as the ASCLD/LAB-Legacy program requirements. In 2007, a separate accreditation program was implemented under the ASCLD/LAB-*International* program for breath alcohol calibration laboratories. As of September 2008, 69 testing laboratories and one

breath alcohol calibration laboratory were accredited under the International program and the remainder under the Legacy program.

With more than three-quarters of the publicly funded crime laboratories in the United States accredited by ASCLD/LAB [25], it is significant to the integrity of the criminal justice system that ASCLD/LAB's accreditation program provides professional regulation and review of a laboratory's quality assurance program. Accreditation is a part of a laboratory's quality assurance program which, under ASCLD/LAB's program, also includes proficiency testing, continuing education, and other programs to help the laboratory achieve excellence and give better overall service to the criminal justice system (*see* **Fire Investigator: Standardization, Accreditation, and Certification**; **Accreditation: Organizational**; **Quality Systems: Toxicology**). A quality assurance program which meets the ASCLD/LAB standards addresses the criticisms leveled at unregulated laboratories.

While the ASCLD/LAB accreditation program is voluntary, some states have mandated accreditation and have chosen ASCLD/LAB as their accrediting authority for multidisciplinary crime laboratories. New York established a Commission on Forensic Science which developed minimum standards and a mandatory program of accreditation for all forensic laboratories within the state [26]. All of the state's multidisciplinary crime laboratories are now accredited by ASCLD/LAB, while some of the toxicology laboratories are accredited by the ABFT. Likewise, Oklahoma requires that all crime laboratories within the state be accredited by ASCLD/LAB and its toxicology laboratories by ABFT [27]. Legislation passed in the state of Texas in 2003 requires the Texas Department of Public Safety (DPS) to establish a program of accreditation for "forensic examinations" [28]. Missouri requires that after December 31, 2012, any crime laboratory providing reports or testimony to a state court pertaining to a result of the forensic analysis of evidence shall be accredited or provisionally accredited by a laboratory accrediting organization approved by the DPS [29].

The ASCLD/LAB-International Accreditation Program

As discussed earlier, the ASCLD/LAB-Legacy program is being phased out of existence, and the ASCLD/LAB-*International* program is replacing it, using the ISO framework. This transition reflects the future of accreditation programs in the United States by which laboratories and accrediting bodies will be embracing internationally accepted accreditation standards.

The ISO has published at least two sets of standards having direct application to the accreditation of laboratories of all types [30]. The first, *ISO/IEC 17025: General Requirements for the Competence of Testing and Calibration Laboratories* [31] is not specific to crime laboratories, but the standards are, as the name implies, applicable to any organization performing tests and/or calibrations. The second ISO standard of interest [32], *ISO/IEC 17011:2004 Conformity assessment – General requirements for accreditation bodies accrediting conformity assessment bodies* [33], establishes a system of internationally recognized standards for the accreditation of laboratories [34].

Only in this century has the American forensic science community looked seriously at adopting ISO/IEC 17025 as the foundation of crime laboratory accreditation programs. NFSTC started conducting ISO/IEC 17025 compliant accreditation inspections of forensic laboratories in 2001 [35]. ASCLD/LAB-*International* was promulgated in December 2003 by the Delegate Assembly, and ISO/IEC 17025 compliant accreditation inspections began in the summer of 2004.

Engaging in ISO/IEC 17025 compliant inspections is but one requirement of ISO/IEC 17011 requirements. Compliance with all elements of ISO/IEC 17011 brings an added dimension of quality to crime laboratory accreditation efforts in America. The ultimate purpose of ISO/IEC 17011 is to establish standards for the recognition of competent accrediting bodies. An ISO/IEC 17025 accrediting body may voluntarily comply with the provisions of ISO/IEC 17011 and self-declare compliance, or apply for formal recognition to a body operating a recognition program for accrediting bodies, which in the Americas is the Inter-American Accreditation Cooperation (IAAC) [36]. Regional cooperations like the IAAC exist in most developed regions of the world for the primary purpose of offering recognition to accreditation bodies and facilitating the cooperation of such bodies in those regions.

In September 2008, ASCLD/LAB was granted formal recognition by the IAAC for meeting all

the applicable ISO and IAAC standards for the operation of a competent accrediting body. After a thorough evaluation by an IAAC international team of evaluators, ASCLD/LAB, and specifically the ASCLD/LAB-*International* accreditation program for testing laboratories, became the first forensic science accreditation body in the United States to gain international recognition for meeting all applicable ISO and IAAC standards for the operation of a competent accrediting body.

ISO standards and concepts in the accreditation of crime laboratories address criticism that previous crime laboratory accreditation programs were designed, adopted, implemented, and overseen solely by the users of each program. Embracing internationally adopted ISO/IEC 17025 standards and opening the accreditation programs to third-party ISO/IEC 17011 scrutiny was the next logical step in the evolution of crime laboratory accreditation in the United States.

Perhaps, the greatest strength in ISO compliant programs of accreditation is the increased physical presence in the accredited laboratories. FQS-I operates their program of ISO accreditation on a 2- to 5-year cycle. Depending on the period of accreditation granted, FQS-I will either conduct a full on-site inspection of the laboratory every second year or conduct periodic surveillance visits if the cycle of accreditation is longer than 2 years. The ASCLD/LAB-*International* program operates on a 5-year cycle of accreditation, but conducts annual on-site surveillance visits in each laboratory. Surveillance visits are abbreviated versions of full assessments.

However, there are weaknesses associated with ISO/IEC 17025. The most critical area where the international requirements for accreditation fall woefully short of American programs like ASCLD/LAB-Legacy is proficiency testing requirements. Undoubtedly as a direct result of the LEAA study in the mid-1970s, proficiency testing has become entrenched as a major part of the compliance monitoring phase of crime laboratory accreditation programs in the United States. Even many nonaccredited laboratories participate in internal and external proficiency tests each year. Interestingly, ISO/IEC 17025 is virtually silent on the subject of proficiency testing. To fill this critical gap, ASCLD/LAB-*International* includes supplemental requirements – like proficiency testing and specific educational requirements for laboratory analysts (*see* **Expert Witnesses: Selection and Investigation of Credentials**).

Embracing ISO standards and concepts should not be viewed, however, as a panacea for curing all the current quality issues in America's crime laboratories. Implementing ISO compliant accreditation programs is but another step in the ongoing process of assuring quality in the forensic sciences and integrity in the criminal justice system.

To that end, ASCLD/LAB-*International* has four objectives which define the purposes and nature of the program. The objectives are

- to improve the quality of laboratory services;
- to develop and maintain criteria that may be used by a laboratory to assess its level of performance and to strengthen its operation;
- to provide an independent, impartial, and objective system by which laboratories can benefit from a total operational review; and
- to offer to the general public and to users of laboratory services a means of identifying those laboratories, which have demonstrated that they meet established standards.

The forensic disciplines for which ASCLD/LAB-*International* affords accreditation include controlled substances, toxicology, trace evidence, biology (including DNA), firearms/toolmarks, questioned documents, latent prints, crime scene, and digital & multimedia evidence. ASCLD/LAB-*International* also offers accreditation to laboratories certifying the calibration of breath alcohol measurement devices. In the area of DNA, the Federal Bureau of Investigation (FBI's) Quality Assurance Standards for Forensic DNA Testing Laboratories and Convicted Offender DNA Databasing Laboratories are applied during the inspection [37] (*see* **Databases**). These quality assurance standards and programs were established pursuant to the DNA Identification Act of 1994 [38]. To receive federal funding for DNA analysis, laboratories must meet these standards. The FBI and ASCLD/LAB have agreed to cooperate in the implementation of these standards in laboratories inspected by ASCLD/LAB.

When a laboratory applies for accreditation, ASCLD/LAB requires an assessment of all the recognized disciplines in the laboratory, with the exception of the crime scene discipline. The applicant laboratory director has the option of including crime

scene and/or breath alcohol measurement device calibration in the accreditation process. Other than exempting those two disciplines, ASCLD/LAB will not do a partial accreditation of any laboratory.

The International program has adopted many accreditation requirements from the well-established standards provided by the Legacy program to supplement ISO/IEC 17025, making the program more relevant and applicable to forensic science testing laboratories. The written format of the supplemental requirements corresponds to the ISO format and contains the basic principles of quality assurance as well as notes to provide clarification or examples. The supplemental requirements are found in the *ASCLD/LAB-International Supplemental Requirements for the Accreditation of Forensic Science Testing Laboratories* and the *ASCLD/LAB-International Supplemental Requirements for the Accreditation of Forensic Science Testing Calibration Laboratories.*

The ASCLD/LAB-International Accreditation Process

As a part of the accreditation process, an assessment team, composed of a Lead Assessor and Technical Assessors, visits the laboratory or laboratory system and assesses the laboratory against all the applicable accreditation criteria in ISO/IEC 17025 and the Supplemental Requirements document. Assessments are conducted primarily by volunteer assessors from accredited laboratories who have successfully completed the ASCLD/LAB assessor training program and who are trained in the assessment criteria [39]. As a result of the growth in the program, there is now a paid staff employed by ASCLD/LAB, who act as lead assessors, program directors, quality manager, training manager, executive director, and support staff [40].

The assessment team determines whether the laboratory has met each of the accreditation requirements. If it has not, the laboratory receives a "no" as to every nonconforming criterion. "nonconformities" are classified as Level 1 or Level 2. The more serious nonconformity is Level 1, the nature of which directly affects and has a fundamental impact on the work product of the laboratory or the integrity of the evidence. All the other nonconformities are Level 2.

Prior to the completion of the on-site assessment, a Summary Assessment Report is prepared by the Lead Assessor and reviewed by an ASCLD/LAB Quality Review Panel to ensure consistency in the application of accreditation requirements and in grading the laboratory. The report is then given to the laboratory director at the summation conference that concludes the assessment visit. In addition, the laboratory director is given a Corrective Action Request for each criterion in which the laboratory was found to be nonconforming. Level 1 nonconformities must be corrected within 180 days and no laboratory will be accredited with an outstanding Level 1 nonconformity. Before the next annual on-site surveillance visit, all Level 2 nonconformities must be corrected or they will be treated as a Level 1 nonconformity.

After the summation conference, the Lead Assessor prepares a full assessment report that is again subject to a quality review, which is then given to the laboratory. This is a more formal report that includes all the nonconformities reported during the summation conference.

When the Lead Assessor determines that all Level 1 corrective actions have been completed, he or she will prepare a final assessment report to the Board of Directors [41]. The Board then grants or denies accreditation, or may require completion of additional corrective actions [42, 43]. When a laboratory system applies for accreditation, each laboratory within the system will be judged and accredited independently of each other.

Accreditation is granted for a period of 5 years, during which the laboratory is expected to remain compliant with the accreditation standards. During the accreditation cycle, compliance with accreditation criteria is monitored on an annual basis by three methods. The first method requires the submission of an Annual Accreditation Audit Report to ASCLD/LAB by each laboratory. If discrepancies with accreditation criteria are revealed, the laboratory is expected to remediate them under the supervision of ASCLD/LAB. If failures appear during the year, the standards require the laboratory to have a procedure in place that must be followed to correct the problems. If there are significant changes in the laboratory during the year, they must also be reported so that ASCLD/LAB can determine whether a special interim assessment is required to assure compliance with the standards.

The second method of determining compliance is on-site surveillance visits conducted annually in each accredited laboratory. These miniassessments

allow for first-hand, personal observations of the laboratory's quality assurance program. Core accreditation requirements are assessed, as well as a number of additional requirements selected for the on-site assessment. The annual surveillance visits are conducted much like the full assessment, with a summation conference, and a full and then final surveillance report, with intervening quality reviews.

Proficiency testing is the third means of monitoring compliance. ASCLD/LAB has adopted a Proficiency Review Program that outlines the review process for external proficiency test results from approved test providers [44]. For each forensic discipline accredited by ASCLD/LAB, there is a Proficiency Review Committee. These committees review external proficiency test results provided by approved test providers in accordance with the ASCLD/LAB Proficiency Review Program. If a discrepancy is indicated in the report, the committee requests a response from the laboratory as to its investigation of the cause of the discrepancy and the corrective measures that have been taken to correct it. There are three classes of discrepancies. Class I discrepancies are the most serious, the nature and cause of which raise immediate concern regarding the quality of the laboratory's work product. The Board of Directors has the authority to impose sanctions for discrepancies and the failure to correct them, including probation, suspension, or revocation of the accreditation status.

If a failure to comply with the accreditation standards is reported from within the laboratory, from outside the laboratory, or discovered by a special interim assessment or surveillance visit, an investigation will ensue in appropriate cases. The same sanctions described above may be imposed by the Board of Directors on a laboratory that fails to remain compliant. The Board has the authority to send an assessment team into the laboratory at any time to determine compliance with accreditation criteria. In these ways, ASCLD/LAB provides oversight in the remediation of problems in accredited laboratories.

For nonaccredited laboratories that experience quality-related problems, ASCLD/LAB has developed an assistance program. At the invitation of the laboratory or the laboratory's supervising authority, ASCLD/LAB will provide a team of trained assessors to conduct an on-site review of the laboratory's processes and casework to determine the cause of the deficiencies and errors in examination.

ASCLD/LAB Accreditation Criteria

ASCLD/LAB-*International* accreditation criteria for testing and calibration laboratories cover the following broad categories: laboratory management and operations, personnel qualifications, and physical plant.

Laboratory Management and Operations

The laboratory management and operations criteria contain the heart of the accreditation program and include the principles mentioned later.

Evidence Control. This series of criteria requires a comprehensive chain of custody to maintain the integrity of the evidence while in the laboratory. Evidence control requires marking evidence for identification purposes, storage under proper seal, and protection from loss, cross-transfer, contamination, and/or deleterious change (*see* **Chain of Possession of Tangible Evidence**).

Management System. A fully documented management system [45] is required, including a quality manual, in which the laboratory documents the policies and procedures that pertain to quality assurance, including a requirement of compliance by the management and staff. A quality manager must also be appointed who is responsible for the quality system in the laboratory. Internal audits are one of the primary tools used to evaluate, confirm, or verify activities related to quality. Their purpose is to assess compliance with the operational requirements of the entire management system. Periodic audits, along with day-to-day review of scientific reports, provide an effective means for ensuring that quality control activities are being implemented and that each forensic examiner performs in a manner consistent with the quality management system.

Procedures that are used in the laboratory must be documented to be demonstrably capable of producing valid results. They must be generally accepted in the scientific field or supported by data gathered and recorded according to the scientific method. New procedures must be scientifically validated before being used. These safeguards, reviewed by the laboratory's quality manager and by ASCLD/LAB assessors, help assure that valid theories and methodologies are in place for the examination of evidence.

The quality aspects of the management system also require that written technical procedures are in place for sample preparation methods, controls, standards, and equipment calibration procedures. These practices are crucial for the reliability of the methodology involved in many scientific tests. These protocols and the protocols established for individual tests in the different forensic disciplines assure that tests are conducted properly and under generally accepted procedures. These protocols not only help to assure validity and reliability but also help to meet the admissibility requirement of the "existence and maintenance of standards controlling the technique's operation" set forth by the Supreme Court [46] (*see* **Expert Opinion in Court: a Comparison of Approaches**; **Expert Opinion: United States**); ***Daubert v. Merrell Dow Pharmaceuticals***; and **Federal Rule of Evidence 702**).

Laboratory reports must be supported by a comprehensive case record that includes all notes, worksheets, photographs, spectra, printouts, charts, and other data or records used by the examiners to support their conclusions (*see* **Report Writing for Courts**). Documentation to support conclusions must be such that in the absence of the examiner, another competent examiner or supervisor could evaluate what was done and interpret the data. Acceptable ways to document the basis for conclusions derived from evidence examination may include a narrative description of the examination process and observations made, photographs, photocopies, diagrams, drawings, and worksheets. This requirement is essential because it allows a technical review. With these requirements in place, it will be much harder for an unscrupulous examiner to hide his or her incompetency, shortcuts, or fraud. Moreover, the complete case record required by ASCLD/LAB allows a more thorough and comprehensive review by defense experts of the tests conducted (*see* **Discovery of Expert Findings**).

As an additional quality assurance procedure to ensure compliance with testing protocols, technical review by another competent examiner of a percentage of laboratory reports is required (*see* **Peer Review as Affecting Opinion Evidence**). In addition, there must be a course of action mandated when discrepancies or nonconforming testing are found. The oversight of the quality of the testing and the reporting is an essential criterion that affords the public confidence that the conclusions issued in reports are accurate and reliable.

The courtroom testimony of each examiner is also reviewed annually for several purposes, including determinations that testimony is scientifically consistent with the work documented in the case file. Periodic, random review of testimony discourages examiners from testifying beyond the scope of his or her report and helps discover those that do [47].

Proficiency Testing. Proficiency testing is an integral part of a quality assurance program. It measures the capability of the examiner and the reliability of the analytical results. Such tests help determine where more training is required or where more stringent quality control may benefit. It also demonstrates, in part, the current competence of the laboratory. One test must be administered annually for each discipline in the laboratory and must be provided by an external proficiency test provider. ASCLD/LAB approves providers meeting its requirements. The external review of proficiency test results is a crucial element of the compliance monitoring process. In addition to the external tests required for each discipline, the program requires that each individual in the laboratory participate in at least one proficiency test annually. It should also be noted that the program encourages laboratories to give proficiency tests to each examiner annually in each subdiscipline in which casework is performed. In addition to participating in external proficiency testing, a laboratory should conduct proficiency testing using blind tests prepared internally or externally and submitted as normal casework evidence or by reexamination by another examiner of evidence on which casework was previously completed.

Personnel Qualifications

The qualifications of a laboratory's examiners are of great importance. These criteria establish minimum education, experience requirements, and training. They also require, for most of the forensic disciplines, a minimum of a baccalaureate degree in a natural science or a related field relevant to the scientific discipline in which the examiner is practicing. These criteria have raised the education levels required in many disciplines [48].

While certification of examiners by an appropriate certification organization is not required by ASCLD/LAB, the accreditation standards do require that examiners have the education, experience, and

training commensurate with the examinations and testimony they provide [49]. When certification is obtained, it should be by a recognized organization [50].

Initial competency and continued proficiency of examiners is also crucial. Each examiner must pass a competency test prior to assuming casework responsibilities and must successfully pass a proficiency test at least annually.

Physical Plant

A well-designed and outfitted laboratory can greatly add to its productivity and reliability. These criteria require that appropriate security measures be practiced and address the adequacy and appropriateness of laboratory space. The laboratory's physical plant should reflect due consideration of space, design, security, health, and safety. A reference guide used by laboratories is the "Forensic Laboratories: Handbook for Facility Planning, Design, Construction, and Moving," publication NCJ168106, prepared by the US Department of Justice, Office of Justice Programs, National Institute of Justice.

Conclusion

While crime laboratory accreditation programs have improved substantially over the last two decades, there is still a lot of work to be done. Report writing, proficiency testing, and ethics training are some of the areas that still need improvement (*see* **Ethics: Codes of Conduct for Expert Witnesses**; **Report Writing for Courts**). Most important, there remain a considerable number of laboratories, both public and private, that have not been accredited by any organization. Forensic sciences now play such an integral role in the criminal justice system [51] that the public and the criminal justice system as a whole demand the implementation of quality assurance programs monitored by outside entities. Accreditation by an internationally recognized program is a safeguard that helps ensure laboratories provide accurate and valid results.

End Notes

[a.] Kenneth E. Melson is a board member on the American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB) and a prosecutor. Ralph Keaton, ASCLD/LAB Executive Director, and John K. Neuner, ASCLD/LAB International Program Manager, contributed to this article, an early version of which appeared in American Bar Association, Criminal Justice Section, *Crime Laboratory Accreditation: The Assurance of Quality in the Forensic Sciences*, The State of Criminal Justice (August 2003).

[29] Mo.Rev.Stat. § 650.060 (2008).
[30] As of November (2008). The website for ISO is www.iso.org.
[31] As of November (2008). *ISO/IEC 17025: General Requirements for the Competence of Testing and Calibration Laboratories*, is available for purchase from the American National Standards Institute (ANSI) at www.ansi.org. IEC stands for the International Electrotechnical Commission.
[32] There are more than two ISO standards related to the work and accreditation of crime laboratories. For example, ISO Guide 43 (Parts I & II) addresses, respectively, standards of proficiency testing by interlaboratory comparisons, and the selection and use of proficiency testing schemes by laboratory accreditation bodies.
[33] In this context, the term "conformity assessment body" means the laboratory being evaluated for accreditation.
[34] As of November (2008). *ISO/IEC 17011:2004 Conformity assessment – General requirements for accreditation bodies accrediting conformity assessment bodies* is available for purchase at www.ansi.org.
[35] NFSTC was the predecessor to FQS-I, and no longer offers full laboratory accreditations.
[36] As of November (2008). Additional information about the Inter-American Accreditation Cooperation (IAAC) is available at http://www.iaac.org.mx/.
[37] As of November (2008). *See* www.fbi.gov/hq/lab/fsc/backissu/july2000/codispre. htm, for the standards.
[38] 42 U.S.C. § 14131.
[39] Using volunteer assessors from accredited laboratories has two distinct advantages. First, these individuals are experts in their field, doing work in the subject matter expertise in the area they are inspecting. Second, participation in the accreditation program gives additional training in quality assurance standards and practices to examiners who work in crime laboratories.
[40] Paid staff assessors were added to the program to assure consistency in application of accreditation criteria in the inspection process and the review of inspection reports. The quality manager is responsible for the Proficiency Review Program and the quality of the accreditation program.
[41] The Board of Directors is composed of nine voting members, a non-voting ex-officio member representing ASCLD (a separate non-profit organization) and a non-voting Executive Director. Seven of the voting members are elected from among the Delegate Assembly. One elected Board member is a representative of law enforcement and prosecuting attorneys and one is

a public member. The Board is elected by the Delegate Assembly, which is composed of the directors of all ASCLD/LAB accredited laboratories and laboratory systems.

[42] Contrary to outside criticism suggesting the accreditation program is a trade association administered by a group of golfing buddies, less than ten percent of applicant laboratories under the Legacy program achieved accreditation following the initial inspection. It is expected that the same will apply under the International program. *See* McDonald, R. (1998). Juries and crime labs: correcting the weak links in the DNA chain, *American Journal of Law & Medicine* **24**, 345–356.

[43] Arvizu, J. (2000). *Shattering the Myth: Forensic Laboratories*, CHAMPION **18**, 20–21, 24-May. Despite these early characterizations of ASCLD/LAB, two of the states requiring mandatory accreditation and the United States Department of Justice Office of the Inspector General have all recognized the ASCLD/LAB as an appropriate accreditation body, despite its peer-reviewer structure. The National Research Council in its second study of DNA analysis recommended that laboratories should make every effort to be accredited for DNA work by such organizations as ASCLD/LAB. COMM. ON DNA FORENSIC SCI., NAT'L RESEARCH COUNCIL, THE EVALUATION OF FORENSIC DNA EVIDENCE 4 (1996). The long-standing practice of accrediting bodies like ASCLD/LAB to use senior forensic scientists, with actual experience in a crime laboratory, and who receive specialized inspection training, meets both the letter and intent of peer-reviewer philosophy shared worldwide. *See* The International Organization of Standardization's (ISO) *ISO/IEC 17011:2004 Conformity assessment – General requirements for accreditation bodies accrediting conformity assessment bodies* (assessors (inspectors) must be selected and used based upon their having appropriate technical knowledge and practical experience directly related to the work of the laboratory being inspected); *KPI 3: Accrediting Body Staff, Assessors and Experts*, in the International Laboratory Accreditation Cooperation's (ILAC) publication *ILAC P7:2003 / Key Performance Indicators (KPIs)* (reiterating the necessity for accrediting bodies to use only inspectors who possess the appropriate "technical qualifications and practical experience.").

[44] As of November (2008). The ASCLD/LAB Proficiency Review Program document may be viewed at www.ascld-lab.org.

[45] The term "management system" is defined in *ISO/IEC 17025:2005 General requirements for the competence of testing and calibration laboratories* as "the quality, administrative and technical systems that govern the operations of a laboratory."

[46] Daubert v. Merrell Dow Pharmaceuticals, Inc, 509 U.S. 579, 594 (1993).

[47] For an example of a capital murder case where the trial testimony of an expert went beyond the conclusions in the lab report, see Troedel v. Wainwright, 667 F. Supp. 1456 (S.D. Fla. 1986), *aff'd* 828 F.2d 670 (11th Cir., 1987).

[48] There are many outstanding forensic science programs being offered in colleges and universities. The American Academy of Forensic Sciences formed an accrediting body, called the Forensic Science Education Programs Accreditation Commission (FEPAC), which has as its mission the accreditation of college-level academic programs that lead to a baccalaureate or graduate degree.

[49] An indication of the growing recognition of certification is the 2003 amendment to the Oklahoma accreditation statute which exempts latent print identifications performed by latent print examiners certified by the International Association for Identification (IAI) (www.theiai.org) from the requirements of a technical peer review system, a proficiency testing program and accreditation. *See* OKLA. STAT. tit 74, § 150.37, *amended by* H.B.1802, 2003 Leg. (OKLA. 2003). For a listing of certification organizations, see Carol Henderson Garcia, *Expert Witness Malpractice: A Solution to the Problem of the Negligent Expert Witness,* 12 MISS. C.L. REV. 39, 62 (1991). Many of the certification organizations may be found by reviewing the website for the American Academy of Forensic Sciences (AAFS) at www.aafs.org.

[50] The American Academy of Forensic Sciences has established an accrediting body, the Forensic Specialties Accreditation Board, to accredit certification organizations.

[51] Evidence from an estimated 2.7 million criminal investigations was submitted to the nation's forensic crime laboratories in 2005. Durose, Census of Publicly Funded Forensic Crime Laboratories, 2005, Bureau of Justice Statistics Bulletin, July 2008.

KENNETH E. MELSON, RALPH KEATON AND JOHN K. NEUNER

Accreditation: Organizational

Introduction

Accreditation is becoming (*see* **Accreditation: Laboratory**; **Fire Investigator: Standardization, Accreditation, and Certification**) more widely present in criminalistics. According to the most important forensic organizations, such as the European Network of Forensic Science Institutes

(ENFSI), the American Society of Crime Laboratory Directors (ASCLD), and the Senior Managers of Australian and New Zealand Forensic Laboratories (SMANZFL), the promulgation of accreditation programs is a visible sign of the increasing importance of accreditation in forensic sciences [1, 2]. As an illustration, the ENFSI 2005–2008 strategic plan states that [3] "All ENFSI laboratories need support in complying with best practices and raising the level of quality and science. To achieve this, ENFSI continuously encourages its member institutes to move toward formal quality management and accreditation. Scientific cooperation within expert working groups needs more momentum and a competence assurance system for ENFSI laboratories will be developed." SMANZFL includes the promotion and enhancement of management and quality practices in their strategic plan (Davey A. *Personal communication 2008*).

There are several reasons for this growing phenomenon. One of them lies in the general tendency for all scientific laboratories to seek accreditation. Forensic DNA laboratories were among the first to follow this development. Simultaneously, the increasing number of private laboratories and customer demand for more accountability also has a great influence. Management systems introduced in the public sector are also undergoing similar changes. Finally, admissibility of scientific evidence is subjected to a constantly increasing scrutiny in the court. Accreditation has been accepted as a means of helping courts to make decisions about the reliability of the evidence provided by a crime laboratory [4].

Contrary to certification (*see* **Training and Certification (in Criminalistics)**), which deals with the evaluation of the competency of a forensic scientist, accreditation is concerned with the overall operation of the organization. It is an overview of the managerial and technical requirements of a laboratory in order to comply with a given standard.

Accreditation

Accreditation, in its broad meaning, can be defined as [5] "the formal recognition of the technical and organizational competence of an authority to execute a specific service as described in the scope of accreditation. Competence is the key to transparency, confidence, and comparability." More specifically, laboratory accreditation can be defined as the [4] "formal recognition that a testing laboratory is competent to carry out specific tests or specific types of tests". It may also include the [4] "recognition of both the technical competence and impartiality of a testing laboratory".

In other words, the entity that wants to be accredited agrees to structure its aims/goals, management system, and technical facilities (i.e., infrastructure, personnel, and methods) so that they meet preestablished agreed criteria (described in a standard). The accrediting body then verifies whether the laboratory seeking accreditation (also referred to as the *applicant*) fulfills the criteria and complies with the standard.

The partnership between the ISO and the IEC has led to the creation of the standard *ISO/IEC 17025 general requirements for the competence of testing and calibration laboratories* [6]. This standard has been chosen by many forensic/criminalistics laboratories around the world for their accreditation purposes. It describes in a very general but exhaustive manner what is necessary to comply with it. ISO/IEC 17025 includes five chapters covering the entire laboratory operation: scope, normative references, terms and definitions, management requirements, and technical requirements. The first three chapters explain cases in which the standard is applicable and references on which it is based. The management requirements chapter deals primarily with the operation and effectiveness of the quality management system in place in the laboratory. It explains how to describe the system in place, how to detail all stages of the working process, and how to deal with more specific situations. The technical requirements part addresses methodology, test/calibration equipment, and competency of personnel. The combination of management and technical requirements covers the entirety of crime laboratory operations.

Because ISO/IEC 17025 is designed for all kinds of testing and calibration laboratories, it does not necessarily consider all of the needs and specificities of a criminalistics laboratory. The application of standards to specific areas may require further explanations through additional documentation called *applications* or *supplementary requirements*. These documents are an elaboration of the more general criteria stated in the standards. Supplementary requirements provide an interpretation of the intent of parent standard (ISO/IEC 17025), when applied to specific disciplines

within forensic sciences. They are usually established with the help of specialists in the field, in the present case criminalists.

In the United States, in addition to ISO/IEC 17025 accreditation available through the ASCLD/LAB International program, the ASCLD/LAB Legacy program also accredits crime laboratories. As a matter of fact, more than 90% of US laboratories do not rely on ISO/IEC 17025, but on the ASCLD/LAB Legacy program [7].

In Australia, the National Association of Testing Authorities (NATA) provides a tailored forensic science accreditation program, which comprises ISO 17025 and supplementary requirements for accreditation in the field of forensic science for organizations whose core business is forensic science service provision. In addition, the "forensic module" is available to organizations that hold ISO 17025 accreditation in another field of testing but conduct a limited amount of forensic testing (Davey A. *Personal communication*, Parsell M. *Personal communication 2008*).

Two other international standards are of interest with regard to accreditation in criminalistics: *ISO/IEC 17020 general criteria for the operation of various types of bodies performing inspections* and *ISO 9001 quality management systems – requirements* [8, 9]. ISO 9001 describes the general requirements of a quality management system. Its application is, thus, much broader than is defined by 17025, as it applies not only to laboratories but also to any entity providing services or products. The managerial criteria defined in 17025 are based on the ISO 9001 requirements; however, the main difference between the two standards is that the former also includes criteria on technical requirements and competency. More recently, there have been many discussions regarding the application of ISO/IEC 17020 to criminalistics, more specifically to crime scene investigation [10], although this is not the case in all countries. However, although the application of 17025 for laboratories and 9001 for management systems is not contested, the use of 17020 for crime scene investigation units is still under discussion and has not been widely accepted yet. ENFSI is presently working on a joint project with the European Co-operation for Accreditation (EA) to define which standard, ISO/IEC 17020 or ISO/IEC 17025, is to be used for the different forensic fields [11]. The latest version of the ENFSI's *standards for accreditation* document states that [12] "For activities other than the testing part of the forensic process e.g. work at the scene of crime, ISO/IEC 17020 can be implemented as the standard used to achieve accreditation".

The main goals and requirements for all three international standards (ISO 9001, ISO/IEC 17020, and ISO/IEC 17025) are the same. One of the most important goals is oriented toward customer service. It is crucial to provide a satisfactory service or product, which is recognized as a basic condition by the customer. Another important requirement is documentation. First, documentation of the goals and procedures allows the accredited laboratory to establish a repository of knowledge existing within their laboratory. When training new employees, this comprehensive body of documentation is available and knowledge can be easily passed on. It should, however, be emphasized that this documentation does not replace in-house training but facilitates the whole process. Second, written documentation assists the laboratory to work in a transparent and traceable manner. Ultimately, this helps to establish customers' confidence. This accountability also renders the customers' task much easier when choosing between various laboratories to meet their requirements. Third, documentation helps to have an efficient quality management system by keeping a documented chain of custody, a particularly important requirement in criminalistics, and by keeping track of errors. Although a complete management system is more than just the chain of custody and corrective actions, several goals are reached by simply applying a comprehensive documentation policy.

Accreditation Process

There are several institutions that are competent to provide accreditations, most of which are national bodies. In the United States, ASCLD/LAB is the most popular. It is also the body chosen by 10 laboratories outside the United States, notably in New Zealand [13]. In Canada, the Standards Council of Canada (SCC) is competent. In Australia, it is the NATA and in the United Kingdom the United Kingdom Accreditation Service/National Accreditation of Measurements and Sampling (UKAS/NAMAS) can provide accreditation.

There are three main stages in the accreditation process: preparing for, obtaining, and maintaining

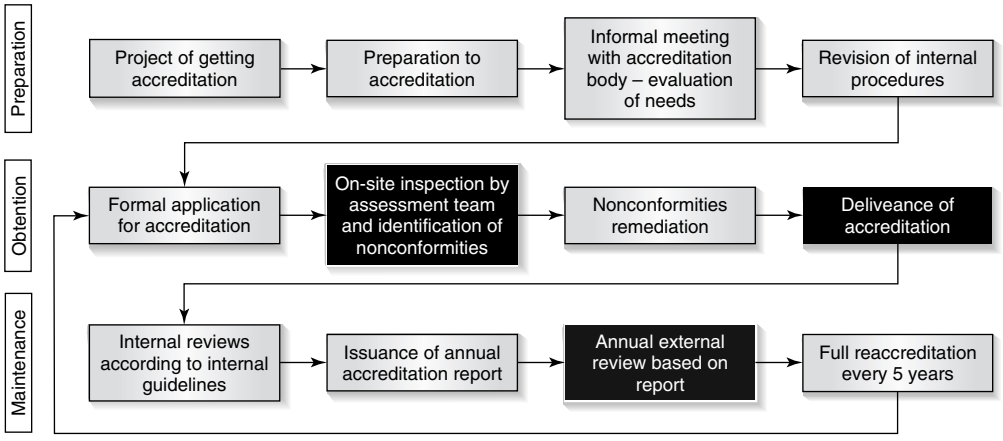

Figure 1 The different steps in the accreditation process. Light gray indicates the steps carried out by the body getting accredited. Dark gray indicates the steps carried out by the accrediting body. The blend of gray indicates the steps involving both the parties

accreditation.[a] Figure 1 shows the detailed process of accreditation as described hereafter.

One of the most important steps in preparing for accreditation is to devise a documented portfolio comprised of the aims/goals, management system, and technical facilities of the laboratory seeking accreditation. This includes the presentation of the laboratory's internal quality manual, which may already exist in one form or another, but which may need to be adapted to the exact needs of the process. The required documentation can usually be classified into three different levels. The most general level is the quality manual that describes, in general terms, the policies and goals of the work done by the laboratory seeking accreditation. It also describes the structure of the entity and its processes (in a general way) and the basic concepts of the (quality) management system. The second level includes guidelines and standard operating procedures (SOPs). These describe the exact processes used to achieve each task carried out at the laboratory and include information on organizational and technical know–how. Finally, the third level comprises detailed documentation, which may include checklists (or pro formas) to perform specific tasks and/or to maintain instruments as well as other specific documents.

Then, the accrediting institution will assign a technical officer who will conduct a preassessment of the laboratory. During this preliminary visit, discussions take place to review the existing measures and procedures in place. These measures and procedures are then evaluated as to their compliance with the requirements of the standard in question, such as ISO/IEC 17025 for a crime laboratory. Next, the laboratory will review its processes, documentation, and facilities in order to adapt to the standard and meet the accreditation requirements. The time required to carry out this step highly depends on what was already in place at the laboratory. If extensive adaptations must be incorporated, this step may be quite long and tedious. Depending on the accrediting body, an advisory visit may be necessary to address any noncompliances identified during the on-site visit.

To obtain accreditation, a formal inspection or assessment of the laboratory by a team of inspectors or assessors must take place. The previously prepared documentation is reviewed in light of the specifications described in the standard. The laboratory is also visited, and the accreditation inspectors scrutinize the operations of the laboratory. All nonconformities are noted and the appropriate corrective actions are discussed. Depending on the accrediting body, there may be two levels of nonconformities [14]. Level 1 nonconformities have a significant impact on the quality of the laboratory product and must be resolved before accreditation is granted. Level 2 nonconformities have a minimal impact and must be corrected prior to the next yearly visit. Some accrediting bodies, such as NATA, require that all conditions identified during the assessment must be satisfactorily addressed before accreditation can be considered.

Once obtained, accreditation must be maintained. To this effect, internal and external evaluation measures are put into place. Internal measures include the constant update of documentation on techniques, methods, and administration. External measures include annual surveillance visits, the submission of an annual accreditation report to the accrediting body, and results of proficiency tests. Depending on the accrediting body, a full reinspection of the laboratory may take place every five years [15]. NATA's surveillance program is a little different and includes 18-month surveillance visits and 36-month reassessment visits, with no annual reports required (Parsell M. *Personal communication*).

Accreditation Applied to Criminalistics

Criminalistics laboratories are not the usual testing and calibration laboratories (as covered by ISO/IEC 17025). Therefore, the propositions made in the international standards have to be interpreted according to the specificities of forensic sciences, in general, and criminalistics, in particular. As mentioned earlier, such a supplemental document is an interpretative document of 17025 and is called *an application document*. One such example is the International Laboratory Accreditation Cooperation (ILAC) *Guidelines for forensic science laboratories* (ILAC-G19:2002), which provides guidance for laboratories involved in forensic analysis and examination to comply with ISO/IEC 17025 [16] or the NATA supplementary requirements. These documents are structured in the same way as 17025. Its scope is illustrated by providing a specific list of activities that might be undertaken by a forensic laboratory, without being exhaustive. A succinct overview of the different techniques used is also provided. Reference is made to various relevant ISO/IEC guides. Some terms and definitions are also explained: objective test, reference collection, and court statement. Following this, the management requirements are specified. This includes not only the control of records (the aforementioned importance of documentation) but also the mention of negative results. The technical requirements include personnel (competency); accommodation and environmental conditions (e.g., contamination issues); test and calibration methods and method validation (how to carry out validation); equipment (maintenance and calibration); measurement traceability (documentation); sampling (also depends on competency of staff); handling of test and calibration items (chain of custody and evidence management); assuring the quality of test and calibration results (quality control measures); and reporting the results (preparation of the report and court testimony).

Although it is relatively straightforward to adopt ISO 17025 and its application (such as ILAC-G19:2002 or the NATA supplementary requirements) to fields such as toxicology, DNA analysis, or drug testing, it is much more challenging with disciplines such as handwriting, fingerprints, and other identification areas. One reason for this is the high similarity of activities between analytical forensic sections (DNA, drugs, toxicology, etc.) and regular analytical/pharmaceutical laboratories, since most processes can be described and handled in a standardized manner. Both fields are also largely numerical or quantitative in nature. Although extensive literature and practices exist describing the best way of handling exhibits for fingerprint enhancement, each incoming item has its particularities. Thus, the methodology cannot be applied in a completely standardized manner, although maintaining the integrity of the evidence does not change with the discipline involved – these procedures remain reasonably standard. This means that the description of the work done by the unit or laboratory is a more difficult task.

A further consequence of the particular and sometimes random nature of forensic samples is that it might be possible that the technique or method needed is not very commonly used. In turn, this renders it difficult to create or maintain standards for them. Likewise, it might be that a certain technique is only used once a year, which will not be sufficient to demonstrate a regular use and guarantee a routine use by laboratory personnel. This specific issue is covered by ILAC-G19:2002 and the NATA supplementary requirements.

The difficulty for the forensic community to adapt to external standards, such as 17025, is not only due to the "degree of subjectivity" of the techniques used but also due to the nature of the work performed, mainly because of the unique and varied character of each item of evidence. As the title of the ILAC application mentions, the guidelines are for forensic science laboratories. The question remains whether or not a crime scene unit falls under the definition of ISO/IEC 17025 (testing and calibrating laboratory). Until now the question has been raised

but no satisfactory answer has been found. In many countries, the tendency has been to accredit laboratories with ISO/IEC 17025 without considering the crime scene units. This is not true in some countries such as Australia where there has been considerable discussion on this issue and the mindset that "the laboratory" is four walls in a fixed building is seen as narrow and incorrect. As a result, in Australia, Crime Scene Laboratories are accredited to ISO 17025. In Switzerland, the question that has been asked is whether ISO 17020 (designed for inspecting bodies) would be appropriate for crime scene units [10]. Another way is to certify according to ISO 9001, which means that the managerial part, including the documentation, is covered, whereas the technical requirements are still not accredited, but will have to be covered by another form of quality control (internal or other entity than an accreditation body). Creating specific standards for crime scene accreditation remains a possibility [10].

Because of the existence of private or public laboratories and the differences of evidence admissibility in court, accreditation has not undergone the same development in different countries. At the same time, as previously mentioned, the development has also not been the same for the different stages of the criminalistic process. In Europe, the development is reflected by the guidelines established by ENFSI, which state that all their member laboratories [12] "should have achieved or should be taking steps toward ISO/IEC 17025 compliant accreditation for their laboratory testing activities". According to a recent survey of ENFSI members, one-third of the laboratories are accredited, one-third plan to become accredited by 2009, and one-third do not have a definite timeline or have not undertaken any action yet [17]. Nevertheless, 94% of the laboratories have a quality assurance system in place or are developing one. Furthermore, accreditation as perceived by a laboratory may not agree with the general understanding of accreditation as granted by an international institution or an official national body. Thus, only 20% of the laboratories surveyed are actually accredited according to the above-mentioned international standard ISO/IEC 17025 [17]. In the United States, 294 laboratories are accredited through the ASCLD/LAB Legacy system and 26 through the ASCLD/LAB International system that corresponds to ISO/IEC 17025 [13]. Only 18 of these laboratories are private. In Australia, approximately 85% of the government forensic science service providers (including crimes scene) are accredited to ISO 17025 and the majority of relevant private laboratories either have forensic science accreditation or are accredited with the "Forensic Module" or are moving in that direction (Davey A. *Personal communication*).

Advantages and Disadvantages

Accreditation offers several advantages: transparency, traceability, and accountability. This profits both the provider of a service and its clients. The laboratory will gain a much clearer understanding of what work is done and how it is done. This information is documented so that it is much easier to transmit to new employees who undertake on-the-job training. The client can have a much better view on how his product or service has been performed. It may also be easier for the client to choose which provider has the best offer to meet his needs. Along with this, accreditation leads by its structure to a certain harmonization between laboratories, as the conditions to fulfill are the same and ISO/IEC 17025 gives a common backbone to all laboratories. By rendering comparisons between laboratories possible, the quality of each of them can more easily be evaluated. An expansion on an international market, rather than a national one, is facilitated, as well. Furthermore, international collaboration based on criminalistics may be simplified by the common approach [17].

Among the first disadvantages, most commonly named are the initial cost of implementing all the measures needed and the permanent cost of maintaining accreditation. Sometimes it is also perceived that the extra paperwork and administrative effort needed is disproportionate to the gain resulting in implementing all the measures. A certain loss of flexibility in applying nonvalidated testing or implementing new techniques or methods has also been advanced as a negative point, as each and every change has to be documented according to procedures and accepted for court purposes. The quality of work may also become limited, as a tendency may prevail to comply only with the standards imposed by regulations, instead of using previously higher internal standards. Accreditation can also be used to limit competition with other laboratories by fixing high standards so that not all (private) laboratories can follow them. However, some of these criticisms may disappear when

it is understood that in reality accreditation sets the "minimum standard only" and not the top standard.

Conclusion

Accreditation, as part of a quality management system, is gaining more and more importance in criminalistics and has been fixed by professional bodies such as ENFSI as one of the goals to be achieved by their members. For criminalistics laboratories, the international standard that seems most appropriate is ISO/IEC 17025 for testing and calibrating laboratories. The specifications of how this standard can be applied to forensic/criminalistics laboratories are found in ILAC-G19:2002 and the NATA supplementary requirements. In the United States, most laboratories are still accredited according to ASCLD/LAB Legacy program. However, ASCLD/LAB also offers an ISO/IEC 17025 accreditation program, which will eventually replace the Legacy program. Future developments are turned toward discussions about how criminalistics/forensic units operating in the field (crime scene units) could comply with these international standards and become accredited. In this regard, the standard ISO/IEC 17020, designed for bodies performing inspections, is being considered by some people. However, one must be cautious about the fact that investigation and inspection are not synonymous.

Acid Phosphatase

Prostatic acid phosphatase (PAP) is an enzyme secreted by the prostate gland and secreted in seminal fluid. Acid phosphatase (AP) is a generic term for a group of isoenzymes, of which PAP is one. AP is not unique to the prostate (although PAP is), being found in other biological fluids such as vaginal secretions. However, AP activity is 50–1000 times greater in human semen than in any other body fluid, and so the test is regarded as a presumptive test for the presence of semen. The only approach to differentiating semen from vaginal secretion is by quantitative analysis or the microscopic inspection for the presence of sperm. In many circumstances, a strong positive reaction for AP indicates that semen is present and that further testing is warranted (e.g., for DNA).

There are a number of ways to test for AP. Most, especially those used to identify semen-stained areas, involve a color change. Clothing and swabs are probably the most frequently analyzed items.

PAP is found in the vagina following intercourse. Its activity was found to correlate better with the time since intercourse than the presence or absence of sperm.

According to Davies and Wilson, and using their test method, a reaction time of less than 30 s was regarded as a "very good indication" of the presence of semen as no vaginal AP reacted within this time.

In a series of postmortem examinations using ELISA methods, a level of PAP greater than $100\,\mathrm{ng\,ml^{-1}}$ was considered positive for sexual intercourse.

Importantly, a number of other materials can produce "false positive" reactions with AP (i.e., positive, but not semen). Examples include cauliflower, clover, bindweed, turnips, raisins, and ginger.

Addictions

Definition

Addictive diseases are complex primary disease states caused by a combination of genetic, psychosocial, and environmental factors and generally resulting in both physical and behavioral manifestations [1] (*see* **Substance Abuse**). Their essential elements are often defined as continued use of a substance or similar maladaptive behavior, such as gambling, despite significant problems resulting from that use or behavior [2]. Extensive scientific research has explored the genetic underpinnings and the environmental contributors [3], the long-term physical findings generally resulting from substance use, and the behavioral differences observed in the addict [4]. For the purposes of this article, psychoactive substances are being used as a prototype addictive agent, but addictive disease also may pertain to other entities, gambling being one which has received diagnostic recognition [2]. Contributions to the literature have also explored other potential addictive agents, including sex, pornography, the Internet [5], videogame [6], and chocolate [7], though whether these represent medical disease states remains a controversial topic.

From a physiologic perspective, addiction takes place when a psychoactive drug is taken for a sufficiently long period of time and in sufficient doses to result in either tolerance or withdrawal phenomena. Tolerance is represented by the need for an individual to take more of a given substance to achieve a given effect, or by the decrease in perceived effect over time when a substance is taken in an unchanging dose. Withdrawal is represented by the presence of measurable physiologic change upon cessation of drug intake. Physiologic addiction need not be present for addictive disease to exist. Similarly, the presence of physiologic addiction does not alone imply the presence of addictive disease. Many psychoactive drugs cause measurable tolerance and withdrawal phenomena after only one dose and within a short period of time. A hangover, for example, after a single night of alcohol use, represents a withdrawal state. There are also longer-term effects of even brief exposure; for example, rats fed alcohol for 4 weeks have abnormal responses 6 months later when reexposed to alcohol [8]. The term *addiction*, as used by the general medical community, or *dependence*, as used by the psychiatric community, are rough equivalents that do not apply simply to physiologic addiction but to the well-characterized disease state involving use of substances that cause physiologic addiction. To wit, alcohol is an addictive drug. It causes physiologic addiction in all humans, and indeed in all mammals, who consume the drug. As a result, any individual who drinks alcohol may experience intoxication, and will experience tolerance and withdrawal to an extent consistent with the quantity and duration of alcohol use. Such experiences are neither indicative of the presence of addictive disease, nor are they necessary for such a diagnosis. Gambling is not a physiologically addictive drug, yet it has been accepted within the diagnostic rubric and leads to comparable behavioral consequences in some of those who participate in the activity.

Substance use itself can be categorized into several groups, using any number of classification schemes. Terminology has been inconsistent, with substance misuse, abuse, overuse, harmful use, addiction, and dependence all holding different meanings depending upon the individuals using the terms. The fourth edition of The Diagnostic and Statistical Manual of Mental Disorders uses the terms abuse and dependence as referring to condition states with respect to addictive substances. The background as to how these terms were developed and why they differ from generally used terminology has been addressed in the literature [9]. There is agreement that substance use refers to any use of addictive substances, whether such use is by prescription or within constraints of legal codes, or if illegal and of such quantity as to lead to intoxication.

Substance use, then, is a quantity-oriented term as it contains all those activities in which substances are used in any quantity other than zero. Addictive disease is not a quantity-oriented term; its presence involves some use during the illness, but neither the quantity nor the frequency of such use is germane to the diagnosis [1, 2].

Addiction within the psychiatric construct [2] can involve alcohol and other sedative agents, amphetamines, cannabis, cocaine, hallucinogens, inhalants, nicotine, opioids, phencyclidine, and steroids.

Once an individual has been diagnosed with addictive disease, the diagnosis remains permanently, just as the disease does, so long as the diagnosis was

retrospectively accurate. Addictive substance use can end as a result of remission, recovery, agonist therapy such as methadone, or a controlled environment such as prison. Where pertinent, such qualifications are added to the diagnosis.

Disease Course

Addictive illnesses are primary illnesses in that they are not symptoms of other disease states. It is natural that people try to determine causality as to why they have developed a disease, and many therefore choose to blame their addictive disease upon depression, anxiety, or specific life stressors. Addictive disease, however, has not been shown to arise as a symptom of any other illness.

Addictive diseases are involuntary in that afflicted individuals did not choose to have their illness, but this does not imply that those with addictive illness are relieved of the responsibility necessary to recover from their illness [1]. The diseases, without intervention, are often progressive and fatal. Patients often focus their attention upon the addictive substance or behavior, have adverse consequences resulting from the addiction, and deny the relationship between their addictive focus and the negative consequences.

In 1990, Block and Shedler published a key longitudinal study which revealed that addictive disease may be present, but for the use of drugs, at a very early stage of life [10]. Psychological differences between frequent drug users and others were noted as being traced to the earliest years of childhood and related to the quality of parenting received. The findings indicated that problem drug use is a symptom, not a cause, of personal and social maladjustment, and that the meaning of drug use can be understood only in the context of personality structure and developmental history. Disease course must therefore examine a complete individual history, not simply document the less important substance use history. More recent studies add the possibility that the problem drug use is not only a symptom of these environmental issues but of specific genetic abnormalities as well; no longitudinal study has yet been conducted, however, to confirm these theories.

At some point, the individual with addictive disease will use an addictive substance for the first time. This is intuitively more likely to take place within a society or subculture that encourages such use. Positive subjective experiences during the first use are more likely in those who have addiction [11]. This may be interpreted in one of two ways: either those with addictive illness are more likely to have the disease because they had a positive initial experience, or those with addictive disease have a physiologic abnormality that causes them to have a positive initial experience. Use of the substance increasingly takes on greater importance for the individual afflicted. Efforts at control may be instituted in which the addict attempts to limit his own use, but nevertheless as time passes, important social, occupational, or recreational activities become less important than the addictive behavior itself [2].

Whether through intervention or through self-awareness, addicts often pass through stages of change related to their ongoing behavior. Such stages include precontemplation, contemplation, and preparation, all of which precede any significant alteration of substance use, and are followed by action and maintenance [12, 13], both efforts to obtain and maintain abstinence. Discontinuation of the addictive behavior is a requirement during the action and maintenance phases. Stages may be, and often are, repeated, with relapses common after an initial attempt at abstinence. Cutting back, sometimes referred to as *controlled use*, is an ineffective treatment approach [14]. Continuation of any addictive behavior places the individual with addictive disease at risk; tobacco use, for example, not only increases the risks of morbidity and mortality due to smoking, but increases the risk of relapse of other substance use as well [15, 16]. Successful long-term recovery may accompany simultaneous long-term abstinence [17] during which no diagnostic signs of the illness remain.

Epidemiology

With respect to illness, the term *prevalence* refers to the percentage of a given population with a given diagnosis at a specific cross-section in time. Widely varying prevalences of addictive disease have been reported, in part because of differing application of definitions. Whether an individual in recovery was counted as one with the diagnosis or not depended upon the study. Some studies separated alcoholism from other drug addictions, again resulting in a

difficulty in determining even approximate figures. The Epidemiologic Catchment Area (ECA) study indicates a lifetime prevalence of alcohol disorders to be 23.8%, with a one-year prevalence of alcohol disorders to be 11.9% [18]. The National Comorbidity Survey (NCS) showed a lifetime prevalence of alcohol dependence to be 20.1% in men, with a one-year prevalence of 10.7% [19]. In women, the parallel figures were 8.2 and 3.7%. The differential between one-year and lifetime prevalence figures suggests that in these cases, the diagnosis was applied only to cases in which an individual is actively using substances. Clearly, though, these studies indicate how much more prevalent alcoholism is than other substance addiction; the ECA revealed an overall lifetime prevalence of drug abuse and dependence, not including alcohol, at 6.2%. Similarly, the NCS indicated a lifetime prevalence of drug dependence to be 9.2% among men and 5.9% among women.

Incidence refers to the risk that any one member of the study population will become afflicted with the disease under study in a specified period of time. In the case of addictive disease, incidence can be difficult to determine, as subjects often have used substances for some time prior to their precisely meeting the definition of illness. Retrospective reviews are therefore problematic. The most dependable findings are those referring to that population at greatest risk: men between 18 and 29 years of age [18].

Treatment

Addictive disease treatment is generally quite successful. The Federal Aviation Administration has demonstrated an 85% rate of success for alcoholic pilots attaining and maintaining recovery while being followed closely by physicians during a nine-year study period [20]. Military studies also indicate high rates of recovery over several years of treatment [21]. Similar research of healthcare professionals with substance use disorders has found similarly strong recovery rates [22]. Each of these studies involved ongoing treatment provided primarily by physicians. There have been many studies [23] indicating a far lower rate of success in which subjects generally have the same occupational or financial issues but in which patients are not provided with physician-provided medical care. No studies have yet been performed to directly compare and contrast outcomes among health care professionals and other clinicians.

Initial treatment focuses on the physiologic addiction to achieve a safe withdrawal from substance use. Cessation of the substance use is merely the first step in the treatment of addiction, however, and an ongoing maintenance plan is critical to a successful outcome [24]. Successful medical care generally involves a combination of therapeutic approaches, treatment of any physical and behavioral comorbidities, and the active involvement by the patient in 12-step recovery groups. Pharmacotherapy has proven useful for treatment of opioid [25] and nicotine [26] dependence. Disulfiram (Antabuse) remains the only medication demonstrated to have long-term value in the treatment of alcoholism [27]. Treatment is entirely ambulatory in many cases, but in more severe cases involves inpatient stays at various levels of care, including hospitalization, rehabilitation, partial day programs, and halfway houses.

Relapse Prevention

Once patients with addictive disease have stopped their addictive behavior, they now begin to feel the discomfort representative of the disease state – the very discomfort that they gained relief from through the use of substances. Abstinence merely solves the physiologic addiction. Prevention of relapse can be obtained only by addressing the discomfort that is present for a sober addict. There are four common myths regarding relapse [28]:

- **The relapse takes place because the patient wants to relapse:**

It is common for treatment professionals to accuse the patient of a moral lapse leading to relapse, as if the relapse is the desired state for the patient. The patient wants only to feel better. A relapse is the best possible alternative the patient can conceive of if the relapse has taken place. One role for the treating physician is to provide alternative options. Punitive policies such as those held by some programs that administratively discharge a patient following a relapse are inappropriate. Patients who relapse require more care, not less.

- **The patient needs to hit bottom before recovery is possible:**

No empirical data exist to support this.

- **Relapse means the patient has begun using substances again:**

Relapse begins long before the patient starts using again. The path to relapse is progressive, with the actual use coming as the final step on the path. Self-help groups often refer to the term *dry drunk* as meaning that an individual is thinking in the same manner as one who is actively using.

- **Once a relapse has taken place, complete loss of control will result:**

Relapses often consist of a brief episode of use after which the patient suddenly and quickly returns to sobriety. These relapses often follow a period in which the patient has dropped out of treatment or out of self-help groups. The patient then denies any further difficulties until the relapse takes place. Then the individual recognizes that indeed the disease has continued despite the past time of recovery; a return to therapy follows. Such a course is not at all atypical.

An individual's risk of relapse may fall within any of three groups [29]:

- **Recovery prone**

Forty percent of addicts attempting recovery fall into this group. Some attain sobriety with no clinical intervention and no attendance at self-help groups. Others seek such assistance and remain sober following this initial intervention.

- **Transitionally relapse prone**

Twenty percent of all patients periodically relapse, generally within treatment, but as time passes their relapse episodes become less severe, with shorter durations and greater time periods separating episodes. These patients often enter a long-term sobriety within 3–5 years.

- **Relapse prone**

This group of 40% are thought to develop progressive patterns of more severe episodes. Levels of functioning decrease during periods of abstinence. These patients often die of their illness within the first two decades of treatment. This group can be subdivided into those with motivation and those without. The group without is unlikely to present for ongoing treatment. The group with motivation will dutifully try, participating in treatment and self-help, but eventually failing to succeed.

Conclusion

As with many other diseases, addictive illnesses have a wide spectrum of severities with an accompanying range of related morbidities. Quantity and frequency of substance use, however, are independent of severity [30] and are therefore neither predictive nor useful measures of disease course. Terminology has caused significant difficulties in the field. Alcoholism, the most common addictive disease, has long been a reference to an illness that involves use of any sedative agent that exhibits cross-tolerance with alcohol. Alcohol dependence, the syndrome originally defined in 1976 [31], has come to focus specifically upon alcohol use; other sedatives are included within the "Sedative Dependence" section of DSM-IV. As a result, studies of alcoholism and alcohol dependence differ substantively, resulting in findings for one group that may not apply to the other. There are also many studies involving heavy use of alcohol in which readers might presume incorrectly that findings apply to those with alcoholism. The literature must be analyzed closely and critically to determine whether findings in any one study or group of studies are applicable to any specific individual.

Adversary Systems of Justice

Legal systems through the world may be classified as belonging in one of two philosophical camps: those that are called *adversary systems of jurisprudence* and those that are typically referred to as *civil law systems* (*see* **Civil Law Systems of Justice**).

Adversary systems of jurisprudence, also referred to as *common law systems*, are in use in that part of the world where English-speaking rule exists or where the English legal system was the predominant jurisprudential system at one point in time. This includes the United Kingdom, the United States of America, Canada, Australia, New Zealand, and some other countries whose juridical systems were created at a time when the Anglo–Saxon tradition of the common law inspired their development.

The adversary system is one that focuses on a fact-finding trial, which is a contest between opposing sides in litigation. In this contest, each side seeks to convince the fact finder that their contentions have merit by offering supporting evidence. The fact finder in such a system is, alternatively, the presiding judge if it is a bench trial (nonjury trial), or a jury of the defendant's peers if a jury trial is permitted under local or constitutional law. In a jury trial, the judge's role is to preside over the trial, rule on matters of law and on objections interposed by counsel for the litigants, and instruct the jurors on the legal principles they should apply to the facts that they have determined, from the evidence presented, to have occurred.

Though there exist many variants in the rules of various jurisdictions, presentation of proof in adversary or common law system countries is subject to an often complex system of rules of evidence. These rules are designed to limit the types of proof that courts will admit. The rules of evidence are designed to assure that the fact finder will base the

outcome of the litigation on mostly appropriately reliable evidence. They also exclude, at times, reliable evidence that, for policy reasons, courts or legislatures have determined to be worthy of special protection and are therefore shielded from disclosure. This would include privileged communications between well-defined classes of individuals, such as communications between doctors, lawyers, clergy, spouses, and parties to civil litigation or defendants in criminal prosecutions.

Aggression

Introduction and Definitions

> *The extreme form of power is All against One, the extreme form of violence is One against All* [1], p. 42.
>
> *The preeminence of aggressiveness in our civilization would already be sufficiently demonstrated by the fact that it is usually confused in everyday morality with the virtue of strength* [2], p. 98.

In ordinary language, the concepts of aggression and violence have taken on broad, often metaphorical, meanings. Diseases may be treated aggressively by physicians. A storm may be violent. An aggressive attitude is necessary in training for competitive sports. These common usages suggest the need to define aggression and violence precisely in the setting of legal proceedings and the scientific study of behavior in its social context.

Aggression refers to a state of destructive intent, with or without harm. It has been studied in insects and animals [3], with an emphasis on biological and evolutionary factors in behavior [4, 5]. Research on human aggression, in contrast, takes into account the

additional specificity of social and cultural processes. The impact of civilization on instinctual drives may largely override biological determinants, making human aggression a phenomenon qualitatively distinct from aggression in animals. In its mildest forms, such as irritation or brief moments of anger, human aggression remains within the range of universal, normative experience. According to Bronfenbrenner and Ricciutti, aggression includes "any action, thought or impulse the presumed aim of which is physical or psychological injury either real or symbolic to an individual or his surrogate" (1960, cited in [6]). In this definition, aggression thus reflects an internal state that manifests in a wide spectrum of behaviors. It is characterized by harmful intent, with destructive feelings toward others as well as objects. Aggression may include "[i]nsults and spreading harmful rumors" [7], p. S7. Anger, fear, and irritation are emotional states often associated with aggression, but are not synonymous with it. Frustration may result in anger that does not involve destructive intent of any kind, and may be resolved through verbal expression. As Rothenberg stated in 1971, "Violence and revenge are destructive direct discharges, but they are not expressions of anger *per se*; they are in part expressions of failed or unattempted communication" [8].

Violence involves physical injury or imminent threat of physical injury to another human being. The Centers for Disease Control (CDC) in the United States conceptualizes violence under the larger public health problem of physical injury, differentiating unintentional injury (accidents) from intentional injury toward self and others [9]. The World Health Organization (WHO) defines violence broadly as "The intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community, that either results in or has a high likelihood of resulting in injury, death, psychological harm, maldevelopment or deprivation" [10], p. 5. Although this definition includes violence to oneself and collective violence, researchers have operationalized violence more narrowly as intentional interpersonal acts resulting in injury of another, in order to focus the object of empirical study. The categorization used by the WHO divides interpersonal violence into family and intimate partner violence on the one hand and community violence (between unrelated persons) on the other hand [10], p. 6.

The authors of the MacArthur Study of Mental Disorder and Violence defined two types of violent incidents as outcome variables: violence and other aggressive acts, distinguishing violence as "the infliction of injury or the threat of considerable, credible harm" [11], p. 18. The authors of the Historical Clinical Risk-20 (HCR-20), one of the most extensively validated rating instruments for structured clinical judgment of violence risk, define violence as actual or attempted harm to a person, or a threat of harm that is unambiguous [12], p. 24. Acts that would induce fear in most people but that do not actually result in injury, such as nonconsensual attempted physical sexual contact or stalking (*see* **Stalking**), are included in this definition. A general guideline according to the HCR-20 is to include as violence any behavior that would be "serious enough to result in criminal or civil sanctions" [12], p. 25 and to exclude from the definition those acts that would not. Verbal insults without overt threat of harm, destruction of property, and harm to animals without intended harm to persons, appropriate self-defense, and sporting injuries are excluded from their definition [12], pp. 25–26.

From a historical and sociological perspective, violence broadly encompasses phenomena such as war, genocide, and revolution. Writing from the point of view of a psychiatrist with extensive experience in the correctional system, Gilligan elaborates on the idea that violence serves either to "achieve and maintain justice, or to undo or prevent injustice" [13], p. 12, and that acts of violence can be construed as a reaction to injustice, either real or perceived [13], pp. 18–19. In his formulation of violence as a medical and public health problem, he goes on to extend its definition beyond interpersonal violence to include accidents, which do not involve the specific intent to harm. This latter definition of violence stems from a conceptualization of *structural violence* as a form of harm that is built into a social system, and for which there is collective responsibility [14]. In this sense, socioeconomic disadvantages such as poverty and large-scale prejudice such as racism are manifestations of structural violence contributing to direct violence, in the sense of preventable deaths [13], p. 192+. The associated problems of war, genocide and torture may become relevant to legal proceedings in international courts of law or in immigration proceedings and merit further discussion, which is beyond the scope of this article.

In addition to structural and direct forms of violence, Galtung defined a third major type in 1990, *cultural violence*, which refers to a system of values that

reinforces or legitimizes both structural and direct violence. In his causal model, structural, cultural, or direct violence can each generate either of the other two types of violence [14]. Although the conceptualization of structural violence is valuable in emphasizing that, with regards to public health outcomes, many events resulting in physical injury are not the result of direct action by individuals with intent to harm others, the empirical study of violence requires differentiation of the phenomena in order to examine them in a meaningful manner. As noted above, for the purposes of research, interpersonal violence is generally distinguished from collective and self-inflicted violence. Different methodologies have been necessary, with reference to the specificities of each type of violence, particularly with attention to the role of human agency and the intent to cause direct harm to another person.

This heuristic approach, differentiating multiple types of violence in order to study them separately, has created problems for the generalizability of findings. Even within the restricted field of interpersonal violence, studies have been organized according to the characteristics of specific kinds of violence, resulting in groupings that provide useful information regarding each subtype of violence but which are lacking in the consistency needed for a general or unified theory. An unresolved question is whether interpersonal violence indeed constitutes a coherent whole or whether the word "violence" is used to describe disparate phenomena that have distinct causation and risk, even if the outcome, physical injury, is the same [15]. Recent attempts at synthesis suggest that child abuse, adolescent violence, and domestic violence share common risk factors and that the phenomena are interrelated [16].

Studies of assaultive behavior have proceeded by distinguishing *different classes of victims* in order to constitute the phenomenon to be characterized, such as child abuse [17], intimate partner abuse [18, 19], violence toward strangers [20], violence among gang members [21], abuse of the elderly [22], victimization of the mentally ill [23–28], targeted violence toward persons in positions of authority (police or politicians [29]), and sexual offenses, where the victims are children [30, 31], adult women [32, 33], or adult men in the context of prison [34, 35]. Another approach has involved the study of violence according to the *location where it occurs*, for example, at home [36] (domestic or intimate partner violence), at school [37, 38], in prison [39, 40], in the psychiatric hospital on an inpatient unit [41, 42], or in the workplace [19, 43–45]. Other studies have focused on the *identity of the perpetrator* by studying violence committed by specialized populations: severely mentally ill patients [11, 46–49], individuals not mentally ill but who meet criteria for psychopathy (*see* **Psychopathy**), women (*see* **Aggression: Gender Differences in**), children [50], adolescents [51–53], individuals with organic brain disease [54, 55] or low IQ [56, 57], military veterans [58], and substance abusers [59–61].

In addition to the above, features that distinguish types of interpersonal violence include characteristics of the act itself. Violent acts have been distinguished according to whether they are *impulsive* (driven by an immediate emotional reaction) *versus premeditated* (planned through thinking in advance) [62, 63]. Studies have also focused on the *magnitude and frequency* of violent behavior, distinguishing between offenders who engage in acts of serious violence (e.g., characteristics of homicide offenders [64, 65]) and those who repeatedly commit low-magnitude assaults.

Homicide refers to the most extreme and irreversible consequence of violence: the loss of life as a result of physical injury by another (see [66]). Although some studies have characterized differences between spousal homicide offenders and perpetrators of lower-magnitude domestic violence [67], the extent to which homicide should be considered a phenomenon fundamentally distinct from assault remains unclear at this time. Further research is needed to determine the frequency with which homicides are the unintended consequence of assaultive behavior.

Behavioral Manifestations

Aggression can be viewed in terms of gradations of severity, ranging from the inner state of irritation, hostility, or anger, to physical injury of another person, to death, and can be examined through outward manifestations in behavior. In its mildest forms, aggression may be expressed through passive-aggressive behavior (avoidance, subtly hostile comments, and neglectful behavior that interferes with task completion), which is rarely the basis for legal proceedings, unless poor work performance has led to a fitness for duty evaluation. An individual who is experiencing aggressive feelings may be aware of

violent fantasies or intense hatred, or he may not have conscious awareness of hostility at all, expressing these feelings instead through maladaptive forgetting of important meetings, complaining, procrastination, or other indirect means.

Escalation

Overt behavior indicative of escalating aggression includes verbal expression of anger, which may involve threats that are stated in either explicit or implicit form (veiled threats). Physical gestures, such as finger pointing, shouting, pacing, or intrusiveness are relevant indicators of increasing aggression and hostile intent, along with confusion and irritability [41]. Other behavioral manifestations of escalation include obtaining a weapon, handling or moving a weapon [68], and aggressive gestures toward objects, such as pounding a fist on the table or the destruction of property [41]. Preparatory behaviors indicative of aggressive intent for sexual crimes may not appear overtly hostile, since these crimes are often organized by the perpetrator in a surreptitious fashion, involving seduction and "grooming" of the victim, or secretive observation of the victim's daily patterns of movement. Acts of violence may also be sudden, impulsive, and without premonitory signs that the individual is moving towards action with harmful intent.

The Act

Gilligan [13] and Junginger [69] each argue that analysis of the specific characteristics of the act may reveal a dimension of violence as "symbolic language" that serves as a form of communication. In addition, some acts of violence may serve as an escape from meaning or a failure in symbolization that later on, afterwards, leads others to interpret the act, even though at the time, it was an act that was "senseless" or beyond any intent to communicate a message (see [70, 71]). As previously noted, acts of violence can be analyzed according to whether they are predominantly impulsive (driven by an immediate emotional reaction) or premeditated (involving a purpose known in advance). Many instances of violence may remain unknown to public authorities, particularly in the context of domestic disputes.

Responses to the Act

After the immediate management of the aftermath of violent behavior, which includes medical stabilization of vital functions and treatment of injuries, a variety of reactions can be anticipated concerning each of the involved parties. The *perpetrator* of violence may or may not experience extreme distress at his own act. If the victim was a loved one who has suffered serious injury or death, or in the context of apprehension by law enforcement, the perpetrator may experience an elevated risk of suicide in the time following the act (*see* **Suicide (Behavior)**). The perpetrator may also have memory loss for the act itself [72], either due to failure to register the memory [73], in the context of an altered state of consciousness during and after the act ("red out") [73, 74], or he may claim amnesia due to malingering (*see* **Malingering: Forensic Evaluations**). Perpetrators of violence may experience flashbacks and other symptoms of posttraumatic stress [75]. The presence of posttraumatic stress disorder symptoms (*see* **Posttraumatic Stress Disorder**) in perpetrators of serious violence is increasingly recognized among psychiatrists and may be the focus of treatment [76].

Posttraumatic stress disorder has been more extensively recognized in the *victims* of violence. Ongoing, repeated victimization may result in chronic syndromes described in legal proceedings as battered spouse syndrome (*see* **Battered Spouse Syndrome**) or sexual abuse accommodation syndrome (*see* **Child Sexual Abuse Accommodation**). Mental health professionals should be alert to the possibility that participation in legal proceedings may itself induce distress in the victim, beyond that arising from the act of violence. Bystanders or others who were not actually present at the time of the violent act may also experience emotional distress in relation to the act.

Sequelae

In cases that are prosecuted, one major consequence is punishment of the offender, who may serve time in prison, in jail, or be constrained by home arrest or electronic monitoring. Whether or not the offender is prosecuted, victims and close relations of the victim or the perpetrator may experience anticipatory fear of future violence. The violent incident may have a profound impact on the relationships between the victim and perpetrator and with other family

members, resulting in social isolation. On the other hand, in some communities, participation in an act of violence may be valorized by the group, such as in rites of initiation in gangs or organized crime. In these contexts, violence may serve the symbolic purpose of establishing the perpetrator's social identity and his or her claim on valued relationships or property. For the victim, enduring physical disability may cause significant impairment and serve as a constant reminder of past trauma.

Sources of Information on Prevalence

The most comprehensive prevalence data regarding violent behavior is collected by governmental agencies, though each of these has limitations and they use different definitions of violence. The subjective experience of aggression, hostility, and anger is nearly universal, however, and its prevalence is therefore difficult, if not impossible, to measure.

At the international level, the most comprehensive study to date was released by the WHO in 2002 [10]. Although this report demonstrated that the United States has a much higher level of homicide and physical assault when compared with other developed countries, the homicide rate in the United States is substantially lower than in underdeveloped regions, even when deaths due to war are excluded [77].

The CDC in the United States conducted a survey in 1996, the National Violence Against Women Survey, in collaboration with the National Institutes of Justice and the National Center for Injury Prevention and Control, in which 8000 women and 8005 men were interviewed with regards to their fear of and experience of violence [78]. The CDC is currently piloting a new study, the National Intimate Partner and Sexual Violence Survey, to provide national and state estimates of the incidence and prevalence of all forms of intimate partner abuse, sexual violence of all types, and stalking [79]. In addition, the CDC maintains continuous collection of data from 17 states in its National Violent Death Reporting System, which began in 2002 with the aim of combining data from multiple sources in order to provide a comprehensive and detailed picture of the circumstances in which a violent death has occurred, and the relationship of the perpetrator and victim [80].

The Federal Bureau of Investigation (FBI) has maintained crime statistics on homicide, forcible rape, robbery, and aggravated assault since the introduction of its Uniform Crime Report program in 1929 [81]. From these data, the FBI generates a yearly report called *Crime in the United States*, compiled from data from over 94% of US jurisdictions, based on monthly reports from state agencies. The US Bureau of Justice Statistics analyses the FBI data and issues yearly and multi-year reports regarding violent crime [82]. Although most homicides and attempted murders do come to the attention of the legal system, crime statistics based on prosecution and convictions are biased in that numerous acts of lower-magnitude violence are reported neither to the criminal justice system nor to medical facilities. The National Crime Victimization Survey (NCVS) is an ongoing data collection project that addresses this bias in law enforcement statistics [83]. Begun in 1973, it underwent a methodological revision that was completed in 1993 in order to improve the wording of questions particularly regarding sexual assault. In its current form, the NCVS collects data on a yearly basis in interviews of a nationally representative sample of approximately 77 200 households, including approximately 134 000 individuals [84].

Many other countries maintain similar databases. Comprehensive statistics regarding mental illness in the perpetrators and victims of violent crime are more difficult for government sources to obtain in a systematic manner. Prevalence information can also be found in articles referenced above under different categories of victims and offenders, though care should be taken to critically examine differences in the sampling methods and definitions of violence.

Causes

> *What a potent obstacle to civilization aggressiveness must be, if the defence against it can cause as much unhappiness as aggressiveness itself!* [85] p. 143.

Human aggression and its behavioral expression as violence comprise a complex interweaving of biological, individual, interpersonal, and social or environmental factors, which cannot easily be summarized here (see [86]). The person who engages in an act of violence may have some awareness of aggressive thoughts and feelings, but the determinants of a decision to take violent action, rather than to use other

strategies for handling aggression, are challenging to identify with precision.

Elias describes a societal process of decreased acceptability of aggressiveness and identifies the end of the Middle Ages as a time when new mores and social practices resulted in the "repression" of aggressive behavior through education and internalized values [87]. The incursion of this "civilizing process" on biological drives was the source, according to Freud, of many modern neurotic symptoms [85]. Scientific and policy debate in the 1960s and 1970s led scientists to issue the Seville statement [88], which counters the claim that violence is biologically inherent in the human organism.

The empirical study of causation of violence is methodologically complex. Relevant variables associated with violence are numerous and interact with one another [89]. Furthermore, the association of variables with an outcome of violence in a study population does not clearly lead to explanatory power in individual cases: the presence of known risk factors does not prove, in a causal manner, that these risk factors led up to a specific act of violence.

Violence is commonly thought of in association with men, though gender differences in aggression have been overestimated and misunderstood (*see* **Aggression: Gender Differences in**). Although all age groups are affected by violent victimization and offending, individuals between the ages of 20 and 24 have the highest rates of homicide victimization and offending [66]. The impact of exposure to forced institutional settings, such as present or past imprisonment, is not directly assessed in currently available rating instruments. The biological study of aggression at a molecular level in animals and humans has improved knowledge regarding neurotransmitter systems and the genetic contribution to aggressive behavior [90], though the integration and application of this knowledge to treatment in humans is in a rudimentary but promising state at this time [91, 92].

Risk factors are commonly categorized as *static* (related to historical elements of the life story that are unlikely to change) and *dynamic* (modifiable) factors. The HCR-20 [12] includes items such as substance use and major mental illness, which may be assessed according to both static and dynamic components. The use of biographical information and the clinical interview to identify static and dynamic risk factors is an approach that may be called *subjective* in the sense that the risk assessment integrates objectively verifiable data and the individual's own report of his reaction to the environment in a manner that is specific to the person being evaluated. Subjectivity, however, in regards to the individual's emotional experience of and attribution of meaning to his past or current life events and situations is not generally measured within validated assessment instruments, even though it is taken into account in the clinical risk assessment interview and plays a significant role in treatment.

A recent emphasis on dynamic risk rather than on risk status (based on unchanging past features of the person's history) has led to the conceptualization and study of *risk state* as a time-dependent convergence of transient and modifiable risk factors [89]. In their 2005 review, Douglas and Skeem called for theory development and recommended that a theoretical model of the individual's risk state over time include a model of "relational complexities" of risk factors leading up to violent acts. They also recommended that theory development include an account of strategies for reducing violence in persons at elevated risk [89], pp. 367–368. The formulation of an explanatory theory would require the integration of known risk factors into a model of their interrelation, which may vary widely from individual to individual. Case-specific risk factors and configurations of risk based on the person's life history are currently not discernible in statistical models using actuarial methods, as these elements emerge only through detailed study of particular cases and may not rise to a level of generalizable patterns within large populations. Qualitative methods have been useful in addressing this gap, by identifying variables of potential relevance to the person's internal reasoning [93, 94].

Studies outside the field of risk assessment *per se* point to additional factors that may lead to more accurate prediction as well as to a general theory of causation. Barratt and Slaughter [63] propose a "discipline neutral" model which integrates cognitive, biological, behavioral, and "environmental (physical and social)" concepts of the person. This conception includes the idea that the person is defined in part by his social relations, and a sense of belonging or not belonging to a group. One study has indicated that, under experimental conditions, social rejection or exclusion results in decreased "prosocial" behavior, defined as behavior that privileges

collective values over immediate self-interest [95]. Reminders of "connectedness" or social ties may restore prosocial tendencies and reduce aggressiveness after experimentally induced social exclusion [96].

From several different theoretical perspectives, dehumanization has been studied in relation to violence. In particular, the finding that animal cruelty in childhood may be a predictor of future violence [97], especially when motivated by amusement [98], suggests that treating animals as objects of destruction is an index of the person's reduced ability to imagine human qualities in other living beings. Bestiality (sexual assault of animals) may represent an inability to socially relate to human beings and a means of obtaining sexual gratification through aggression, coercion, and manipulation of animals as objects [99]. A lack of empathy or reduced capacity to appreciate the mind of another human being [100] suggests a willingness to harm without appreciating the consequences for others. These latter traits are characteristic of individuals with psychopathy (*see* **Psychopathy**), which has been strongly associated with an increased risk for violence.

Desensitization to and minimization of aggressive behavior, either due to environmental exposure to violence [101] or due to exposure to cultural representations, may be a developmental and dynamic risk factor. Violence in the media includes visual representations of aggression in video games and fictional works as well as in the news and may have an impact analogous to "an environment filled with real violence" [7]. Controversy exists regarding the correlation of violent video games or representations in the media with acts of serious violence [102]. Some studies suggest that there is a process of identification with violent perpetrators when individuals view these scenarios [103]. Although there is solid evidence that viewing violent media produces short-term increases in aggressive behavior (verbal and physical) in children, adolescents, and young adults [7, 104–106], the long-term effects of violent media are difficult to demonstrate, due to intervening factors in the individual's life story and environment [102, 106].

On the basis of extensive clinical observation, Gilligan theorizes that interpersonal violence is largely driven by feelings of shame or of being disrespected and he brings known risk factors to converge upon this common final pathway. He writes, "... it is not poverty, racism, sexism, or age-discrimination, as such, that cause violence. It is, rather, that each correlates with violence because each increases the statistical probability that individuals exposed to these social forces will be subjected to intolerable and potentially self-destroying intensities of shame, from which they do not perceive themselves as having any means of rescuing themselves except by violence..." [107], p. 66. A relationship between pathologies of narcissism (threatened egotism) to violence has begun to be studied empirically. Whereas previous authors had posited that low self-esteem was correlated with violence, Baumeister *et al.* [108] reanalyzed the literature in light of the alternative explanatory hypothesis that self-protective behavior in the face of perceived threat is guided by elevated self-esteem. In a subsequent study, Bushman and Baumeister found that the construct of egotism could be differentiated into stable self-esteem and narcissism, the latter condition being unstable and particularly hostile in response to perceived threat [109]. Perceived threat to egotism has also been associated with aggression in psychopathic individuals [110].

Implicit in this theorization of the stimulus for and mechanism of violent action is that past life events, through their effects on the individual's inner experience, set the stage for interpretation of present experiences, particularly of perceived threat to the individual's sense of self. Lacan wrote in 1948 that there may be a "persistence in the subject of the shadow of 'bad internal objects,' related to some accidental 'association' ... [R]e-evoking certain imaginary *personae* and reproducing certain situational inferiorities may *disconcert* the adult's voluntary functions in the most rigorously predictable way – namely, by their fragmenting impact on the imago involved in the earliest identification" [2], p. 94. Although Lacan's focus is on persons who remind the perpetrator of past experiences of structural inferiority during infancy, the internal mental mechanism he describes is in principle relevant to past situations, such as the recollection of environments where potential violence was the norm. In this regards, given that perpetrators may be sentenced to prison, it is possible that, beyond learned behavior, exposure to incarceration may contribute, by these means, to an increased future risk for violence.

Assessment and Treatment

In clinical settings as well as in sentencing or postsentence release hearings, assessment of risk for violence (*see* e.g., **Dangerousness: Risk of**) is an essential step in individualized treatment planning (*see also* **Psychopathy**; **Psychopathy Checklists**; **Addictions**; **Substance Abuse** and [111]). When violence risk assessment is specifically requested by the court, the examiner often performs both a clinical interview and a standardized assessment using a validated rating scale, since these approaches are complementary. Assessment of risk is an appreciation of likelihood and does not rise to the level of accuracy for prediction *per se*. It allows clinicians and decision makers in the judicial system to determine what interventions are needed to reduce an individual's risk for future violence, on a case-by-case basis [112], whether that risk arises from psychiatric or criminological factors (*see* e.g., **Insanity: Defense**; **Therapeutic Jurisprudence**).

Prevention

> *Power and violence are opposites; where the one rules absolutely, the other is absent. Violence appears where power is in jeopardy, but left to its own course it ends in power's disappearance . . . Violence can destroy power; it is utterly incapable of creating it* [1], p. 56.

Viewed from a public health perspective, prevention may be primary (general measures to prevent the condition from developing), secondary (efforts focused on individuals who are at elevated risk of developing the condition), or tertiary (measures introduced to prevent recurrence in individuals known to have the condition) [107], pp. 20–22+. In the setting of legal proceedings, the latter two types of prevention are of greatest relevance.

In 1969, Ilfeld categorized the prevention of violence into treatments of three main types focusing either on the individual or the environment: (i) redirection of aggression through alternate means of expression; (ii) modification of social learning; and (iii) modification of sources of frustration, such as socioeconomic factors [113]. Significant advances have been made in the past decades in understanding the effective basis for treatment at individual and organizational levels. Institutional and community responses [114], including public information campaigns, have resulted in a decrease in the rate of domestic violence, due to increased reporting and help seeking [115]. One study indicates that employers' awareness of intimate partner violence and the availability of support in the workplace are predictors of a victim's continued employment [43].

Although institutional responses such as mandatory arrest may also have a deterrent effect by indicating to the public that violence is not acceptable, prosecution and intervention programs have not consistently demonstrated a reduction in recidivism of offenders [36]. Data collection and the compilation of accurate statistics using combined emergency room and local police sources allow for improved surveillance and planning for prevention strategies [116]. Further study of risk factors and protective factors that serve as a basis for effective prevention programs in widely different but overlapping types of violence may provide indices for a common theorization of aggressive behavior [101].

Conclusions

Aggression and its behavioral manifestations encompass a wide range of phenomena that cannot at this time be meaningfully studied as a whole. Reductionist approaches have been useful in defining different types of violence in specialized populations of victims, offenders, and locations. At the present time, a unified theory of causation of violent acts is lacking, even when the field of study is limited to interpersonal violence, at the exclusion of war, torture, genocide, poverty, racism, and other forms of collective or structural violence. In principle, the widely varied forms of violence have in common a choice in favor of destruction, whether this destruction is directly intended or intrinsic to the structure of social institutions. The violent individual's subjective point of view as a factor in his choice of behavior remains a relevant topic to explore from a clinical or ethnographic perspective, and has implications for a theory of causation. Although the risk for future violence appears to be strongly associated with environmental factors and static features of the individual's past life experience that are not susceptible to change, the issue of the person's capacity to choose how to express aggressive

feelings and his willingness to change past patterns is an important element to consider in future studies of the possible treatment and prevention of violent behavior.

SUZANNE YANG

Aggression: Gender Differences in

Female aggression traditionally has received little attention in the research literature and has been regarded with a certain degree of skepticism by the public and professionals alike. In the past three decades, however, the precipitants and purpose of female aggression and the profiles of girls and women who commit aggressive, violent, and criminal acts have increasingly attracted the attention of researchers, criminal justice, mental health professionals, advocates, and policy makers. The field is beginning to flourish with a small number of longitudinal and large-scale examinations of sex differences and similarities in antisocial behavior and aggression [1–5].

In addition, the importance of examining female aggression separately from male aggression and using that data to inform policies and practice is increasing, and now appears to be well-recognized in developed nations worldwide [6]. This relatively abrupt turnaround reflects increasing numbers of girls and women being charged, arrested, and incarcerated for violent crimes. In addition, research demonstrates that in certain contexts (e.g., romantic relationships and parent–child relationships) and in highly specific populations and settings (e.g., inpatient psychiatric patients) the gender gap in the perpetration of aggressive actions is largely reduced or entirely absent. These circumstances require scholars and practitioners to evaluate the extent to which our understanding of female aggression reflects substantiated research findings *versus* unsubstantiated generalizations and stereotypes.

This article operationalizes aggression and violence (*see also* **Aggression**) and reports the prevalence and incidence of aggression among females; documents sex differences and similarities in aggressive and violent behavior; critically examines the assertion that risk and protective factors are sex-specific, briefly explores clinical implications for prevention and intervention, and closes with reflections on gaps in knowledge and directions for future research.

Prevalence and Incidence of Aggression among Females

There is virtually universal agreement that males are more aggressive than females. Across age categories, regardless of the data source (i.e., self-report, family/collateral reports, official records, and victimization surveys), males outnumber females in the perpetration of physical and sexual aggression, violence, and crime. However, methodological advances (e.g., data collection strategies and sources) to studying aggression and more inclusive definitions of aggression have revealed comparable rates across the two genders for some types of aggression and/or in discrete settings and populations. Given the importance of developmental milestones in understanding human behavior, in terms of diagnostic categories (e.g., diagnostic and statistical manual of mental disorders (DSM-IV)-TR, [7]) and with regard to prevention and intervention in the criminal justice system, we present the prevalence and incidence of aggression among females separately for female youth and adult women.

Operationalizing Aggression

Although there remains little agreement in the literature regarding how best to operationalize aggressive and violent actions, increasing clarity has been achieved as a result of important studies such as the MacArthur violence risk assessment study [4]. Building on prior definitions [8] and psychometrically advanced measures (Conflict Tactics Scale, [9]), the MacArthur study operationalized "physical aggression" as laying one's hands on another with the intention to cause physical harm. In contrast, "violence" was defined as actions that result in injury, sexual assaults, or verbal threats of physical aggression with a weapon in hand [4]. "Relational aggression" refers to interpersonal interactions and verbal exchanges intended to harm others through social exclusion and public humiliation [10]. Finally, "verbal aggression" includes threats, ridiculing, name-calling, and

shouting. Although imperfect, with these definitions in mind, we can explore the question: how common is female aggression?

Female Youth

Boys perpetrate approximately three times as many violent acts as girls. Girls are also less likely to report carrying a weapon and tend to engage in violent acts at a lower frequency than their male counterparts [3, 11, 12]. Nonetheless, multiple sources of data consistently show increased rates of violence among girls. In the United States, between 1988 and 1998, person-related offenses increased at more than twice the rate among adolescent females (157%) than among adolescent males (71%; [13]) and between 1993 and 2002, arrests for aggravated assault decreased 29% for boys but increased 7% for girls. Canadian statistics show comparable trends: between 1988 and 1998, the violent crime rate more than doubled for girls (+127%) compared to a smaller increase for boys (+65%; [14]). Furthermore, between 1996 and 2002, when a small decrease was noted in the rate of violent crime committed by boys, a modest increase was observed for girls [15].

Outside North America, the picture is much the same: in the United Kingdom, between 1981 and 1999, there was a 23% decrease in juvenile male offenders and an 8% increase in female offenders, although in 1999 males still outnumbered females by 3 : 1–4 : 1 [16]. Similar trends are evident in epidemiological studies. According to the US Surgeon General's report [17], between 1993 and 1998, the gap between adolescent girls' and boys' self-reported engagement in violent acts shrunk by approximately 50%. Turning to relational aggression, research shows that girls engage in at least equal or higher levels of relational aggression than do boys [18].

Relational aggression can be reliably detected as early as preschool and children who engage in it are more likely to suffer rejection from their peers and are more likely to affiliate with deviant peers who also engage in relational aggression [19, 20]. Rates of relational aggression increase during elementary school for girls but not boys [21], possibly reflecting sex differences in the complexity and psychological relevance of relational contexts. The fact that social aggression can have social "payoffs" for some girls has garnered support from recent studies. For example, Cillessen and Mayeux [22] found that young adolescents who were relationally aggressive to others held high social prominence, although they were not well-liked by their peers. This was particularly true for girls. Girls also experience relational aggression as more distressing and harmful than do boys [20].

Adult Women

Official criminal data and incarceration rates confirm that within the general population, men are considerably more aggressive than women and come into conflict with the law with much greater frequency. In North America, men vastly outnumber women in correctional settings. Early in 2006, there were 408 women federally incarcerated in Canada [23] compared with 12 263 men. Although the actual number of women admitted to federal institutions increased from 238 to 276 between 2004–2005 and 2005–2006, women constitute a very small proportion (5.8% in 2005–2006) of all federal admissions. The gender disparity in incarceration is most apparent for violent offenses (homicides, sexual offenses, and other violent crimes (men = 96.5%; women = 3.5%).

In the United Kingdom, the total prison population is comprised of 6.1% women, 17% of whom were incarcerated for violent offenses [24]. In the United States, a country with one of the highest incarceration rates in the world, females comprised just 7% of the total prison population in 2005 [25]. In other words, males were 14 times more likely than females to be incarcerated, relative to the general population. The gender breakdown for violent offenders, in particular, is slightly higher in the United States relative to Canada and the United Kingdom (4.4% female, 95.6% male). Thus, the picture that emerges from a consideration of official criminal justice data sources clearly demonstrates a vast disparity in criminal offending by gender of perpetrator, that is even greater for when one considers violent offenses.

We find that although women are markedly underrepresented in criminal courts and criminal justice settings, female aggression is *not* uncommon. That is, the gender disparity in aggressive behavior noted in the general population does not appear to be evident among individuals with mental illness [2] nor when one examines aggression that occurs within romantic and familial relationships [26, 27]. Among civil psychiatric patients [28] and forensic psychiatric patients (Nicholls, Brink, Greaves, Lussier, and Verdun-Jones,

in press) women match, and sometimes exceed, men in the prevalence and incidence of aggression. Similarly, it has long been recognized that women perpetrate as much as 50% of aggression within familial and intimate relationships (i.e., child abuse, elder abuse, and partner abuse) [29, 30].

Is Female Aggression Increasing?

Between 1980 and 2001 the proportion of females incarcerated in the United States nearly doubled (4–7%, respectively) [31]. The US Department of Justice, Bureau of Justice Statistics reported that the number of women under the jurisdiction of State or Federal prison authorities increased 4.5% from year end 2005, reaching 112 498, and the number of men rose 2.7%, totaling 1 458 363 [32]. The increase in female contact with the US criminal justice system is particularly remarkable given that the number of serious violent offenses committed by persons ages 12–17 declined 61% from 1993 to 2005, while those committed by persons older than 17 fell 58% (see [32]). In Canada, the rate of "serious violent crime" committed by adult women increased from 25 to 46 per 100 000 between 1986 and 2005 [6]. Similarly, as noted above, the rate has more than doubled among female youth since 1986, growing from 60 per 100 000 to 132 by 2005 [6].

Despite claims that female offending is rapidly escalating, any increase should be understood in relation to the low base rate of violent crime among women. It is also noteworthy that the rate at which female youth have been charged with serious violent crimes has been on a slow downward trend since 2001. Comparisons between females and males for the same offenses and over the same period of time provide a clearer picture of trends. Between 1986 and 2005, with the exception of a few downturns over the years, the rate at which women were charged with assault level 1 (simple assault) more than doubled (44–93 per 100 000 population). In comparison, the rates among male adults have shifted downward since the early 1990s. Between 1991 and 2005, the charge rate for male adults for serious violent crime dropped 30% (412–290 per 100 000). From 1993 to 2005, the charge rate for assault level one for male adults fell 25% (from 606 to 455 per 100 000 population). These data confirm the narrowing gap between adult females and males charged with violent crime: in 1986, nine men were charged with a violent offence for every one woman charged. In 2005, this ratio had decreased substantially from five to one. These statistics raise two important questions: what accounts for decreasing male aggression and what contributes to female aggression increasing in both the United States [32] and Canada [6] despite the fact that the rate of violent crime is dropping?

It is clear from the accumulation of knowledge to date that the "myth of female passivity" [33] is not borne out of the extant empirical data. Knowledge of these base rates is essential, particularly for informing violence risk assessments and public funding decisions; for instance, but an appreciation of the nature of female aggression, what motivates females to aggress against others, and the consequences of those actions is likely to drive treatment and intervention policy, research, and clinical efforts.

Exploring the Topography of Female Aggression: Sex Differences and Similarities in Aggressive and Violent Behavior

Recent research shows a slow but progressive trend in developing research objectives and methodologies to better understand the contexts, functions, targets, and implications of women's aggression. Moving beyond the question of how often females are aggressive relative to males, research now compares and contrasts the topography in which male and female aggression occurs [34]. An appreciation of the contexts in which aggression occurs and the purposes it serves for females helps us understand, prevent, and reduce the risk of female aggression.

Form and Function

Topographical similarities in aggressive acts may serve to mask gender differences, thereby obscuring the underlying motivations and mechanisms involved in females' use of aggression and exaggerating similarities in the potential risk posed to victims. Trends have been evidenced in research, which reveal both gendered and nongendered forms and functions of aggression. Emerging findings continue to indicate similarities (e.g., perpetration of any assaultive act, instigation, and injury incurred, [35]; nature and

location, Nicholls *et al.*, under review), in addition to a substantial amount of divergence (e.g., use of very severe forms of violence, [35]), between male and female aggression.

Form – What is the Nature of Female Aggression?. Self-report surveys and victimization reports generally confirm what we see in the official criminal justice and corrections databases reviewed above; violent crimes remain disproportionately low in women and, that is particularly true of certain forms of interpersonal offending. Data from the United States indicates that, as reported by victims, females account for only 1 out of 7 violent offenders. Further, 1 in 50 offenders committing a violent sex offense (including rape and sexual assault) were women; one in 14 robbers were women; 1 in 9 aggravated assault perpetrators were women; as were approximately 1 in 6 offenders who committed a simple assault [32]. Corresponding Canadian figures for those convicted in 2003–2004 indicate that women accounted for approximately 1 in 99 sexual offenders, 1 in 12 robbers, 1 in 6 offenders committing a major assault, and 1 in 7 who committed a common assault [6]. Charges for murder or manslaughter are rare, regardless of gender (in 1991, 48 charges were laid against women, and 486 against men).

Overall, women's violent criminal charges are primarily for common assault [6]. Fewer are brought about by the commission of robbery, and sexual forms of aggression by women are an exceedingly rare occurrence [36], a pattern that is similar in both Canada and the United States [37, 38]. As with sexual offenders, females engaging in stalking behaviors are relatively rare as compared to their male counterparts (accounting for 15–20% of those who perpetrate stalking offenses, with one in five ultimately attacking the victim; [39]), their occurrence may be a function of stalking as a variant of domestic violence (see [40]). It is important to note that when women are aggressive their assaults occupy the entire continuum of aggression. To clarify, women commit both minor (e.g., verbal aggression) and severe forms of aggression (e.g., kicking, beating, choking, and using weapons), particularly within intimate relationships and against family members (see [41, 42]). In fact, when there is reciprocal aggression (i.e., both partners are abusive) or when only one partner is abusive it is most likely to be the woman who uses severe aggression (see [41, 42]; see [26, 29] for reviews).

Setting and Targets – Where Does Female Aggression Occur and Who Do Females Aggress Against?. As compared with men's aggressive acts, women's expressions of aggression are more likely to occur in the private (e.g., the perpetrator's home) *versus* the public (e.g., bars) domain; a finding that holds in data gathered from psychiatric patient samples [35, 43] and is highly consistent with the disproportionate amount of women's aggression that involves domestic violence, child abuse, and elder abuse. Similar to data from other sources on female aggression, female-perpetrated homicide data suggests that women are less likely than males to aggress against strangers (3% of victims killed by women *vs*. 14% killed by men) or casual acquaintances (13% *vs*. 21%, respectively) than men. The relational aspect of female aggression, however, is perhaps most evident across forms of aggression involving abuse of others who are intimate (or perceived intimate).

Differences across gender are readily apparent when considering perpetrator-victim relationship in instances of homicide. In 1994, Statistics Canada reported that 71% of Canadian women charged with homicide were related "domestically" to their victim, whereas this was true among only 24% of their male counterparts. Indeed, in general, the most common target of women's aggressive acts is the current or previous spouse or common-law partner (30%). Further, in the context of domestic violence, women often report themselves to be either the primary [44] or sole aggressor against their nonviolent partners [42, 45]. Another frequent target is the woman's child (28% of violent convictions in the United States [6]; 10.4% of females convicted of murder in Canada killed their child/stepchild, [46]). Between 1976 and 1997 in the United States, parents and stepparents killed nearly 11 000 children. Mothers and stepmothers perpetrated about half those child killings [46].

According to the Canadian Centre for Justice Statistics, females (3%) and males (15%) are both unlikely to have more than one victim of a homicide [6]. Child maltreatment studies have long identified mothers perpetrating abuse to a comparable extent as fathers [41, 47]. Sexual abuse as a form of women's aggression has only recently been examined as perpetrated against adults [48] and in its more prevalent form, against children [49] (for a review see [36]). Consistent with other forms of female aggression, it is also the case that women more often

than men sexually offend against those to whom they provide care (their own offspring or other related children, children they baby-sit or educate [50]).

Function – What Motivates Female Aggression?. An appreciation of why women use aggression and to what extent women's aggression has similar or unique roots to men's aggression is an essential means of developing theoretical explanations and informing prevention and intervention strategies. Felson [51] asserted that there are principally three reasons that people perpetrate aggression: (i) to obtain compliance or control the target; (ii) to attain retribution or justice; and (iii) to promote or defend their self-image.[a] A fourth motive, self-defense is a predominant theme in much of the debate about women's involvement in intimate abuse. In a comprehensive review of the literature, Graham-Kevan [52] found that, in the context of intimate relationships, there are no consistent sex differences in the use of controlling behaviors. Even in samples selected for high rates of physical aggression, she noted that women sometimes use controlling behaviors with similar frequency men. A consideration of the empirical data suggests that men and women do not differ in their desire to control their partners though they may use different methods to achieve control (for reviews, see [52, 53]).

Both men and women experience jealousy, frustration, and disappointment in relationships; thus, efforts to save face are not unique to men and it is not surprising that women are motivated to use aggression for retribution just as are men. Empirical work in the area details both similar and divergent motivations cited by domestically aggressive women themselves. Women often report using aggression against their partners for purposes that are similar to those of men who perpetrate partner violence, that is, a desire to control or punish their partners, to get their attention, as a response to partner emotional abuse, and to express anger [54]. Yet a number of other studies do cite women's additional motivations of self-defense or retaliation [55, 56], which some feminist scholars argue are not common motivations among males but in fact are frequently cited by men and women [57, 58]. For instance, Follingstad *et al.* [54] found that women were significantly more likely to report using physical force in retaliation for emotional hurt (55.9% *vs.* 25.0%; $\chi^2 = 13.11$, $p < 0.0001$) and men were more likely to report using physical force in response to being hit first (29.2% *vs.* 13.6%; $\chi^2 = 5.61$, $p < 0.05$) whereas men were more likely to report jealousy (41.7%) as a motivator than women (8.5%) ($\chi^2 = 29.62$, $p < 0.0001$).

It is also noteworthy that there was no difference in the likelihood that men and women used aggression to "punish the person for wrong behavior" (12.5 *vs.* 16.9%). Contrary to widely held conceptions [59], the notion that women are aggressive against partners primarily in self-defense has not withstood empirical scrutiny [54]. Briefly, women are known to initiate physical assaults, aggress against nonabusive partners, and as few as 10–20% of women report using physical aggression to defend themselves (for a discussion, see [26]). In fact, the varied motivational influences reported to account for female aggression against intimate partners and stalking victims tend to relate to dysfunctional expressions of anger, loneliness, and frustration; and to that of power and anger, very similar to their male counterparts [60, 61]. In the particular case of female stalkers, rage at abandonment and perceived betrayal are most often driven by the desire to establish intimacy with their targets [39].

Among Canadian female homicide offenders, the most common motives cited were escalation of an argument (39%) and frustration (22%) [6]. In only 11% of the cases did women cite revenge, jealousy, or resolving accounts as their motive, compared to 27% cited by male homicide offenders [6]. Laboratory research has also offered considerable insight into female aggression, demonstrating the circumstances under which females aggress [33, 62] and challenging traditional conceptions of females. Briefly, studies suggest that many of the same contexts and circumstances that promote male aggression are also found to increase the likelihood that females will aggress (e.g., emotional arousal, rumination).

Summary. In sum, women are unlikely to commit certain forms of aggression (e.g., robbery, sexual assault, and physical attacks against strangers) but they are equally represented among perpetrators of physical violence in North American family homes and there is increasing evidence that this finding is consistent in other developed nations [42]. Overall, the general trends concerning the form (i.e., interpersonal/familial based), location (i.e., outside the public domain), and target (e.g., family members) of female aggression are likely contributors to underreporting, lower arrest rates for females perpetrating violence,

and a persistent perception of lower severity. It is important to note here that both men and women view female aggression as less severe than that perpetrated by males. Although it is essential not to lose sight of the fact that women suffer more harm as a result of domestic violence, it may be the expectation of less harm and injury that is fueling increasing rates of female aggression, and thus allows females to justify and minimize the impact of their aggressive behaviors. Moreover, we need to always be mindful of the implications of female aggression (and male aggression) for child witnesses to partner abuse and direct child abuse [63, 64].

Outcomes and Implications – How Serious Is Female Aggression?

Aggression is known to have deleterious implications for victims and witnesses that include physical, psychological, emotional, and financial harm (e.g., physical injuries, fear, shame, and posttraumatic stress disorder). Now that there is considerable agreement that the frequency of aggression in women may be on par with men in certain populations (e.g., hospitalized mentally ill patients) or contexts (i.e., within romantic and familial relationships), the debate has shifted to a consideration of whether the consequences of female aggression are on par with the consequences suffered as a result of male aggression. Most scholars agree that female aggression is at least somewhat less likely to result in injury than male aggression. As we have done throughout the manuscript, we focus here on family violence and inpatient aggression, because those are areas of our expertise and there is an abundance of data on the topic. Finally, we end this section by comparing and contrasting the severity of male and female offending as demonstrated by criminal justice statistics on injuries and weapon use.

Several studies have found that, compared to men, women sustain more severe injuries as a result of partner abuse [58, 65]. In a meta-analysis of domestic violence research, Archer [66] reported that women were more likely than men to be injured by a partner and men were more likely than women to inflict an injury. Perhaps given physical differences in size and strength it seems to reason that men would be more likely to injure their targets; however, women often even the playing field with weapons or attack their partners when they are defenseless (e.g., sleeping; [26]). On the basis of their review of the literature, Noller and Robillard [67] concluded that several studies show that women commit a larger share of severe violence. Nonetheless, some studies find sex differences in the reaction of victims confronted with male *versus* female perpetrators [68]: some male victims of female aggression reportedly find the abuse "humorous"[b] whereas female victims of male aggression do not report such a response [69]. Ultimately, however, it is essential to evaluate harm on a case-by-case basis; it is the extent of exposure to trauma, not gender that predicts the long-term emotional implications of aggression [70, 71].

When evidence of the correspondence between inpatient aggression among male and female psychiatric patients became available, critics argued that the findings failed to address the severity of women's aggression and the likelihood that women would cause serious injury [35]. Increasingly, however, research is demonstrating that while it is certainly the case that the victim of a male perpetrator faces a greater risk of harm than the victim of a female perpetrator, that discrepancy is small (Nicholls *et al.*, under review). Conversely, in some circumstances female aggression may have more severe consequences than male aggression, at least in part, as a function of the relationship with the victim. For instance, maternal aggression results in severe consequences to children that are unique from the implications of paternal aggression. Maternal aggression may have particularly salient influences because mothers are the primary attachment figure throughout the lifespan and mothers spend more time interacting with their children [64]. It should be noted, however, that there is considerable between-victim variability in this regard, and furthermore, the majority of children from violent homes (35%–45%) do not experience clinically significant outcomes [63]. Finally, there is a likelihood of early parenthood, and a negative implication of maladaptive parenting. These features are not completely unique to females, but are of greater consideration given that most single parent households continue to be headed by women [72].

Criminal justice statistics evaluate the level of injury sustained by victims and the use of weapons as indicators of the seriousness of violent crimes. Statistics show that compared to males, females rarely commit violent crimes, but when they do they are just as likely to injure their victim and to use weapons [6]. Just over half of victims sustained no injury from either female or male perpetrated violence (51 and

54%, respectively), minor injury requiring no professional medical treatment was less frequent (43 and 38%) and a small minority resulted in major injury requiring professional treatment or death (2 and 4%; [6]).

In closing, it is important to be mindful that there is considerable evidence that the gap between the suffering experienced by male and female victims of aggression has historically been exaggerated because of methodological limitations and political agendas [26, 27, 29, 33, 73] further research in this area is required. The field is still relatively new and emerging methodological sophistication (e.g., prospective longitudinal examinations including mental health and physical injury outcomes) enhances our full understanding of the different consequences of male and female aggression [69].

Understanding Female Aggression

Are Risk Factors for Aggression Sex-Specific?

Considerable discussion in the literature has revolved around the extent to which common or unique risk factors underlie aggression in males and females. Despite sound rationale for the importance of gender-sensitivity, few efforts have been made to study empirically whether the predictors and moderators of aggression are sex-specific. Similarly, in the development of risk assessment instruments and other forensic assessment measures (e.g., psychopathy measures) it has been rare for them to incorporate theoretical evidence of sex differences and similarities in the variables of relevance. In addition to an insufficient amount of research, an examination of the extant literature suggests that the findings to date have been equivocal; thus, we examine (i) the extent to which risk factors operate in a similar way, increasing the likelihood of aggression in both males and females; (ii) the differential influence of the same risk factors as a function of gender (i.e., being more influential in one gender than the other); and (iii) gender-specific risk factors (i.e., increasing risk in males or females, but not in both; having the opposite effect, increasing risk for aggression in one and decreasing risk in the other).

Many Commonalities. Not surprisingly, many of the factors that leave males vulnerable to committing aggressive behavior also increase the risk of aggression among females. There is considerable evidence that static risk factors (i.e., unchangeable variables such as a diagnosed serious mental illness, a history of child abuse, etc.) as well as dynamic risk factors (i.e., changeable predictors that are potentially influenced by treatment and interventions, such as substance abuse, anger, impulsivity, and poor social support) are relevant across populations and settings (e.g., mentally disordered and nondisordered offenders; correctional inmates, civil psychiatric patients, and forensic psychiatric patients). Thus, it stands to reason that risk factors known to be relevant to male aggression are potentially relevant to female aggression (see [28, 74–76]).

On the rare occasions that scholars have made efforts to develop gender-informed assessment measures from the ground up (e.g., [77]; service planning instrument SPIN) the result has been a remarkable degree of overlap in the variables found in measures previously developed for males. For instance, Blanchette and Taylor [77] examined 176 variables identified as theoretically, empirically, or operationally relevant to security classifications of women in correctional settings. The result was a measure composed of nine variables – all but one of which was common to classification measures developed for men. The authors concluded that despite the attempt to develop a gender-informed measure their results suggest there is little evidence for gender-specific variables; however, they caution that "the order of relevance and weighting of predictive items might differ by gender" (p. 376). Blanchette and Taylor went on to note that evidence of considerable overlap in risk factors for male and female offending is highly consistent with well-established theory [78] and prior research in the field of corrections [79, 80].

Another approach to addressing the question of the extent to which risk factors have a common influence over male and female aggression has been to study the psychometric properties of existing measures constructed based on research with males and test their applicability to populations of females. These efforts have yielded revealing, though generally inconsistent, results. Some studies have found predictive accuracy of existing measures result in similar or better predictive capacity with females [28, 81–84] while other studies have found small or moderate and often insignificant associations with women's aggression [85–87] (for a review of violence risk assessment with women see [88].

In their longitudinal study of a birth cohort (ages 3–21) Moffitt *et al.* [3] concluded that the same risk factors predict antisocial behavior in both males and females (also see [1]). Although they did *not* find any evidence of "replicable sex-specific risk factors" the authors did note that family adversity, compromised intelligence, difficult temperament, and hyperactivity had somewhat stronger effects on males than females. They caution, however, that the sex differences are small and "at best, offer only weak support to the hypothesis that males are more vulnerable than females to risk factors for antisocial behavior" [[3], p. 108]. Given these findings it is important to consider to what extent the same risk factors have a unique bearing on the expression of aggression in males *versus* females.

The Differential Influence of Similar Variables. While there appears to be considerable symmetry in male and female risk markers for violence, evidence also exists for potential differential influences by a number of those shared variables. One particularly noteworthy domain is exposure to elements often present in dysfunctional families of origin. Findings suggest that child abuse and witnessing domestic violence may be more influential in the development of aggression among girls than it is among boys. Differential outcomes are evidenced when the nature of the abuse and the perpetrator gender are taken into consideration as a function of the gender of the victim. For instance, some evidence suggests that childhood maltreatment in the form of sexual abuse may be a risk factor that is especially important in the emergence of girls' antisocial behavior [89, 90]. Further, experiencing childhood abuse at the hands of ones' mother has been found to be a powerful predictor of relationship violence [91], as has childhood abuse perpetrated by ones' father, which appears to explain more of the statistical variance among females than males [64, 92].

There is still reason to expect a greater likelihood of previously victimized women employing violent strategies in their own intimate relationships, as witnessing parental aggression has predicted women's subsequent use of verbal and physical aggression toward their partner [90]. These findings have been replicated and further refined through more recent research, albeit utilizing a similar sample. Explaining an astounding 51% of the variance in violence, women reported perpetrating more violent acts toward their partners if they had seen their mothers aggress against their fathers [91]. That various gender differences have been evidenced with regard to the impact of witnessing domestic violence, for instance, suggest refinement of the current blanket conceptualization as applied across gender.

Evidence from epidemiological studies [93], population-based research [2, 5, 94] and many patient-based studies (see for citations and brief discussions, [28, 93]) call into question the extent to which the gender gap in aggression witnessed in the general population is reflected among individuals with serious mental illness. Mental disorder, a robust predictor of violence, may have a differential association with the likelihood of aggression among females, although the findings to date are equivocal [93]. Swanson *et al.* [5] assessed the prevalence of self-reported violence over one year in community participants. The authors found that among persons with no mental disorder, violence was much more common among males. The gender difference was substantially reduced among mentally ill individuals. Hodgins [2] reported similar findings through an examination of mental disorder and intellectual disabilities in a Swedish birth cohort. She found that these risk factors had a substantial and differential impact on the risk of crime and violence among females. Specifically, Hodgins [2] reported that women who had a serious mental illness or intellectual handicap were five times more likely to commit a criminal offence than women without those characteristics. Particularly notable for the present discussion, that was twice the increased risk reported for men for the same variables.

When specific aspects of mental disorder have been considered, differences are again evident in the expression of violence; for instance, the presence of positive psychotic symptoms has been found to be more prominently associated with physical violence in women than in men [95], although the reason for these differences remains unspecified. Substance abuse as a contributing factor in violence perpetration is more prevalent, and relates more strongly with physical assault in men than in women [95]. Among homicide perpetrators, 71% of males and 65% of females were reportedly under the influence of drugs and/or alcohol during the commission of the offence [6]. Gender differences in substance use-related aggression are further evident when the type of drug is separated in further analysis [96]. Together,

these findings suggest the differential impact of certain clinical and psychosocial factors on subsequent aggression, and emphasize the need to "drill down" past only the first level of factors under investigation.

Socialization and the influence of societal norms and values may have a unique influence on the likelihood of aggression in females as well, protecting females by promoting prosocial behavior, the development of empathy, and an appreciation of caregiving. Conversely, our gender-role socialization of males may actually promote subsequent displays of aggression through rewarding competitiveness and machismo. In general, the influence of protective factors has been overlooked in much of the literature [97, 98] this seems to be no less true of females [82].

Gender-Specific Variables. Reflecting the limited body of evidence to inform this field, it remains unknown to what extent there may be risk variables or protective variables that are unique to the risk of aggression for one gender or the other. For instance, precocious pubertal development and having a mature and/or sexualized physical appearance may present a sex-specific risk for girls entering into aggressive and antisocial behavior [3]. There is also some evidence from the general population and particularly from the sexual offending literature, [36] that antisocial male partners may play an important role in some female aggression. Official criminal statistics offer some support to this hypothesis, demonstrating that women committing violent offenses are more likely to have done so in partnership with a male than are male violent offenders to have committed violent offenses in partnership with a female.

Logan's [36] review of the sexual offending literature reminds us that women do commit serious offenses independently of males and a small but robust proportion of women's involvement in aggression may reflect the influence of antisocial men (the reverse is likely also true). Though the impact of antisocial peers and negative relationships is hardly unique to females, the role of antisocial male partners, (perhaps particularly older men) may be a unique predictor of adolescent girls' involvement in aggression. There is some evidence for this in the expression of antisocial and aggressive behaviors emerging later in girls, typically in adolescence, around the time that same-sex socialization gives way to increasing mixed gender socialization and sexuality. Moreover, criminologists have suggested that being in a romantic relationship with a woman generally inhibits antisocial behaviors in males [99]. Not surprisingly, though, antisocial males and females selectively mate (assortative mating), likely escalating the risk of aggression in both partners, as well as the risk of an intergenerational transmission of aggression to offspring.

In what appears to be the most comprehensive examination of empirical data on the etiology of physical violence by male and female dating partners, Medeiros and Straus [57] asserted that most of what has been written about the causes and motives for women's aggression has been based on writers' assumptions, in the absence of empirical evidence. Based on their extensive review of the literature Medeiros and Straus [57] found four types of studies they categorized by the type of data reported: (i) seven studies evaluated 25 variables and the statistical relationships between motive and gender; 72% of the relationships analyzed demonstrated no significant gender difference. (ii) The second type of study compared violent men and women on 56 characteristics (e.g., educational attainment, measures of anger, etc.) and demonstrated that in 73% of comparisons no significant difference was found. (iii) The third category also examined violent men and women but did not test significance; therefore, they categorized gender differences that were 20% or more as a gender difference. According to that threshold, they concluded that 43% of variables were similar for men and women (28 variables in six studies). (iv) Finally, the fourth category included studies that examined risk factors for partner assault separately for men and women but did not test for significant differences.

In 23 studies, reporting results in relation to 147 risk factors, 60% of variables showed the same relationships for men and women, 39% showed the direction of the relationship to the risk factor was the same for men and women but was significant in one but not the other, and 1% of variables showed opposite relationships in men and women (one positive and significant, the other negative and significant). The authors interpreted these findings to mean that of the risk factors considered there was a similar etiological pattern for men and women for 60% of the risk factors examined, or that 99% of the studies showed the effect of the variable was in the same direction for men and women [57].

Much work remains to parse out the underlying mechanisms by which female aggression emerges. These disparate findings highlight the need for gender-sensitivity when considering female aggression. Although further study is necessary, the research to date seems to suggest that many of the same clinical, psychosocial, and environmental risk factors pertain to males and females, however, there is some evidence that the clinical and psychosocial factors that are associated with increased risk for aggression have a different impact on males and females [3, 95]. As Crick [100] speculated, nonnormative forms of aggression (i.e., overt aggression and physical violence) may reflect maladjustment more than gender normative forms of aggression (i.e., relational aggression and verbal aggression). The as yet unresolved question remains whether gender-specific models of aggression are necessary to explain female, as separate from male, perpetrated aggression. Further methodologically sound exploration into disparities and overlap concerning the roots of female aggression may definitively direct us to adopting extant male models, or alternatively, to considering female aggression as a separate phenomenon.

The Developmental Trajectory

Until recently, research on aggression and violence in childhood and adolescence was based on the assumption that aggressive behavior increased from childhood to adolescence, often as a result of exposure to various risk factors. New work on developmental trajectories reveals a different picture: first, aggressive acts such as hitting and biting are *sometimes* present in over 40% of two-year old boys and almost 35% of girls, and are *frequently* present in 5% of boys and 1% of girls [101]. After age 2, aggressive behavior tapers off quickly, and by age 11 only 10–15% of boys and girls *sometimes* engage in aggressive acts and fewer than 5% do so *frequently* [102]. From age 6 to 16, further desistance is noted for the vast majority of children; however, 4% of boys continue to be aggressive [103]. While girls also show drops in physical aggression with age, girls but not boys increase their use of relational aggression during primary school [21]. Together these findings show that most children learn to inhibit aggression very early in childhood, however a small proportion of boys and girls are not taught or do not learn how to desist, and girls in general begin to use greater amounts of relational aggression.

The failure to desist in childhood aggression, and to acquire new aggressive behavior early in childhood, is a clear marker for future pathology. Approximately 95% of boys who show severe aggressive behavior early in development (i.e., prior to age 10) continue to show antisocial and aggressive behavior into adolescence and adulthood, thereby lending credence to the distinction between early-onset life-course persistent (LCP) *versus* adolescent limited (AL) conduct disorder [104–106]. Moffitt *et al.* [3] asserted that the LCP *versus* AL taxonomy applies equally well to males and females, however the rate of early-onset *versus* adolescent-onset cases is extremely low among females. For example, only 6 of the approximately 450 females (1.3%) from the Dunedin Longitudinal Study were identified as life-course offenders, whereas 78 (17%) were identified as adolescent-onset. Consistent with this finding, the gender gap in rates of conduct disorder is greater in childhood than in adolescence (for reviews see [3, 107, 108]).

The fact that adolescent-onset aggression is more common in girls than is childhood-onset has led some to question the validity of this distinction in girls [104, 109]. Silverthorn and Frick [109] proposed that the delayed-onset pattern in girls is comparable to the early-onset pattern in boys in terms of risk markers, stability, and persistence to adulthood. They present findings that show adolescent-onset girls resemble early-onset boys on a range of risk factors [109], and they are more likely to suffer from a multitude of mental health problems in adulthood, including substance dependence, poor physical health, involvement in abusive relationships, antisocial personality disorder, and social welfare dependence [3, 109–111]. However, Moffitt and Caspi [112] proposed that the same model applies to the development of antisocial behavior in girls and boys, and that the delayed onset in girls simply reflects the slower rate of accumulated risk factors for girls. In particular, the higher prevalence of neurocognitive and temperamental risk markers in boys than girls exerts a significant impact on early development and results in boys reaching a threshold of risk for antisocial behavior more quickly than do girls [112]. Yet, whether or not risk factors operate similarly for girls and boys is unclear. Moffitt and Caspi [112] assume a linear and additive model of risk; however, consideration of other

models is warranted. Some risk factors may have gender-specific impacts, or may interact with other risk factors in a gender-specific way [113]. There is simply too little research to conclude that the risk models developed primarily on boys are accurate in predicting onset and developmental course in girls.

Conclusions: Implications, Gaps in Knowledge, and Future Directions

Female aggression remains a topic fraught with controversy and heated debate. Despite widespread consensus of large gender disparities in the amount and consequence of aggression committed by males *versus* females, we recommend exercising caution in the wholesale acceptance of "well-established" knowledge for which there is little or equivocal empirical evidence. Aggression is complex [114] and no one variable, including gender is a sufficient explanation for why one person is aggressive and another is not [115]. The lens through which society has traditionally examined female aggression has been colored largely by our knowledge of women's engagement in criminal violence that comes to the attention of the criminal justice system. As we have reviewed here, the picture that emerges from a consideration of arrest and incarceration data clearly confirms a vast disparity in violent criminal offending by males *versus* females.

For this reason, it is not surprising that research calling into question the accuracy of our comfortable classification of females as gentle, nurturing, empathic, caregivers is often received both by the research community and the general population with disbelief and caution and at other times with outrage (see [73]). People who study female aggression have been ostracized and vilified, their efforts to solicit funding and to communicate their research findings have been blocked [73, 116]. Similarly, advocates who work to provide support to victims of female aggression have encountered severe criticism and empty pockets [117]. Readers should be cognizant that sex differences have been exaggerated in the literature as a result of ideology and stereotypes and assumptions have been maintained often due to a lack of empirical evidence to contradict our socially sanctioned assumptions about females [33]. In fact, the extent to which this wisdom holds depends very much on the population and setting, as well as the type of aggression being examined.

As we have suggested, gaining a more thorough understanding of aggression requires a consideration of the multiple manifestations it takes, discriminating between verbal and physical assaults, physical aggression and severe violence, for instance. The extant literature offers compelling evidence that violent females are vastly outnumbered by violent males in the general population but that women contribute to nearly half of the aggression that occurs in inpatient psychiatric settings, intimate and familial relationships; though, they remain somewhat less likely than males to commit harm that results in injury.

Violence by females has not been recognized as a public health concern, there is little public education along those lines, funding for research has been purposely directed away from examining the issue (Straus) and the study of relevant variables has been intentionally blocked (e.g., psychopathy, [118]; for a discussion see [84, 119]). As we have demonstrated here, avoiding the difficult questions is not an effective means of achieving increased health and safety. While male aggression is on the decline, female aggression is increasing and that aggression is now known to have widespread, lasting, and substantial implications for victims, perhaps most importantly, children. To move ahead, to effectively reduce aggression in society (i.e., not only among females because female aggression has implications for male aggression and the intergenerational transmission of violence) we must be willing to challenge our most firmly held beliefs about gender, patriarchy, and sexism.

As Murray Straus, one of the pioneers in this field has admonished, we have to ask ourselves if we are more committed to maintaining our political perspectives or are we committed to reducing aggression? While always remaining cognizant of many important gender differences, an increasing recognition that female aggression is not uncommon means that we can now can turn our attention away from attempting to credit or discredit research showing gender equity and begin to uncover what contributes to, or conversely prevents, female aggression [29] and why it might be that in certain settings and populations female aggression is uniquely common. Continued contributions to the female aggression knowledge base carry the potential for directly informing development of proactive aggression prevention programs, as well as clinical treatment options to curtail further expressions of violence amongst those most at risk.

End Notes

[a] There are other potential motives of which readers should be mindful, but they are beyond the scope of this article (e.g., excitement, [51]).

[b] While this finding may offer important insight into gender differences with respect to the fear experienced by female *versus* male victims of intimate partner abuse several related issues require further study and careful consideration. For instance, it is unknown to what degree reporting reflects male socialization and sex-role expectations (e.g., we do not teach male children to fear their female peers). Further, although men may report less fear than women that offers little evidence that they are actually at less risk. As we noted above, when women commit violent offenses generally and when they are violent to their partners, specifically, there is relatively little difference in the risk of injury to the victim.

Anthropology: Aging the Living

Airbags

As with any electronic system, air bag system technology is evolving and being used in more creative ways. Passenger vehicle air bag systems have three main components: the air bag module, the sensors, and the main computer. Within each of these groups,

there are several types of components. Additionally, items such as seatbelt pretensioners and steering column shear capsules factor into the design of the overall passenger safety system.

Air bags are passive safety devices. They require no action by the occupants, other than turning on the vehicle, to perform their protective role in the event of an accident. They are designed to work in conjunction with seatbelts. More advanced air bag systems not only work in conjunction with seatbelts, but also use the information regarding whether or not the seatbelt is actually buckled to aid in deployment decisions. This was one of the first types of occupant detection incorporated into air bag systems.

Occupant detection is an area of air bag technology that is rapidly evolving. From the simple seatbelt switch to the more complicated seat sensors and cameras, occupant sensing and position discrimination employ some of the newest technologies. But, before the newer systems are discussed, an understanding of the basics of air bag systems must be understood.

As stated before, there are three main components to air bag systems: the air bag module, the sensors and the computer. The air bag module is the actual fabric air bag. It is the most visible component. Before it is deployed, the fabric bag is folded in a specific manner and housed behind a molded plastic housing. This housing is designed with a deliberate weak area, called the tear seam, which allows the air bag to break through the housing when it is deployed. This housing is what the occupant sees in the steering wheel or instrument panel of their vehicle. On the back side, there is an inflator containing the electrical components and chemicals that when ignited by the squib create the gas needed to deploy the air bag. When a deployment decision is made, an electrical current is sent through the wires to the squib causing the ignition of the chemicals and the gas that inflates the air bag.

The decision to deploy the air bags is made by the system in the vehicle. Early air bag systems (late 80's –early 90's) were called distributed sensor systems. In a distributed system, there are at least two inertia-based switches located outside of the computer box and one inside the computer box. An inertia-based switch is a mechanical switch that closes due to a change in momentum of the vehicle. There is no accelerometer.[a] To deploy the air bags, one of the external switches and the internal switch had to be closed simultaneously to complete an electrical circuit, sending current to the squib and deploying the air bags simultaneously, as shown in Figure 1. Distributed systems do not contain the amount of crash data that is commonly found in today's vehicles. Since there is no accelerometer, no acceleration or Delta V[b] data can be recorded. The timing of the sensor closures can be recorded along with the status of the seatbelt switch (generally driver only).

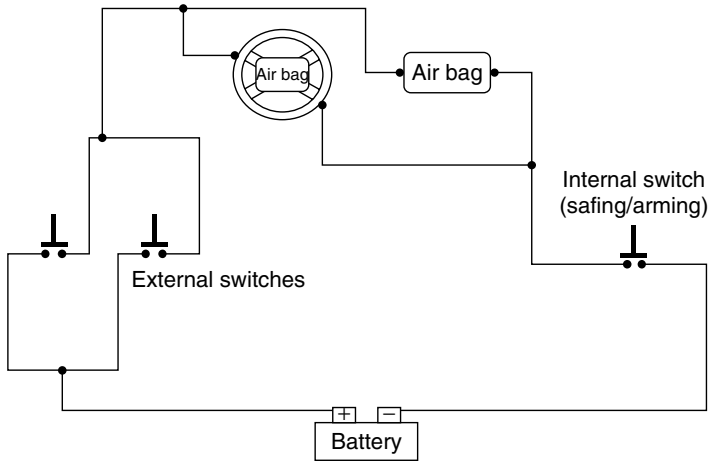

Figure 1 A distributed air bag system employs the use of electromechanical sensors. One is on the battery side of the air bag circuit, and one is on the ground side of the air bag circuit. Both must be closed simultaneously to deploy the air bags

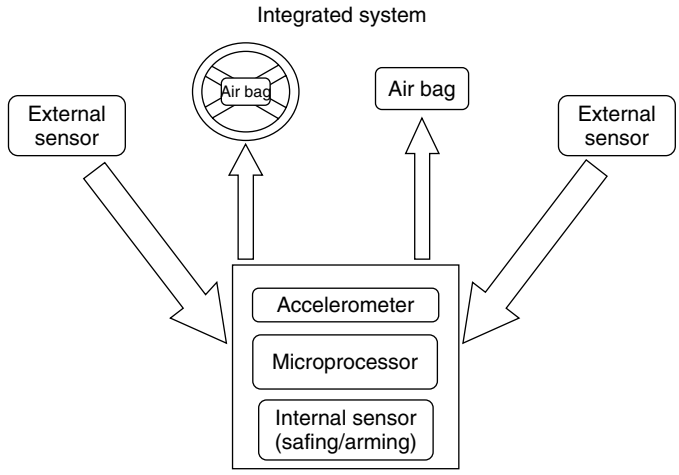

Figure 2 An integrated air bag system uses external sensors connected to the air bag computer in conjunction with the internal accelerometer and internal sensor to make a deployment decision

The next generation of air bag systems began appearing in the early to mid 90's. These systems employed accelerometers located inside the computer box along with a sophisticated algorithm that analyzed the incoming data to make a deployment decision. The fundamental difference between this integrated system and the distributed system is that the simple completion of an electrical circuit does not deploy the air bags. The air bag computer algorithm must make a deployment decision. The integrated system consists of an accelerometer, an inertia-based switch, and a microprocessor with a deployment algorithm housed inside the computer box. Generally at least one external inertia-based switch is used; however, some integrated systems do not use any external sensors, as shown in Figure 2. With the addition of the accelerometer, more detailed crash data including acceleration and/or Delta V of the crash can be recorded.

Successive generations of air bag systems have built upon the basic integrated sensor design. The external sensors have become more sophisticated–some are accelerometers themselves. The algorithms have become more finely tuned. The air bag computer is part of a vehicle-wide network that shares information to help with deployment decisions. Some of the data from the other vehicle computers is saved in the air bag computer crash data files. Seatbelt switches are included in the deployment decision making process, especially when seatbelt pretensioners are present. Seatbelt pretensioners are pyrotechnic devices that remove the slack from the seatbelt webbing to minimize the forward excursion of the occupant. The air bags are not necessarily deployed simultaneously. And occupant detection systems can override a deployment decision if the air bag may do more harm than good. The amount and type of information recorded by each system is completely dependent on the manufacturer of the vehicle and the manufacturer of the air bag system.

Before a discussion on data, directional sensitivity must be addressed. All of the sensors involved in the air bag system are installed in a specific orientation to respond to acceleration pulses coming in certain directions. The sensors associated with frontal air bags are oriented longitudinally on the vehicle. They only respond to acceleration pulses coming from the front to the back of the vehicle. In the same manner, sensors oriented laterally are for side air bag systems. They only respond to acceleration pulse moving right-to-left (passenger side) or left-to-right (driver side). If the acceleration pulse does not occur exactly perpendicular to the front or side of the vehicle (as it rarely does in an actual crash), then the accelerometer is responding to either the lateral or longitudinal component of the crash pulse. As shown in Figure 3, this is called the angle of impact. The farther the angle of impact is from perpendicular, the greater the impact force required to close the sensor, as shown in Figure 4. Issues

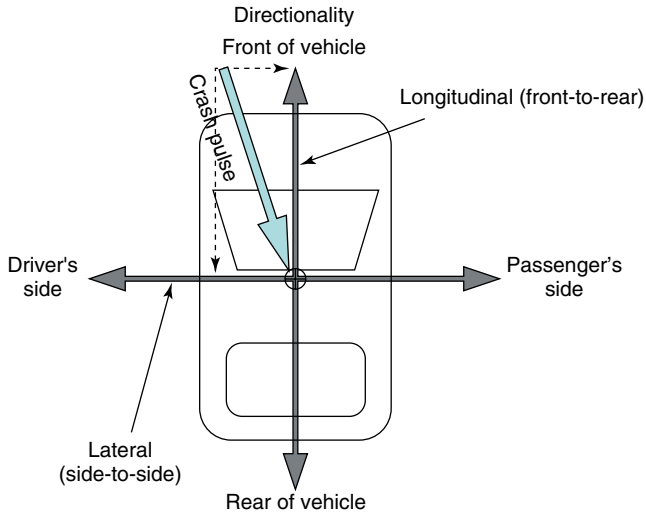

Figure 3 The direction of the crash pulse is important in determining whether or not the air bags will deploy. The front air bags are deployed based on the severity of the longitudinal component of the crash pulse. Side air bags are deployed based on the severity of the lateral component of the crash pulse

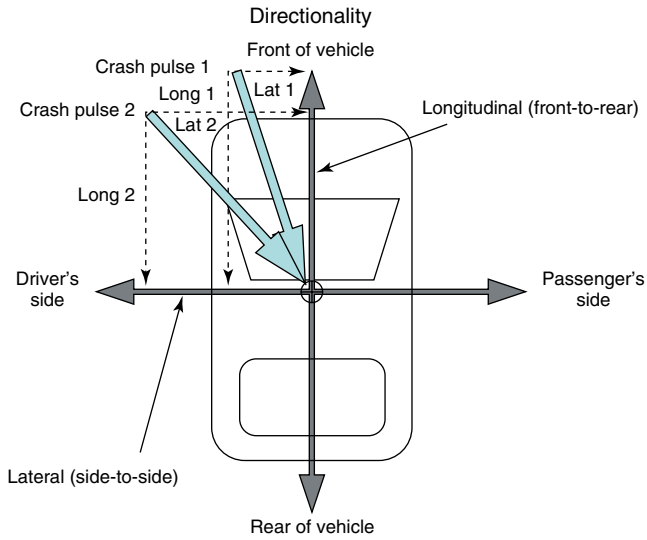

Figure 4 Crash Pulse 1 has a larger longitudinal (front-to-rear) component than lateral (side-to-side). Crash Pulse 2 has equal longitudinal and lateral components

regarding the angle of impact are best resolved by accident reconstruction.

The second part to making sensors an effective part of the air bag system is their placement. The sensors must be placed so that they correctly respond to different crash pulses. In distributed systems, there are two types of sensor placement: triangular and in-line. A triangular sensor placement used two sensors at the front of the vehicle, left and right. Generally, these sensors are found in the area between the headlight and the outside edge of the radiator. The third sensor is the safing/arming sensor located inside

the air bag computer case, which is located near the center of the occupant compartment.

The in-line sensor placement used one sensor at the front, center of the vehicle and one sensor behind the firewall in the occupant compartment. The firewall sensor is variously located. The third sensor is the safing/arming sensor, again located inside the air bag computer case.

The introduction of integrated systems consolidated all of the sensors into the same casing as the air bag computer through the use of an accelerometer. The use of a centrally located accelerometer only required the development of complex computer algorithms to analyze the acceleration data. Eventually, external sensors were brought back into the air bag system to give additional information to the algorithms and help discriminate whether or not to deploy in crashes that may be borderline or have a very narrow pulse transmission zone, such as poles or trees.

A very general rule of thumb for deployment parameters in terms of miles per hour is in a full frontal crash with an impact severity equivalent to hitting a rigid barrier at 8 mph or less the air bags should not deploy. In the same type of crash described above with the impact at 15 mph, the air bags should always deploy. The area between 8 mph and 15 mph is called the gray zone. As air bag systems have become more sophisticated, especially in the area of occupant detection, this general range of deployment parameters can vary widely, going up as high as 20 mph for a properly positioned and seatbelted occupant.

Now that all of the parts of the air bag system have been discussed, the basic types of decision tree structures can be presented. These are all meant to be general examples of the progression of air bag technology.

Starting with the distributed system, the only requirement for deployment is to have one crash sensor and the safing/arming sensor close simultaneously. This would deploy both frontal air bags simultaneously. There is no input from the air bag computer. This is illustrated in Figure 5.

Next, there is an integrated system. In the first generation of integrated systems, the computer algorithm analyzes the accelerometer input and the closure of any external sensors to make a deployment decision, as shown in Figure 6. As the integrated system gains more inputs, the decision process becomes more complicated. The status of seatbelts and the position of

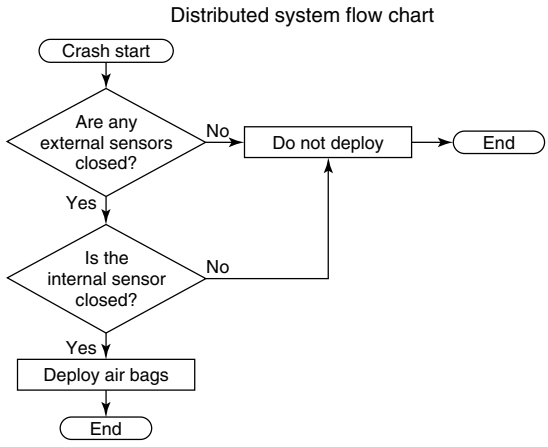

Figure 5 This flow chart outlines the base logic behind a distributed air bag system

the front seats can override the air bag deployment command. This is shown in Figure 7. Additionally, in many trucks and SUVs the passenger air bag can be manually turned off by a keyed switch.

As the air bag system has become more complicated, the amount of information saved by the air bag computer has increased. The first air bag computers were not intended to record information regarding the deployment event. They were there to monitor the status of the air bag system components and record any diagnostic trouble codes (DTCs or fault codes) that occurred. These DTCs would activate the air bag light in the instrument panel signaling the vehicle should be brought in for service. When being serviced, the technician can access the DTCs through a handheld scan tool to help identify the component causing the air bag light.

The first crash-relevant piece of information recorded in the air bag computer was the timing between sensor closures. This time was recorded in milliseconds (1/1000th of a second) and enabled some determination of how quickly the air bags were commanded to deploy. The next piece of data that began to show up consistently was whether or not the driver's seatbelt was buckled. As air bag systems migrated to integrated systems, the recorded timing data became the time from when the computer recognized the possibility of a non-normal event (wake-up or algorithm enable) to the time the air bags were commanded to deploy. Additionally, since these integrated systems employ an accelerometer, the crash

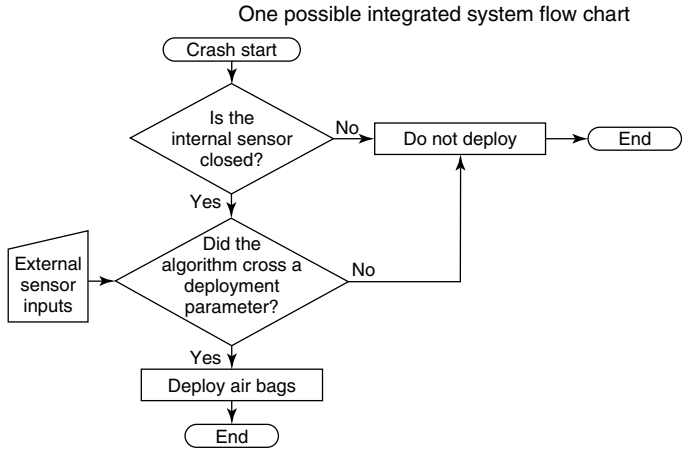

Figure 6 This flow chart outlines the base logic behind one possible configuration of an integrated air bag system

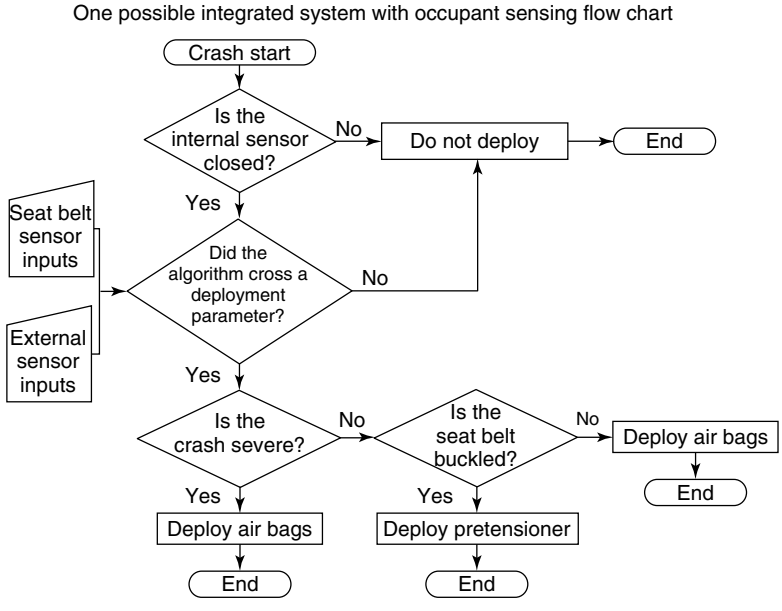

Figure 7 This flow chart outlines the base logic behind one possible configuration of an integrated air bag system that includes occupant sensing

data began to include longitudinal acceleration and/or Delta V. With the advent of side air bags, lateral acceleration and/or Delta V may also be recorded.

The final major piece of crash data that may be recorded is pre-crash data. As of the writing of this article, only two manufacturers, GM and Ford, have employed this type of data. In GM's pre-crash data, four parameters are recorded independently and continuously in a data storage buffer. When a non-normal event is detected, the last five data samples of these parameters are saved into the crash data. The four parameters that GM currently records are vehicle speed, engine RPM, throttle percent and brake switch status. In Ford's pre-crash data, there are many additional data parameters saved for a time interval varying between 26 seconds and over 6 minutes,

depending on the vehicle in question. However, Ford does not save this data in the actual air bag computer. It is stored in volatile memory in the powertrain control module. This data must be retrieved very carefully to prevent its loss. Additionally, power must not be applied to the vehicle in question or Ford's pre-crash data will be overwritten with information pertaining to the current, post-accident state of the vehicle.

If the vehicle in question has seatbelt pretensioners or any form of occupant position sensing, the status of these parameters may also be recorded, especially if they are part of the deployment decision tree. If one front seat occupant is wearing their seatbelt and that seatbelt has a pretensioners and the other front seat occupant is not wearing their seatbelt, the air bag computer algorithm may make the decision to deploy the pretensioners of the belted occupant and the air bag of the unbelted occupant. Belting and occupant position may also factor into the force with which an air bag is deployed. Some air bag systems have two inflators for their air bags which can be timed to change how fast the air bags are deployed or how long they stay inflated.

Once it has been determined that the vehicle in question has the ability to save crash-related data, it can frequently be retrieved. This retrieval process involves the subject vehicle, an interface box, and a laptop computer. There is currently one publicly available interface that allows the user to download the crash data from certain vehicles. If the vehicle in question is not on the list of this public interface system, then the data stored on the air bag computer must be retrieved by the vehicle manufacturer.

The amount and type of crash data saved in the air bag computer varies widely by manufacturer. It can also vary within the manufacturer by model and model year. There are also situations, such as power loss during the accident, which can cause the data to not be recorded or to be only partially recorded. The first priority of the air bag computer is to discriminate between a deployment and non-deployment event and deploy the air bags when necessary. The second priority is to record the crash-related data. The data is first stored in a volatile memory called RAM. This type of memory is erased if power is lost. However, the data must be stored in RAM first because, until a deployment decision is made, the computer would not know whether to place the data in the non-deployment or deployment section of the permanent memory. This permanent memory is called EEPROM. Once the data is in EEPROM it cannot be erased due to a power loss. The air bag computer only has a limited amount of backup power which would first be used to deploy the air bags and then record the crash data.

Now, manufacturers are just beginning to add crash prevention systems. One type of system employs different types of radar to determine how close the vehicle is getting to the one in front of it. The crash prevention system then predicts whether or not the distance between the vehicles is becoming too small. If it is, the vehicle's brakes are applied automatically through the cruise control system. This is called adaptive cruise control. The next level of adaptive cruise control will be able to be used at low speeds which will help to prevent minor accidents in bumper-to-bumper traffic.

Another facet of crash prevention systems are warnings for lane-departure or side alerts if another vehicle is getting too close. Some manufacturers offer night vision, a head-up display, and even a drowsy driver monitor. As of the writing of this article, not only cost is preventing the widespread use of these technologies, but also the integration of the multiple computers and cameras over the vehicle network needs to be developed that is fast and reliable. As this technology continues to evolve, it will help the air bag system by creating more detailed pre-crash inputs.

End Notes

[a.] An accelerometer is a device that changes voltage when subjected to a mechanical stress. This change in voltage is measured and calibrated to relate to acceleration values through the use of known pulses.

b. ΔV is the difference between the initial velocity and final velocity. It is not the barrier equivalent velocity or the initial velocity of the vehicle before impact.

HOLLY A. ADAMS

Alcohol

Introduction

Alcohol (ethanol or ethyl alcohol) is the world's favorite recreational drug, legally available to adults and widely used for pleasure and relaxation without consequence. Indeed, moderate drinking (one to two glasses of wine each day) has a number of beneficial effects on health and is often recommended as a prophylactic treatment to reduce the risk of dying from coronary artery disease and stroke [1]. However, ethanol is also a drug of abuse and chronic drinking eventually leads to dependence and craving for alcohol with serious consequences for the individual and society [2]. Binge drinking and drunkenness have emerged as major public health problems and overconsumption of alcohol is frequently a catalyst and contributing factor in violent crimes such as physical and sexual assault and homicide [3]. This means that alcohol ranks as the foremost psychoactive substance encountered in forensic investigations of unnatural deaths such as suicides, drowning, and especially road-traffic fatalities where 20–40% of crashes are caused by drunken drivers.

Forensic investigators need to understand what happens to alcohol in the body and how excessive drinking influences a person's behavior in a negative way [4]. The ability to perform skilled tasks, to comprehend and communicate and to form intent are questions that often arise in forensic casework and legal proceedings. The need to translate a person's blood-alcohol concentration (BAC) into the quantity of alcohol consumed is also important and, indeed, ethanol is one of the few drugs for which this calculation is feasible and defensible (see later in this section for details).

During prosecution of drunken drivers, a forensic investigator or expert witness might be asked to perform a backward extrapolation of a person's BAC from the time of blood sampling to an earlier time, such as the time of driving [5]. This procedure is known as *retrograde extrapolation, back-calculation*, or *back-tracking* and is a dubious practice, owing to the many assumptions and unknown factors involved.

Alcohol is the foremost psychoactive substance encountered in postmortem toxicology and heavy drinking and drunkenness, either directly or indirectly, are responsible for considerable morbidity and mortality. Whether or not acute alcohol poisoning was the cause of death is not always easy to determine because of wide variation in the sensitivity and reaction of different people to the same dose of alcohol.

Interpreting the concentration of a drug measured in blood or other body fluid in relation to the dose administered or the effects produced on the individual is fraught with difficulties. Much depends on the interplay between chemical, pharmaceutical, physiological, psychological, and genetic factors. In the case of ethanol, the situation is simplified thanks to its special physiochemical properties, namely, small molecular size, distribution into the total body water (TBW), and lack of binding to plasma proteins. Table 1 gives a summary of the main physicochemical properties of ethanol.

The BAC reached after drinking a known amount of alcohol depends on a host of factors, the most important of which are the quantity consumed and the speed of drinking. Higher doses and more rapid ingestion lead to higher peak BAC (C_{max}) and an earlier

Table 1 The major physicochemical properties of ethanol

Property	Ethanol
CAS number[a]	64–17–5
Molecular weight	46.07
Molecular formulae	C_2H_6O
Chemical formulae	CH_3CH_2OH
Structure	Primary aliphatic alcohol
Common name	Beverage or grain alcohol
Boiling point	78.5 °C
Melting point	−114.1 °C
Density	0.789 at 20 °C
Water solubility	Mixes completely with water

occurring time to peak (t_{max}), and consequently more pronounced effects on the individual concerned. Among pharmacological agents, ethanol is classified as a depressant of the central nervous system even though drinking small quantities tends to elicit a state of excitement and euphoria. However, these feelings arise by suppression of inhibitions in the cerebral cortex and not as a direct stimulant action of the drug [6]. Ethanol is sometimes administered by intravenous infusion, such as 8–10% v/v solutions in physiological saline, as is common practice in some research applications and also in the emergency clinic as an antidote for treatment of methanol poisoning [7]. Absorption of ethanol is rapid when given rectally as an enema, but for all practical purposes alcohol is ingested orally by drinking an alcoholic beverage.

Trace amounts of ethanol are produced naturally in the body, either by fermentation of carbohydrates in the gut or during certain minor biochemical reactions of the intermediary metabolism [8]. The concentrations of the so-called endogenous alcohol in blood are normally so low ($<0.001\,g\,l^{-1}$) that they are without forensic significance, except under very exceptional circumstances. Ethanol is produced endogenously via reduction of acetaldehyde, which is generated from pyruvate during microbiological and fermentation processes. Many Asians (e.g., Japanese) lack an effective hepatic enzyme for the catabolism of acetaldehyde, which means that the concentrations of this precursor of ethanol can increase appreciably. Moreover, in people suffering from yeast infections, such as C*andida albicans* in the gut, concentrations of endogenous ethanol are likely to be higher after intake of carbohydrate-rich meals, such as rice (*see also* **Alcohol: Analysis**).

How much Alcohol was Consumed?

The strengths of different alcoholic beverages (beers, wines, and spirits) are usually written on the labels, and are almost always expressed in terms of percentage of alcohol by volume (% v/v) and sometimes as proof spirit. The use of the term proof spirit has a long history, and in North America a beverage declared as being 100% proof contains 50% v/v alcohol. In any type of blood-alcohol calculation, the concentration of alcohol in the drink consumed needs to be converted from % v/v to % weight/volume (w/v) to arrive at the number of grams of ethanol ingested [9].

Examples of commonly imbibed alcoholic beverages such as beers, table wines, desert, or fortified wines as well as distilled spirits and the concentrations of ethanol they contain are given in Table 2. The concentrations of ethanol are expressed as %

Table 2 Relationships between the alcoholic strength of different beverages (vol%) and quantity of ethanol (EtOH) they contain and the corresponding amounts of ethanol ingested in a typical serving

Beverage type	EtOH conc. (% v/v)	EtOH conc. (% w/v[a])	Volume of a typical drink (ml)	Ethanol (g)	Ethanol (g) in one bottle[c]
Beer[a]	3	2.4	500[b]	12.0	7.9
	4	3.2		16.0	10.6
	5	4.0		20.0	13.2
	6	4.7		23.5	15.6
Table wine	9	7.1	150	10.6	53.3
	10	7.9		11.9	59.2
	12	9.5		14.2	77.3
Fortified wines (sherry and port)	16	12.6	100	12.6	94.5
	18	14.2		14.2	106.5
	20	15.8		15.8	118.5
Spirits (whisky, gin, vodka, and brandy)	35	27.6	25	6.9	201
	40	31.6		7.9	231
	45	35.6		8.9	267

[a] % v/v × 0.79 (density of ethanol)
[b] In the United Kingdom, a pint of beer is equivalent to 568 ml
[c] Beer (330 ml), wines (750 ml), and spirits (750 ml)

v/v and % w/v and these are related by the density of ethanol (Table 1), which is 0.79 g ml^{-1} at room temperature. Also, Table 2 lists the volumes of the above-mentioned beverages dispensed in a typical serving along with the quantity (grams) of ethanol they contain. Lastly, the number of grams of ethanol contained in one bottle of each beverage, namely, beer (330 ml), wine (750 ml), or spirits (750 ml) is listed.

If a person drinks two bottles of beer (5 vol%) and one bottle of table wine (12 vol%), this corresponds to an intake of 2 × 13.2 g or 26.4 g ethanol from the beer and 77.3 g from the wine making a total consumption of 103.7 g of pure ethanol. This information is necessary when various types of blood-alcohol calculations are made for clinical, research, and legal purposes [9].

Alcohol in the Body

Knowledge about the disposition and fate of ethanol in the body and the factors influencing these processes is necessary to answer many questions arising in routine forensic investigations and medicolegal casework. The basic facts relating to absorption, distribution, and elimination of ethanol have been known for many decades and a vast scientific literature exists on this topic [10].

Absorption

Absorption is the process by which a drug passes from the site of administration into the bloodstream and gets transported to all body organs, fluids, and tissues. Alcohol (ethanol) is a small uncharged molecule totally miscible with water and absorption from the gut occurs by passive diffusion across mucous membranes according to the concentration gradient as predicted by Fick's law. Small amounts of alcohol can be absorbed through the mucous surfaces of the oral cavity if an alcoholic drink is kept in the mouth sufficiently long enough.

Alcohol is absorbed along the entire gastrointestinal tract and the speed of absorption depends on the absorption surface area and the concentration gradient of ethanol across the membrane. The absorption of alcohol begins in the stomach but is considerably faster from the upper part of the small intestine, owing to the much larger area of the absorption surface furnished by the microvilli in the duodenum and jejunum. The absorbed alcohol enters the portal venous blood and passes through the liver and then to the heart, and after picking up oxygen in the lungs, it returns back to the heart and distributes throughout the entire systemic circulation.

Absorption of alcohol occurs much faster when gastric emptying is rapid, facilitating passage through the pyloric sphincter into the small intestines. Under normal conditions, the pylorus remains nearly totally closed because of tonic contraction of the pyloric muscle. Factors that influence gastric emptying play an important role in the rate of uptake of alcohol from the gut, which in turn influences the maximum concentration in the blood (C_{max}) and the intensity of the effects of alcohol on the individual.

Consumption of alcohol together with or after a meal slows the rate of absorption because of a food-induced delayed stomach emptying, as reflected in a lower C_{max} and a later-occurring t_{max}. The amount of food ingested is seemingly more important than its composition in terms of fat, protein, or carbohydrate content [10].

Table 3 lists the main factors that can impact on C_{max} and the time of its occurrence (t_{max}) after drinking a given dose of alcohol. Most of the variables listed either alter gastric emptying or are important for the distribution of ethanol between the blood and tissue water (e.g., gender and adiposity), owing to differences in TBW.

Distribution

Ethanol distributes into the aqueous compartment of the body and the concentrations reached in all body fluids and tissues at equilibrium depend primarily on the water content of these fluids and tissues. Specimens such as sweat, saliva, and urine, which are almost 100% water, will contain a higher concentration of ethanol than whole blood, which is ~80% w/w water. Likewise, the concentrations of ethanol in plasma and serum (~93% water) are higher than the concentration in whole blood. Studies have shown that the plasma/blood distribution ratio of ethanol on average is 1.16 : 1 [11]. Note that plasma and serum are the body fluids mostly analyzed at hospital clinical chemistry laboratories, whereas specimens of whole blood are analyzed at toxicology laboratories.

The speed with which ethanol equilibrates between blood water and the extracellular fluid and

Table 3 Factors influencing the peak blood-alcohol concentration or C_{max} reached after drinking the same quantity of alcohol under various conditions

Variable/conditions	Possible mechanism and explanation	Effect on peak BAC (C_{max})
Low body weight	Less body water	Higher
Appreciable adiposity	Less body water	Higher
Female gender	Less body water	Higher
Rapid drinking	Faster absorption	Higher
Drinking on empty stomach	Faster absorption	Higher
Drinking after a meal	Delayed absorption	Lower
More concentrated alcoholic drinks	Faster absorption	Higher
Obstruction in liver blood flow	Slower absorption	Lower
Smoking cigarettes	Delayed absorption	Lower
Drugs that alter gastric emptying	Slow or more rapid absorption	Lower or higher
Gastric bypass surgery	Faster absorption	Higher
Trauma and massive blood loss	Delayed absorption	Lower

tissue water depends on the cross-sectional area of the local capillary bed and the blood flow per gram of tissue. Studies have shown that the volume of distribution of ethanol corresponds very closely with the TBW. Indeed, a person's TBW can be determined by dilution experiments with ethanol as a marker and the results agree well with isotope dilution when ^2H_2O and ^3H_2O are used as tracers.

Between 50 and 60% of a person's bodyweight is water and the volume of the blood amounts to about 5 l in an adult. This makes it clear that large amounts of ethanol must be consumed to increase a person's BAC to a level that causes inebriation and drunkenness. Once absorbed into the blood, the alcohol easily passes through capillary walls into the various tissues and fluids and equilibration is achieved in about 60 min after the end of drinking. Heavier people tend to have a larger body water space to dilute the alcohol they consume resulting in a lower BAC (Table 3) compared with a person of lesser weight. During aging, especially in men, TBW per kg bodyweight decreases as it does in obesity. Elderly (>60 years) and those overweight reach higher BAC for the same dose of ethanol administered compared with a young nonobese individual.

Well-known gender differences exist in the distribution space for ethanol because women tend to have less body water per kilogram body weight than men. On the basis of experiments dating back to the 1930s, the average V_d for women was determined as $0.61\,kg^{-1}$ compared with $0.71\,kg^{-1}$ for men [12]. Note that these values represent the distribution ratio of alcohol between the body as a whole and the blood compartment. Since the experiments used to determine V_d for ethanol date back to the 1930s, they probably need updating considering the epidemic of obesity in modern society [13].

Table 4 shows the relationship between body mass index (BMI) and clinical manifestations or stages of obesity, which should be considered when choosing the most appropriate distribution factor for use in blood-alcohol calculations. Higher BMI (>30) is associated with lower values of V_d such as $0.4–0.51\,kg^{-1}$ rather than $0.6–0.71\,kg^{-1}$ [14].

Instead of using the population average Widmark *r*-factors for men and women, another approach is to calculate a person's TBW from information available about age, height, and weight (see later in this article). As a general recommendation, an intersubject variation of ±20% should be used in

Table 4 Clinical manifestations of obesity in relation to body mass index (BMI), which might impact on the distribution volume of ethanol (Widmark *r*-factor)

Classification	BMI ($kg\,m^{-2}$)
Underweight	<18.5
Normal	18.5–24.9
Overweight	25.0–29.9
Obesity class I	30.0–34.9
Obesity class II	35.0–39.9
Obesity class III	>40

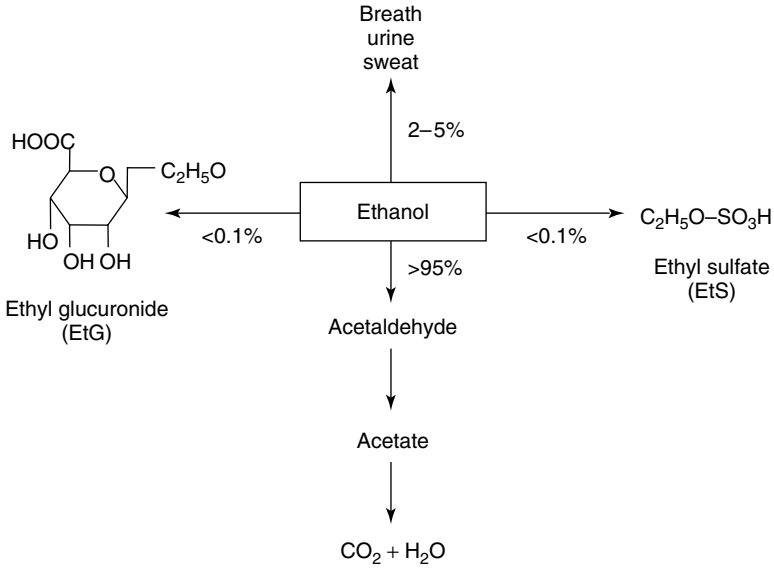

Figure 1 Scheme showing the metabolism of ethanol in the body, the relative amounts excreted unchanged in breath, urine and saliva, and the oxidative and nonoxidative pathways

blood-alcohol calculations to allow for variations in the proportions of fat-to-lean body mass. In obesity (Table 4) or emaciation, a larger variation in body water is expected to occur, which impacts on the BAC reached after a given dose of ethanol.

Metabolism and Excretion

Most of the ethanol a person drinks (95–98%) is removed from the body by oxidative metabolism and a minor fraction (<0.2%) undergoes conjugation reactions to produce ethyl glucuronide (EtG) and ethyl sulfate (EtS), which are the major nonoxidative metabolites [10]. The remainder of the dose of alcohol (2–5%) is eliminated unchanged via the kidney in the urine, through the skin by perspiration and also by pulmonary excretion via the lungs. Figure 1 schematically illustrates the fate of alcohol in the body, showing the relative amounts metabolized and excreted unchanged.

The metabolism of ethanol occurs primarily in the liver by oxidative reactions that liberate considerable energy, actually 7.1 kcal g^{-1} (29.7 kJ), which exceeds the energy content of both proteins and carbohydrates. The liver cells (hepatocytes) are equipped with enzymes that specialize in the degradation of ethanol, the most important of which is the class I alcohol dehydrogenase (ADH), which is located in the cytosol. Enzymatic oxidation of ethanol produces acetaldehyde and this toxic metabolite is converted to acetate by the action of low K_m aldehyde dehydrogenase (ALDH), located in the mitochondria. The acetate produced during the biotransformation of ethanol is transported away from the liver and enters the Krebs cycle where it is converted to CO_2 and H_2O in peripheral organs and tissues. Figure 2 summarizes the salient features of the ADH and ALDH pathways for oxidative metabolism of ethanol.

During the oxidation of ethanol to acetaldehyde and subsequent conversion of the latter to acetate, the coenzyme nicotinamide adenine dinucleotide (NAD^+) is involved. The NAD^+ is simultaneously reduced to NADH and the ratio NADH/NAD^+ increases appreciably, which affects other NAD-dependent metabolic reactions in the liver [15]. Among others, the reduction of pyruvate to lactate is favored, which results in hyperlactacidemia (lactic acidosis) and there is also a reduced rate of gluconeogenesis. The latter is important when the glycogen stores in the liver are depleted, such as when food intake is negligible, leading to a dangerous ethanol-induced hypoglycemia (low blood sugar). The increased NADH/NAD^+ ratio also diminishes

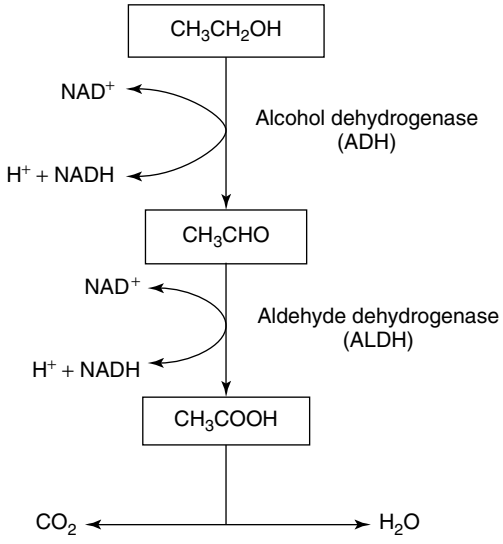

Figure 2 Scheme showing alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) pathways for oxidation of ethanol. The same coenzyme nicotinamide adenine dinucleotide (NAD^+) is involved in these redox reactions. The final metabolism of acetate into CO_2 and H_2O occurs mainly in extrahepatic tissues

the oxidation and utilization of fatty acids, which results in an accumulation of fat in the liver and hence the fatty liver (hepatic steatosis) seen in heavy drinkers and alcoholics at autopsy [15].

The class I ADH has a low K_m for oxidation of ethanol ($0.05-0.1\,g\,l^{-1}$), so the enzyme becomes saturated with substrate after just a couple of drinks [16]. Another ADH enzyme (class IV), which is mainly located in the gastric mucosa, has been said to account for presystemic metabolism of ethanol. Both gender and ethnic differences in the activity of gastric ADH exist, which has implications for first-pass metabolism (FPM) and bioavailability of the dose of alcohol administered [17]. Differences of opinion exist regarding the quantitative importance of FPM and whether this is primarily of gastric or hepatic origin.

Besides the ADH pathway, alcohol-metabolizing enzymes are also located within the smooth endoplasmic recticulum, particularly the microsomal fraction. The microsomal enzymes constitute a large family of proteins, known as the *cytochrome P450 monooxygenases*, being responsible for oxidation and reduction of a wide range of foreign chemicals (xenobiotics) that might enter the body, including atmospheric pollutants, industrial solvents, as well as diverse pharmaceutical agents [18]. The particular form of P450 enzyme that converts ethanol to acetaldehyde is denoted by CYP2E1 and has a Michaelis constant (K_m) of $0.6-0.8\,g\,l^{-1}$, being appreciably higher than that of class I ADH ($0.05-0.10\,g\,l^{-1}$). Accordingly, CYP2E1 plays a more important role in the oxidation process when relatively high BACs are reached, such as in heavy drinkers and alcohol-impaired drivers.

$$CH_3CH_2OH + H^+ + O_2 \xrightarrow{CYP2E1} CH_3CHO + NADP^+ + 2H_2O \quad (1)$$

Another feature of CYP2E1 is that its activity increases after sustained periods of heavy drinking lasting weeks or months. The enzyme becomes more effective in the oxidation of its substrate, which explains the old observation that alcoholics on a drinking spree acquire an enhanced capacity to eliminate alcohol from the bloodstream. Involvement of CYP2E1 in the metabolism of alcohol is also responsible for a number of undesirable drug-alcohol interactions [7]. For example, the widely used over-the-counter antipyretic drug paracetamol (acetaminophen or Tylenol®) is converted into a potentially toxic metabolite by CYP2E1. If this enzyme is activated, as it might be in an alcoholic, this can potentially cause hepatic necrosis, loss of liver function, and death. The older sedative–hypnotic drug chloral hydrate (Noctec®) is more potent if taken together with a large dose of ethanol and this adverse drug-alcohol interaction has sometimes led to serious life-threatening consequences [7].

A third liver enzyme that in theory can oxidize ethanol is catalase, which is located in the peroxisomes. This enzyme is capable of oxidizing ethanol under *in vitro* conditions although its role *in vivo* has been questioned because of the lack of hydrogen peroxide necessary for the reaction to proceed. For all practical purposes, ADH and CYP2E1 account for the oxidative metabolism of ethanol in humans.

The fate of ethanol in the body and the pathways of metabolism by the major oxidative enzymes ADH and ALDH are shown in Figures 1 and 2.

The Blood-Alcohol Curve

The time course of alcohol in the body is usually displayed as a graph on which the BAC is plotted on

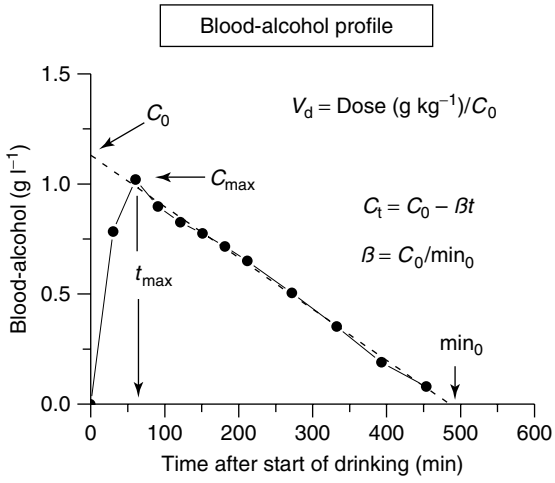

Figure 3 Concentration-time profile of ethanol in blood in one subject after consumption of 0.70 g ethanol per kilogram body weight as neat whisky on an empty stomach

the *y*-axis and the time of sampling blood, measured from the start of drinking, is plotted on the *x*-axis [12]. The shape of the resulting blood-alcohol curve furnishes important information about the absorption, distribution, and elimination processes. Hundreds or even thousands of BAC curves have been generated over the years by scientists from various countries by experiments with healthy volunteers under controlled conditions. The doses of ethanol generally ranges from 0.3 to 1.0 g kg^{-1} and blood samples are then taken for analysis at 15- to 30-min intervals for up to 3–10 h, depending on the dose. A plot of BAC *versus* time is a neat way to visualize the concentration-time profile of ethanol and absorption, distribution, and elimination stages of alcohol metabolism.

A typical blood-alcohol curve obtained after a male subject drank a moderate dose of alcohol as neat whisky on an empty stomach is shown in Figure 3. The quantitative evaluation of BAC profiles is fundamentally important in forensic pharmacology and the basic principles and concepts were developed and introduced already in the 1930s by a physician and scientist from Sweden, namely, Erik MP Widmark [19]. The results of this research remain valid today and have become the cornerstone of forensic blood-alcohol calculations and interpretation of BAC in relation to the quantity of alcohol a person has consumed.

The Widmark Equation

In 1922, a reliable method was presented for the quantitative determination of ethanol in small amounts of blood (~0.1 ml). The blood specimens were obtained without medical risk simply by pricking a fingertip or an earlobe [12]. The controlled experiments on human drinking showed that after the absorption of alcohol was complete and the peak concentration in blood (C_{max}) was passed the declining portion of the BAC curve followed more or less a straight line. This was interpreted to mean that the rate of metabolism of ethanol occurred at a constant rate independent of the prevailing BAC according to zero-order elimination kinetics [12, 19]. This contrasted with the metabolism and pharmacokinetics of most other drugs for which the rate of elimination from the blood decreases at lower concentrations as expected for a first-order process [20].

Extrapolating the linear declining portion of the BAC curve back to the time of starting to drink (the dotted line in Figure 3) gives the BAC expected if absorption and distribution had occurred instantaneously without any metabolism taking place. Widmark denoted the *y*-intercept on the blood-alcohol axis with the symbol C_0 that stands for concentration (BAC) at zero-time. This pharmacokinetic parameter has gained great importance in studies of clinical pharmacokinetics of ethanol and other drugs [21].

If the entire dose of ethanol had been absorbed and distributed evenly in all body fluids and tissues, one would have expected that the ratio of the dose (grams) to body weight (kilograms) would be identical (within experimental error) to the C_0 value in units of gram per kilogram. But this was not the case; the C_0 was always higher than the concentration of alcohol in the body as a whole (g kg^{-1}). Because ethanol dissolves in the body water compartment and solubility in lipids and bone is negligible, Widmark introduced a correction to the body weight (reduction factor), which he denoted as *r* or *rho* [12]. This *r*-factor was less than unity and meant that the concentration of alcohol in the body when calculated as g/(kg × r) was the same as C_0 given by the *y*-intercept of the BAC curve.

$$C_0 = \text{gram alcohol}/(\text{body weight} \times r) \quad (2)$$

$$\text{Grams alcohol } (A) = C_0 \times \text{body weight} \times r \quad (3)$$

The basic Widmark equation above expresses a quantitative relationship between the BAC (C_o) and

the amount of alcohol absorbed and distributed in all body fluids and tissues (A) at the time the blood was sampled. The Widmark equation can also be written as follows

$$A(\text{g}) = \text{BAC (mg g}^{-1}) \times \text{BWt (kg)} \times r \text{ (w/w)} \quad (4)$$

$$A(\text{g}) = \text{BAC (g l}^{-1}) \times \text{BWt (kg)} \times r \text{ (v/w)} \quad (5)$$

The decision as to which of the above two equations should be used depends on the concentration units used to report BAC, whether mass/mass or mass/volume. In Widmark's fundamental work, the BAC was reported as mass/mass (mg g^{-1} or g kg^{-1}) because the aliquots of blood analyzed were measured by weighing. The subject's body weight was in kilogram so the original r-factor was a dimensionless ratio. Today, it is more common to measure and report BAC in units of mass/volume (mg ml^{-1} or g l^{-1}) so the Widmark factor will have the units of liters per kilogram. The connection between mass/mass and mass/volume is the density of whole blood, which is 1.055 g ml^{-1} on average [11]. Accordingly, both the C_o value and the Widmark r-factor are 5.5% less if the BAC is measured and reported in mass/volume units.

Table 5 summarizes values of the distribution factor (r-factor) for men and women based on Widmark's work and the corresponding values if mass/volume (g l^{-1}) units are used to report BAC as is more common today. The gender-related difference (0.68 for men and 0.55 for women) depends primarily on differences in body composition and especially the lower TBW and the higher proportion of fat-to-lean tissue in women.

In any individual case, the r-factor depends on age, gender, adiposity, and BMI although population average values of 0.7 for men and 0.6 for women are generally used in BAC calculations [9]. An important assumption when using the Widmark equation is that the entire dose of alcohol has reached the systemic circulation at the time the blood sample was obtained. However, this is only feasible if alcohol was administered intravenously (100% bioavailability) although drinking a bolus dose on an empty stomach, so that gastric emptying is rapid, gives close to 100% availability.

During social drinking, some of the ingested alcohol might be metabolized either in the stomach or the liver or both organs before reaching the central compartment and this is known as *FPM*. This might be appreciable if the absorption of alcohol is slow and when drinking extends over several hours, such as when dining out and drinking with a meal or in small repetitive doses.

Widmark's equation is useful and widely used in forensic science practice to translate a person's BAC into the amount of alcohol absorbed and distributed in all body fluids. If alcohol remains unabsorbed in the stomach when the blood sample is taken, then it is not considered as being in the body; hence, the total quantity consumed is underestimated by use of this calculation.

Figure 4 shows the relative frequency distribution of BAC in drunken drivers apprehended in Sweden. The mean and median concentrations were about the same, being close to 1.8 g l^{-1} (180 mg/100 ml). Most drunken drivers (>85%) are men, so if one assumes an average body weight of 80 kg and a Widmark r-factor of 0.71 kg^{-1} a simple calculation using equation (4) or (5) shows that 100.8 g of ethanol are absorbed and distributed in the whole body at the time of sampling the blood. Using the information in Table 2 leads to the conclusion that there are 325 ml of whisky or vodka (40% v/v) in all body fluids.

Table 6 presents further examples of how the Widmark equation can be used to calculate the quantity of

Table 5 Mean, standard deviation, and range of Widmark r-factors depending on whether BAC is measured and reported as mass/mass (g kg^{-1}) or mass/volume (g l^{-1}) units

Gender	Widmark's r-factor, mean ± SD (range)[a]	Adjusted r-factor, mean ± SD (range)[b]
Men ($N = 20$)	0.68 ± 0.085 (0.51–0.90)	0.64 ± 0.081 (0.48–0.85)
Women ($N = 10$)	0.55 ± 0.055 (0.46–0.65)	0.52 ± 0.052 (0.44–0.62)

[a] Blood-alcohol reported as milligram per gram (gram per kilogram)
[b] Blood-alcohol reported as milligram per milliliter (gram per liter) where 1.0 mg g^{-1} = 1.055 mg ml^{-1}

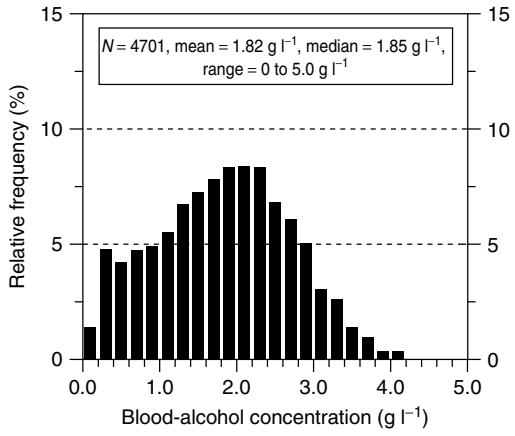

Figure 4 Relative frequency distribution of the concentrations of ethanol in blood from people apprehended by the police in Sweden for drunken driving

alcohol in the body at certain BAC spanning from 0.5 to 4.5 g l^{-1} (50–450 mg/100 ml) for men with body weights of 60, 80, or 100 kg. Besides the amount of ethanol absorbed and distributed in the body at the time of sampling blood (*r*-factor 0.7), some of the ingested alcohol is lost by hepatic metabolism during the 3-h drinking spree. A good rule of thumb for use in this calculation is that the rate of ethanol metabolism is 0.1 g kg^{-1} body weight per hour independent of gender.

Equations (4) and (5) can also be used to calculate the BAC expected at some future point in time after absorption and distribution are complete. Widmark insisted that such a calculation should not be attempted until at least 1.5–2 h had elapsed after the end of drinking. This amount of time was necessary to ensure that negligible amounts of alcohol

Table 6 Relationship between blood-alcohol concentration (BAC) and the quantity of alcohol absorbed and distributed in all body fluids of a healthy male subject. Also shown is the total quantity of ethanol consumed if metabolism had taken place over 3 h

BAC g l^{-1} (mg/100 ml)	Body weight kg[a]	Ethanol (g) in body	Amount metabolised during 3 h[b]	Ethanol (g) consumed[c]

[a] The calculations assume a healthy male subject with Widmark *r*-factor of 0.71 kg^{-1}
[b] Ethanol is metabolized at a rate of 0.1 g ethanol per kg body weight per hour from the start of drinking
[c] The sum of alcohol in body and the amount metabolized over 3 h

still remain unabsorbed in the gut when blood was sampled.

Total Amount of Alcohol Ingested

The metabolism and elimination of ethanol start to occur immediately after the start of drinking and continues for as long as alcohol is still measurable in the blood. When BAC drops below 0.1–0.2 g l^{-1}, the major metabolizing enzymes are no longer saturated with substrate and zero-order kinetics changes to first-order kinetics. The BAC time curve changes from a straight line to become curvilinear and the elimination rate thereafter decreases with diminishing BAC [22]. In reality, however, ethanol is a good example of a drug that displays dose-dependent saturation kinetics and the shape of the elimination phase spanning from high- to low-BAC looks more like the shape of a hockey stick rather than a straight line [20–22]. Mathematically, the concentration–time data in the postabsorptive part of the BAC *versus* time curve is best described by the Michaelis–Menten equation as

$$\text{Rate of metabolism } (-dC/dt) = (V_{max} \times \text{BAC})/K_m + \text{BAC} \quad (6)$$

This equation assumes the existence of a single enzymatic reaction with a Michaelis constant K_m and a maximum velocity of V_{max} and BAC represents the substrate concentration [20]. When the BAC is considerably higher than the value of K_m (0.05–0.1 g l^{-1} for ADH), the above equation simplifies to an equation resembling zero-order kinetics.

$$\text{Rate of metabolism } (-dC/dt) = V_{max} \quad (7)$$

When the BAC is much less than K_m, the Michaelis–Menten equation reduces to the equation for first-order kinetics with the elimination rate being directly proportional to the substrate concentration. The first-order rate constant (k_1) is given by the ratio of V_{max}/K_m.

$$\text{Rate of metabolism } (-dC/dt) = (V_{max}/K_m) \times \text{BAC} \quad (8)$$

$$\text{Rate of metabolism } (-dC/dt) = k_1 \times \text{BAC} \quad (9)$$

Since BAC greatly exceeds 0.2 g l^{-1} in most forensic science applications, the concepts of zero-order kinetics as developed by Widmark are still widely used and remain valid.

As mentioned above, the rate of ethanol metabolism from the whole body is close to 0.1 g kg^{-1} body weight per hour or 7 g h^{-1} for a 70 kg person. The Widmark equation, which was used above to calculate the quantity of alcohol in the body, can be expanded to allow for metabolism of ethanol since the time of starting to drink ($0.1 \times \text{BWt} \times t_h$), where t_h is the number of hours elapsed.

$$A = [(\text{BAC} \times \text{BWt} \times r) + (0.1 \times \text{BWt} \times t_h)] \quad (10)$$

The above formula is useful to evaluate statements made by drunken drivers as to how much alcohol had actually been consumed that evening. The quantity of alcohol obtained in grams can then be converted into the volumes of different kinds of beverages depending on their alcoholic strength (Table 2).

Making forward projections of BAC from information provided by a person suspected of alcohol-impaired driving is not recommended because of the obvious lack of truthfulness in such statements. Moreover, there is always uncertainty, as mentioned above, in the extent of FPM of orally ingested alcohol. The concentration of alcohol in a specimen of venous blood provides the most reliable information about the amount of alcohol a person has consumed. Use of the above equation tends to give a conservative estimate of the amount of alcohol actually ingested because bioavailability of the dose is rarely 100%.

The BAC expected to exist some time after the end of drinking when absorption and distribution are complete is given by the equation below, where t_h is the time in hours after drinking started, β is the factor developed and used by Widmark to represent the rate of alcohol elimination form the bloodstream (see later), A is dose (g) of ethanol ingested, kg is body weight, and r is the apparent volume of distribution of ethanol.

$$\text{BAC} = (A/\text{kg} \times r) - (\beta \times t) \quad (11)$$

Updating the Widmark Equation

Widmark's pioneer work on alcohol pharmacokinetics was done in the 1930s with 20 men and 10 women serving as the test subjects [12]. A number of attempts have been made to update the Widmark factors, which seemed to be motivated considering that body composition has changed considerably since the 1930s with more obese people in today's society [13].

The results from many controlled drinking experiments led to the conclusion that C_0 values as derived by Widmark's method were less than expected, which meant that the r-factor (ratio of dose/C_o) was correspondingly higher. This finding led to the notion of an alcohol absorption deficit amounting to about 10% of the dose of ethanol administered. The most likely explanation for this deficit is FPM of ethanol occurring in the stomach, the liver, or both organs. Accordingly, there is a general agreement that under social drinking conditions a part of the dose of alcohol ingested (~10%) never actually reaches the systemic circulation, which has consequences when blood-alcohol calculations are made for legal purposes.

Another modification of the Widmark formula entailed calculating a person's TBW based on readily available anthropometric data such as age (years), weight (kg) the height (cm) [23]. The TBW derived in this way and knowledge of the water content of whole blood (80% w/w or 84% w/v) allow calculation of the Widmark r-factor as the ratio between the percentages of water in the body to that in the blood. Two widely used formulae for computing TBW for men and women using anthropometric data are given below:

$$\text{TBW (liters for men)} = 2.447 - 0.09516\ \text{age (years)} + 0.1074\ \text{height (cm)} + 0.3362\ \text{weight (kg)} \quad (12)$$

Residual standard deviation = 3.78 l

$$\text{TBW (liters for women)} = -2.097 + 0.1069\ \text{height(cm)} + 0.2466\ \text{weight (kg)} \quad (13)$$

Residual standard deviation = 3.60 l

The above equations offer the advantage that they are tailored for the individual concerned and consider differences in body shape and size. Note that the water content of blood in this equation should have the same unit mass/volume or mass/mass as used for reporting the BAC. For a man aged 45 years, a body weight of 85 kg, and a height of 184 cm, use of equation 12 gives TBW as 46.5 l or 54% of body weight. If the water content of whole blood is taken as 84 g/100 ml (84% w/v), the ratio of TBW (%) to blood water (%) is 0.64 l kg^{-1}, which is another way to derive the Widmark r-factor for this person.

The residual standard deviation (SD) in the above equations gives an idea of the amount of uncertainty in the calculation of TBW using anthropometric data. Thus, 95% of individuals will have a TBW within $\pm 2 \times$ SD of mean, which corresponds to roughly $\pm$ 20% for a person with a TBW of 40 l.

Interindividual Variations in Elimination Rate of Alcohol from Blood

Two pharmacokinetic parameters of alcohol are important when BAC is interpreted in forensic science and legal medicine. The first is the distribution volume of ethanol, which corresponds to the Widmark r-factor discussed in detail above and the second is the rate of elimination of alcohol from the bloodstream, corresponding to the slope of the linear elimination phase (see Figure 3). On the basis of hundreds of controlled alcohol dosing studies in healthy volunteers as well as in alcoholics during detoxification and in drunken drivers, a wide range of values for the alcohol burn-off rate have been published [10, 22].

Figure 5 presents a cumulative frequency distribution of the elimination rates of alcohol from blood in drunken drivers. These values were derived by taking two blood samples about 60 min apart from each apprehended driver and using the equation β-slope = $(BAC_1 - BAC_2)/t_{diff}$ [24]. This calculation assumes

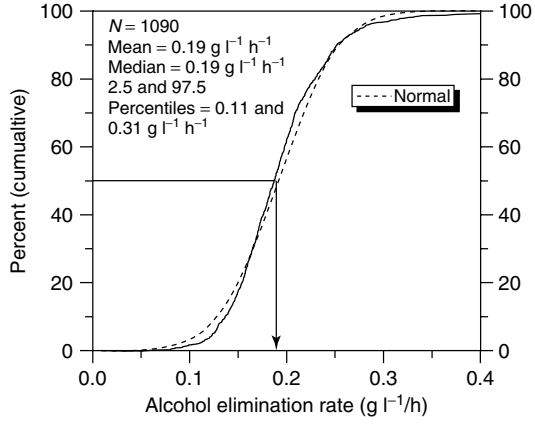

Figure 5 Cumulative frequency distribution (%) of elimination rates of ethanol from blood in drunken drivers derived from double blood samples (1 h apart), which assumes the existence of the postabsorptive stage of the blood-alcohol curve when the first blood sample was taken

that all individuals are already in the postabsorptive phase of the BAC curve when the first sample of blood was taken. The frequency distribution shows a good fit to a Gaussian curve with mean and median values 0.19 $g\,l^{-1}\,h^{-1}$ and a 95% range from 0.11 to 0.31 $g\,l^{-1}\,h^{-1}$. Values less than 0.1 $g\,l^{-1}\,h^{-1}$ should be considered suspect and probably represent those individuals still absorbing alcohol when the first-blood sample was taken.

On the basis of hundreds of controlled alcohol dosing studies with moderate drinkers as well as alcohol-dependent individuals, a realistic physiological range of ethanol elimination rates from blood in humans (Widmark's β-factor) is given in Table 7. The rate of elimination of ethanol in the vast majority of people can be expected to range form 0.1 to 0.25 $g\,l^{-1}\,h^{-1}$ and these extreme values are recommended for use if a retrograde extrapolation is made [5, 25]. The average elimination rate in drunken drivers is 0.19 $g\,l^{-1}\,h^{-1}$, which can be compared with 0.15 $g\,l^{-1}\,h^{-1}$ in moderate drinkers. The difference can be explained by a higher proportion of heavy drinkers and alcoholics among apprehended drivers having an enhanced capacity to metabolize alcohol via the CYP2E1 pathway.

There is some evidence of racial and ethnic differences in the rate of ethanol elimination from the bloodstream, because of polymorphism of the class I hepatic ADH enzyme. Studies have shown that metabolism of ethanol in East Asians, such as Japanese, occurs at a slightly faster rate than in Caucasians, judging by a steeper slope of the BAC curve in the postabsorptive state [10, 17]. Genetic polymorphism of the class I ADH enzyme means that Asians inherit a β_2 enzyme with higher V_{max} for ethanol as substrate [10]. Nevertheless, Asians show a considerable overlap with Caucasians and African Americans in the elimination rate of ethanol from blood, so the racial differences probably lack any forensic significance.

Forward and Backward Extrapolation of BAC

The BAC is a valid and reliable measure of the concentration of ethanol in the blood only at the time of sampling. In forensic casework, police authorities often want to know what the BAC was a few hours before or after the blood sample was taken [5, 25]. For example, after involvement in a traffic crash, a blood sample from the driver might not be obtained until several hours afterwards and the question naturally arises what was the BAC at the time of the crash.

Another situation arises in cases of alleged sexual assault when the victim reports the attack several hours afterward. The long delay between time of the

Table 7 Suggested physiological range of ethanol elimination rates from blood and the body as a whole under various conditions and circumstances

Elimination rate from blood ($g\,l^{-1}\,h^{-1}$)	Elimination rate form body ($g\,h^{-1}$)[(a)]	Subject conditions, treatment, or special circumstances
0.08–0.10	4–5	People with liver dysfunction (e.g., owing to cirrhosis or carcinoma) or who might be malnourished or on low-protein diets. Treatment with the drug fomepizole (4-methyl pyrazole), which blocks activity of alcohol dehydrogenase.
0.10–0.12	5–6	Consumption of moderate doses of alcohol by healthy individuals after an overnight (10 h) fast.
0.12–0.16	6–8	Consumption of moderate doses of ethanol under nonfasting conditions.
0.16–0.25	8–12	Drinking by healthy individuals to reach intoxicating BAC ($>1.2\,g\,l^{-1}$ or 120 mg/100 ml) such as in many drunken drivers.
0.25–0.35	12–17	Alcoholics during detoxification and people that drink continuously over several days or weeks to reach high BAC ($>3\,g\,l^{-1}$). People with a genetic predisposition or in a hypermetabolic state (e.g., after burn trauma or hyperthyroidism).

[(a)]This calculation assumes a normal nonobese person with a body weight of 70 kg and a Widmark r-factor (distribution volume) of 0.71 kg^{-1}

crime and obtaining a blood sample for toxicological analysis means that some drugs are no longer measurable. The police therefore might want to know what the BAC was at the time of the alleged assault and whether the victim was incapacitated because of too much drink or drugs [26].

In an actual case of drunken driving, a man was arrested by the police and a blood sample was taken for determination of alcohol content. The man was released but sometime afterward he was again observed driving, although on this occasion a blood sample was not available for analysis. Under these circumstances, the police might want to know whether the man was above the legal limit on the second occasion based on the concentration in the first blood sample and information about the rate of alcohol metabolism.

Since the metabolism of ethanol occurs at a constant rate per unit time in a large segment of the BAC curve, this makes forward or backward extrapolation feasible under certain circumstances [5, 10, 25]. The first condition necessary is that the postabsorptive phase was reached at the time of driving or when a crash occurred (e.g., 90 min in Figure 3). The second is that the rate of alcohol elimination from the bloodstream is known or a value that does not prejudice the suspect (e.g., $0.1\,g\,l^{-1}\,h^{-1}$) is assumed. Third, a deduction should be made from the average BAC to allow for uncertainty in the analysis and back-extrapolation should then start from this lower value and not the average BAC.

Interpreting Blood-Alcohol Concentrations in Samples Obtained at Autopsy

The use and abuse of alcohol in society has meant that drunkenness is a prime factor in many accidents on the roads, at home and in the workplace [3]. Alcohol intoxication is often an underlying factor in violent crime such as homicide, muggings, and sexual assault. Alcohol therefore tops the list of drugs identified in blood specimens taken during routine forensic autopsies and investigations of all out of hospital deaths [27, 28].

During investigations of road-traffic fatalities, a key question is whether the driver was under the influence of alcohol or drugs at the time of the crash. This becomes important when responsibility for the crash is investigated and insurance claims are made. Likewise, alcohol intoxication and drunkenness are prominent in many other traumatic events including fights, homicides, suicides, and drowning. Knowledge of the BAC in the deceased provides useful information when the cause of death is determined.

The methods used to measure alcohol (ethanol) in blood and other body fluids are the same regardless of whether specimens are obtained from the living or the dead [29]. However, great care is needed when the results of postmortem analysis are interpreted and a conclusion is reached about the state of inebriation or drunkenness at the time of death. Unlike drawing blood from a living person, there are a number of artifacts that should be considered in postmortem toxicology [27–29]. However, the situation is simplified because a much wider section of biological specimens are available from a corpse, thus making toxicological results easier to interpret.

Postmortem Aspects

The quality and composition of the blood samples obtained at autopsy can vary widely depending on the circumstances surrounding the death and the condition of the body, such as degree of trauma and whether decomposition and putrefaction had commenced [28–30].

The recommended sampling site for blood in postmortem toxicology is a femoral vein after cross-clamping. Sampling blood from the heart or pleural cavity is not recommended because of the risk that alcohol might have escaped from the stomach to contaminate the sampling site. Aspiration of stomach contents during the agonal period means that alcohol gets into plural cavity blood via the lungs. After death the body should be handled with care by the crime scene investigators or during transportation and storage at the mortuary to minimize spread of any alcohol. All such factors can lead to redistribution of alcohol from stomach contents if heavy drinking had occurred just prior to death [31].

In bodies autopsied within 24 h of death and when trauma is minimal, the concentration of alcohol in femoral venous blood is the closest one can come to knowing the antemortem concentration. Indeed, there is some evidence that a decrease in concentration occurs after death because metabolizing enzymes retain some activity for a few hours after death as the body cools. If the autopsy and sampling of blood

for toxicology is done the same day, then a chemical preservative, such as sodium fluoride, is probably not necessary. For longer delays and when specimens are sent by mail to another laboratory, it is imperative to include sodium or potassium fluoride as a preservative in blood and other biological specimens (1–2% w/v). The fluoride ion functions as an enzyme inhibitor and prevents the synthesis of ethanol by fermentation processes after sampling. However, this does not rule out that ethanol had already been produced before the autopsy was performed [30, 32] (*see also* **Toxicology: Analysis**.)

Alternative Body Fluids

The results of postmortem blood-alcohol analysis are considerably strengthened if other body fluids are submitted for analysis along with the blood sample (e.g., urine and vitreous humor (VH)). In postmortem work in addition to cardiac or femoral venous blood, urine, VH, and cerebrospinal fluid (CSF) are the most useful specimens for determination of ethanol [33, 34]. These other biofluids, which are ~100% water, are obtained from the urinary bladder, the eye, and the back of the neck (cisternal fluid), respectively. The concentrations of alcohol depend on water content and also on time after drinking and the status of alcohol absorption and distribution in the body when death occurred. The concentrations of alcohol measured in VH, urine, and CSF are displaced in time compared with the venous BAC. During the absorption stage, the concentrations of alcohol are lower in these alternative fluids compared to the blood, although 1–2 h later when equilibration of ethanol in all body fluids is complete, the VH, urine, and CSF contain a higher concentration, by ~20%, compared with that of the blood samples.

Vitreous fluid from the eye is an important biological specimen in postmortem toxicology for several reasons. First, VH is a relatively clean watery fluid easily obtained with syringe and needle even without conducting a complete autopsy. Second, the remote nature of the eyes compared with the gut means that the spread of bacteria to contaminate the VH is much less likely than the contamination of central or peripheral blood during autolysis [34]. When the corpse has been subjected to severe trauma, a suitable blood sample might not be available and with some reservations the BAC can be estimated indirectly by the analysis of ethanol in the VH or the urine, albeit with considerable uncertainty.

When the body has undergone putrefaction, the BAC result is obviously suspect, owing to the risk of microbial formation of ethanol from glucose present in the blood. Under these circumstances, VH gives a more reliable indication of whether the deceased had consumed alcohol and might have been drunk at the time of death. Figure 6 shows a high correlation between the concentrations of ethanol in VH and in femoral blood ($r = 0.98$) at autopsy. The average VH/BAC ratio of ethanol concentration was 1.19 : 1 (SD = 0.28) and the range was from 0.28 to 2.90 [34].

The distribution ratios for urine/blood, vitreous/blood, and CSF/blood change as a function of time after drinking. Much depends on the position of the alcohol curve and absorption or postabsorptive phase of metabolism at the moment of death [27]. On the ascending limb of the BAC profile, the concentrations of ethanol in urine, VH, and CSF are lower than or about the same as in venous blood. In the postpeak descending limb of the BAC profile, which corresponds to the postabsorptive phase, the concentration of ethanol in urine, VH, and CSR are always higher than that in the blood. Indeed, alcohol might still be measurable in these alternative specimens even though BAC is reported as negative. Table 8 compares the water contents of body fluids and tissues usually available for the analysis of ethanol at autopsy and gives expected ratios of the concentrations of ethanol relative to blood samples.

Traumatic injuries and death by blunt force with open wounds and massive blood loss are factors that increase the risk of bacteria entering the body. Under these circumstances fermentation processes might produce ethanol before an autopsy is performed. This risk is heightened at elevated environmental temperatures (summer months) and when a long time elapses before recovery of the body, e.g., after an air disaster or death at sea [28]. Although a fluoride preservative is routinely added to blood specimens taken at autopsy, some alcohol might have been synthesized in body cavities between the time of death and autopsy.

After skull trauma, blood is often sampled from a subdural hematoma or a clot in the brain, which furnishes useful information in postmortem toxicology. Because of reduced or nonexistent blood circulation to the clot, any alcohol it contains does not

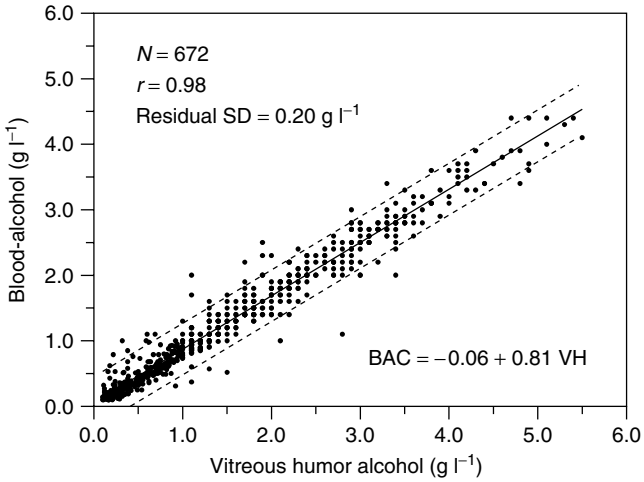

Figure 6 Correlation between the concentrations of ethanol determined in femoral venous blood and vitreous humor samples obtained at autopsy

Table 8 Average water contents of whole blood, body fluids, organs, and tissues and the concentration ratios of ethanol relative to whole blood

Specimen	Water content (% w/w)	Ratio of ethanol concentration relative to whole blood[a]
Whole blood[b]	78–81	1.0
Plasma/serum	91–93	1.1–1.2
Erythrocytes	68–71	0.8–0.9
Urine	98–99	1.2–1.4[c]
Vitreous humor	99–100	1.1–1.3
Cerebrospinal fluid	98–99	1.1–1.3[d]
Bile	87–97	0.8–1.0
Synovial fluid	92–96	1.1–1.2
Liver	80	0.6–0.8
Brain	75	0.8–1.0
Skeletal muscle	76	0.8–0.9
Kidney	79	0.6–0.7

[a] The values can differ depending on the concentration of alcohol in the samples and the time after drinking when death occurred
[b] Depends on water content and hematocrit of blood sample, which in turn depends on gender and the condition of the body
[c] The ratio depends on the stage of alcohol absorption and distribution at time of death
[d] Lumbar fluid taken during postabsorptive phase

undergo metabolism. The concentration of ethanol in the sequestered hematoma therefore gives an indication of the person's BAC some hours earlier, such as when the trauma occurred. For example, if a person suffers a blow to the head when drunk but survives for many hours before death, considerable amounts of alcohol are eliminated by metabolism ($0.15\,g\,l^{-1}\,h^{-1}$). If 10 h elapses before death, then a BAC of $1.5\,g\,l^{-1}$ is no longer measurable. However, the concentration measured in the blood clot can furnish useful information about the BAC at an earlier time, such as when the clot was formed. Contamination of the wound with bacteria and the rate of formation of the clot and other factors need to be considered.

Any emergency life-saving treatment administered at the crash site, such as intravenous fluids to counteract shock, and massive blood loss are also important to consider. Table 9 lists many of the considerations necessary when results of postmortem alcohol analysis are reported and interpreted.

Biochemical Markers of Alcohol Consumption

Considerable research has been done to develop a biochemical marker of acute and chronic alcohol consumption. In this connection, the formation of the nonoxidative metabolites of ethanol, namely, EtG and EtS, has attracted a lot of attention [35, 36]. The presence of these metabolites in body fluids taken at autopsy means that ethanol must have undergone metabolism during life, which supports

Table 9 Factors to consider when the results of blood-alcohol analysis in postmortem specimens are interpreted

1. Specificity of the analytical method and whether other volatile substances might have interfered with the determination of ethanol.
2. Time between death, recovery of the body, and the postmortem examination.
3. Condition and location of the body:
   (a) Indoors or outdoors
   (b) Time of year
   (c) Temperature and humidity of the environment
   (d) Extent of traumatic injuries
   (e) Abdominal trauma, e.g., ruptured stomach
   (f) Incinerated body
   (g) Body recovered from water
   (h) Extent of decomposition/putrefaction, bad smell, maggots, etc
4. Was a preservative (NaF ~2%) added to all specimens submitted for toxicology?
5. Risk of contamination of specimens with extraneous solvents during emergency service treatment at hospital, the mortuary, or the analytical laboratory.
6. Was the body embalmed and if so what embalming fluids were used and did they contain any alcohols?
7. Compare and contrast the concentrations of ethanol expected in different sampling sites after considering water content of the specimens (blood, urine, and vitreous humor)
8. Should the water content of blood be determined and results of alcohol analysis adjusted to blood-water content of 80% w/w?
9. Variations in alcohol concentration depending on absorption or postabsorptive stage of the blood-alcohol curve when death occurred.
10. How was the body handled at the scene of death and during transport and storage at the mortuary?
11. Any evidence of recent consumption of alcohol before death?
12. Concentration of ethanol in stomach contents, risk of postmortem diffusion, and aspiration of vomit during the agonal period.
13. Changes in ethanol concentration caused by evaporation, dilution, or degradation of ethanol after death.

antemortem consumption of alcohol. If ethanol was present in blood and urine taken at postmortem and EtG and EtS were shown to be negative, then this would raise a warning flag that the ethanol was probably produced after death as a result of microorganisms acting on carbohydrates or other substrates. Even other urinary markers of acute alcohol ingestion such as the metabolites of serotonin and the ratio of 5-hydroxytryptophol (5HTOL) to 5-hydroxyindole acetic acid (5HIAA) are available [36].

Biochemical markers are useful to detect damage to organ and tissue as a consequence of heavy drinking so that treatment can be given before liver cirrhosis and death occurs. This entails measuring the concentration of certain hepatic enzymes such as gamma-glutamyltransferase (GGT), aspartate aminotransaminases, and alanine aminotransaminases (AST and ALT). Concentrations are elevated in serum after a long period of heavy drinking because they leak into the bloodstream when the liver is damaged by the alcohol [37]. Enlarged size of the red blood cells, mean corpuscular volume (MCV), is another widely used marker of chronic drinking in combination with the enzyme markers [36].

Carbohydrate deficient transferrin (CDT) is another marker of heavy drinking used in clinical medicine but also with forensic applications thanks to good sensitivity and high specificity. Transferrin is a plasma protein synthesized and secreted by the liver that serves to transport iron in the body [36]. After a period of continuous heavy drinking (60–80 g/day over many weeks), glycosylation of the transferrin molecule is altered and this is reflected in the loss of one or more of the carbohydrate moieties, hence the name carbohydrate deficient.

The methods used to determine serum CDT are now much improved, e.g., by use of capillary electrophoresis and high performance liquid chromatography (HPLC), and interlaboratory reporting of the results of CDT analysis is now better standardized. CDT is the marker of choice to screen individuals for excessive drinking before the liver is too severely damaged and helps to corroborate results from the use of clinical interviews and questionnaires [35–37]. CDT is considered to be the most specific marker of

Table 10 Typical signs and symptoms of alcohol influence in relation to the person's blood-alcohol concentration (BAC)

BAC $g\,l^{-1}$ (mg/100 ml)	Signs and symptoms of alcohol influence[a]
0.0–0.2 (0–20)	Sobriety, no untoward effects, or outward signs
0.3–0.5 (30–50)	Less inhibited (euphoria), more talkative, impairment of certain cognitive tasks and skills that require divided attention
0.5–1.0 (50–100)	More rowdy and daring, sensory and motor disturbances, slowed reaction time especially in choice situations
1.0–1.5 (100–150)	Lack of coordination, unsteady gait, slurred speech, prolonged reaction to sights and sounds.
1.5–2.0 (150–200)	Obvious drunkenness, aggressive behavior, and ataxia significantly slowed reaction time even when relatively simple tasks are performed; nausea and vomiting in some individuals especially if the BAC increases rapidly to reach these levels
2.0–3.0 (200–300)	Not able to stand upright or walk unaided, incoherent speech, and motor areas of the brain are markedly influenced, thus distorted perception of time and judgment and near comatose state
3.0–4–0 (300–400)	Confusion, stupor, or coma with shallow breathing, risk of respiratory arrest, loss of gag reflex, and risk of inhalation of vomit
4.0–5.0 (400–500)	Profound risk of death from respiratory paralysis and cardiopulmonary arrest

[a]Both subjective and objective measures of alcohol influence are more pronounced on the rising part of the BAC curve close to the C_{max} compared with several hours later during the postabsorptive phase. This difference in the effects of ethanol is related to the phenomenon of acute tolerance or the Mellanby effect (see main text for details)

excessive drinking and false-positive test results are rare. CDT has found forensic applications to evaluate drinking habits of convicted drunken drivers before they are allowed to retake a drinking test. Biomarkers find use in many other situations when there is a need to verify that a person is no longer a problem drinker, such as when it comes to rehabilitation of alcoholics and custody of children, etc.

Development of Tolerance to Ethanol

It is common knowledge that the effects of drugs differ widely between different individuals despite intake of the same dose under otherwise identical conditions [16]. Regular drinkers can tolerate more alcohol and appear less influenced compared with moderate or nondrinkers with the same BAC. Among other things, this raises the question of whether BAC is really such a reliable indicator of the degree of alcohol influence in any individual case.

Table 10 lists various clinical signs and symptoms of alcohol influence as a function of increasing BAC. Much variation can be expected in the individual case, depending on the time after drinking when the observations are made. The degree of impairment after drinking alcohol depends on the speed of drinking, and elapsed time after the end of drinking when tests or observations were made. People feel more impairment on the rising limb of the BAC curve compared with the declining limb although previous experience with drinking alcohol and habituation are important considerations.

The development of tolerance to the effects of alcohol or other drugs and the underlying mechanisms involved are complex topics involving behavioral changes and learning effects [38, 39]. Tolerance implies the ability to lessen the untoward effects of drugs after repeated exposure. To the pharmacologist, tolerance is often illustrated by a shift in the sigmoid dose–response curve to the right so that larger doses of a drug are required to produce the same degree of effect on the individual. Several different kinds of tolerance need to be distinguished and defined in connection with interpretation of BAC in forensic casework.

The first and simplest kind of tolerance is referred to as *dispositional tolerance*, which has to do with altered absorption, distribution, metabolism, or excretion of ethanol during chronic treatment. The rate of absorption of ethanol is closely linked to gastric emptying, which in turn depends on factors such as dose and speed of drinking, fed or fasting state, concentration of ethanol in the beverage, and various hormonal influences [10]. Speed of distribution is determined by blood flow and tissue mass and the proportion of lean-to-fatty tissue in the body. The amounts of ethanol eliminated via breath, sweat, and urine are trivial (2–5%) and are dependent on simple physical

diffusion, which in turn is a function of the BAC. These diffusion processes are not markedly altered after a period of continuous heavy drinking.

The rate of metabolism of ethanol is accelerated after a period of continuous heavy drinking, although the amounts of ethanol that have to be consumed and the duration of drinking are not well defined. The mechanism seems to involve the CYP2EI enzyme, which acquires an enhanced capacity to oxidize ethanol after chronic administration of substrates, such as ethanol as well as other drugs (e.g., barbiturates). This faster elimination of certain drugs from the body after chronic exposure is referred to as *metabolic tolerance*. However, studies have shown that after a few days of abstinence from alcohol, the rate of metabolism returns to normal as CYP2E1 enzyme becomes resynthesized. Thus, heavy drinkers or alcoholics do not necessarily show a faster rate of ethanol metabolism after they have remained sober a few days. Some alcoholics might have an abnormally slow rate of metabolism owing to malnutrition and liver damage (cirrhosis) caused by the abuse of alcohol.

A well-studied and well-recognized form of tolerance is *acute tolerance*, which develops during a single exposure to ethanol [40]. The degree of intoxication, both subjective and objective, changes as a function of time after the end of drinking a known amount of ethanol. The signs and symptoms of alcohol influence are less pronounced on the descending limb of the BAC curve about 3–4 h after the end of drinking compared with the ascending limb before reaching C_{max}.

Acute tolerance to alcohol is therefore characterized by a diminished effect of the drug at the same blood or brain concentration on the descending phase of the BAC curve compared with the ascending phase [41]. This phenomenon seems to be related to an adaptation of the brain cells and membrane receptors to an alcohol environment within a few hours of exposure to a single intoxicating dose. The exact mechanisms involved are unknown but seem to involve both learning phenomenon and adaptation to the impairment effects of the drug [38, 39]. Acute tolerance to alcohol is sometimes referred to as the *Mellanby effect*, named after the British pharmacologist (Sir Edward Mellanby), who first observed the phenomenon and published results of his experiments of alcohol intoxication in dogs [41].

Chronic tolerance is a more gradual process resulting in a diminished intoxicating effect after a period of continuous heavy drinking lasting several days or weeks without a period of abstinence. Those with a developed chronic tolerance at first sight will not exhibit overt signs of drunkenness, apart from a strong smell of alcohol on the breath, with BAC of $2–3\,g\,l^{-1}$ (0.2–0.3 g%). Table 11 shows the results from a clinical examination and questionnaire administered to a large number of apprehended drunken drivers 2 h or more after they were arrested. The examining physicians were not aware of the person's BAC and the assessment was based on answers to questions and simple clinical tests of motor and cognitive functioning. The physicians were asked to grade their findings and to conclude whether the people examined were not influenced, slightly influenced, moderately influenced, or heavily under the influence of alcohol.

The data in the table demonstrate large discrepancies at one and the same BAC depending on, among other things, differences in training, experience, and enthusiasm on the part of the physician for

Table 11 Relationship between blood-alcohol concentration (BAC), number and percent of individuals judged not, slightly, moderately, or severely influenced by alcohol according to a clinical examination and questionnaire administered by a physician (police surgeon)[(a)]

BAC ($g\,l^{-1}$) (mg/100 ml)	N	Not under influence (%)	Slightly under influence (%)	Moderately under influence (%)	Severely under influence (%)
0.0–0.49 (0–49)	103	52 (50)	47 (46)	4 (4)	0 (0)
0.50–0.99 (50–99)	223	111 (49)	90 (40)	22 (10)	0 (0)

[(a)] Those examined were suspected for drunken driving in Sweden

this task, and inherent differences in tolerance (acute and chronic) in the people being examined.

The type of tolerance that develops after long-term use of alcohol is sometimes referred to as *behavioral or functional tolerance* because it relates to an altered sensitivity of the brain to the effects of the drug. The underlying mechanism of functional tolerance, which manifests in marked behavioral effects of the drug after repeated exposure, is complex involving environmental, psychological, and genetic factors. The drinking pattern and amounts of alcohol necessary to elicit a chronic tolerance also causes physical dependence. Evidence of this comes from the physiological disturbances after cessation of drinking and when the BAC drops toward a zero concentration. Indeed, the severity of physiological disturbances during alcohol withdrawal can prove life threatening. To alleviate the withdrawal symptoms, patients are treated with drugs, such as barbiturates or benzodiazepines, that exhibit cross-tolerance to ethanol. The corresponding withdrawal stage after acute ingestion of ethanol (a single exposure) corresponds to the well-known hangover syndrome.

How Dangerous is Ethanol?

In the field of forensic toxicology, drugs are classified as either licit or illicit and also in terms of their toxicity. Along with nicotine from use of tobacco products and caffeine from consumption of coffee or tea, ethanol is a socially accepted legal drug. All pharmaceutical products are legal drugs although many such as opiates and benzodiazepines are classified as narcotics and are subject to abuse. The classic illicit drugs are heroin, cannabis, cocaine, ecstasy, lysergic acid diethylamide (LSD), amphetamine, methamphetamine, and gamma-hydroxybutyrate (GHB). When assessing the dangerousness of drugs, there are many factors to consider besides the risk of acute toxicity, such as dependence liability and social and medical harm caused to the individual and the costs to society for treatment and rehabilitation of those addicted to drugs [42].

With regard to acute toxicity, ethanol should be considered a fairly dangerous drug. The BAC associated with mild euphoria ($0.4–0.5\,g\,l^{-1}$) is only 10 times less than the BAC that could cause death ($4.0–5.0\,g\,l^{-1}$), through respiratory paralysis. This gives a ratio of lethal dose to effective dose of 10 : 1, which is a narrow safety margin for a legal drug. Besides acute toxicity, it is also important to consider the potential of a drug to cause physical and psychological dependence and craving.

In a large case series of forensic autopsies ($N = 693$), the concentration of ethanol in femoral venous blood was evaluated when the cause of death was attributed to acute alcohol poisoning [43]. Figure 7 depicts the frequency distribution of BAC in these blood specimens and this shows a good fit to a bell-shaped or Gaussian curve. This means that ~95% of cases are within ±2 SD around the mean. The mean, SD, and median concentration of ethanol in femoral

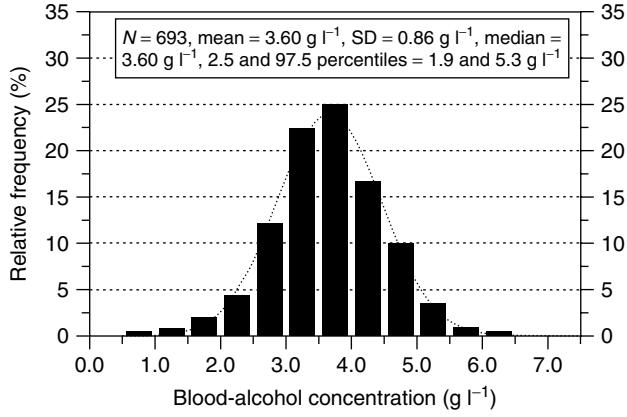

Figure 7 Frequency distribution of the concentration of ethanol in femoral blood in deaths attributed to acute alcohol poisoning (no other drugs present in blood) by the pathologist

blood were 3.6 , 0.86, and 3.6 g l^{-1}, respectively, and therefore 95% of cases are within 1.9 and 5.3 g l^{-1} (mean ±2SD).

Multiple sampling is a golden rule in forensic medicine and toxicology, so besides blood or plasma urine should be also obtained and sent for the analysis of ethanol and other drugs. Figure 8 shows the frequency distribution of urine–alcohol concentration (UAC) in deaths attributed to acute ethanol poisoning and when no other drugs were detected [44]. The mean and median concentrations are noticeably shifted toward higher values compared with BAC (Figure 7) as expected from the difference in water content between blood and urine. The frequency distribution of UAC is also a good fit to a Gaussian curve; mean, median, and 2.5 and 97.5 percentiles of 4.3, 4.3, and 2.4 and 6.1 g l^{-1}, respectively.

The UAC is higher than BAC not only because of the higher water content of ~100% in urine compared with that of ~80% in blood, but also because most people die after ethanol is fully equilibrated in all body fluids [44]. The value of the UAC/BAC ratio can give a clue to whether absorptive was ongoing (UAC/BAC values <1.1) or whether the postabsorptive phase was reached (UAC/BAC values >1.25) at the time of death [33, 44].

The BAC and UAC curves are shifted in time with UAC being less than BAC during the absorption phase and always higher than BAC in the postabsorptive period (Figure 9**).** This difference in the concentration–time profiles of ethanol in successive urine voids and in blood has implications for the pharmacokinetic parameters of ethanol in blood and urine. In the experiment depicted in Figure 9, each subject emptied the bladder of residual urine before the start of drinking. Alcohol was served as neat whisky (0.85 g kg^{-1}), which was finished in 25 min and consumed on an empty stomach after an overnight fast.

Lethal Dose of Ethanol

Deaths caused by uncomplicated alcohol poisoning, that is, through depression of the central nervous system and paralysis of respiration and collapse of circulation generally occur at a BAC between 4 and 5 g l^{-1} [40, 43]. After drinking massive amounts of alcohol, the individual progresses through various stages of intoxication (see Table 10) before death occurs. If a BAC of 5 g l^{-1} is considered sufficient to cause death, then the Widmark equation can be used to calculate the amount of ethanol that needs to be consumed to reach this level.

Table 12 gives the results of this calculation showing the number of grams of ethanol that are absorbed and distributed in all body fluids in a person with a BAC of 5 g l^{-1}. The results are illustrated for males and females with body weights ranging from 10 to 100 kg. Besides the mean quantity of ethanol in the body, the 95% range is included based on knowledge about intersubject variation in the distribution volume of ethanol (Widmark's *r*-factor). The lethal dose of ethanol is slightly higher for men 3.5 g kg^{-1} (range 2.8–4.2 g kg^{-1}) compared with that

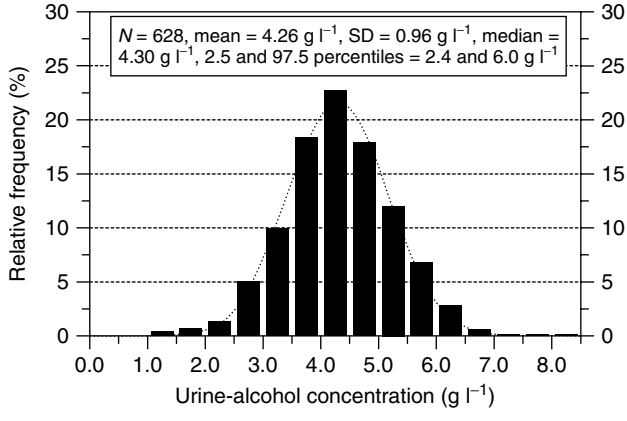

Figure 8 Frequency distribution of the concentrations of ethanol in bladder urine in deaths attributed to acute alcohol poisoning

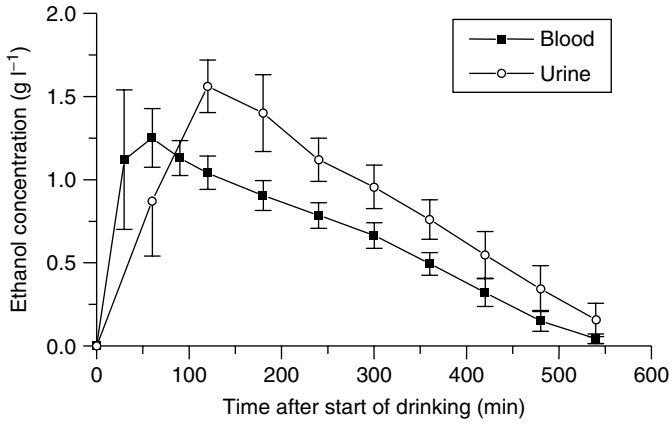

Figure 9 Concentration–time profiles of ethanol in successive urinary voids and in blood samples from healthy volunteers after they drank 0.85 g ethanol per kg body weight on an empty stomach

Table 12 The amounts of ethanol absorbed and distributed in all body fluids and tissues and the 95% range considered necessary to cause death by acute alcohol poisoning. Results are shown for both sexes as a function of body weight. In the calculation, a BAC of 5 g l^{-1} was considered sufficient to cause death by paralysis of respiratory centers in the brain

Body weight (kg)	Males[a] (g ethanol) Mean (95% range)	Females[b] (g ethanol) Mean (95% range)
10	35 (28–41)	30 (24–36)
20	70 (56–84)	60 (48–72)
30	105 (84–126)	90 (72–108)
40	140 (112–168)	120 (96–144)
50	175 (134–216)	150 (120–180)
60	210 (168–252)	180 (144–216)
70	245 (196–294)[c]	210 (168–252)
80	280 (224–336)	240 (192–288)[c]
90	315 (252–378)	270 (216–324)
100	350 (280–420)	300 (240–360)

[a] Average r-factor for males = 0.71 kg^{-1} with 95% range ±20%
[b] Average r-factor for females = 0.61 kg^{-1} with 95% range ±20%
[c] A bottle of spirits 40% v/v contains about 240 g ethanol

for women 3.0 g kg^{-1} (range 2.4–3.6 g kg^{-1}). For a man with a body weight of 70 kg, he would need to consume 240 g of ethanol or the amount contained in a whole bottle (750 ml) of liquor (whisky or vodka) to die from acute alcohol poisoning.

Heavily intoxicated people are overrepresented among patients admitted to hospital for treatment of head trauma and brain hemorrhage, which is a common cause of death in alcoholics [3]. Drinking on an empty stomach and neglecting to eat properly is dangerous because of ethanol-induced disturbances in carbohydrate metabolism and risk of developing life-threatening hypoglycemia (low blood sugar). The combined effect of alcohol and other drugs, such as barbiturates or benzodiazepines, has resulted in many adverse drug-related fatalities [7]. Exposure to the cold, such as if a person sleeps outdoors after a night of heavy drinking, has been responsible for many hypothermia-related fatalities because ethanol lowers core body temperature in addition to the low ambient temperature.

Inhalation of vomit (aspiration) and asphyxia has killed many drunken people, especially young inexperienced drinkers, who have a nonfunctional gag reflex inactivated owing to gross intoxication and lack of consciousness [29]. A semicomatose person should not be allowed to "sleep it off" unattended and instead should be placed in a semiprone position and inspected regularly until they regain consciousness. A partial obstruction of the trachea during the time a person is in a comatose state after heavy drinking is yet another circumstance that could lead to death by asphyxiation [27–29].

Drinking alcohol too quickly to reach a BAC of 1.5 g l^{-1} or more often causes nausea and vomiting, especially in novice drinkers. This vomit reflex has saved the lives of many young people by removing unabsorbed alcohol from the stomach contents. However, if a person vomits when already in a state

of gross intoxication with depressed gag reflex, there is a grave risk of vomit entering the airways and death being caused by asphyxiation [29]. Many teenagers with little or no previous experience with alcohol consumption have lost their lives in this way. The BAC determined in blood taken at autopsy is often considerably lower than the level that caused incapacitation at some earlier time because of decreases through metabolism at a rate of $0.15\,g\,l^{-1}$ per h until the time of death.

Concluding Remarks

Overconsumption of alcoholic beverages and drunkenness play a major role in many types of accidents, trauma deaths, suicides, muggings, and other crimes of violence, as evidenced by death certificates and reports from hospital accident and emergency departments worldwide [3, 45]. Moreover, heavy drinking and drunkenness are often the underlying factor in domestic violence, sexual assault, and road-traffic crashes. Accordingly, requests to determine the concentration of ethanol in blood and other body fluids and to interpret the results in relation to degree of impairment and ability to form intent are everyday services obtainable from forensic science and toxicology laboratories [26, 46].

Because a diagnosis of alcohol influence has deep-rooted social, medical, and legal ramifications, great care is needed when the analytical results are interpreted and conclusions reached for use in civil and/or criminal proceedings. Whether a person's BAC was above or below a threshold limit, such as the legal limit for driving, makes the difference between punishment (fines, loss of driving permit, or incarceration) and acquittal [47].

The qualitative and quantitative determination of ethanol in body fluids is a relatively simple analytical procedure and the use of gas liquid chromatography provides accurate, precise, and specific results [48]. However, correctly interpreting these results requires knowledge about the pharmacokinetics and pharmacodynamics of ethanol as well as intersubject and intrasubject variation, drug-alcohol interactions, and the development of tolerance [11].

When it comes to interpreting the results of ethanol determinations in autopsy specimens, a number of other considerations are necessary, owing to the risk of various postmortem artifacts [27–29]. These include the condition and type of specimen, the stability of ethanol in the body after death, diffusion from the gut to other tissue after death, and the possibility of microbial synthesis occurring if the body has undergone decomposition [26–31]. Police investigations, insurance claims, and financial compensation to surviving family members might be jeopardized or invalidated if the deceased was judged to be drunk and incapable at the time of death. An accurate and precise measurement of the BAC is indispensable to reach a conclusion about a person's state of inebriation at the time of death. Alcohol: Analysis

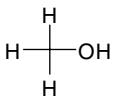
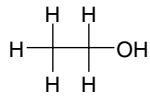
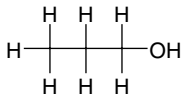
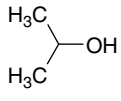
Introduction

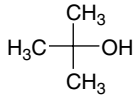
In the field of forensic science and legal medicine, investigators are mainly concerned with just one type of alcohol, namely ethyl alcohol or ethanol, which is the pharmacologically active constituent in all alcoholic beverages. However, the word alcohol is a generic term used by chemists to denote a family of organic compounds, the simplest member of which is methanol or methyl alcohol (CH_3OH). Ethanol (CH_3CH_2OH) is the second member in this homologous series of aliphatic alcohols and is known as a *primary alcohol*, because the hydroxyl bearing carbon atom is attached to one alkyl group. Next comes *n*-propyl alcohol ($CH_3CH_2CH_2OH$) along with its structural isomer isopropyl alcohol $(CH_3)_2CHOH$, the latter is designated as a *secondary alcohol* because the hydroxyl carbon is bonded to two methyl groups. Structural formulae of the simplest alcohols are given in Table 1.











The common feature shared by the entire family of alcohols is that they contain one or more hydroxyl (–OH) functional groups. This property determines solubility in water and body fluids, ability to form hydrogen bonds with other biomolecules as well as many chemical and biochemical reactions, such as oxidation, reduction, and conjugation.

Ethanol is produced on a huge scale by the fermentation of carbohydrates (beverage alcohol) or by the catalytic addition of water to ethylene (nonbeverage usage). Ethanol is considered as a clean fuel and is widely used in industry as a solvent and also occurs in many household products, pharmaceuticals, cosmetics, toiletries, perfumes, etc. Even certain foodstuffs, such as fresh fruits and fruit juices, might contain trace quantities of ethanol or ethyl esters that can undergo hydrolysis in the stomach to form ethanol.

Alcoholic beverages are made by fermentation of the sugars contained in a wide variety of naturally occurring raw materials such as potato mashes, barley corn, fruit juices, beet, cane sugar, and molasses. The enzymes in yeast convert one molecule of glucose into two molecules of ethanol and two molecules of carbon dioxide. Depending on the fermentation conditions, such as the source of the yeast and the nature of the starting material, the endproduct might contain up to 15% v/v ethanol. Beers contain 3–5% v/v ethanol and wines generally contain 9–15% v/v. A drink containing higher concentrations of ethanol cannot be produced by fermentation alone, because the yeast enzymes become inactivated. Distillation or fortification of the primary fermentation product is necessary if more concentrated alcoholic drinks (distilled spirits), such as whisky, vodka, gin, and brandy (35–55%v/v) are required.

Alcohol is a dependence-producing drug and excessive drinking and drunkenness lead to many negative social, medical, psychological, and economic consequences for the individual and society [1]. Overconsumption of alcohol, binge drinking, and drunkenness constitute major public health issues in today's society. Intoxicated people are overrepresented at hospital emergency rooms to receive

Table 1 Chemical structures of the simplest monohydroxy aliphatic alcohols

treatment for injuries and in deaths caused by drowning, suicide, or road-traffic fatalities. Forensic science and toxicology laboratories worldwide have a long standing interest in the analysis and the interpretation of a person's blood-alcohol concentration (BAC), which requires considerable knowledge and expertise about methodological, physiological, and pharmacological aspects of ethanol [2, 3].

This article deals with the principles and practice of ethanol determination in biological specimens. The major emphasis is given to the analysis of ethanol in blood and breath, which are the specimens used in forensic casework as evidence for prosecuting drunken drivers [4]. However, the procedures described for handling blood samples can be applied to many other biological liquids such as urine, plasma, serum, and saliva [5, 6]. Indeed, any biofluid or tissue that contains water can serve as a specimen for the analysis of ethanol.

Punishable Alcohol Concentration Limits for Driving

Alcohol-related motor vehicle crashes are a major cause of premature death and disability. Many case-controlled studies have established that the risk of a crash appreciably increases as the driver's BAC increases above 0.5 $g\,l^{-1}$ (50 mg/100 ml or 0.05 g/100 ml). Impaired drivers are overrepresented in crash statistics and 30–40% of those killed on the roads test positive for alcohol and most victims have BACs above the legal limit for driving. To improve traffic safety and deter drunken driving, governments have enacted punishable limits of alcohol concentration in specimens of blood, breath, or urine above which it is an offense to drive a motor vehicle on the public roads and highways [7, 8]. However, these statutory alcohol limits differ among different countries, which has a lot to do with alcohol control policy and local politics rather than traffic safety research (Table 2).

In many publications dealing with forensic aspects of alcohol, confusion arises owing to the different concentration units used to report the results. Examples of the various blood- and breath-concentration units and the countries where they apply are given in Table 3. Also shown is the concentration unit used in clinical and laboratory medicine, namely millimoles per liter (21.7 $mmol\,l^{-1} = 1.0\,g\,l^{-1}$). Note also that hospital laboratories commonly determine ethanol in specimens of plasma or serum and not in whole blood. The differences in water content among the different biofluids have important consequences if and when results from hospital clinical laboratories are later used as evidence in legal proceedings, such as impaired driving trials [2].

Ethanol distributes into the water compartment of the body and unlike many other drugs, it does not bind to plasma proteins. The water content of whole blood is ~80% w/w on average compared with ~93% w/w for serum or plasma. Because the

Table 2 Threshold concentration limits of alcohol (statutory limits) in blood and breath for operating a motor vehicle in various countries and the blood/breath ratio assumed when setting the corresponding breath-alcohol concentration limit

Country/nation[a]	Blood-alcohol concentration	Breath-alcohol concentration	Assumed blood-to-breath ratio
Most European nations	0.50 $mg\,ml^{-1}$ ($g\,l^{-1}$)	0.25 $mg\,l^{-1}$	2000 : 1
The Netherlands	0.50 $mg\,ml^{-1}$ ($g\,l^{-1}$)	220 $\mu g\,l^{-1}$	2300 : 1
Norway and Sweden[b]	0.20 $mg\,g^{-1}$ ($g\,kg^{-1}$)	0.10 $mg\,l^{-1}$	2100 : 1
Finland	0.50 $mg\,g^{-1}$ ($g\,kg^{-1}$)	0.22 $mg\,l^{-1}$	2400 : 1
The United States	0.08 g/100 ml	0.08 g/210 l	2100 : 1
The United Kingdom and Ireland[c]	80 mg/100 ml	35 µg/100 ml	2300 : 1
Canada	0.08 g/100 ml	0.08 g/210 l	2100 : 1
Australia	0.05 g/100 ml	0.05 g/210 l	2100 : 1
New Zealand	80 mg/100 ml	400 $\mu g\,l^{-1}$	2300 : 1

[a] In several countries listed above a lower limit of alcohol concentration operates for novice or provisional drivers (e.g., 0.02 g% in the United States), for drivers under 21 years and 0.04 g% for operators of commercial vehicles

[b] Because a BAC of 0.20 $mg\,g^{-1}$ is equivalent to 0.21 $mg\,ml^{-1}$, the actual blood/breath ratio operating in Norway and Sweden is close to 2100 : 1

[c] If urine is the specimen donated the threshold concentration of alcohol is 107 mg/100 ml

Table 3 Concentration units used to report blood-alcohol concentration (BAC) and breath-alcohol concentration (BrAC) for clinical and forensic purposes in different countries

Concentration unit for blood alcohol	Countries where used	Concentration unit for breath-alcohol	Countries where used
$mg\,g^{-1}$ ($g\,kg^{-1}$)	Sweden, Denmark, Norway, Finland, Germany	$mg\,l^{-1}$	Sweden, Denmark, Norway, Finland, Germany, Spain, other EU countries
$mg\,ml^{-1}$ ($g\,l^{-1}$)	France, Holland, Spain, Belgium	$\mu g\,l^{-1}$	Holland
mg/100 ml ($mg\,dl^{-1}$)	The United Kingdom, Ireland, Canada, New Zealand	µg/100 ml	The United Kingdom, Ireland, New Zealand
g/100 ml (g%)	The United States, Australia	g/210 l	The United States
mmol/l[a]	Hospital clinical chemistry laboratories in most countries	ppm[b]	Environmental health applications

[a] Molecular weight of ethanol is 46.07; thus, a concentration of 21.7 mmol l^{-1} is equivalent to 1.0 g l^{-1} (100 mg/100 ml or 0.1 g/100 ml)
[b] ppm stands for parts per million where 200 ppm = 0.365 mg ethanol per liter of breath at 34 °C

distribution of alcohol between plasma and whole blood follows the distribution of water, the mean concentration ratio (plasma/blood) for ethanol is 1.16 : 1 and this can be used as a conversion factor [2]. The actual plasma/blood distribution ratio depends on the factors influencing the water content of the specimens analyzed such as hematocrit value and any medical conditions that influence the volume of red cells (e.g., anemia). Abnormal blood lipids tend to influence the concentration of alcohol in the blood sample. The gender-related differences in hematocrit (men 42–50 ml/100 ml and women 37–47 ml/100 ml) also have a small effect on the plasma/blood distribution ratio of ethanol.

If nothing is known about the individual concerned and a request is made to convert the plasma alcohol concentration (PAC) or the serum alcohol concentration (SAC) into the blood alcohol concentration (BAC) the factor used should be chosen to the person's advantage if the results are intended for use as evidence in a criminal prosecution.

$$BAC = (PAC \text{ or } SAC)/1.16 \quad \text{(gives the best average estimate)} \quad (1)$$

$$BAC = (PAC \text{ or } SAC)/1.20 \quad \text{(gives a lower limit for most people)} \quad (2)$$

Analytical Methods for the Determination of Ethanol

The first analytical methods for the identification and determination of ethanol in human body fluids and tissues were described approximately 150 years ago [9]. Because of the strong association between a person's BAC and the impairment of performance of skilled tasks, such as driving, it has become increasingly necessary to interpret the results of analysis in a legal context.

The BAC encountered in most forensic casework ranges from 0 to 5 $g\,l^{-1}$ (500 mg/100 ml), and a concentration below 0.1 $g\,l^{-1}$ is usually reported as negative and no further action or interpretation is necessary. Although the analytical methods used in many forensic toxicology laboratories are capable of measuring much lower concentrations of ethanol below 0.1 $g\,l^{-1}$, this level is appropriate as a practical cutoff concentration for reporting negative results.

The limit of quantitation (LOQ) of an analytical method is an important concept in clinical, forensic, and laboratory medicine and this is defined as the lowest concentration of analyte that gives acceptable precision and accuracy under the stated operating conditions of the method. In practice, LOQ is approximately 3.3 times the limit of detection (LOD), which is defined as the lowest concentration of analyte that can be detected. With instrumental methods of analysis, LOD corresponds to a signal to background noise ratio of about 3 : 1.

During the development of new analytical methods, a good starting point is to consider the physical, chemical, and structural properties of the substance of interest – the analyte. Ethanol is a low-molecular weight volatile substance (boiling point 79 °C) with a specific gravity of 0.789 and mixes with water in all proportions. The hydroxyl group is chemically

reactive and readily undergoes oxidation to an aldehyde group (–CHO) or a carboxylic acid group (–COOH), depending on the reaction conditions such as time and temperature.

Methods Based on Chemical Oxidation

The earliest methods suitable for the analysis of alcohol in blood and urine were based on chemical oxidation of the hydroxyl group (–OH), to yield the corresponding aldehyde (–CHO) and then carboxylic acid (–COOH). Various oxidizing agents, such as acidified potassium dichromate or potassium permanganate, were employed. Prior to adding the required chemicals to start the reaction, it was necessary to remove the ethanol from the biological matrix by distillation, desiccation, or aeration or also by the precipitation of blood proteins, e.g., with perchloric acid [10]. The oxidizing reagent was added to the aqueous distillate or filtrate containing ethanol and when necessary the mixture was heated (e.g., to 50 °C) to speed up the completion of the reaction. The amount of ethanol in the original sample could then be determined by titrimetric analysis or by colorimetry by comparison with known strength standard solutions of ethanol.

The basic equation for the oxidation of ethanol with a mixture of potassium dichromate and sulfuric acid is shown below.

$$2K_2Cr_2O_7 + 8H_2SO_4 + 3C_2H_5OH \longrightarrow$$

(yellow color)

$$2Cr_2(SO_4)_3 + 2K_2SO_4 + 11H_2O + 3CH_3COOH$$

(green color) (3)

Methods based on chemical oxidation were rather time consuming and required considerable training to ensure reliable results and not many samples could be completed each working day. Moreover, the oxidation reaction was not specific and other alcohols or acetone if present in the blood samples could not be distinguished from ethanol. Nevertheless, only wet-chemistry oxidation was used between 1900s and 1950s for the quantitative analysis of ethanol in body fluids for legal purposes [8, 9]. When specimens were taken during autopsy, various preliminary chemical tests were necessary to resolve whether other volatile substances might be present that could compromise the reliability of the analytical results.

Methods Based on Enzymatic Oxidation

Milder oxidation conditions and improved selectivity of analysis were achieved when enzymatic procedures were developed in the early 1950s. This coincided with the isolation and purification of the liver enzyme responsible for the oxidation of ethanol *in vivo*, namely alcohol dehydrogenase (ADH). Mammalian ADH was not so suitable for forensic analysis because other aliphatic alcohols (e.g., methanol and isopropanol) were also oxidized and under certain circumstances, these substances might be present in the blood samples. Accordingly, the enzyme derived from yeast was developed commercially and widely used in the enzymatic (ADH) determination of ethanol. Methanol reacted very slowly or not at all under optimum reaction conditions and did not interfere with the determination of ethanol [11].

A major advantage of enzymatic methods over chemical methods was that the procedures could be more easily automated. Indeed, this was becoming increasingly necessary considering the huge increase in forensic casework as drunken driving escalated in the 1950s and 1960s.

The oxidation of ethanol to acetaldehyde by ADH is a reversible reaction. Under *in vitro* conditions, the reaction is facilitated by adjusting pH to 8.8 and adding a reagent (semicarbazide hydrochloride) to trap the acetaldehyde produced. The semicarbazide forms a semicarbazone by reacting with the acetaldehyde to drive the reaction (see below) to the right. During the redox reaction, the coenzyme nicotinamide adenine dinucleotide (NAD^+) is converted to the reduced form NADH and its formation is monitored by UV spectrometry at a wavelength of 340 nm for quantitative analysis.

$$CH_3CH_2OH + NAD^+ \overset{ADH}{\longleftrightarrow} CH_3CHO + NADH + H^+$$

CH_3CHO + semicarbazide gives a semicarbazone driving the reaction to completion (4)

Enzymatic methods gradually replaced the chemical oxidation procedures and became widely used until the emergence of physicochemical methods in the early 1960s. The upsurge of immunoassay methods designed for analysis of drugs of abuse in urine has led to a renaissance for the NAD^+-NADH reaction. Highly automated and sophisticated

instruments are available for the analysis of abused drugs including ethanol by immunoassay. Indeed, some laboratories make a rapid preliminary screening analysis of all specimens by enzymatic methods so as to distinguish negative and positive specimens. Those specimens that tested positive for ethanol are then reanalyzed by more specific methods, such as gas chromatography [12].

Nowadays, the method of choice for blood-alcohol analysis in clinical, forensic, and research applications is gas-liquid chromatography (GC). For the determination of alcohol in samples of breath, dedicated instruments are available that utilize infrared spectrometry or electrochemical oxidation as the analytical principles (see later in this article).

Methods Based on Gas Chromatography

The development and implementation of gas liquid partition chromatography in the early 1960s and onwards revolutionized the practice of analytical chemistry at forensic science and toxicology laboratories. The instrument bay in a modern toxicology laboratory is dominated by advanced separation methods involving either gas- or liquid-chromatographic procedures with various detector systems depending on the particular analyte or drug of interest [13].

Basic Principles of Gas Chromatography

The principle components of GC are an inert carrier gas (nitrogen or helium), which represents the moving or mobile phase. This is made to flow through a long thin coiled tube (the chromatographic column) containing the liquid stationary phase. The column is kept in an oven held at a precisely controlled temperature, which is a key parameter for the effective separation of the components of a mixture. The liquid stationary phase is coated onto an inert support material to provide a large surface area and to facilitate an intimate contact and mixing of components between the moving gaseous phase and the stationary phase.

The components in the sample are vaporized before mixing with the gaseous mobile phase, which transports the substances to be separated through the column. During passage through the column, the components of the mixture partition between the moving gas phase and the liquid stationary phase. Different compounds partition differently depending on their physical and chemical properties and are retained for a shorter or longer time inside the column so that a partial or complete separation occurs.

The effluent from the column passes to a detector, which produces a signal proportional to the amount of substance it detects. Different detectors are available for different applications depending on the chemical structure and elemental composition of the target analytes. For compounds with C–C or C–H bonds in the molecules, a flame ionization detector (FID) is widely used. The carrier gas and the substances eluting from the column enter an air-hydrogen burning flame to produce ions and electrons that pass between anode and cathode. The current flowing at a particular voltage between the positive and negative poles is amplified and the signal is monitored as a trace on a recorder known as *the chromatogram*.

The choice of stationary phase is important and when water-soluble alcohols are analyzed hydrophilic phases, such as polyethylene glycols of different average molecular weights, are appropriate. The traditional packed columns, which worked very well for decades and still do, have gradually been replaced by capillary or wide bore columns, which are more expensive and less robust compared with packed columns.

The main advantage of gas chromatographic analysis over other methods is that the target analyte (ethanol) is separated from impurities or potential interfering compounds (e.g., acetone) that might be normally present in forensic blood samples. Moreover, both qualitative and quantitative analysis is possible in the same analytical run. The time that elapses after injecting the sample into the column to the appearance of the apex of the peak on the chart recorder or electronic integrator is called the *retention time* (*RT*) and is useful for qualitative analysis. The RT of the unknown substance can be compared with the RT of authentic known standards purchased from a reliable source. The integrated area under the detector response (peak) on the chromatogram is the parameter used for quantitative analysis and is directly proportional to the amount of substance in the sample.

Analytical Details

In forensic casework, the specimens of blood or other body fluids should always be analyzed in duplicate and whenever possible, these determinations

should be made by different technicians working independently with different sets of equipments [14]. Importantly, the chromatographic conditions, such as the nature of the stationary phase, should be such that different RTs are obtained for potential interfering substances. The risk that two closely related compounds will have the same RT when analyzed on two different stationary phases is very remote. Alternatively, an increased selectivity can be achieved by the use of two independent analytical methods, such as GC and an enzymatic oxidation procedure, to make the duplicate determinations.

Approximately 1–5 µl of the diluted blood specimen is injected directly onto the chromatographic column or into a heated injection port attached to the column where vaporization occurs. Any volatile substances in the sample mix with the mobile phase (carrier gas) and pass through the column, where separation occurs. The effluent from the column is then directed to the detector for quantitative analysis. Blood and other body fluids contain nonvolatile constituents (proteins, fats, etc.), which tend to clog the syringe and injection port of the GC and the column packing material deteriorates after many samples are analyzed. To avoid this problem, investigators developed the headspace sampling technique and this entails the analysis of the vapor phase above the diluted blood sample. The diluted blood specimen is held in a glass vial, which is kept airtight with a stopper and crimped on aluminum cap and is heated to 50 or 60 °C to achieve a liquid-vapor equilibration. The use of the headspace method meant that the GC column was not contaminated with nonvolatile substances and several thousands of blood samples could be analyzed without damaging the column and the overall analytical performance. A scheme that illustrates the basic features of headspace GC applied the determination of blood ethanol concentration is shown in Figure 1.

A short analysis time and adequate resolution of components in the sample are the key elements in any chromatographic analysis. Ethanol and other low molecular volatiles can be analyzed under isothermal temperature control of the chromatographic oven, which saves much time compared with a temperature program (heating and cooling) being used. For routine applications, the analysis takes about 2–3 min after the injection was made into the GC. By raising the oven temperature or operating with a higher carrier gas flow rate, the RTs can be shortened but often at the expense of an incomplete separation of the components in a mixture.

Examples of the RTs (min) for GC analysis of nine different volatile agents analyzed on four different

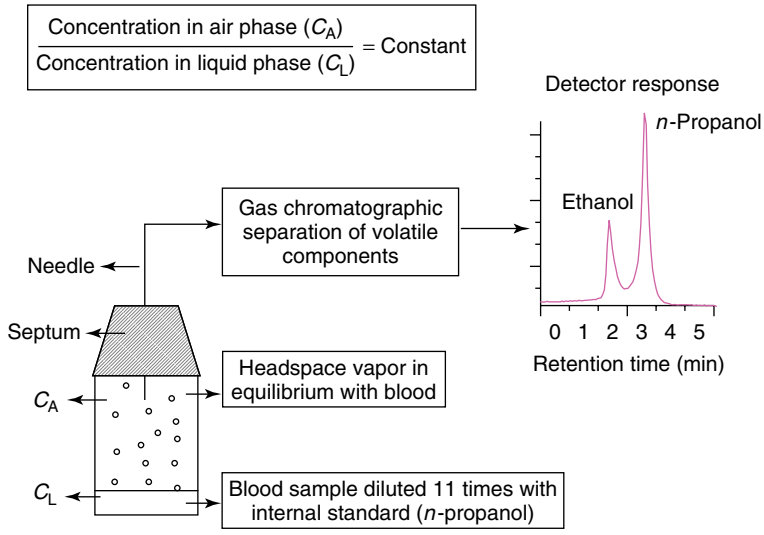

Figure 1 Diagram showing the main features of static headspace gas chromatography where an equilibration is achieved between volatiles in the diluted blood specimen (*n*-propanol internal standard) and the air phase above the blood. After equilibration is reached (20–30 min), a portion of the air-phase is removed and directed into the gas chromatograph where a separation of the components and a quantitative analysis is made with a flame-ionization detector

Table 4 Retention times (RT) of ethanol and other low molecular volatile substances analyzed by headspace gas chromatography on four different stationary phases commonly used in forensic toxicology laboratories. RT's relative to *n*-propanol as internal standard are shown in brackets

Volatile substance	Retention time (min) Carbopak C[(a)]	Retention time (min) Carbopak B[(b)]	Retention time (min) Rtx-BAC1[(c)]	Retention time (min) Rtx-BAC2[(d)]
Acetaldehyde	0.56 (0.38)	0.53 (0.29)	1.19 (0.53)	0.82 (0.34)
Acetone	1.00 (0.68)	0.86 (0.46)	2.05 (0.91)	1.36 (0.57)
n-Butanol	4.68 (3.16)	4.11 (2.22)	4.63 (2.06)	5.28 (2.20)
Ethanol	0.72 (0.49)	0.98 (0.53)	1.32 (0.59)	1.27 (0.53)
Methanol	0.49 (0.33)	0.67 (0.36)	1.06 (0.47)	0.96 (0.40)
Methyl ethyl ketone	2.45 (1.66)	1.49 (0.81)	3.08 (1.37)	2.49 (1.04)
Isopropanol	1.16 (0.78)	1.31 (0.71)	1.66 (0.74)	1.48 (0.62)
n-Propanol	1.05 (1.00)	1.85 (1.00)	2.25 (1.00)	2.40 (1.00)
t-Butanol	1.90 (1.28)	1.68 (0.91)	1.98 (0.88)	1.65 (0.69)

[(a)] Packed glass column (2 m × 0.5 mm i.d.) with 0.2% Carbowax (polyethylene glycol) 1500
[(b)] Packed glass column (2 m × 0.5 mm i.d.) with 5% Carbowax (polyetheylene glycol) 20 M
[(c)] Capillary column, 30 m × 0.53 mm i.d.
[(d)] Capillary column, 30 m × 0.53 mm i.d.

columns and stationary phases (two packed and two capillary) under isothermal oven temperature conditions are shown in Table 4. Also listed are the RTs of the *n*-propanol peak – the internal standard. The overall time of analyzing these nine compounds was only 4–5 min and the longest RT was for *n*-butanol.

Recommended Procedure for Routine Purposes

The basic steps in a well tested and recommended procedure for the quantitative determination of ethanol in blood or urine for legal purposes by GC are outlined below [15].

1. The tube with the material to be analyzed should be gently inverted for some time to ensure homogeneity of the specimen. This step is important when ethanol is determined in blood samples because the red cells and the plasma fraction tend to separate out on standing.
2. An aliquot (0.1 ml) of the specimen (whole blood, plasma, serum, or urine) is accurately removed from the tube and immediately diluted with an aqueous solution of an internal standard (usually another type of alcohol). This maneuver is best done by the use of specially constructed diluter-dispenser equipment although micropipettes can be also be used. The dilution of the biofluid with aqueous internal standard should be at least 1 : 5 (6-fold) or 1 : 10 (11-fold). Adequate dilution of the specimen eliminates matrix effects, which is an important consideration when headspace GC analysis is used and determines the choice of the calibration standards. With 6- to 11-fold dilution of blood meant that aqueous ethanol standards can be used to construct a calibrate plot for use in quantitative analysis. Suitable internal standards are aqueous solutions of *n*-propanol (specimens from living subjects) or *t*-butanol (in autopsy work) at concentrations of 0.05–0.10 g l^{-1}. It is important that the substance used as the internal standard is not likely to occur or be produced in the biofluid analyzed.
3. For headspace analysis, the diluted blood specimens are ejected into a glass vial, which is made airtight with a Teflon-coated stopper and crimped on aluminum cap. For analysis of liquid samples the diluted specimens are ejected into a clean dry glass vial and an aliquot (1–5 µl) is injected into the GC using a microsyringe.
4. The peak area ratio of the responses for ethanol and the internal standard are recorded and compared with the corresponding ratios after the analysis of a series of aqueous ethanol solutions with known concentrations as the calibration standards. Alternatively, the ratio of heights of the two peaks on the gas chromatograph can be measured and used for the quantitative analysis.

The plot of peak height or peak area ratio against concentration of ethanol in the standards is used to construct a calibration line for quantitative analysis. A linear relationship exists between the detector response (peak area ratio) and the concentration of ethanol in the sample analyzed over a wide range, such as 0–5 $g\,l^{-1}$ (0–500 mg/100 ml) that might be encountered in forensic blood samples.

5. Quality control standards should be included within each analytical run dispersed liberally between the unknown blood samples.

Besides the analysis of unknown blood specimens, each analytical run should include one or more blank specimens (blood without any ethanol) and control standards of known concentration positioned at intervals in the series. Some laboratories might also include a sample containing a mixture of potential interfering substances (e.g., acetaldehyde, methanol, acetone, and isopropanol). The ethanol control standards should be prepared independently from the solutions used as calibrators and the latter should have good traceability to a primary source.

A wide range of instruments are available to perform a GC analysis of ethanol in blood and some manufactures produce dedicated instruments for headspace sampling and analysis (e.g., Perkin-Elmer Corporation). Other types of GC instruments are more flexible and can handle liquid injection and are adaptable for headspace analysis [16].

The first GC methods for alcohol analysis involved the use of a packed column, which consisted of a coiled tube made of glass, copper, or stainless steel that was normally 2–3 m long with an inside diameter of a few millimeters. The column contained an inert solid support material impregnated with the stationary liquid phase to facilitate separations and analysis. Currently, most GC analysis in forensic toxicology is done with capillary columns made of fused silica of normally 20–30 m long and with an inside diameter of 0.3–0.5 mm.

Figure 2 shows examples of chromatograms obtained from analysis of blood containing methanol, acetone, isopropanol as well as ethanol and the *n*-propanol internal standard. The blood specimen was analyzed on two different columns and stationary phases thus furnishing different RTs for the volatile components in the mixture. The detector response was normalized to 100% for the most prominent component in the sample. Note that the chart speed has been purposely increased for clarity, which causes the peaks to be fairly broad compared with if a slower chart speed had been used.

Few substances of physiological and forensic interest can be determined with such high accuracy and precision as the BAC. The analytical principles involved and brief practical details of the procedures used for the forensic determination of ethanol in biological specimens spanning the past century are presented in Table 5 in chronological order (*see also* **Confirmation Testing: Toxicology**).

Blood Sampling from Living Subjects

The quality of the specimen sent for analysis is often a neglected aspect of the overall procedures, which can have negative consequences for the reliability and acceptance of the results for legal purposes. The preanalytical stages include sampling, labeling, transport, and storage prior to arrival at the laboratory [17]. Factors to consider include obtaining informed consent from the subject or suspect, the blood sampling site on the body, the use of a disinfectant to swab the skin, the type of blood-sampling equipment used, whether an evacuated tubes or a syringe and needle. The procedures used to draw blood, the volume and type of container and whether chemical preservatives were added, the mode of transport of specimens, and the storage after arrival are all key elements in the overall reliability of the final results. The chain of custody of the specimens also needs to be well documented to guarantee integrity of laboratory work that might be used as evidence in criminal prosecutions.

Table 6 outlines major issues that deserve consideration when blood samples are collected and sent for forensic analysis of alcohol from living subjects.

The sampling site for obtaining blood might be a vein, an artery, or a capillary but for all practical purposes the sample is taken from a cubital vein. The blood is conveniently taken using a sterile evacuated glass tube (gray stopper) containing sodium fluoride as a preservative and potassium oxalate as an anticoagulant. The evacuated tubes usually hold a volume of 9–10 ml when full and 100 mg NaF (1% w/v) and 25 mg of potassium oxalate are present as preservatives. Immediately after sampling, the tube of blood should be gently inverted for about 20 s

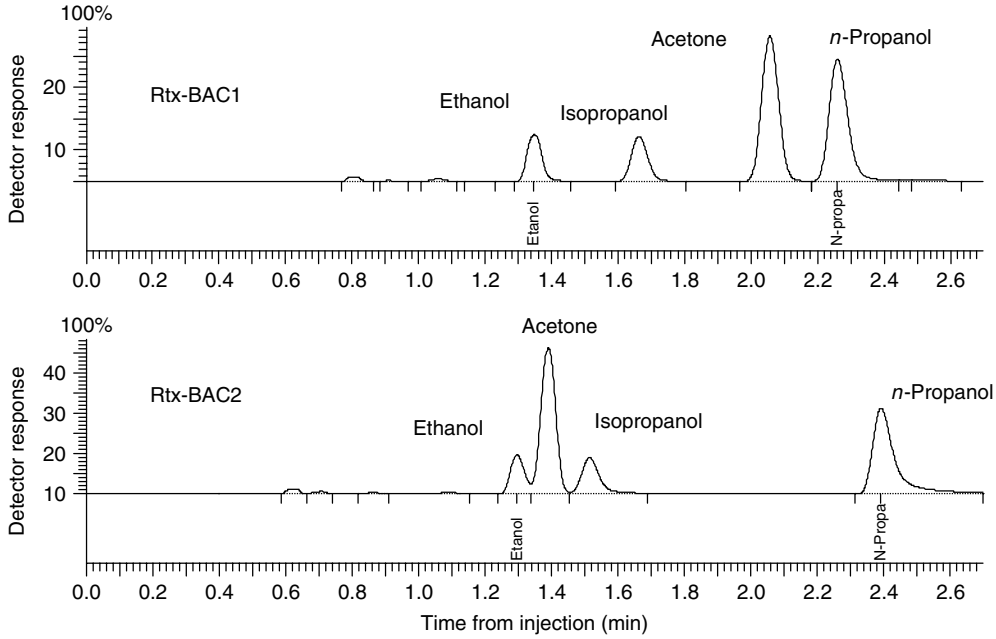

Figure 2 Chromatographic traces from analysis of ethanol and other volatiles in a blood sample also containing acetone and isopropanol. On two different stationary phases (Rtx-BAC1 and Rtx-BAC2) thus furnishing different retention times for identification of components

to ensure proper mixing with the preservatives to prevent coagulation. In practice, the volume of the blood in the evacuated tubes might vary from about 1 to 10 ml depending on the care taken with the sampling procedure. Such a variation in volume does not impact adversely on the accuracy or precision of the resulting BAC even when the volume of blood in the tube is abnormally low.

The evacuated tubes (5 ml) often used at hospital laboratories for collecting specimens for the analysis of blood-glucose are also suitable for blood-alcohol analysis. These 5 ml tubes normally contain less sodium fluoride and heparin instead of potassium oxalate is present as the anticoagulant. Because the tubes used to sample blood for alcohol analysis are sterile, one might wonder whether an enzyme inhibitor, such as sodium fluoride, is really necessary. However, a claim could be made that microorganisms had entered the blood when the needle penetrated the skin and ethanol, at least in part, was produced by the fermentation of blood-glucose after sampling. Swabbing the skin with a nonalcohol disinfectant or simply cleaning with soap and water is a standard practice before sampling blood. Studies have shown that even if an alcohol-containing swab had been used by mistake, the risk of contamination of the sample by carryover of ethanol from the skin is negligible.

Ethanol can be determined in any body fluid that contains water and methods have been described for the analysis of cerebrospinal fluid, saliva, sweat, and urine by the same GC methods described above for dealing with blood samples.

Specimens Taken at Autopsy

The methods described above for the determination of ethanol in blood from living subjects are the same as those used to analyze autopsy specimens [2]. During the postmortem examination a much wider selection of fluids or tissues are available for analytical toxicology. The composition of the autopsy blood samples in terms of fluidity, presence of clots, and degree of putrefaction might differ widely depending on the condition of the body and the circumstances surrounding the death [18]. When the analytical results are interpreted, the water content of the blood

Table 5 Historical developments in the methods used for determination of ethanol in blood and urine samples

Time period	Analytical procedure and brief details of the principles for ethanol determination
1900–1950s	The first analytical methods were based on chemical oxidation of the hydroxyl group in the ethanol molecule. After separation of ethanol from the biological matrix by diffusion, distillation or aeration or protein precipitation, an oxidizing agent such as a mixture of potassium dichromate ($K_2Cr_2O_7$) and sulfuric acid (H_2SO_4) was added. The ethanol is oxidized to acetic acid and the endpoint of the reaction is either determined by volumetric titration or by photometry
1950–1970s	Oxidation of ethanol by means of enzymes, such as alcohol dehydrogenase (ADH), offered milder conditions and gave a higher analytical selectivity when the enzyme derived from yeast was used. Ethanol was first separated from the biological matrix by precipitation of the blood-proteins with perchloric acid ($HClO_4$) and then centrifugation. After adjusting pH of the supernatant to alkaline conditions (e.g., pH 8.8) with buffers that contained the coenzyme (nicotinamide adenine dinucleotide, NAD^+), the ADH enzyme was added to start the reaction. This redox reaction, which is reversible, was driven to completion by adding semicarbazide hydrochloride, which reacts with the acetaldehyde produced from the oxidation of ethanol. During the reaction, the coenzyme (NAD^+) is reduced to NADH, which is monitored by absorption of ultra violet light at a wavelength of 340 nm. Enzymatic methods were better suited for automation, e.g., with various autoanalyzer instruments
1960s	Gas chromatography (GC) is today the method of choice and furnishes both a qualitative identification and a quantitative analysis of ethanol. An aliquot of the blood sample (~100 µl) is first diluted 1 : 5 or 1 : 10 with an aqueous solution of another alcohol (*n*-propanol or *t*-butanol) to serve as the internal standard. About 1–5 µl of the diluted blood is then injected into the heated injection port of the gas chromatograph and vaporized in a stream of nitrogen carrier gas (mobile phase). The volatiles pass through a long thin metal or glass tube (the GC column) containing the stationary liquid phase held on an inert support material. Depending on physicochemical properties and solubility in the liquid phase, the volatiles are held in the column for different times thus achieving separation. A detector, usually a flame ionization detector (FID), is used to measure the effluents when they emerge from the column. The time after injection to appearance of the apex of the peak (retention time) is a characteristic of the substance analyzed and can be used for identification. The area under the peak was related to the amount of analyte. Quantitative analysis required calibration of the detector response with known strength alcohol standards
1970s	Instead of injecting the diluted blood specimen a modification of the basic GC procedure involved the use of headspace analysis. This entailed sampling a portion of the vapor phase in equilibrium with the blood sample. This offers the advantage that the column packing material is not contaminated by nonvolatile constituents of the biological matrix. As with liquid injection, the blood samples and ethanol standards are first diluted (1 : 5 or 1 : 10) with internal standard and transferred to glass vials made airtight with rubber septa and crimped on aluminum caps. The vials are equilibrated at 50 or 60 °C and after about 30 min a portion of the vapor phase is removed for GC analysis. Sampling is done with the aid of a gas-tight syringe or by an automated procedure. The original packed GC columns have been gradually replaced by capillary or wide bore columns. The sensitivity of the headspace method can be enhanced and matrix effects can be eliminated by saturating the blood samples and aqueous ethanol standards with salt (NaCl or K_2CO_3), e.g., 0.5 ml blood + 1 g salt
1980s	Positive identification of ethanol is accomplished by mass spectrometry with an electron-impact detector producing characteristic ion fragments m/z 31 (base peak for primary alcohols), m/z 46 (molecular ion), and m/z 45 after loss of a proton. The ions m/z 31 and m/z 45 are sufficiently intense to allow quantitative analysis and deuterium-labeled ethanol can serve as internal standard

deserves consideration, such as when conclusions are reached regarding the antemortem BAC. Some investigators recommend that the water content of autopsy blood samples should be determined in conjunction with the analysis of ethanol. This is easily done by desiccation or freeze drying an aliquot of the specimen so that the BAC can then be adjusted to a blood-water content of 80% w/w, which applies to fresh blood from living subjects.

Table 7 gives a list of the biological specimens recommended for use in connection with forensic analysis of ethanol from living subjects and also in postmortem toxicology. (*see also* **Toxicology: Analysis**).

Table 6 Important considerations (preanalytical factors) in connection with sampling of blood from suspected drunken drivers intended for analysis of ethanol for legal purposes

Aspects of blood sampling	Considerations
Qualifications of the person commissioned to draw blood	Doctor, nurse, laboratory technician, or trained phlebotomist
Preparation of the patient or person	Informed consent about the purpose of sampling and information whether the person was sitting, standing, laying down, struggling, conscious/unconscious, or a victim of a traffic crash?
Blood source and sampling site	Source of the blood sample whether left or right arm cubital vein, artery, fingertip, or earlobe? Any medical treatment given to the person prior to sampling, such as intravenous fluids
Sampling technique	Type of skin disinfection used if any. Syringe and needle or an evacuated tube – was a tourniquet applied? Volume of blood specimen collected and the time needed for obtaining the sample
Identification and labeling of the specimen.	Record name of suspect, date of birth, time and date of blood draw, and name of the person who took the blood sample
Collection tubes for blood and preservatives	Volume of tubes and whether these were made of glass or plastic. What anticoagulant was present and whether an enzyme inhibitor such as sodium fluoride was included and at what concentration
Transport of sample to forensic laboratory	Tamperproof packaging, mode of transport to the laboratory (normal postal service or special delivery). Where the specimens were refrigerated during transport. How was chain of custody ensured
Inspection and registration at the laboratory	Date and time of arrival (date stamp). How many tubes of blood were received? What volume of blood in the tubes? Was there obvious hemolysis or clotting, any attempt at manipulation? Were security tapes or seals still intact? Had the tubes been opened
Storage prior to analysis	Time delay from sampling to analysis, storage of blood in a refrigerator or frozen and known stability of the analytes

Importance of Method Validation

Quality assurance and process control are crucial in all kinds of routine analytical laboratory work and especially when results are used in criminal investigations [19]. All analytical methods should undergo a rigorous validation and standardization before they can be considered fit for purpose. A careful documentation of the method characteristics including information on accuracy, precision, and the results of external proficiency tests are essential in today's laboratory environment [19]. The uncertainty

Table 7 Biological specimens suitable for analysis of ethanol in living subjects and also at autopsy

Living subjects	Dead bodies
Venous blood (10 ml)[a]	Femoral blood (20 ml)[b]
Capillary blood (fingertip)	Heart blood (if femoral unavailable)
Plasma/serum	Blood clot (subdural hematoma)
Urine fresh void (10 ml)[a]	Urine (50 ml)[b]
Tear fluid	Vitreous humor (all available both eyes)[b]
Cerebrospinal fluid (lumber fluid)[c]	Cerebrospinal fluid (cisternal fluid)[d]
Saliva	Bile (gall bladder)
Perspiration/sweat	Synovial fluid (knee joint)
Breath (end expired)[a]	Tissue (brain, skeletal muscle, liver)

[a] Recommended for analysis in people arrested for drunken drivers
[b] Recommended for analysis in connection with forensic autopsies
[c] From base of spine with the patient in a crouching position
[d] From back of neck (lumber sampling not practical)

in the analytical results also needs to be recognized, reported, and allowed for especially if these are compared with some threshold value, such as the legal alcohol limit for driving [15].

Method validation embraces the process and events by which a newly developed method or laboratory procedure is subjected to a strict testing protocol to establish key performance characteristics including accuracy, precision, specificity, bias, linearity, LOD, and LOQ.

Many of the terms used in connection with validation and accreditation of laboratory methods are defined in Table 8.

Over the past few decades, more and more attention has been given to laboratory accreditation, which is a formal process by which a laboratory is evaluated for its competence to perform designated analytical tasks or measurements [20]. Aspects of the accreditation process include participation in external proficiency schemes as well as regular onsite inspections by outside experts who examine and evaluate protocols, oversee laboratory facilities, and verify that the staff has appropriate qualifications and training for their task. In today's climate a forensic science or toxicology laboratory would not survive for long without being accredited for the services it provides including regular inspections and some form of peer recognition.

When the results of blood-alcohol analysis are reported to the police authorities, some laboratories consider the uncertainty in analytical results and allow for this in the report. This is done by making a deduction from the mean result of duplicate or replicate determinations. The amount deducted depends on the reliability of the analytical method and the magnitude of random and systematic errors. Because precision tends to decrease as the concentration of ethanol in the blood increases, the amount deducted is greater at high BAC to ensure the same degree of confidence (e.g., 99 or 99.9%) in the final result. After making the deduction, a statement can be made to the court to the effect that the person's BAC is not less than the value reported with a high degree of confidence such as 99 or 99.9%.

Principles and Application of Breath-Alcohol Analysis

It must be a very old observation that some portion of the alcohol a person consumes gets exhaled via the lungs and can be detected on the breath [9]. Indeed, the smell of alcohol on the breath, together with the person's general appearance and behavior, often constituted the first indications, albeit primitive, of overindulgence in alcohol. The first scientific studies attempting to measure accurately the concentration of alcohol in a person's breath were published over 150 years ago [9]. These showed that only a small fraction of the alcohol consumed (2–5%) could be recovered unchanged in the breath and urine collected for several hours afterward. The bulk of the dose of alcohol ingested underwent biochemical oxidation in the liver to provide a rich source of calories (7.1 kcal per gram ethanol).

These first studies on breath-alcohol concentration (BrAC) also identified the potential problem caused by the presence of alcohol dissolved in the mucous surfaces of the mouth from a recent drink. This led to a warning (cited below from FE Anstie, The Lancet, Sept. 28, 1867), which still holds true. When a breath-alcohol test is made for evidential purposes there is always a mandatory 15–20 min deprivation and observation period after the last drink to avoid the risk of contaminating the sample with alcohol in the mouth [21].

> Much caution is necessary, however, in applying this test. It must not be tried during at least the first quarter of an hour after a dose has been taken, for the mouth retains the characteristic smell, even of the most moderate dose, of any of the stronger smelling drinks, for fully this time.

Human breath consists of a mixture of gases being mainly oxygen, nitrogen, carbon dioxide and is saturated with water vapor at body temperature [22]. Additionally, expired air contains trace amounts of other organic volatile compounds (VOCs), which are produced either naturally in the body (endogenous volatiles) or inhaled together with the ambient air breathed. The most abundant VOCs in human breath are ethanol, methanol, acetone, carbon monoxide, methane, and isoprene. The concentrations of these substances are normally extremely low and have no practical relevance to challenge the results when these are used for legal purposes. However, under some circumstances, such as diabetes or other metabolic disorder, or after eating very low carbohydrate diets or if a person consumed denatured alcohol, the concentrations of acetone and isopropanol in breath samples might increase appreciably.

Table 8 Important characteristics to consider during validation of an analytical method intended for forensic purpose, such as the determination of ethanol in biofluids

Characteristic of the analytical method	Brief description and/or definition of the characteristic
Accuracy	Accuracy is a measure of the closeness of agreement of analytical results with the true or known concentration of substance in the sample. The true value might be the accepted reference value or a "target" concentration obtained by spiking with a known quantity of analyte
Bias	Bias is a systematic deviation either constant or proportional to the concentration of the analyte. Bias has to do with correctness of the analytical result and is derived as the difference together with its sign between the known quantity or target value and the result or average of several determinations by the method
Precision	Precision is the degree of mutual agreement between independent measurements under specified test conditions. This reflects the spread of analytical results when the method is applied repeatedly to aliquots of a homogenous sample. Random errors inherent in the method determine the analytical precision. In mathematical terms precision is computed as the standard deviation of repeated measurements
Repeatability	This term is used to define within-run analytical precision, same laboratory same operator same equipment – short-term precision
Intermediate precision	Precision of analysis between-runs in the same laboratory over longer time periods (weeks) by different operators, instruments, reagent batches, and calibrations
Reproducibility	This term is used to define precision of the analytical method when performed in different laboratories, with different instruments and analysts, such as the standard deviation in external proficiency testing
Linearity	The ability of an analytical method to give results directly proportional to the concentration of the analyte in the sample within a defined range of values
Range	The concentration interval between the upper and lower levels of analyte that can be determined with acceptable accuracy and precision. The range usually represents the difference between the lowest and the highest points on the calibration curve
Sensitivity	This is defined as the difference in analyte concentration corresponding to the small detectable difference in the detector response. It is represented by the slope of the calibration curve.
Specificity/selectivity	These terms are often used interchangeably and are related to the ability of a particular method to quantify the target analyte in the presence of interfering compounds
Recovery	Normally expressed as a percentage, recovery refers to the amount of drug removed from the original sample which reaches the end of the analytical procedure. Poor recovery can be compensated for by adding an internal standard to the biofluid before staring the analysis
Limit of detection (LOD)	LOD is the lowest concentration of analyte in a sample that can be detected but not necessarily quantified
Limit of quantitation (LOQ)	LOQ is the lowest concentration of an analyte in a sample that can be quantified with acceptable precision and accuracy. LOQ is approximately $3.3 \times$ LOD
Robustness	Robustness is the capacity of an analytical method to produce accurate and precise results despite small deliberate changes in test conditions and method parameters. In GC analysis of ethanol the addition of an internal standard helps to ensure the method is robust
Ruggedness	Ruggedness is a measure of the degree of reproducibility of the analytical results when performed under varying tests conditions, such as when work is done by different technicians, instruments, source of reagents, laboratories, or even in different countries
Traceability	Traceability means that a result of measurement can be traced back, through an unbroken chain of comparisons, to a national or international standard value. The traceability of the ethanol standards used to calibrate the gas chromatography needs to be well documented
Uncertainty	The word uncertainty means having doubt in something, such as the result of analysis. Analytical uncertainty is defined as a parameter associated with the result of a measurement, which characterizes the spread or dispersion of the results that could reasonably be attributed to the quantity being measured

The physiological principles that govern the excretion of alcohol in breath and the notion of indirectly estimating the BAC by breath analysis emerged in the 1930s when the concept of a blood/breath distribution ratio was formulated [22]. The first use of BrAC was to estimate the person's coexisting BAC, because this was accepted as the best objective evidence of drunkenness. The concentration of alcohol in the breath sample analyzed was multiplied by the blood/breath ratio of alcohol (2100 : 1), which allowed reporting the corresponding BAC. Some breath-test instruments, such as the Breathalyzer®, was designed and calibrated based on the assumption of a 2100 : 1 factor [22].

$$BAC = BrAC \times 2100 \quad (5)$$

Experience has shown that use of the above formulae tended to underestimate the true coexisting venous BAC by about 10% [23]. In some applications of breath-alcohol testing, the factor 2300 : 1 is used for calibration, which gives a more unbiased estimate of the venous BAC. However, the above equation is physiologically incorrect because BrAC runs closer to the concentration of ethanol in arterial (A) blood, whereas the sample analyzed for legal purposes is venous (V) blood. The arterial BAC (e.g., blood from a radial artery) is higher than the venous BAC (e.g., from a cubital vein) during the absorption and distribution stages of the BAC curve. The arterial BAC and venous BAC are the same at one time point (60–90 min post drinking), which marks complete equilibration of the ingested dose between the blood and tissue water. After this time, the arterial BAC is less than the venous BAC and remains less for the remainder of time that alcohol is being metabolized. The A–V differences are more pronounced on the rising or absorption phase of the BAC curve and the negative A–V differences on the descending postabsorptive phase is rather small or negligible and can be ignored [2]. In forensic practice it has become common to assume that most drunken drivers are apprehended 1–2 h after the end of drinking when the blood-alcohol curve has entered the postpeak descending phase.

Methods of Analyzing Alcohol in Breath

The first methods of breath-alcohol analysis employed chemical oxidation principles as exemplified by the classic Borkenstein Breathalyzer® device, which was widely used for law enforcement purposes, such as for testing drunken drivers in the United States, Canada, and Australia. The oxidizing reagent consisted of a mixture of sulfuric acid and potassium dichromate contained in a glass ampoule through which a known volume of the subject's breath was passed. Any ethanol present in the breath sample was oxidized to acetic acid with a concomitant reduction of chromium VI (yellow) in dichromate to chromium III (green) and this color change was monitored by photometry after exactly 90 s of reaction. Accordingly the reaction endpoint and the quantitative analysis of ethanol in breath were determined by optical photometry.

In the 1970s, physicochemical methods were developed for the analysis of alcohol in samples of breath particularly the use of infrared absorptiometry, which was incorporated in the Intoxilyzer range of instruments [24]. Figure 3 shows the infrared spectrum of ethanol in the gas phase and the major absorption bands corresponding to vibrational frequencies in the ethanol molecule. Those used for quantitative analysis at 3.4 μm (C–H stretch) and 9.5 μm (C–O stretch) are indicated.

The quantitative analysis of ethanol utilizes the Lambert–Beer law and monitors the absorption of radiation at 3.4 μm, which corresponds to the carbon–hydrogen stretching in the alkyl groups of ethanol. Under some conditions, acetone might be present in human breath at elevated concentrations and can also absorb IR radiation at 3.4 μm, which suggests a potential interference problem. Accordingly selectivity of the analysis of ethanol was enhanced in later versions of the Intoxilyzer instruments by monitoring IR radiation and more than one wavelength by use of narrow band-path filters set at 3.38 and 3.49 μm so that acetone could be distinguished from ethanol. The latest generation of infrared breath-alcohol instruments incorporate filters to monitor IR radiation also at a wavelength of 9.5 μm, which corresponds to the C–O stretching frequency in the alcohol molecule (see Figure 4). A few instruments (e.g., Intoxilyzer 9000) use both 3.4 and 9.5 μm to give an added analytical selectivity. By contrast, the Alcotest 7110 is a dual detector device with IR absorption at 9.5 μm and electrochemical oxidation (fuel cell) to ensure high selectivity for identification of ethanol. The advantage of IR analysis is that this is a nondestructive analytical method and

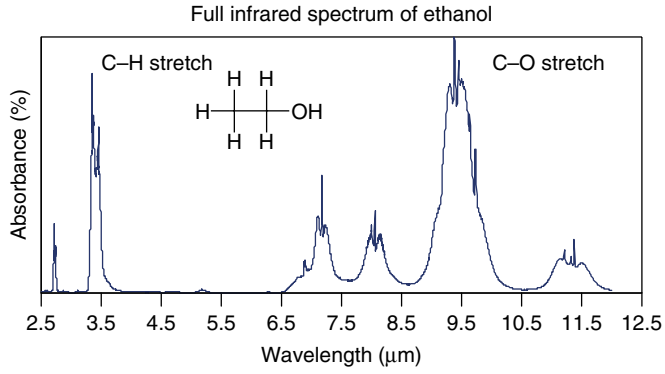

Figure 3 Infrared spectrum of ethanol in the vapor phase showing the absorption bands around 3.4 μm (C–H stretching) and 9.5 μm (C–O stretching) used for quantitative determination in modern evidential breath-ethanol analyzers

if necessary the sample analyzed can be preserved and used for other purposes.

The methodologies (analytical principles) incorporated into a wide selection of devices and instruments for breath-alcohol testing over many years are described in Table 9 [24, 25]. In this table, one should distinguish breath analyzers intended for roadside screening analysis with those designed for evidential purposes. The first screening devices were constructed from chemical tubes containing potassium dichromate and sulfuric acid impregnated on a silica gel support material. This mixture of chemicals changed in color from yellow to green if there was alcohol in the suspect's breath after blowing through the tube and inflating a balloon of fixed volume (~1 l).

The breath-alcohol screening devices used today by the police for roadside mass testing of motorists are small handheld instruments that incorporate an electrochemical sensor for the analysis of ethanol. Many such instruments are available such as Alcolmeter, Alcotest, AlcoSensor, and LifeLoc, which are sometimes referred to as *fuel cell instruments* (see Table 9).

The ethanol contained in a small portion of the end-exhaled breath (~1.0 ml) is directed via an inlet tube into a chamber fitted with an electrode (platinum black) and an acidic electrolyte solution, such as phosphoric acid. Oxidation of ethanol at the electrode surface produces acetaldehyde with a simultaneous liberation of electrons. These are captured, amplified, and displayed as a measurable current in direct

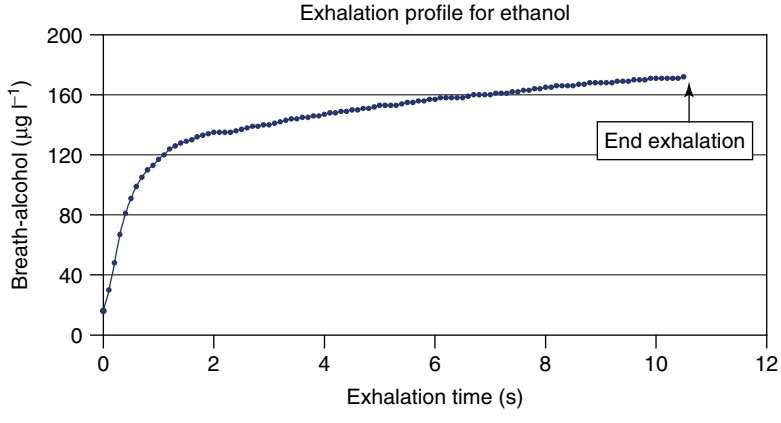

Figure 4 Increase in breath-alcohol concentration during a prolonged exhalation into a modern infrared breath-alcohol analyzer

Table 9 Analytical principles used for determination of ethanol with a wide selection of instruments and devices intended for breath-alcohol analysis

Analytical method	Example of breath instruments	Brief details of the operating procedure and principles
Chemical oxidation	Drunkometer Alcometer Breathalyzer Alcotest tubes Alcolyzer tubes	Ethanol in a known volume of breath is analyzed by oxidation with a mixture of potassium dichromate and sulfuric acid, or potassium permanganate or iodine pentoxide. The endpoint of the reaction was either a visual color change (Alcotest and Alcolyzer tubes) or by UV photometry (Breathalyzer)
Gas chromatography	GC Intoximeter AlcoAnalyzer GC	Compact instruments designed for analysis of ethanol in exhaled breath or vapor samples. The gas chromatograph (GC) Intoximeter incorporated a flame ionization detector and the AlcoAnalyzer used a thermal conductivity detector. The need for an external gas supply and frequent recalibration and maintenance meant they these instruments were not very practical for use at police stations
Infrared spectrometry	Intoximeter DataMaster Intoxilyzer Alcotest Evidenzer	Ethanol in the exhaled breath passes through a sample chamber ($\sim$50 ml) and analysis is done by measuring the absorption of infrared radiation according to the Lambert–Beer law. Ethanol molecules absorb radiation at wavelengths of $\sim$3.4 μm corresponding to the C–H stretching and $\sim$9.5 μm corresponding to the C–O stretching frequencies. To enhance selectivity for identifying ethanol, the absorption of infrared radiation is done at several different wavelengths
Electrochemical oxidation	AlcoSensor Alcolmeter Alcotest Lifeloc	Ethanol in a fixed volume of breath ($\sim$1.0 ml) undergoes electrochemical oxidation with the help of a platinum black catalyst and acid electrolyte mounted with electrical connections to form a fuel cell. The molecules of ethanol enter one side of the cell and are oxidized to acetaldehyde thus liberating electrons. The current produced is proportional to the concentration of ethanol in the sample of breath
Metal oxide semiconductor (Taguchi cell)	ALERT J4X	Many small handheld devices incorporate a Taguchi sensor and these are generally inexpensive and mainly intended as self-testers for use by the public. The ALERT J4X incorporated a Taguchi cell and this unit gained approval as a breath-alcohol screening instrument by police forces in Canada. The Taguchi sensor incorporates a tin-oxide (SnO_2) bead mounted on a ceramic cylinder that measures changes in surface conductivity. The heated bead has a high surface resistance in ambient air but when exposed to combustible gases the surface conductivity increases in proportion to the concentration of substance in the gas phase. The semiconductor is not specific for analysis of ethanol and constituents of cigarette smoke as well as acetone on the breath give a response

proportion to the number of molecules of ethanol reacting at the platinum electrode surface. The output from the fuel cell changes as a function of time after starting the reaction to reach a peak response after about 20 s. The response curve then exponentially falls back to zero. Quantitative analysis is achieved by measuring the peak response or the area under the entire response curve. To speed up the time between tests, the return to a zero signal is achieved by short circuiting the cell in readiness for the next subject test.

One important category of breath-alcohol instruments are those intended and used for evidential testing, that is to generate evidence of sufficient reliability that drunken drivers can be prosecuted. Most evidential breath-alcohol instruments incorporate infrared technology for the detection and analysis of ethanol as discussed above [25]. The test subject

exhales into the heated breath inlet tube and makes a continuous forced exhalation for as long as possible, usually for at least 6 s. The concentration of ethanol increases as a function of time during a prolonged exhalation, first rapidly and then more slowly as the volume of exhaled breath reaches a maximum forced exhalation (Figure 4).

Quality assurance of the breath sample is achieved by means of slope detectors that help to monitor the shape of the breath-alcohol exhalation profile to ensure that it conforms to that expected for normal human breath containing only ethanol [24, 25]. The BrAC at the end of exhalation gives a good indication of the concentration of alcohol residing in the deep lung alveolar air as it leaves the lungs. Instruments used for evidential testing should provide a print-out of the results in real time including identification of the person tested, proof of calibration control of the instrument and the date and time of testing as well as all analytical results. It is good forensic practice to make two independent tests of the person's breath-alcohol concentration about 6 min apart and take the average result [24].

An important aspect of any chemical analysis is the calibration and standardization of the measuring equipment used [19,21]. Calibration refers to the process by which the relationship between the output signal or response of the instrument and the value of the input quantity or concentration is determined. For the purpose of calibration, a series of ethanol standards with known strength are prepared to cover the range of interest. The calibration and control of breath-alcohol instruments is done either by means of a so-called wet-bath simulator device or by use of a compressed dry gas cylinder containing a known content of ethanol mixed with an inert gas such as argon. The wet-bath simulators are the traditional way of calibrating breath analyzers and have the advantage that they resemble the biological specimen (human breath) in composition, that is, being saturated with water vapor at the temperature of exhaled breath (34 °C). However, the compressed gas standards are more convenient to handle when tests are made away from the laboratory, such as at a police station or in a police vehicle [24]. It seems that compressed dry gas standards are gradually replacing the traditional wet-bath simulators for the purpose of calibration control checks of evidential breath-testing instruments.

Considerable interest exists in the marketing and sale of breath-testing instruments that are intended primarily for use by the general public as a means of self-testing. These devices are usually small, compact and battery operated, and fairly cheap to buy. However, the results obtained are not always reliable and trustworthy for several reasons. First, a proper control of the way the sample of breath is introduced into the instrument cannot be guaranteed. Second, the alcohol sensors incorporated are usually tin-oxide semiconductors that measure changes in conductivity, which is a nonspecific way to measure ethanol (Table 9). Third, a control of the calibration stability of the instrument is rarely done during long-term usage. Fourth, cigarette smoke, carbon monoxide, exhaust fumes, methane, and other combustible gases react and give a response indistinguishable from ethanol. Accordingly, the use of these self-testers for alcohol should not be encouraged. Another rapidly emerging public safety application of breath-alcohol testing is in connection with ignition interlock devices or so-called alcolocks. These devices are fitted to public transportation vehicles (e.g., buses and trains) and also into many private cars. The aim is to prevent a person who has consumed too much alcohol from being able to start the vehicle and reduce the risk of drunken driving. If alcohol is detected on the person's breath above a predefined threshold level, the ignition switch is locked and the vehicle will not start.

The concentration of ethanol in breath at which the vehicle fails to start is usually set to be fairly low, such as at a BAC of $0.2\,g\,l^{-1}$ (20 mg/100 ml) or less, even though the legal limit for driving might be higher (e.g., 0.5 or $0.8\,g\,l^{-1}$). The overall aim of interlock devices is to improve traffic safety by reducing the risk of alcohol-related crashes. Interlocks are particularly useful as a countermeasure to prevent a previously convicted drunken driver from reoffending. Indeed, some countries make it one of the requirements for relicensing to have an interlock fitted to the vehicle belonging to a previously convicted drunken driver. Most of the currently available interlock devices make use of the electrochemical oxidation reaction to analyze ethanol (Table 9).

Concluding Remarks

Knowledge about a person's BAC or BrAC provides compelling evidence when a conclusion is reached about the effects of alcohol, such as the degree of drunkenness, impairment of cognitive and

psychomotor functioning, and the ability to form intent. Discussion and debate about culpability is tightly linked to a person's BAC and this has gained paramount importance in criminal proceedings, such as investigation of alcohol-related crimes including murder, physical and sexual assaults, and drunken driving. This means that the quantitative analysis of alcohol in body fluids is undoubtedly the highest volume investigation performed at most forensic science and toxicology laboratories worldwide [26, 27].

Few substances can be determined in blood and other body fluids with such a high degree of accuracy, precision, and selectivity as the concentration of ethanol [15, 19]. Because the alcohol a person drinks becomes diluted with the total body water, which is ~50–60% of body weight, the amount of ethanol necessary to cause inebriation and impairment vastly exceed that of all other drugs of abuse. The BACs, typically encountered in legal medicine ($0.2–5.0\,g\,l^{-1}$), are about 1000 times higher than those for most other licit or illicit drugs.

The sampling and analysis of alcohol in breath has the advantage that it is noninvasive and the results of the test are obtained immediately afterward [4]. The on-the-spot results of a breath-alcohol test allow immediate decisions to be made, such as allowing a motorist to continue driving, or whether a casualty patient might require emergency surgery e.g., for head trauma or simply be allowed to recover from gross intoxication. Breath-alcohol instruments are being increasingly used in connection with workplace alcohol testing, at probation and rehabilitation centers where people must refrain from drinking and also at school parties and dance venues where alcohol use is forbidden.

This review hopefully made it clear that ethanol can be determined in body fluids with a high degree of accuracy, precision, and specificity by a variety of analytical methods [20, 23]. However, the gold standard procedure is the application of GC together with the headspace sampling technique. Such GC methods furnish both a qualitative analysis, based on the comparison of the RT of components in the sample with authentic known substances, and also a quantitative analysis based on detector response (peak height or peak area) displayed on the chromatogram [16]. The GC methods of analysis are easily automated and under optimum conditions, the response for ethanol is adequately resolved from that of other low molecular weight volatiles that might be present in forensic bloods samples, such as acetaldehyde, methanol, acetone, and isopropanol [15].

Although the methods are the same for dealing with specimens from the living and the dead, the analytical results from autopsy specimens are more difficult to interpret, owing to various postmortem artifacts. This limitation is offset to some extent by the fact that many different biological specimens are available for toxicological analysis during a postmortem examination. Aspects of postmortem alcohol analysis and interpretation have been dealt with in depth in several recent review articles [27, 28]. The recommended specimens for the determination of ethanol in corpses are femoral venous blood from the left or right leg (Table 7) and use of heart blood or from the chest cavity should be avoided. To simplify interpretation of analytical results, pathologists should strive to obtain additional specimens, such as urine from the intact bladder and vitreous fluid from the eyes, for the analysis of ethanol [29].

The consumption of alcoholic beverages is part and parcel of normal social life in most countries and for many individuals, especially among men, moderate drinking often escalates into overconsumption, abuse and dependence. Binge drinking and drunkenness have many negative consequences for the individual and society and results in premature death. Heavy drinking tends to trigger deviant and aggressive behavior, such as family violence and drunken driving. The continued use and abuse of alcohol in society ensure that requests to measure this drug in body fluids and to interpret the results in a legal context will remain the most commonly requested service from forensic science and toxicology laboratories in the distant future.

ALAN W. JONES

Alcohol: Behavioral and Medical Effects

Introduction

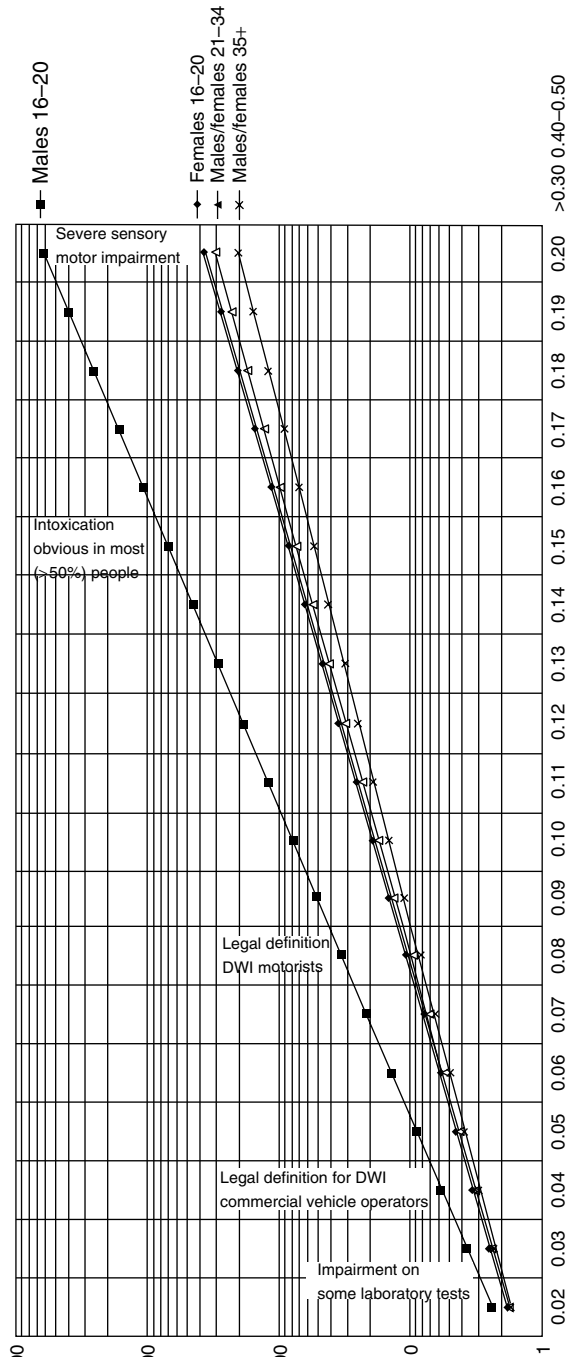
Alcohol is one of the oldest drugs known and it affects virtually every organ system in the body. The medical consequences including the economics of medical treatment of alcohol-related disorders are staggering and can have important forensic implications. Alcohol damages the heart and can elevate

blood pressure, increasing the risk of heart failure and stroke and can impair biochemical regulation of a variety of cellular and metabolic functions that can increase the risk for certain forms of cancer, the risk for accidental injuries and impairs the recovery from those injuries and significantly contribute to the years of life lost. This article reviews the most significant and well-known medical consequences of alcohol in three basic areas of forensic interest: accidental injuries, skeletal fragility, and liver pathologies.

Alcohol and Accidental Injuries

Accidental injuries are a direct medical consequence of alcohol intoxication. Laboratory as well as epidemiological field studies conducted over the last few decades clearly establish the fact that alcohol-induced impairment of cognitive and psychomotor functioning while engaging in a variety of behavioral activities increases the risk for injury. Among these, the effects of alcohol on automobile, bicycle, motorcycle, boating, aquatic, and pedestrian injuries, as well as homicide, suicide, and death from fire have been examined.

Impaired Driving



Driving while intoxicated is probably the well-studied injurious consequence of drinking of interest and is of importance to forensic examiners. The use of alcohol coupled with increased risk taking and impulsivity, at least among young males [1], and decreased seat belt use [2]. Even at very low blood–alcohol concentrations (BACs), the performance of complex divided attention, a critical factor in a variety of tasks both inside and outside the laboratory, is impaired and the most likely cause of motor vehicle collisions. At BAC above 50 mg/dl that impairment translates into actual highway statistics (in which the intoxicated driver is deemed to be the cause of the accident). At higher BACs (e.g., 150 mg/dl, or more), impairment in proprioception, visual perception, and lengthened simple reaction time are additional significant contributing factors that should be considered into forensic investigations of crashes involving intoxicated drivers, pedestrians, and others. Most people who present with obvious symptoms of intoxication are impaired drivers and at increased risk for a fatal crash. However, the lack of obvious intoxication does not mean lack of impairment. Most subjects do not appear visibly intoxicated, even though they are intoxicated according to law in regard to motor vehicle operation [3–6]. When most people appear obviously intoxicated, their BAC is probably well in excess of any legal definition of intoxication.

Regardless of which functions are affected by alcohol, impaired drivers clearly present a public health risk because of the increased number of accidental injuries due to intoxication. About 16 000 fatalities occur each year related to drunken driving [7] and about 10% of all personal injury accidents and at least 180 000–200 000 property and personal injury crashes, respectively, are caused by alcohol intoxication per year [8]. The risk of injury as well as the responsibility for causing a collision when driving while intoxicated is proportional to the BAC. With the current legal definition of driving while intoxicated in the United States (80 mg/dl), the relative risk for a crash is significantly greater compared with sober drivers. When the interaction among blood alcohol, gender, and single *versus* multiple vehicle collisions is considered, the relative risk is many times greater than previously believed. For example, the relative risk of a fatal crash in an 18-year-old male with a BAC of 80 mg/dl is about 34 times greater than a sober driver. In comparison, a 40-year-old male with the same BAC has a relative risk that is about 11 times greater than a sober control [9, 10]. A more specific breakdown of relative risk based on age, gender, and BAC is presented in Figure 1.

Pedestrian and Fall-down Injuries

Earlier studies estimated that about one-third of all fatally injured pedestrians had a BAC of 100 mg/dl or more at the time of their death. More than two-thirds of drivers, pedestrians, and bicyclists (see below) killed each year are intoxicated [12]. Driving and pedestrian activity rely on divided attention and visual motor processes. Therefore, it is reasonable to infer that these behaviors share similar alcohol-induced changes in relative risk. However, driving is obviously a more challenging task than walking, but both behaviors require divided attention, vigilance, and other cognitive skills that are sensitive to the impairment produced by alcohol, even at low BACs [13].

In the United States, injuries related to falls are the second leading cause of accidents and account for about 13 000 deaths per year. Most studies suggest

Age 16–20 females*	1.8	2.5	3.3	4.5	6	8	11	15	20	27	37	49	67	90	122	164	221	299	403	Comatose	~LD:50	
Age 16–20 males	2.4	3.7	5.8	9.0	14	22	34	53	82	127	196	305	473	735	1141	1772	2752	4273	6634

Figure 1 Alcohol intoxication, behavior, and relative risk for a fatal crash. Line graph shows relative risk (log) as a function of BAC, age, and gender. Data derived from stepwise logistic regression coefficients for relative risk based on single vehicle fatalities [9]. Note that for women age 16–20, a coefficient of 0.03 (range 0.044–0.014) was used. Coefficients are rounded to nearest 10th or whole number [Reproduced from Ref. 11. © Taylor & Francis Group, 2008.]

that alcohol increases the risk for injuries due to falls. Honkanen *et al.* [14] evaluated intoxicated emergency room patients involved in fall-down injuries and compared them with sober pedestrians who were at the same location of the accident one week later at the same time of the day. The comparison revealed the relative risk or a fall was three times greater for patients with blood–alcohol levels between 50 and 100 mg/dl, 10 times greater for patients with blood alcohol levels between 100 and 150 mg/dl, and 60 times greater for patients with BACs 160 mg/dl, or higher.

Bicycling

Also, there are about 200 fatalities and 7000 injuries from alcohol-related bicycle crashes each year. The relative risk of an alcohol-related bicycle crash found that alcohol was involved in 25% of the collision accidents and in 63% of the single accidents involving cyclists aged 15–64 years compared with intoxication in 4% of the nonaccident controls. A relative risk was of the order of 3 overall, and 58 for the collisions related to alcohol use [15]. Moreover, bicyclists who died at the scene were four times as likely as those who died at hospitals to be at or above the legal definition of intoxicated driving. This increased mortality may be due to the effects of alcohol on injury outcome (discussed later in this article). Other studies suggest that fatally injured bicyclists were about twice as likely to be intoxicated as cyclists treated for nonfatal injuries [16].

Fires and Burns

In the United States, alcohol intoxication plays a role in the estimated 5000 fatalities and about 1.4 million burn injuries each year [17]. In a review of studies on alcohol and burn injuries published between 1947 and 1986, Howland and Hingson [18] and reported on the percentage of the victims who were intoxicated with alcohol. In the overwhelming majority of the studies published in that period, alcohol exposure was found to be more likely among those who died in fires ignited by cigarettes than from other causes, suggesting that alcohol plays a role in the cause of fires, subsequent burn injuries, and is overly represented in burn victims. In fact, one-third to two-thirds of these victims had blood alcohol levels greater than 100 mg/dl. The authors concluded from these data that alcohol intoxication is a risk factor for fire deaths [18]. Later studies further revealed that alcohol was a factor in about 22% [19] to 26% [20] of burn injuries. Overall, intoxicated patients have a significantly higher fatality rate in severe burn cases. These data are reviewed elsewhere [21].

Although, impairment from alcohol is a risk factor in a substantial percentage of burn victims, it is not the only factor and may also interact with other factors. For example, Brezel and Kassenbrock [22] examined alcohol and drug abusers, psychiatric patients, and those with neurological dysfunction to determine whether this group had more medical complications, surgical procedures, and longer hospital stays than burn patients without these disorders. Alcohol abuse (defined as six or more cans of beer or the equivalent, per day) was the most common form of impairment, and the authors found that these patients had more complications and required a longer period of hospitalization, alcohol intoxication was only one of the several contributory factors.

Both acute and chronic alcohol abuse contribute to burn injuries. In a study of 1074 patients admitted to a medical center burn unit, 40% who were positive for alcohol were more likely to have a greater proportion of bodily burns and greater incidence of smoke inhalation than the controls [23]. Chronic alcoholics also seem to have a higher fatality rate than do patients without a history of chronic alcohol abuse [24].

In a recent review of the incidence and toxicological complications of burn cases, Brick [25] concluded that there is a clear relationship between alcohol or drug intoxication and the risk for thermal injury. It was suggested that the reason alcohol-intoxicated persons were at increased risk for accidental thermal injuries is impaired judgment or psychomotor coordination while engaging in normal fire-starting activities (e.g., cooking). We also noted that psychomotor impairment might be only one part of the problem. Other factors including neuropsychological status while intoxicated may impair various domains of cognitive functioning resulting in a decreased ability to anticipate problems, lowered inhibitions, and increased risk taking. For example, once a fire has started, mental confusion, and failure to recognize risk or danger may lead to an inability to anticipate or respond to danger, particularly at high levels of intoxication.

Water Sports

Alcohol is infinitely miscible in water, at least chemically, but with regard to water sports, alcohol and water do not mix. Nearly half of drowning victims in one study had consumed alcohol and 22% were intoxicated with BACs of 100 mg/dl, or more [26]. More recent studies suggest that alcohol consumption significantly increases the risk for boating fatalities was a factor in up to 21% of reported boating [27]. As alcohol deleteriously impairs balance, motor function, and judgment, intoxicated passengers, as well as vessel operators, are probably at risk for injury [28].

Alcohol intoxication also contributes to and aggravates spinal cord injuries following diving accidents. In this context, Perrine *et al.* [29] examined the effects of alcohol on the ability to perform shallow-water entry dives under experimental conditions. A progressive and significant impairment of specific aspects of diving performance was detected at blood alcohol levels as low as 40 mg/dl. This study also correlated diving performance with psychomotor performance using the Standardized Field Sobriety Tests (SFSTs). Impaired diving correlated well with impaired SFST performance criteria for the detection of drivers with a blood alcohol level of more than 100 mg/dl [29].

Aircraft Operation

Pilots who must divide attention and process information derived from an array of instrumentation and make perceptual and cognitive decisions based on a large amount of information in a multidimensional environment should not drink and fly. It is known that alcohol deleteriously influences the ability of pilots to evaluate their performance [30] and that low levels of alcohol (25–40 mg/dl) impair performance of trained pilots in flight simulators [31, 32]. Although it might appear that both motor vehicle drivers and aircraft pilots are impaired at similar low BACs (e.g., 30–40 mg/dl), there is evidence to suggest that piloting an aircraft is significantly more sensitive to the effects of alcohol. For example, there is some research suggesting that alcohol continues to impair performance on flight simulators many hours after blood alcohol levels have returned to zero [33]. Although some laboratory studies failed to find impairment 12 h after drinking [34], the forensic implications of impairment when alcohol is not in the blood are enormous, need to be evaluated further.

Suicide

Suicide is the 11th leading cause of death for young people (aged 15–34), and the third leading cause of death in the United States [35]. Suicide is also highly correlated with alcohol intoxication.

In a review of suicide attempts, intoxication was present in 40% (range 10–73%) for attempted suicide and 10–69% for completed suicides. The relationship between alcohol use and suicide is not difficult to understand. Acute intoxication reduces inhibitions, narrows attention, impairs the ability to appreciate the consequences of behavior, and may promote depressive thoughts and hopelessness. Chronic alcohol abuse is often complicated by mental illness, including depression [36–38]. Both acute and chronic intoxication, impair cognitive skill, may enhance aggression including self-aggression, or the combination with medications may precipitate pathways mediating this behavior [39]. Although, it is unlikely that people commit or attempt to commit suicide simply because they are intoxicated, premorbid suicidal ideology is more likely to be acted upon while intoxicated. Acute intoxication may be a greater risk factor for suicide than the previous drinking history [40] but the causal mechanism for the interrelationship among alcohol intoxication, alcohol dependence, and suicide is only partially understood [37, 41].

Miscellaneous Injuries

People die from many causes including accidental injuries, homicide, and suicide, in which alcohol intoxication is a significant risk factor. Relative to lifetime abstainers and infrequent drinkers, the risk of death from external causes increased logarithmically among infrequent binge drinkers [42] and no evidence of reduced risk of death among light or moderate drinkers. The group at highest risk of death from external causes was drinkers who consumed five or more drinks less than once a month. Within this group of binge drinkers, older subjects (defined as 65-plus years) were at the highest risk. High risk was also observed in younger drinkers (defined as 18–24 years of age), probably because of their lack of tolerance and experience, as middle-aged drinkers (25–64 years of age) who presumably have more experience both as drinkers and drivers, did not show the same increased mortality risk. In summary, infrequent binge drinking increases risk as a function of

age, possible tolerance, age-related experience, and other variables.

Intoxication and Injury Outcome

Alcohol intoxication not only contributes significantly to accidental injuries but may also affect injury outcome, particularly among patients with head injuries. This is highly significant as up to half of the traumatic brain-injured patients have BACs that exceed the legal definition for intoxicated driving at the time of injury [43]. For example, motorcycle riders with head injuries are about twice as likely to have fatal head injuries if they are intoxicated, compared to injury matched, sober riders [44]. Drunk drivers are more likely to be seriously or fatally injured than sober drivers [45] and alcohol-intoxicated accident victims with central nervous system injuries were more than twice as likely to die sooner than anatomically matched controls [46].

Such a belief is not supported by the majority of more current research on this topic [47]. The biochemical cause of the deleterious effect of intoxication in the injury outcome is not proven but there are some intriguing potential mechanisms. For example, it is now believed that the severity of hemorrhagic shock is greater when intoxicated and results in a higher mortality rate compared with the sober controls [48]. Hemorrhagic shock also induces acidosis with marked hypercarbia. In such cases, alcohol-induced acidosis would likely increase morbidity and mortality [48–50] possibly because of the effects of acidosis on ventilatory responses.

Alcohol and the Skeletal System

The relationship between alcohol abuse and increased risks for skeletal fractures was observed by the ancient Egyptians [51–53], but the epidemiology and mechanisms of this effect have only recently come under scientific scrutiny. Since alcohol is known to increase risk for injuries that may involve skeletal fractures, generalized skeletal fragility among alcoholics may be an important contributing factor to such injuries.

Alcohol-induced Fractures

Epidemiological research on the prevalence of fractures in alcoholic subjects suggests positive association between alcohol intake and fractures. For example, men hospitalized for alcohol-related problems are four times more likely to have rib fractures than nondrinking patients [54] and up to 14 times more likely to have spinal crush fractures [55, 56]. Two to six drinks per week also increases the risk for fractures in men compared with the same injuries in subjects who consumed less than two drinks per week, and for heavy drinkers, there was almost 10 times the risk of hip fractures as men in the same age group who drank lightly [57].

Weekly alcohol intake was associated with greater risks for osteoporotic fractures in postmenopausal women [58], and women who consumed more than eight drinks per week, the fractures were almost twice as likely as in nondrinkers. Other studies show that the equivalent of two standard drinks per day is associated with a significant increase in hip, wrist, and other fractures [59–61]. However, other investigators have not identified any significant association between alcohol intake and the risks for various fractures in women [62–66].

In addition to the risk of falls and related injuries, alcoholics may also suffer from a generalized skeletal fragility. Low bone density (osteoporosis) is a predictor of fractures [7], and a consequence of excess alcohol use reduced bone density has been confirmed in by many, but not all studies [67–73]. Dietary [68], hormonal [69], metabolic [73], and other factors contribute to this phenomenon (see [11] for a review).

Alcohol-induced Liver Injury

Underreporting of alcohol consumption makes the exact prevalence of alcoholic liver disease in the United States difficult to measure, but health statistics suggest that some form of alcoholic liver disease affects more than 2 million drinkers [74]. It is estimated that 900 000 Americans have cirrhosis, and of the 26 000 who die each year, 40–90% have a history of alcohol abuse [74]. It is clear that the development of alcoholic liver disease is due to a combination of factors, most notably, prolonged alcohol consumption. Alcohol abuse is the leading cause of liver-related mortality in the United States. Excessive alcohol consumption leads to three serious types of liver injuries: fatty liver, hepatic inflammation (alcoholic hepattits), and progressive liver scarring (fibrosis or cirrhosis). Chronic heavy drinking can alter the normal metabolism and lead to an accumulation of fat

in the liver. As a result, the liver cells become so infiltrated that the liver itself becomes enlarged and cell damage may occur. However, fatty liver is reversible with abstinence. Continued alcohol abuse may result in hepatitis, a more serious medical condition, characterized by prolific inflammation and tissue damage.

Hepatitis is life threatening but there can be significant recovery of function following abstinence. The most serious form of liver damage is cirrhosis, an irreversible disease characterized by scarring and cell death. Impaired liver functioning can also cause primary hepatic encephalopathy. Although this brain disorder precipitated by liver disease is rare, forensic examiners should be aware of it because it is characterized by altered psychomotor, intellectual, and behavioral functioning absent acute intoxication.

Chronic, heavy drinking may produce metabolic tolerance and unusually high rates of alcohol elimination. Hepatitis and fibrosis will ultimately impair liver function and produce a reverse metabolic tolerance and impaired oxidation of alcohol. When justified, pharmacokinetic analyses used in making estimates of alcohol consumption or intoxication should account for potential metabolic changes.

One question of interest to many people is, "How much alcohol does one need to drink before liver damage occurs"? Epidemiological studies suggest that reliable signs of injury begin after a "threshold" dose of about 600 kg for men and between 150 and 300 kg for women. To place this in perspective, at the high end (for men), this is roughly equivalent to the average consumption of 10–12 drinks a day for 10 years, and at the low end (for women), about three drinks per day. Below these doses, it is difficult but not impossible to reliably detect liver injury [75–78]. The differences in threshold doses between genders cannot be accounted for by anthropometrics or pharmacokinetics. For example, many individuals who consume large amounts of alcohol never develop liver disease and less than one-half of heavy drinkers develop alcoholic hepatitis or liver fibrosis [75]. This suggests that hereditary and/or environmental factors interact with alcohol to affect the natural history of liver injury [76]. Numerous possible mechanisms may affect the susceptibility of certain people to alcohol-induced liver damage. Nevertheless, alcoholic liver disease is a significant cause of death in the United States and significantly contributes overall ages to 24 (in men) to 28 (in women) years of potential life lost [79, 80].

Summary and Conclusions

As a pharmacological agent, alcohol is a relatively simple compound. The ubiquitous nature of this drug on most, if not all major organ systems is consistent with its simple molecular structure and its widespread use [11]. Of specific interest to forensic issues, alcohol directly affects hepatic and skeletal systems and indirectly affects health and well being when accidental injuries due to intoxication are considered. From the available alcohol research, several conclusions may be drawn regarding the medical consequences of alcohol use. Most notably and across physiological systems, the effects of alcohol are complex and vary as a function of gender, diet, environment, lifestyle, genetics, dose and frequency of alcohol use, use of other drugs, and age. Even so, the majority of studies suggest that, overall, higher doses of alcohol are deleterious to many physiological systems and precipitate a range of psychosocial and biobehavioral problems including shortened lifespan that would be of interest in forensic evaluations.

Alcohol: Interaction with Other Drugs

Introduction

The interaction between alcohol (ethanol, unless otherwise specified) and therapeutic medications is often encountered in accident, homicide, and suicide investigations. This review will focus on alcohol–other drug interactions most applicable to forensic evaluations. Reviews of the interaction between alcohol and a broader range of medications on health are available elsewhere [1, 2]. The widespread use of alcohol is coupled with extensive medical consequences and overly represented in accidental or other injuries and criminal actions. For a variety of reasons, including the ability to routinely test for the presence of medications and illicit drugs, the use of alcohol with drugs in accidents and crimes is of increasing forensic interest.

The term *drug* is used here to refer to both licit and illicit drugs, whereas the term *medication* will refer specifically to therapeutic medications and the term *alcohol* refers to *ethanol*, unless otherwise indicated. In the controlled environment of the laboratory the biobehavioral effects of drug interactions are often complex. Outside of the laboratory alcohol–drug interactions are often complicated by real-world variations in dose and drug potency, duration and frequency of use, use of other drugs, and individual characteristics of the user, including physiological factors such as tolerance, metabolic state, diseases, and anthropometrics.

Understanding Alcohol

Alcohol is a central nervous system (CNS) depressant, although under some conditions, it is perceived as a stimulant because it increases locomotor activity, loquaciousness, and other behaviors. The biphasic effect of alcohol is probably more related to the

decrease in inhibitions produced by this drug rather than actual stimulant effects, at least in humans. Pharmacologically, alcohol acts much more like a CNS depressant or anxiolytic [3, 4]. Suffice it to say, the pharmacology of alcohol is complex and its biobehavioral effects quite broad, since alcohol is capable of altering receptors, ion transport, cell membranes, most cellular mechanisms critical to neurophysiology, and ultimately a range of behaviors. Alcohol also has the ability to alter the pharmacokinetics and pharmacodynamics of other drugs. Changes in bioavailability and efficacy of drugs in the presence of alcohol, or in patients with a history of alcohol dependence, have important implications for diagnoses, treatment, and outcome and should be part of a complete clinical evaluation.

Why Multiple Drug Use?

Persons trained in neuropharmacology, toxicology, or medicine are aware of the pernicious effects of some of the more commonly used drugs. The inherent dangers of combining drugs and public service announcements have saturated the media for decades. Yet multiple drug use is still relatively common. Although the biopsychosocial factors of drug use and drug interactions are complex and not fully identified, drug use is usually related to the reinforcing effects of the drug, psychosocial influences, and enhanced performance. Multiple drug use is may be motivated by many factors, including increasing the primary drug effect (e.g., increasing the intensity of the "high" or, when used clinically, increasing the effectiveness of treatment), self-medication to decrease the undesirable side effects of the primary drug (e.g., a depressant may be used to alleviate the edgy feeling after the desired effects of a stimulant wear off), or short supply of the primary or preferred drug (e.g., when the availability of the drug of choice is limited, another drug with similar properties will be substituted).

Heroin addicts, for example, may use or combine drugs for many reasons. Among these are sensation seeking (e.g., drug combinations without regard to safety and without any particular rationale other than the desire to become intoxicated), medical management (e.g., in the course of medical treatement, it is not uncommon to prescribe drugs that may interact with therapeutic or nontherapeutic drugs), or they may consume large quantities of alcohol or use other depressants to reduce or delay the opioid withdrawal syndrome until additional narcotics can be procured). Physicians must recognize the potential for these interactions (since in addition to a prescription medication, their patients may ingest other drugs, alcohol being the most common) and advise patients accordingly.

Pharmacological Basis of Alcohol–Drug Interactions

Drug interactions can produce alterations in physiology and ultimately behavior through changes in pharmacokinetics or changes in pharmacodynamics. Pharmacokinetic mechanisms account for drug interactions when the presence of one drug affects the bioavailability of another drug. Pharmacodynamic interactions account for drug interactions when drugs interact at the receptor level.

Pharmacokinetic Interactions

Pharmacokinetics can alter the bioavailability of the drug. If bioavailability increases or decreases the quantity of drug that interacts with receptors or other cellular components, the effect of the drug will in most instances, increase or decrease as well, depending on the dose. Pharmacokinetic interactions can occur through changes in drug absorption, distribution, metabolism, and excretion.

Pharmacodynamic Interactions

Pharmacodynamics is the study of the physiological and biochemical effects of drugs and their mechanism of action. Psychoactive drugs alter the functional activity of receptors or endogenous ligands (i.e., neurotransmitters and hormones) in the brain, whereas other drugs may exert similar effects outside the CNS (e.g., cardiac β-receptor antagonists). Changes in the pharmacodynamics or functional activity of neurons that modulate cognitive and psychomotor effects, for example, will alter physiology and behavior. Pharmacodynamic drug interactions can be classified as addictive, synergistic, potentiated, and antagonistic.

Additive Effects. Addictive effects occur when the combination of two drugs is equal to the sum of the effect of each drug (e.g., $2 + 2 = 4$). For example,

the CNS depressant effects of many benzodiazepines and alcohol are additive, as are the effects of many barbiturates with alcohol.

Synergistic Effects. Synergistic interactions occur when the combination of two drugs produces an effect that is greater than the sum of the effect of each drug (e.g., $2 + 2 = 6$). Synergistic interactions produce effects far greater than would be predicted from the sum of effect of either drug. For example, alcohol and carbon tetrachloride, a cleaning fluid, are toxic to the liver. However, the combination of the two produces much more liver damage than would be predicted from the sum of their individual effects. Similarly, in some cases, alcohol synergistically enhances the sedative effect of barbiturates and some effects of opiates.

Drug Potentiation. Potentiated drug effects are similar to synergistic effects, but usually describe an increase in the toxic effect of a drug when combined with a nontoxic drug (e.g., $0 + 1 = 2$). Histamine (H_2) antagonists such as cimetidine can be considered to potentiate the toxic effects of alcohol by increasing alcohol bioavailability.

Antagonism. An antagonist is a drug that blocks the effect of another drug (e.g., $2 + 2 = 1$ or $2 + 2 = 0$). Antagonists are very specific. For example, Naloxone has a much higher affinity for opiate receptors than heroin. Administering Naloxone to someone who has overdosed on heroin will produce a rapid reversal of the respiratory depression produced by heroin. Some drugs exhibit dispositional antagonism when the absorption, metabolism, distribution, or excretion of one drug is affected by another drug. For example, ethyl alcohol decreases the metabolism of methanol.

Specific Alcohol–Drug Interactions

With a basic understanding of the pharmacological mechanisms by which alcohol–drug interactions may occur, let us examine specific alcohol–drug interactions that may be of forensic interest.

Alcohol and Acetaminophen

The over-the-counter (OTC) medication acetaminophen (Tylenol) is one of the most commonly consumed medications in the United States because of its effective analgesic and antipyretic properties. Acetaminophen is metabolized by the CYP2E1 isozyme to a toxic intermediate, *N*-acetyl-*p*-benzoquinone imine (NAPQI). Normally, NAPQ1 is detoxified by the antioxidant glutathione [5], but chronic alcohol use reduces the amount of the glutathione produced in the liver. In other words, the combination of large amounts of acetaminophen reduced glutathione levels from chronic alcohol use increases the bioavailability, and the result is toxic. The resulting hepatotoxicity may progress to the point of fulminant hepatic failure and death. There is no agreement in the medical community as to the amount of alcohol consumed and/or the amount of acetaminophen necessary to cause this toxic effect to occur. Earlier studies indicated that liver damage can occur in alcoholics at therapeutic doses of acetaminophen [6–8], but a more recent study found no increase in liver toxicity among alcoholics given the maximal therapeutic dose (4 g/day) of acetaminophen [9]. They concluded that there was no clinical evidence of increased risk for these patients when acetaminophen is used within recommended doses.

Alcohol and Antibiotics

Most medications have some side effects, but when antibiotics used to treat infectious diseases are combined with acute alcohol consumption, some may cause nausea, vomiting, headache, and possibly convulsions. Among these antibiotics are furazolidone, griseofulvin, metronidazole, and the antimalarial quinacrine. Isoniazid and rifampin are used together to treat tuberculosis, a disease especially problematic among the elderly in nursing homes and among homeless alcoholics. In addition, acute alcohol consumption decreases the bioavailability of isoniazid in the bloodstream, whereas chronic alcohol use decreases the bioavailability of rifampin. The pharmacokinetic interaction between alcohol and some antibiotics may reduce their effectiveness [10]. Erythromycin accelerates gastric emptying and may reduce first-pass metabolism of alcohol in the stomach, resulting in increased absorption in the intestines and higher blood alcohol levels. Conversely, many aerobic bacteria in the colon are capable of metabolizing alcohol because they possess alcohol dehydrogenase (ADH) activity. In rats, treatment

with ciprofloxacin totally eliminated the colonic metabolism of alcohol, resulting in increased blood alcohol concentrations [11]. Although controversial, patients drinking alcohol while taking metronidazole or ketoconazole may suffer from symptoms similar to those found with disulfiram (Antabuse): abdominal distress, nausea, vomiting, and headache [12]. Similarly, cefoperazone (Cefobid), griseofulvin (Fulvicin, Grisactin), isoniazid (INH), metronidazole (Flagyl), nitrofurantoin (Furadantin, Macrodantin), and sulfamethoxazole (Bactrim, Septra) inhibit aldehyde dehydrogenase and may also produce a disulfiram-like reaction.

Alcohol and Anticoagulant Medications

Warfarin (Coumadin) reduces the ability of the blood to clot and is commonly used to treat patients with irregular heart rhythms, artificial heart valve, and following open-heart surgery. Warfarin is metabolized by the cytochrome P450 enzyme system in the liver, which is also part of the pathway of alcohol metabolism. Therefore, if a person consumes alcohol, the anticlotting effect of warfarin may be increased above the desired therapeutic effect. This increased bioavailability of warfarin is due to alcohol-related inhibition of warfarin metabolism by the cytochrome P450 enzyme system [13]. This increase could result in the emergence of potentially life-threatening hemorrhages. However, in people who drink alcohol regularly, and especially in some alcoholics, the chronic consumption of alcohol will result in induction of the cytochrome P450 enzyme system. The result of this will be an increased rate of metabolism of warfarin, thereby decreasing its bioavailability and interfering with its effectiveness in reducing blood clotting [13]. Such individuals will often need larger doses of warfarin to achieve the desired therapeutic effect, but there is no reported effect of warfarin on alcohol pharmacokinetics or pharmacodynamics.

Alcohol and Anticonvulsants

More currently available anticonvulsants in comparison with the classic agents have good absorption, linear kinetics, and minimal potential for interaction with other drugs. The newer anticonvulsants are eliminated through different combinations of liver metabolism and direct renal excretion, such as felbamate, gabapentin, lamotrigine, topiramate, tiagabine, levetiracetam, oxcarbazepine, and zonisamide. Depending on its chronicity of use, alcohol will have totally different pharmacokinetic effects with the older anticonvulsants such as phenobarbital, phenytoin, primidone, ethosuximide, carbamazepine, and valproate. Acute alcohol consumption increases the availability of phenytoin and the risk of drug-related side effects. Chronic drinking may decrease phenytoin bioavailability, significantly reducing the patient's protection against seizures, even during a period of abstinence [14, 15].

Alcohol and Antidepressants

The literature on the correlation between alcoholism and depression is well established [16] and particularly important in forensic evaluations because alcoholics are often involved in accidents and crimes. Many active alcoholics are prescribed antidepressants leading to a high potential for alcohol–antidepressant interactions. Several classes of antidepressants are available and are defined by how they affect brain neurochemistry. Some antidepressants cause varying degrees of sedating activity but these drugs should not be described as depressants or sedatives. Nevertheless, alcohol increases the sedative and other effects of tricyclic antidepressants such as amitriptyline (Elavil) [17]. In addition, alcohol-induced liver disease further impairs antidepressant metabolism and causes significantly increased levels of active medication in the body [18]. The disposition of imipramine in alcoholic and nonalcoholic patients with depression varied significantly. For example, oral imipramine clearance was more than 2 times greater in alcoholic patients than controls [19] and in recently detoxified men with alcohol dependence, and the elimination half-life for imipramine was more than doubled in alcoholics after intravenous infusion. Plasma concentrations of imipramine were also significantly lower in the alcoholics, suggesting that standard doses of some antidepressants may fail to produce adequate therapeutic changes in alcoholics. For imipramine, the doses may have to be doubled [19].

Popular serotonin reuptake inhibitors (SSRIs) such as fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), and citalopram (Celexa) have the best safety profile of all antidepressants, and no serious interactions seem to occur when these agents are consumed

with moderate doses of alcohol [20]. In addition, neither fluoxetine nor alcohol alters the pharmacokinetics or psychomotor effects of the other, although alcohol impairs performance of most subjects on psychomotor tests [21, 22].

The use of the monoamine oxidase inhibitors (MAOIs) with alcohol will potentially precipitate a hypertensive crisis and enhance sedation. The mechanism for this reaction has been attributed to increased concentrations of the amino acid tyramine [23], which is a potent hypertensive agent present in many alcoholic beverages (e.g., wines) and foods (e.g., cheeses and bananas). Although most dietary tyramine is destroyed by MAO in the intestines and liver, tyramine will enter the circulation in patients treated with MAOIs and may produce hypertension and, rarely, sudden death [24]. Therefore, alcohol use should be avoided in patients prescribed MAOIs and considered by medical examiners in such cases.

Atypical antidepressants generally do not seem to have any problematic interactions with alcohol. However, mirtazapine (Remeron), when combined with alcohol, causes impaired cognition and decreased motor performance [25].

Alcohol and Antidiabetic Medications

Oral hypoglycemic agents are commonly prescribed for the treatment of diabetes mellitus in patients not requiring insulin. As previously noted, chlorpropamide (Diabinase), glyburide (Diabeta, Micronase), and tolbutamide (Orinase) inhibit aldehyde dehydrogenase and can cause disulfiram-like reactions following alcohol consumption. Metformin (Glucophage) may increase lactic acid levels in the blood following alcohol ingestion, which could result in acute lactic acidosis with potentially lethal results. Alcohol consumption by patients taking many of these medications could increase the risk of causing lower than normal blood sugar levels owing to impairment of gluconeogenesis during fasting when blood sugar is already low and the body depends on the production of new glucose [18]. Since low blood sugar can cause symptoms of impairment virtually indistinguishable from alcohol intoxication [26], behavioral observations of patients who are diabetic, or diabetics who have consumed alcohol, should be interpreted cautiously.

Alcohol and Antihistamines (H_1-Antagonists)

Antihistamines (H_1-antagonists), such as diphenhydramine, are commonly used to treat allergic disorders, and some antihistamines, such as hydroxyzine (Vistaril, Atarax), to treat anxiety. Many antihistamines cause drowsiness, which make them useful to treat insomnia, but are potentially dangerous because they can impair psychomotor and cognitive skills. Alcohol can substantially enhance the sedating effects of these agents and may further impair the ability to drive or operate other types of machinery [27]. Common sedative antihistamines, such as chlorpheniramine and diphenhydramine, significantly impair psychomotor performance and significantly increase the deleterious effects of alcohol on reaction time, coordination, and related psychophysical tests [28–30]. Newer antihistamines such as fexofenadine, loratadine, and cetirizine have been developed to minimize drowsiness and sedation while still providing effective therapeutic value. Nevertheless, these newer medications may still increase risk of hypotension and fall-down injuries among the elderly, particularly when combined with alcohol [18].

The effects of many of the antihistamines with alcohol have not been fully investigated, but it seems more probable than not that the combined use of these drugs will result in increased drowsiness and increased driving risks [31], possibly due to the observation that histamine receptor antagonism can affect alcohol metabolism and change the sensitivity to the hypnotic effects of alcohol [32].

Alcohol and Antipsychotics

Many antipsychotics produce sedation and psychomotor impairment. When combined with alcohol, they may increase sedation, impair coordination, and fatally depress respiration. This effect appears to be additive, but the mechanisms of this interaction are uncertain. Antipsychotics, such as chlorpromazine and thioridazine, are more sedating than the high-potency antipsychotics such as haloperidol and fluphenazine and tend to cause more significant CNS depression. For example, chlorpromazine coupled with very low blood alcohol concentrations ($\sim 40\,\text{mg dl}^{-1}$) impairs skills related to driving and produces subjective complaints of feeling sleepy, lethargic, dull, groggy, and poorly coordinated behavior [33]. Less psychomotor impairment was observed

when alcohol was combined with flupenthixol [34, 35] or thioridazine [34–36] but not with haloperidol [34, 35]. Changing doses, steady-state pharmacokinetics, and types of antipsychotic medication make predictions about the acute interactions of these drugs with alcohol difficult. Long-term use of some psychotropic medications may result in extrapyramidal motor system disorders that can be misinterpreted as some form of intoxication. Also, chronic alcohol consumption causes increased metabolism of the antipsychotic medications, resulting in lower blood levels and, ultimately, lesser efficacy of the medication. Since antipsychotic medications are typically used to treat mental illnesses such as schizophrenia, when combined with alcohol, the results may be particularly challenging and unpredictable.

Alcohol and Cannabinoids

It is well known by forensic examiners, police, and toxicologists that alcohol and tetrahydrocannabinol (THC) are two of the most widely used and commonly encountered drugs detected in motor vehicle collisions. Tetrahydrocannabinol is the primary psychoactive compound in marijuana and presumed to be the effect-producing drug in studies where marijuana is smoked. The effects of THC on drowsiness, memory, and distortion of space and time are particularly important because of the obvious need for such skills in motor vehicle operation, for example.

In one of the earlier interactive studies on the effects of THC and alcohol on driving, Casswell [37] found that (i) alcohol alone increased speed and impaired steering, (ii) THC alone reduced speed and slowed response to instruction, and (iii) alcohol and marijuana tended to increase speed, impair steering, and increase response times to instructions. More recent studies concluded that the effects of THC and alcohol appear to be additive. When THC is combined with low blood alcohol concentrations (BACs) (40 mg dl^{-1}), there is evidence of impaired visual search patterns while driving, and reaction times are greater than from either drug alone. The authors point out that the effects of alcohol are greater than those produced by smoking marijuana, noting that the combination is particularly dangerous with regard to motor vehicle operation [38, 39].

Although the majority of more recent studies support the conclusion that alcohol and THC impair driving [40–42], not all investigators found an interaction between these drugs. For example, Smiley, Ziedman, and Moskowitz [43] found that after smoking marijuana, drivers became more cautious in overtaking tasks. Alcohol (45 or 75 mg dl^{-1}) had a slight effect, but no interaction between alcohol and smoked marijuana was observed. Using a driving simulator, Stein *et al.* [44] found that after alcohol consumption (100 mg dl^{-1}), drivers had more "accidents" and "speeding tickets" and slower and less accurate responses to road signs. Smoking marijuana had "only an occasional effect" and no interaction was observed.

The nature of any pharmacodynamic interaction between alcohol and cannabinoids is difficult to explain since the neuropharmacological effects of these drugs are complex and diverse. There is some evidence of a pharmacokinetic interaction between these drugs. Lukas *et al.* [45] found that smoking marijuana decreases the bioavailability of alcohol, reducing the maximum serum alcohol concentration and delaying the time to peak concentration from 78 mg dl^{-1} (50 min after drinking) to about 55 mg dl^{-1} (105 min after drinking).

More research on this potential pharmacokinetic interaction is needed, and forensic examiners are cautioned that pharmacokinetic and pharmacodynamic interactions that are measurable at low drug concentrations may be obscured at the higher concentrations, which are more likely to be encountered in forensic evaluations.

Alcohol and Cardiovascular Medications

Acute alcohol consumption interacts with some cardiovascular medications (e.g., nitroglycerin, used to treat angina; reserpine, methyldopa (Aldomet), hydralazine (Apresoline), and guanethidine (Ismelin), used to treat hypertension) to cause dizziness or fainting upon standing (orthostatic hypotension). Chronic alcohol consumption decreases the availability of propranolol (Inderal), used to treat high blood pressure, potentially reducing its therapeutic effect. Since alcohol acts as an osmotic diuretic and also causes hypokalemia, patients taking loop diuretics (e.g., furosemide, ethacrynic acid, and bumetanide) or less potent thiazide and various sulfonamide derivatives, are at greater risk for dehydration, hypokalemia and, therefore, risk of seizure. Verapamil, which inhibits the metabolism of the alcohol by the liver, can increase blood alcohol content, whereas alcohol may

increase the bioavailability of nifedipine by inhibiting its metabolism [46].

The inhibition of aldehyde dehydrogenase by the coronary artery dilator isosorbide dinitrate (Isordil, Dilatrate, and Sorbitrate) and nitroglycerin (Nitro-Bid and Nitrostat) can produce a disulfiram-like reaction (described in the following section) when combined with relatively low amounts of alcohol. Such interactions may complicate drug recognition evaluations (DREs).

Alcohol and Disulfiram

Disulfiram (Antabuse) is used to control drinking through aversion therapy, but the combination of drugs has serious and even fatal consequences due to their interactive biochemistry. Alcohol is metabolized by ADH to acetaldehyde, which is metabolized by aldehyde dehydrogenase. Disulfiram inhibits the enzyme aldehyde dehydrogenase, resulting in the accumulation of acetaldehyde. Acetaldehyde is highly toxic and produces many aversive sympathomimetic effects including facial flushing, nausea, vomiting, breathing difficulties, and headache. In extreme cases, respiratory depression, cardiovascular collapse, cardiac arrhythmias, unconsciousness, and convulsions leading to death can occur.

In addition to disulfiram, other prescription medications can inhibit aldehyde dehydrogenase and can produce a disulfiram-like reaction in people who consume alcohol while taking them [47]. The following medications may produce severe sympathomimetic reactions when combined with alcohol: the antidiabetic oral medications chlorpropamide (Diabinase), glyburide (Micronase, Diabeta), tolazamide, and tolbutamide; a number of antibiotic medications including cefoperazone (Cefobid), griseofulvin (Fulvicin, Grisactin), INH, metronidazole (Flagyl), nitrofurantoin (Furadantin, Macrodantin), and sulfamethoxazole (Bactrim, Septra); the analgesics phenacetin and phenylbutazone; and the coronary artery dilator medications isosorbide dinitrate (Isordil, Dilatrate, and Sorbitrate) and nitroglycerin (Nitro-Bid and Nitrostat). In patients with certain medical conditions (i.e., those with coronary artery disease), the disulfiram-like reaction could be potentially fatal as a result of cardiovascular effects involved in the pathogenesis of the disulfiram-like reaction (dilation of blood vessels, hypotension, and tachycardia). As it is impossible to predict with certainty the severity of the disulfiram-like reaction, individuals taking any of these medications should be advised to avoid alcohol, and a thorough review of prescription medications should always be part of any forensic examination if unusual symptoms are present in intoxicated patients.

Alcohol and Histamines (H_2-Antagonists)

Alcohol abuse may contribute to gastrointestinal diseases, including gastritis, ulcers, and gastroesophageal reflux disorder (GERD). H_2-antagonists, such as cimetidine (Tagamet), ranitidine (Zantac), and nizatidine (Axid), are commonly used to treat these disorders.

As a result, these medications can increase the bioavailability of alcohol. Moreover, gastric ADH may account for a significant percentage of alcohol metabolism [48], at least at low blood alcohol concentrations. In addition, the first-pass metabolism of alcohol is also reduced by cimetidine because of the effect it may have on increasing the rate of gastric emptying, again resulting in increased blood alcohol levels [49]. In many studies, the effect was quite significant – increases of blood alcohol concentrations of about 17–33% by cimetidine and to a much lesser degree by rantidine, if at all [50, 51]. Although these investigators examined this effect through a series of detailed studies and identified dose, drug type, gender, and drinking history to be important variables, the clinical significance of this interaction has been questioned by some researchers [52], and this effect is not universal to all H_2 antagonists. For example, Famotidine (Pepcid) appears to have no effect on blood alcohol levels.

The use of the H_2-antagonists for the treatment of gastroesophageal reflux disease (GERD) has largely been supplanted by a newer class of agents that reduce gastric acid secretion, the proton pump inhibitors (PPIs) such as omeprazole (Prilosec), lansoprazole (Prevacid), esomeprazole (Nexium), and rabeprazole (Acidphex). The PPIs do not appear to interact significantly with alcohol. Therefore, broad generalizations about alcohol and H_2 antagonists should be avoided, and careful examinations of the specific medications and dose should be made in evaluating the role of these new medications in combination with alcohol. In other words, some, but not all, H_2 antagonists affect alcohol pharmacokinetics.

Alcohol and Lipid-Reducing Medications

Statins, medications used to reduce elevated lipids and cholesterol, are usually metabolized through the cytochrome P450 enzyme system. Atorvastatin (Lipitor), simvastatin (Zocor), and lovastatin (Mevacor, Altocor) are metabolized through the CYP3A4 isoenzyme, which is also involved in the metabolism of alcohol and a number of other medications that bind more strongly to the enzyme than statins. When alcohol or any of these substances block the statin from binding to the CYP3A4 enzyme, the metabolism of the statin is reduced, resulting in increased statin levels and the potential for statin-related toxicity [53–56]. The major toxic reactions include myotoxicity (myalgia, myopathy, and rhabdomyolysis) and hepatotoxicity. Milder cases are often reversible without serious sequelae with substance discontinuation, but severe cases, although rare, may be potentially fatal.

Alcohol and Methanol

Alcoholics may drink other forms of alcohol such as methanol when beverage alcohol (ethanol) is not available. Methanol (methyl alcohol) is highly toxic, and consumption of small quantities may result in metabolic acidosis, blindness, and death. Interestingly, the interaction between ethanol and methanol is critical in treating methanol poisoning. Methanol is metabolized by the enzyme ADH to formaldehyde and then to formic acid, a highly toxic compound [57]. Even when relatively small doses of methanol (several ounces) may cause metabolic acidosis, blindness, and cardiovascular instability and death. It is noteworthy that methanol poisoning can be prevented by the administration of ethyl alcohol because ethanol (alcohol) is preferentially metabolized by ADH, thereby decreasing the formation of toxic metabolites from methanol. The decrease in methanol metabolism allows methanol to be excreted unchanged and before toxic metabolites are formed. Patients admitted for acute alcohol intoxication or detoxification should be screened for methanol use so that appropriate prophylactic treatment (e.g., hemodialysis, ADH inhibitors, and ethanol administration) can be initiated.

Alcohol and Non-narcotic Pain Relievers (ASA and NSAIDS)

Aspirin (acetylsalicylic acid (ASA)) and nonsteroidal anti-inflammatory drugs (NSAIDs) frequently used to treat mild to moderate pain also decrease the activity of gastric ADH. This biochemical damage increases the bioavailability of ingested alcohol and heightens the effects of a given dose of alcohol [50] at least at low blood alcohol concentrations. There are a number of other non-narcotic pain relievers including phenacetin, an acetaminophen precursor (and often found in other drugs including acetaminophen, aspirin, caffeine, codeine, and propoxyphene), and phenylbutazone (Butazolidin), both of which inhibit aldehyde dehydrogenase. Therefore, the use of these drugs with alcohol may result in an aversive disulfiram-like reaction (see previous section on Alcohol–Disulfram interactions).

Alcohol and Opiates

The effects of opiate medications such as codeine, morphine preparations, propoxyphene (Darvon), oxycodone preparations (Percocet, Oxycontin), hydromorphone (Dilaudid), hydrocodone (Vicodin, Lortab), meperidine (Demerol), and fentanyl can be enhanced by the depressant effect of alcohol, resulting in decreased motor skills, respiratory problems, drowsiness, and sedation. For example, a single dose of alcohol can increase the bioavailability of propoxyphene, potentially increasing its sedative effect [58]. Opiate medications (i.e., codeine, propoxyphene, and oxycodone) are manufactured as combination products with the non-opiate analgesics (e.g., acetaminophen), which can result in an interaction between alcohol and the acetaminophen, as well as the opiate. The accumulation of toxic breakdown products forms an acetaminophen/alcohol interaction and can be potentially dangerous, resulting in liver damage or failure. Patients who are prescribed any of the opiate/acetaminophen combination preparations should be cautioned about consuming any additional amounts of acetaminophen.

Methadone, a synthetic opioid with a relatively long half-life, is used to reduce heroin use in opiate-dependent patients. New patients or patients receiving a significant increase in their daily oral dose of methadone may present with symptoms of mild psychomotor and cognitive impairment. However, unlike many other opioids, prolonged methadone use, even at relatively high doses, does not impair cognitive or psychomotor performance [59] including driving [60–62]. However, the combination of alcohol and opiates does increase respiratory depression. It is

generally advisable not to drink alcohol while taking methadone for a variety of reasons related to recovery, but the interaction between these drugs is limited.

Alcohol and Sedative Hypnotics

The depressant effects of barbiturates range from mild sedation to general anesthesia and are similar to alcohol. The interaction between these drugs is additive probably because of both pharmacokinetic and pharmacodynamic mechanisms. Alcohol may also inhibit the hepatic metabolism of barbiturates [63], which would increase their bioavailability and effectiveness. Gamma aminobutyric acid (GABA) interacts with receptors containing recognition sites for anxiolytics and sedative benzodiazepines and barbiturates, which regulate gating of chloride channels. Since alcohol also alters the gating properties of these receptors, a pharmacodynamic interaction between alcohol and these medications exists even though alcohol has little affinity to recognition sites for GABA, benzodiazepines, or barbiturates [3].

Both barbiturates and alcohol derive some pharmacodynamic properties through the $GABA_A$ receptor. Barbiturates enhance the binding of GABA to $GABA_A$ receptors. Alcohol also shares the ability to increase GABA-mediated synaptic inhibition and chloride ion flux, which explains in part interaction of these drugs. Although other mechanisms are involved in the psychoactive effects of both drugs, the combination of alcohol and barbiturates will result in greater psychomotor and other CNS impairments than either drug alone.

Many benzodiazepines and alcohol share similar pharmacokinetic and pharmacodynamic mechanisms, so it is not surprising that the combination of alcohol and benzodiazepines is associated with drug-induced deaths, drug overdoses, and traffic accidents or fatalities [64, 65].

A pharmacokinetic interaction between alcohol and benzodiazepines also exists. For example, there is a decline in the efficiency of the metabolism of the benzodiazepines as a result of increasing age or liver disease. In the elderly, there is a 50% decrease in clearance, with a four- to ninefold increase in half-life, and a two- to four fold increase in the volume of distribution [66].

Alprazolam (Xanax), a benzodiazepine analog, is used in the treatment of anxiety disorders and is currently the most prescribed medication in the United States. Although there is no synergistic action between this medication and alcohol, an additive interaction has been reported on certain psychomotor and cognitive tasks, such as information processing and memory [67]. The combination of alcohol and alprazolam produces increases in self-reported drowsiness [67], but no significant interaction between alprazolam and alcohol was reported [68] even though each drug produces several effects.

Some nonbenzodiazepine anxiolytics, such as buspirone, also do not appear to interact with alcohol to potentiate cognitive or motor performance impairment. Unlike some benzodiazepines, buspirone has been found to have no significant effect on body sway, coordination skills, tracking skills, or nystagmus even when combined with alcohol [69]. This lack of alcohol interactions with some benzodiazepine-like medications should be noted when interpreting DREs performed by police.

Alcohol and Stimulants

Although there is some evidence that stimulants decrease fatigue and reaction time while causing an increase in arousal, body temperature, heart rate, blood pressure, and other changes that may decrease some of the depressant effects of alcohol (e.g., sleepiness), the combination of a stimulant and a depressant is often erroneously assumed by laypersons to result in a neutralizing or balancing out of these two opposite effects. The scientific literature indicates the interactions between alcohol and stimulants to be inconsistent and often complex. For example, studies reported no antagonistic effect of dextroamphetamine on the mental and psychomotor impairment produced by alcohol, whereas others have found improved performance compared with controls [70, 71]. Perez-Reyes *et al.* [71] reported that alcohol ($100\,mg\,dl^{-1}$)) significantly increased the bioavailability of high, but not low, doses of dextroamphetamine ($25.5\,ng\,ml^{-1}$ vs. $15.7\,ng\,ml^{-1}$). Moreover, amphetamine did not significantly alter peak blood alcohol concentrations, but alcohol significantly increased the bioavailability of dextroamphetamine. Dextroamphetamine attenuated alcohol-induced increases in latency and accuracy while performing an eye–hand–foot reaction time task believed to be related to driving abilities. As the effect was greatest about 4 h after alcohol administration, when blood alcohol concentrations had dropped

from a peak of about 100 mg dl^{-1} to about 60 mg dl^{-1}, fatigue and dose were probably important factors in the latter finding [71]. The statistical significance of these results probably outweighs their actual value.

Although the interactions between alcohol and amphetamines have been studied, the only clear conclusion is that the interaction is complex and task specific, and that there is no simple antagonism between the drugs.

There does seem to be an interaction between alcohol and another stimulant, cocaine. One novel consequence of cocaine and alcohol use is that a third compound, cocaethylene, is formed. Cocaethylene (sometimes referred to as *ethyl cocaine* or *cocaine ethyl-ester*) is not a natural alkaloid of the coca plant and is not found in pharmaceutical or street cocaine. In fact, cocaine is metabolized to its ethyl configuration only in the presence of ethanol. Cocaine and cocaethylene have similar effects, but the latter extends the euphorogenic and reinforcing effects of the former. In humans, the combination of alcohol and cocaine is greater than the effect of either drug alone, and is associated with an enhanced subjective euphoria, increased heart rate, and increased plasma cocaine concentrations [72, 73]. In humans, insufflation of cocaine before alcohol ingestion does not appear to alter blood alcohol levels or subjective ratings of intoxication of alcohol intoxication. However, when alcohol is administered prior to cocaine insufflation, there is a significant increase in both cocaine plasma levels (possibly due to an inhibition of hepatic cocaine metabolism produced by alcohol) and an augmentation of cocaine's subjective and heart rate effects [74, 75]. In another study, combining cocaine and alcohol produced a nonsignificant decrease in subjective feelings of drunkenness, an increase in cocaine-induced euphoria, and a significant improvement in alcohol-related changes in psychomotor performance along with a marked increase in heart rate. Subjects who were administered cocaine and alcohol interpreted the effects as "more pleasant" than compared to alcohol alone [76]. Although many drugs are metabolized to form other psychoactive compounds, cocaethylene is the only known example of a third psychoactive drug being formed as a result of administering two other psychoactive drugs of abuse. As cocaine-induced deaths have been observed with a wide range of postmortem cocaine concentrations, often with presence of low blood alcohol levels, the possibility exists that cocaethylene may be partially responsible for these deaths [77]. Additional research is clearly required in this area.

Summary and Conclusions

With some exceptions, such as the interaction between drugs and specific antagonists to receptors for those drugs, or combinations of drugs of the same class, drug interactions are often difficult to predict with great precision. The interactions between alcohol and therapeutic medications or other drugs are very complex, highly variable events, and dependent upon a number of pharmacodynamic and pharmacokinetic factors. These interactions are further complicated by the potential for alcohol to cause liver pathologies that impact on the therapeutic effectiveness of some medications, even if the patient is sober at the time of the testing. In evaluating drug effects and drug interactions, there are a multitude of factors that can affect outcome including, but not limited to, the anthropometric characteristics of the patient (age, gender, body weight, and height), medication/drug dosage, and the amount and frequency of alcohol consumption. Patients in certain populations (e.g., geriatric) may use multiple medications or be susceptible to age-related physiological effects that could increase the potential for more severe drug interactions. When interpreting empirical research or clinical studies, forensic examinations must be cognizant of the fact that most of these studies involve relatively small alcohol doses for a variety of practical and ethical reasons, and the effects observed at relatively low blood alcohol concentrations may be very different than those in highly intoxicated patients. Similarly, the lack of a significant interaction with low doses of a drug does not guarantee the same results when higher doses are used. As a result, it is very difficult to stipulate a safe dose of alcohol that can be consumed when taking medications. Individuals with little or no tolerance to alcohol or other drugs may be more sensitive to these interactions. In conclusion, the CNS depressant effects of alcohol can be expected to increase the depressant effects of most medications and other drugs with similar CNS effects, but the significance of that interaction will be drug specific, even within some classes of medications. Generalizations about medication or drug effects in combination with alcohol should be avoided, as not alcohol–other drug

or medication combinations produce pharmacokinetic or pharmacodynamic interactions.

Alcohol: Use, Abuse, Tolerance, and Dependency

Alcohol use, abuse, tolerance, and chemical dependence are often factors in the forensic investigation of crimes, accidents, or deaths (accidental or otherwise). Although these terms apply to other drugs, this article

will focus on and review basic concepts in defining alcohol, its use, abuse, tolerance, and dependence.

What is Alcohol?

Most people know what the term *alcohol* is, but unless specified it can be misleading or inaccurate. In some instances, this may result in a fatal misunderstanding. To an alcohol research scientist, toxicologist, or chemist, three of the most common alcohols are ethyl alcohol (ethanol), methyl alcohol (methanol), and isopropyl alcohol (isopropanol). Each has a similar chemical structure; a hydroxyl group attached to a saturated carbon molecule, each causes intoxication, and each has been represented in forensic cases. The general intoxicating effects of ingesting different alcohols are somewhat similar, but the side effects are quite different.

Methanol, also known as *wood alcohol*, is the most toxic of the three examples given. Relatively small amounts (less than one ounce) may cause retinal damage. Larger quantities (one or more ounces) can be fatal, but toxicity varies greatly [1, 2]. Methanol's toxicity is the result of its metabolism to formaldehyde, which is metabolized to formic acid, a cellular toxin that is about 6 times more poisonous than methanol itself. Formic acid produces severe metabolic acidosis and tissue hypoxia, and more than 6 to 7 ounces of methanol is lethal for many adults [1, 2]. Methanol intoxication usually occurs by accident, because of lack of knowledge about its harmful effects. For example, mixing methanol in "jungle juice" (a concoction of many different types of liquors and juices), typically served to large groups and popular among college students in the United States, may place the uninformed drinker at significant medical risk.

Methanol is also consumed by some alcoholics who, in the absence of beverage alcohol, may consume products containing it, such as antifreeze or dry gas used in automobiles. Initial symptoms of methanol intoxication are somewhat similar to those of beverage alcohol. Unless specifically alerted to possible methanol intoxication, a patient who becomes ill from methanol may be misdiagnosed by untrained or unobservant medical personnel and not receive proper treatment for methanol poisoning. For example, emergency treatment for methanol poisoning, such as ethanol administration, is highly unlikely if the patient is believed to be "drunk".

As mentioned, methanol's toxicity is derived from its metabolism to formaldehyde and formic acid. Methanol is metabolized by the enzyme alcohol dehydrogenase (ADH), which also metabolizes beverage alcohol. Because the affinity of beverage alcohol (ethanol) for ADH is about 10–20 times greater than that of methanol, when beverage alcohol and methanol are present at the same time, the liver preferentially metabolizes beverage alcohol. This allows time for methanol to pass through the excretory system before it is metabolized to harmful metabolites. Therefore, a rapid emergency treatment for methanol poisoning is beverage alcohol. Beverage alcohol, such as whiskey, vodka, rum, etc., is not likely to be administered to an unknown patient who presents symptoms of intoxication in an emergency department.

Isopropanol, or common rubbing alcohol, is less toxic than methanol but about twice as toxic as beverage alcohol. Small amounts, as little as several ounces, can also cause permanent damage to the visual system, and 8 ounces is estimated to be lethal [1]. Dose estimates are often based upon postmortem findings. Obviously, it would be highly unethical and illegal to conduct a range of dose–response studies in humans to determine the lethal dose. Actual lethal doses may be lower or higher, depending upon many factors. Some alcoholics may also consume isopropanol intentionally (e.g., some brands of dry gas contain both methanol and isopropanol) or unknowingly, also with potentially harmful or even lethal consequences.

However, the alcohol that is the primary subject of this review, and the alcohol consumed as a beverage by most people is ethyl alcohol (ethanol). Ethanol is a relatively odorless chemical formed through a process of fermentation and a drug that affects most organs of the body, including the brain [3, 4]. Ethanol is also lethal but at much higher doses than methanol or isopropanol. The lethal dose (LD50) of acute ethanol is estimated to be a blood alcohol concentration (BAC) of about 400–500 mg/dl, although death may occur at higher or lower concentrations depending upon factors such as tolerance or the presence of other drugs. For example, compared to 6 or 8 ounces of methanol or isopropanol, it would require about 24 ounces of 80 proof liquor (about 16 standard drinks) in a 150-pound male consumed over an hour to reach a BAC that would probably be lethal for about half the population. In this article, unless

otherwise indicated, the term *alcohol* will be used to denote ethanol.

Alcohol Use

Use in the United States

Alcohol use predates recorded history, but for all practical purposes the medical literature documenting the consequences of alcohol abuse goes back less than 200 years. Alcohol consumption and related problems have been well documented. Alcohol-related medical problems account for a disproportionate number of hospital admissions and medical complications [5, 6]. Yet, despite general public awareness about alcohol-related problems, longitudinal studies suggest that nearly 9% of adults in the United States consume, on average, more than two drinks per day [7]. Among senior high school students (typically 17–18 years old), about 3% use alcohol daily and about half had used alcohol within 30 days of being surveyed. About two-thirds of the adult population in the United States consumes alcohol to varying degrees, and 6% of adolescents (age 12–17) and about 8% of adults meet diagnostic criteria for alcohol abuse or alcohol dependence [8].

Defining Alcohol Use, Abuse, and Dependence

Alcohol use can first be defined in terms of how much alcohol was consumed. For example, a standard alcoholic drink is defined as 1.5 ounces of 80 proof liquor (e.g., rum, whiskey, vodka), a 12-ounce beer (about 5.0% v/v), or a 5-ounce glass of wine (12% v/v). Each of these drinks contains the same amount of ethanol. However, drink size can vary considerably in restaurants, bars, or at parties [9–11]. Nevertheless, for reporting purposes, standardization of drinks is useful and recommended in research and in forensic analyses [11].

The term *social drinker* or *light drinker* is often used by laypersons and some professionals but these terms may be inaccurate or misleading if not defined correctly. For example, the social use of alcohol is now generally described as a cold beer after a ball game, a glass of wine with meals, or a glass of champagne at festive occasions [12]. Similarly, the terms *light, moderate,* and *heavy* drinking are also used to describe drinking habits, but these terms are relative and may have different meanings when other factors are considered. For example, the US Department of Agriculture Health and Human Services defines moderate drinking as one drink per day or less for women and two or fewer drinks per day for men [13]. However, if someone admits to drinking six or seven drinks per week, that might equate to moderate drinking since it averages about one drink per day, but have an entirely different implication if all six or seven drinks were consumed on Friday nights. Such a pattern of drinking constitutes binge drinking, now defined as four to five drinks within 2 h or a BAC of 80 mg/dl [8]. Whereas one to two drinks per day is considered moderate, heavy drinking is considered by many scientists as the consumption of more five or six drinks a day, but many other factors are considered in making a diagnosis of heavy, or other types of drinking [13, 14], including the impact of drinking on life events [15]. Therefore, the terms *light, moderate*, and *heavy* should be interpreted carefully on the basis of individual drinker characteristics or research design.

The most recent edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) [16] defines two types of drinkers: those with alcohol abuse, and those with alcohol dependence. Alcohol abuse is intentional, conscious, and voluntary. Abusers drink too much too often, and make poor choices and decisions regarding their drinking. Their subsequent intoxication often results in injuries to themselves or others, medical consequences and expenses, lost productivity, and family problems. An example of alcohol abuse is drinking and then driving a car, or possibly drinking when pregnant. Most people with alcohol "problems" are alcohol abusers.

In contrast to abuse, alcohol dependence is pathological and unintended. Alcoholics lack control over their use of alcohol in lifestyle situations in which abusers would ordinarily stop drinking, even if the desire to do so is strong. For example, a man who drinks a quart of whiskey a day cannot stay employed, has lost his family and friends because of constant drunkenness and is vomiting blood several times a day, and consults with his medical doctor. Even when he is told that alcohol is causing bleeding in his esophagus, the man still cannot stop drinking. Even though there are serious medical consequences to continued drinking, he cannot stop. This is alcohol dependence.

The new classifications of dependence are confusing to those who remember the old 1950 World Health Organization definition. This latter definition, no longer valid, stated that an addicting drug had three qualities: (i) psychological dependence (equating generally with habituation or "craving"), (ii) tolerance (reduced drug effect so that more drug is needed to produce the original desired effect), and (iii) physical dependence (adaptation of the body to the drug so that one could only function normally when the drug was present. When the drug is discontinued, the previous adaptation of the nervous system no longer functions in the drugfree cellular environment and physical withdrawal symptoms appear). While this definition properly describes dependence on central-nervous-system (CNS) drugs such as heroin and alcohol, the definition falls short of describing dependence on cocaine, a CNS stimulant that has profound emotional withdrawal symptoms, but no significant physical withdrawal.

Impaired control, which is at the center of our new definition of addiction, is a characteristic of all drugs that are "addicting". The new term *dependence* (addiction) still has both psychological and physical components, but they are different from the old WHO definition. For example, impaired control is an obsessive preoccupation with the use of the drug (psychological) caused primarily by a neurochemical (physical) dysfunction in the brain. Older concepts such as "physical addiction" and "psychological addiction" have no accurate meaning and terms such as *alcohol addict* or *drug addict* do not appear in the current edition of DSM-IV. Terms such as *addict* or *addiction* are vague and scientifically imprecise and should not be used. Erickson [12] points out that these are pejorative terms (e.g., addict, junkies, and drunks) that detract from the science of alcohol (or drug) dependence as a brain disease [12, 16].

Tolerance and Dependence

Tolerance and physical withdrawal are side effects usually associated with moderate to heavy drug consumption, but are not rigid criteria for diagnosing alcohol dependence. In fact, social drinkers and alcohol abusers can demonstrate tolerance.

Tolerance is a decrease in the response to a drug as a function of exposure to that drug. The several types of tolerance are discussed below. Although tolerance is still a criterion for alcohol dependence, it cannot be inferred that if someone is tolerant they are an alcoholic. Tolerance is merely one of seven maladaptive patterns of use leading to a possible diagnosis of alcohol dependence [17]. Similarly, while anyone who consumes alcohol acquires some form of tolerance (see below), evaluations of alcohol-dependent patients should avoid the error of assuming that all "alcoholics" have a degree of tolerance that precludes any interpretation of their behavior while intoxicated. Although tolerance varies within and between subjects, it rarely confers immunity from most of the intoxicating effects of alcohol that would be of interest in forensic examination (e.g., drinking and driving). However, tolerance (or lack thereof) may be a factor in dramshop or comparative liability cases, where the question of general appearance (not performance on tests) is of legal interest. There are five primary forms of tolerance: acute, chronic, dispositional/metabolic, cross, and nonpharmacological.

Acute tolerance was first noted by Mellanby, who observed that in dogs there is greater behavioral impairment when the BAC is rising compared to the same BAC when alcohol is post absorption and declining [18]. A similar effect was observed in humans [19–22], and has since been termed *acute tolerance.* This phenomenon, which can occur in a single drinking episode, is termed *acute tolerance*.

Chronic tolerance develops in response to chronic or repeated exposure to ethanol and is a resistance to the intoxicating effects of the drug. Chronic tolerance occurs as the nervous system responds to the presence of alcohol and adapts to maintain homeostasis. A history of heavy drinking is likely to confer tolerance and less impairment compared to those in people who are moderate drinkers or abstainers [19, 23]. All drinkers acquire one or more forms of tolerance, but some chronic heavy drinkers become of exceptional tolerance and are able to function (to varying degrees) at BACs that would render less-tolerance drinkers unconscious or dead [23, 24]. Contrary to popular belief, although chronic drinking may reduce obvious symptoms of alcohol intoxication in some drinkers (compared with drinkers having little or no tolerance), it does not confer the same immunity from the impairment of complex tasks, such as driving, particularly at the high BACs often achieved by such drinkers.

Dispositional and metabolic tolerance results from differences in ethanol absorption and distribution, whereas metabolic tolerance occurs from more efficient metabolism. The key factor here is tolerance

occurs because of a change in drug availability to some target tissue.

Alcohol is metabolized primarily by enzymes in the liver. For many drugs, including alcohol, repeated administration results in enzyme induction. Under such circumstances, the increased availability of enzyme results in more rapid metabolism of the drug and, therefore, less pharmacological effect. In human alcoholics, the magnitude of metabolic tolerance can vary significantly. For example, most men and women eliminate alcohol at a rate of about 15–20 mg/dl h^{-1}, but in some chronic heavy drinkers that rate can be significantly higher [25]. When a history of chronic heavy drinking is known or suspected, metabolic tolerance should be considered in pharmacokinetic analyses. In such cases, a range of elimination rates should be used and not a single "average [11]".

Cross-tolerance is present when the use of one drug results in a change in response to a different drug. In other words, the effect of the use of one drug may increase or decrease the response of another drug. Cross-tolerance may be due to changes in CNS sensitivity or metabolic tolerance that occurs when drugs share similar pathways of metabolism. For example, oxidative metabolism catalyzed by cytochrome P-450, reduced nicotinamine–adenine dinucleotide phosphate (NADP), and the microsomal oxidizing system (MEOS) pathways are shared by barbiturates and some minor tranquilizers. In the presence of alcohol, the removal of these drugs can be delayed, resulting in higher than expected drug concentrations [26, 27]. Interactions between ethanol and environmental factors as well as other drugs may also contribute to cross-tolerance [28].

Nonpharmacological or learning-based theories of tolerance demonstrate state-dependent learning, in which a task learned and practiced under a drug state is better performed in the same drug state. The work of Siegel and others has provided additional evidence that learning plays a significant role in the development of tolerance. This research suggests that environmental stimuli preceding drug intake elicit a conditioned compensatory response that attenuates the drug effect. In a classical Pavlovian conditioning paradigm, the conditioned stimuli (CS) consist of the various experimental procedures and environmental stimuli associated with the administration of the drug. The unconditioned stimuli (UCS) are the actual direct pharmacological effects of the drug. The conditioned response (CR), once formed by repeated administrations of the drug, may then be demonstrated with a placebo by presenting the usual drug administration cues (CS) in the absence of the pharmacological effects of the drug (UCS). Conditioned tolerance has been demonstrated for many different drugs, including ethanol, both in animals [29–31] and in humans [32–34].

Conclusions

Alcohol comes in many forms, including ethanol, the form contained in beverages. Alcohol is one of the most widely used and abused drugs in the United States and elsewhere, and is frequently found in toxicology results stemming from investigations of accidental and intentional injuries. Forensic evaluations of cases where alcohol is involved should take into account differences between social alcohol use and alcohol abuse when describing drinker characteristics. Similarly, the biobehavioral consequences of alcohol abuse and dependence should be interpreted in the context of current definitions of abuse and dependence. Multiple forms of tolerance can result from acute or chronic alcohol use. Tolerance is a relative term and should not be considered indicative of alcoholism. Similarly, a diagnosis of alcohol dependence (alcoholism) should not lead to speculation regarding exceptional tolerance unless supported by additional evidence. Finally, tolerance should be considered in pharmacokinetic estimates of alcohol use for example, as well as in describing or predicting behaviors following the consumption of alcohol. By using standardized definitions of what constitute use, abuse, dependence, and understanding the nature of tolerance, forensic examiners can communicate accurately and without bias information relevant to jurors and the court.

Introduction

Short tandem repeat (STR)-based DNA profiling methodology is effectively at the theoretical limit of detection (LOD) in that typable results can be generated from as little starting material as a single cell [1, 2]. However, one of the most challenging aspects of forensic DNA analysis is the interpretation of low-level testing results where it is difficult to reliably distinguish between noise and signal from template DNA that is associated with an evidence sample [3, 4]. This difficulty with minimal samples is often compounded by the consumptive nature of PCR-based DNA testing [5, 6] when material is unavailable for replicate testing. Forensic DNA testing laboratories typically endeavor to minimize the effect of baseline noise and stochastic artifacts by relying upon very conservative minimum peak height thresholds (commonly fixed in the range of 50–200 relative fluorescent units (RFUs)) that are established during the course of their validation processes [7–10]. However, the conservative nature of these commonly employed thresholds can also arbitrarily remove from consideration legitimate signal from trace and secondary contributors to an evidentiary sample – matters of critical importance in many criminal investigations.

Any measurement made with a light-detecting instrument, such as a genetic analyzer is subject to at least some level of background noise [11] – defined here as signal not associated with amplified DNA. Instrument-related factors that may contribute to background noise in DNA testing experiments are typically run-specific and include (but are not necessarily limited to) the age and condition of the polymer and capillary being used, dirty capillary windows, and dirty pump blocks [12]. Background noise may also differ between instruments due to differences in charged couple device (CCD) detectors, laser effectiveness and alignment, and cleanliness and alignment of the optical components [10]. Many amplification-related factors that contribute to background noise (such as analyst skill and stocks of chemicals) are also run-specific and might be reasonably expected to have varying impacts over time.

Limits of Detection and Quantitation

Many analytical disciplines aside from forensic DNA profiling have needed to rigorously account for background noise mixed with low levels of signal [13, 14]. It is common for background noise, such as that associated with DNA testing results, not to be constant and for noise levels to be distributed in a Gaussian fashion that can be effectively characterized with a mean and a standard deviation [11, 13–15]. In such circumstances, the LOD is expressed as a statistical confidence limit of noise error, usually 99.7% (i.e., three standard deviations) or

$$\mathrm{LOD} = \mu_b + 3\sigma_b \tag{1}$$

where μ_b is the average amount of background noise and σ_b is the standard deviation associated with that value [11, 13–15]. A limit of quantitation (LOQ) represents the threshold beneath which measurements of signal strength cannot be reliably used to determine the relative quantity of detected analyte (e.g., because such measurements may include an appreciable amount of signal arising from background noise). LOQ is commonly expressed as the average background signal plus 10 standard deviations [11, 13–15] or

$$\mathrm{LOQ} = \mu_b + 10\sigma_b \tag{2}$$

Forensic DNA testing laboratories routinely test a positive control, negative control, and reagent blank with every DNA analysis run [7–9]. While these controls are utilized primarily as sentinels for gross failures of the DNA testing processes, such as cross contamination of samples, as well as contamination or inappropriate activity of reagents, they also contain an abundance of subtle but important information about

the running environment of the DNA testing system – particularly as it pertains to background noise. These ubiquitous controls can be used to establish objective run-specific electropherogram peak height thresholds that need to be exceeded to minimize the possibility that noise will be considered signal arising from a sample being tested [16].

LOD thresholds have been found to be consistently much lower (often by an order of magnitude) than what testing laboratories had previously established as minimum peak height thresholds [16]. Disregarding information associated with electropherogram peaks well above an analytical threshold of detection (and even above an analytical threshold of quantitation) might be considered abundantly conservative in some circumstances, given that DNA testing is a very sensitive process subject to a variety of technical artifacts such as pull-up, voltage spikes, and stutter. However, in this abundance of caution, valid information about the presence of real DNA peaks is being discarded or ignored – especially concerning given that means of reducing or at least identifying most technical artifacts are known or could be developed.

Technical Artifacts – Stutter

Among the most commonly observed technical artifacts in PCR-based DNA profiling are signals associated with DNA polymerase "stutter" [17]. Stutter artifacts can be particularly problematic in mixed DNA samples where small peaks situated in stutter positions may be interpreted as either being due to stutter or to amplification product corresponding to an allele from a secondary contributor. Stutter products are amplification products that differ in size from a primary peak (corresponding to the actual genomic template) by integral numbers of the underlying core repeat sequence. They result from slippage of *Taq* DNA polymerase on template molecules during amplification: either forward (resulting in $n-4$ stutter or in $n-8$ stutter if two core units are skipped) or backward (resulting in $n+4$ stutter) [18]. Numerous organizations including the Scientific Working Group on DNA Analysis Methods (SWGDAM) [9] and the DNA Advisory Board (DAB) [7] have recommended that forensic DNA testing laboratories conduct validation studies to develop cutoffs or thresholds that allow stutter artifacts to be reliably distinguished from faithfully amplified genomic DNA. The result has been the publication of numerous validation studies that address the prevalence of $n-4$ stutter (i.e., [17]) with relatively consistent observation of stutter artifacts that correspond to 10% or less of the signal strength associated with faithfully amplified templates from the 13 tetranucleotide repeat Combinded DNA Index System (CODIS) loci. Fewer studies on the prevalence of $n+4$ stutter have been conducted but a cutoff of 6% is generally considered to be sufficient to remove more than 95% of $n+4$ stutter peaks.

Technical Artifacts – Pull-up

Amplification products generated during this process are typically labeled with one of three or four different fluorescent dyes to facilitate the examination of several loci simultaneously. Signal associated with one dye color can sometimes give rise to the mistaken perception of signal in a different color in a phenomenon commonly known as *pull-up* or *bleed-through*. Remedies such as shorter injection times or reamplification with smaller amounts of template can usually be invoked to prevent signal strengths from exceeding the 4000 rfu saturation-level threshold. However, situations where these alternatives are not viable (e.g., in mixed samples where the genotype of an unknown secondary contributor is of interest) are commonly encountered in the course of forensic analyses. It is also possible that pull-up artifacts can be associated with primary peaks below saturation thresholds. As a result, significant portions of electropherograms can correspond to regions where legitimate amplification products cannot be reliably distinguished from pull-up artifacts.

Technical Artifacts – Spikes and Blobs

"Spikes" are narrow peaks usually attributed to fluctuation in voltage or the presence of minute air bubbles in the capillary. Spikes are usually seen in the same position in all or most of the dye colors used to generate DNA profile electropherograms. "Blobs" are false peaks thought to arise when some colored dye becomes detached from the DNA and gets picked up by the detector. Blobs are usually wider than real peaks and are typically only seen in one color. Spikes and blobs are not reproducible, which means that if

the sample is run through the genetic analyzer again these artifacts should not reappear in the same place. Hence, the generally accepted way to confirm that a potential spike or blob is an artifact is to rerun the sample. However, analysts often simply rely on their "professional experience" to decide which results are spurious and which are real. This practice can be problematic because no generally accepted objective criteria have yet been established to discriminate between artifacts and real peaks (other than retesting).

Alterations: Erasures and Obliterations of Documents

Introduction

Forensic document examiners (FDEs) are routinely tasked with the examination of a document to determine if there has been an alteration to an entry or erasures, or to decipher an entry that has been obliterated by overwriting. The documents may be as varied

as a check that has been altered for a different payee and amount, a business contract in which some terms have been changed, or medical records in which the amount of a dosage was changed. The FDE uses techniques that are generally nondestructive, although as a last resort (and with the approval of all parties involved), destructive techniques may be used. Evidence of alteration, obliteration, or erasure is not necessarily pejorative. Changes to documents are often made in the normal course of business and any such evidence found has to be interpreted in the context of the case.

If the FDE finds that a document has been subject to alteration, erasure, or obliteration, his next task is usually to restore and decipher what the original entry was. This is accomplished by visual and instrumental means, though in several cases, no success is gained. ASTM International Standard Guide for the Examination of Altered Documents E2331-04 describes procedures that should be followed by FDEs in examinations involving altered documents. The guide includes some very useful definitions [1].

Equipment

The FDE uses a variety of instruments and lighting sources in the detection of alterations, obliterations, and erasures. Natural light together with low magnification (X5–X40) is used to examine the obverse and reverse sides of the document. The document is examined with backlighting and with oblique (or side) lighting.

The human eye can normally see light wavelengths in the range of 400–700 nm. This is called the *visible light range*. However, alternative wavelengths that are produced using filters and light sources are quite useful in detecting, deciphering, and restoring questioned entries. These wavelengths are in the ultraviolet (UV) range (200–400 nm) and the infrared (IR) range (700–1000 nm). UV and IR wavelengths are used in combination with a variety of filters to examine how papers and inks fluoresce or luminesce.

Specialized instruments have been developed for FDEs and other people who need to look at documents for alterations or security features. Foster & Freeman Ltd. (UK) is a company with offices in the United Kingdom and United States whose video spectral comparator (VSC) range of instruments is used in institutions such as banks to full-service Crime Laboratories. Projectina AG is a Swiss company with a similar line of instruments generally known as the *DocuCenter* or *Docubox*. These instruments allow the examiner to examine documents quickly with a wide range of wavelengths. It allows for easy documentation of evidentiary information resulting from the examinations. Some enterprising FDEs also build their own instruments and get good results [2].

Fuji introduced a UV/IR camera that allows an examiner to take direct digital photographs of effects seen in the UV and IR wavelengths [3]. Dichroic filters are often used to compare inks. The results complement those obtained with the other instruments [4].

Imaging software such as Adobe Photoshop is used to enhance faded entries and also differentiate between inks [5]. The LAB-Color Mode in Photoshop has shown some promise as an analytical tool for ink comparison [6].

Electrostatic detection devices (EDDs) are used to detect indented impressions in paper. There are several suppliers of such instruments such as the electrostatic detection apparatus (ESDA) manufactured by Foster & Freeman Ltd. and the indentation materializer (IMED) made by Kinderprint. These instruments work on the principle of electrostatics. When entries are handwritten on the top page of a writing pad, impressions of the handwriting are made on the pages below. Indentations have been reported to have been developed as far as eight pages down. Sequencing on impressions and ink strokes may disclose evidence that entries were not written in the time frame as they appear.

Research is being conducted using EDDs to detect impressions made by rollers within printers. This may be used to show that a page from a multipage contract was produced by a different printer than that used for the rest of the document [7].

Alterations

Alterations can be classified into two types: additive and subtractive (some authors sometimes present a third type: substitution, which in essence is a subtraction followed by an addition). Additive alterations are made by adding content to a document. The content may be as little as a single pen stroke to change a 1 to a 7, for example, or entire paragraphs or pages of writing or printing that changes the context or meaning of a document. In the case of checks in

which a check writing machine imprinted the amount, the alteration is conducted by simulating the impression of the check writer. This alteration can only "raise" the amount of a check, since the original entry involves perforation of the check stock.

Alterations can be quite subtle and a document such as a medical record can be altered by simply changing a decimal point to indicate a different dosage. This alteration would take place on one page amongst possibly hundreds. The FDE has to employ techniques that include overall visual examination, microscopic examination, alternative light sources with various filters, and careful measurement using specially designed rulers or grids.

Visual examination on the obverse side of a document may disclose entries that are out of alignment. In handwritten documents, this may be reflected in entries that are cramped into a small space and not in keeping with the remaining handwritten entries on the document. In some instances, an alteration can be shown when line crossings are out of the expected sequence. In handwritten documents, the reverse side of the document is examined with oblique lighting to determine if there is any difference in the degree of embossing made by the pen pressure from the obverse side. Differences may indicate that the document was prepared on different writing surfaces and therefore, possibly, at different times.

In typewritten documents, alterations may be detected if different fonts were used. If the alteration was made by addition of text after it was originally typewritten (even using the same typewriter and typing element), the use of special grids can show that the contested text was added later. The increased use of laser and ink-jet printers has made the detection of such additions more difficult. Whereas, in a typewriting case the tolerances would have been one-tenth or one-twelfth of an inch, for a laser printer it is about 1/7200 of an inch. A type of ruler called an *E-ruler*, which is used in the graphics industry, is the measurement tool for the font size and interlineal spacing. The line spacing and paragraph spacing together with the use of capitalized and bold fonts can make a difference in the measurements and conclusion as to whether an alteration by insertion has been made [8].

Occasionally a crude insertion is seen when different printers are used. Under magnification, it can quickly be determined when this is done.

Toner is a resinous material that sits on the paper and has a slight embossed feel. Ink-jet (for the most part) uses liquid ink that soaks into the paper. There are some ink-jet printers that use solid inks. These were introduced in 1991 by Tektronix.

On occasion, a page is substituted into a multipage document such as a will, contract, or medical record, for example. It may be an additional page, or more likely, a page that contains different information than the substituted page. An EDD is essential to these types of cases. Impressions from the pages above the questioned page may not be found on the questioned page as could be expected. Impressions from the questioned page may be found in areas where they should not be. If an impression of a signature and date on a page is found on a page with a later date, this is indicative that the questioned page had been backdated and possibly substituted. If the first page of a document is signed and impressions are found on pages three and four, but not page two, this will raise questions as to the sequence of events in which the document was prepared and signed.

Documents produced by two different printers may exhibit differences in the printing media (see Figure 1). Some toners have magnetic properties and some are nonmagnetic. These properties are determined with the aid of a magnetic viewer [9]. Different ink-jet inks may exhibit dissimilarities under IR wavelengths. Dissimilarities in drop size and

Figure 1 Two entries on the same contract. The majority of the contract was printed with toner (laser printer) (a). One line was added with an ink-jet printer (b) [Reproduced with permission from Rile & Hicks.]

distribution of the ink-jet droplets may also indicate different manufacturers [10].

Documents produced with different photocopiers can sometimes be distinguished by different "trash marks" left on the copies. These marks arise from blemishes on the copying platen, from rollers within the machine, from the drum and charging devices or cleaners [11]. Copies made from the platen and from the automatic document feeder on the same machine may also display different trash marks since the copying mechanism is different for both processes [12]. Different color copiers and certain high-end color laser printers also produce characteristics that allow copies or prints to be identified to a particular machine [13–15]. Thus page substitution can be proved if a different machine is used.

In multipage documents, marks left by items such as staples and paper clips can be of significant evidentiary value to proving page substitution. The number of staples and staple-holes through each page should be the same. Holes that are unaccounted for or not present when they should be, place doubt on the integrity of the page and the document as a whole. Similarly, paper clips or other binding devices and their impressions are useful in exploring the history of how a document was produced.

Additions can be produced by a single ink stroke. A difference in the width of the pen lines could indicate that a different writing instrument was used for the addition. IR reflectance and IR luminescence are very powerful tools in detecting different inks (see Figure 2).

It is important to note that the IR techniques cannot conclude that inks are the same. The technique can only differentiate different inks. Some different inks from different pens will have similar formulations and will give similar results under IR. Further information can be found in **Ink Analysis**.

Raman spectroscopy, thin-layer chromatography, gas chromatography, and liquid chromatography are other techniques that can be used for further ink differentiation. However, the majority of these techniques will involve some destructive testing and are best performed by specialized ink chemists (*see* **Ink Analysis**). The latter specialists can apply ink dating techniques, which may prove that a questioned entry was written at a later date or is contemporaneous with the nonquestioned entries [16, 17]. Security documents normally have specialized antialteration features some of which are incorporated during the manufacture of the paper stock and others during printing [18].

In questions of alteration, the FDE has to be very careful when presented with a photocopy for examination. It is fairly easy to use readily available imaging software to conduct "cut and paste" alterations. The original document is scanned and the image is then manipulated by electronically cutting or adding various portions of text or images [19, 20]. The changed document is then printed and offered as a genuine document. Signatures are probably the most popular choice for an alteration by addition to make a document appear to be genuine. If the original signature is found, it can be proved that it was used as the model for the "cut and pasted' document.

Erasures

There are two types of erasures: mechanical and chemical. A mechanical erasure is one in which the entry is rubbed off using an abrasive substance. Erasure of penciled entries is perhaps the most common form of mechanical erasure. Ordinary black pencil has a marking core containing principally a mixture of graphite and clay. In writing, flakes of graphite form the black stroke. They rub off the point and adhere to the paper surface wedged between the paper fibers. The graphite cannot and does not penetrate the paper fiber as does ink [21]. The hardness of a pencil is a contributory factor in the ease of erasing its line. A soft black pencil leaves an intense black line with little pressure while a hard pencil leaves a lighter trace.

Examination of pencil erasures is time consuming and can involve use of oblique lighting and EDDs. IR reflectance is useful since graphite is opaque to IR and so the pencil traces appear darker. This makes the faint entry easier to read. It is often necessary to photograph the erased area with lighting from each side at a time. These photographs can then be electronically "stitched" to make a composite picture, which shows the entire erased area lighted from all sides. It is a useful technique both for decipherment and court display [22].

Mechanical erasure involves an abrasive rubbing over the paper surface. This results in the paper fibers being disturbed. This is easily seen with oblique light. The use of lycopode spores has also been shown to detect erasures [23]. However, this together with other powder and chemical means should be used as a last resort [21]. Excessive rubbing may wear away the fibers such that the paper in the area of the erasure becomes almost translucent. Backlighting quickly reveals this effect. UV light is also used to detect these erasures as there will be a difference in the reflection between the erased portion and the smooth paper. It should be noted that different erasers also have different effects on the paper. A soft art gum eraser will leave much less trace of an erasure than a typical rubber eraser.

Chemical erasures are normally used to remove ink lines or commercial printing. Typical solvents include bleach, acetone, brake fluid, and other cocktails of chemicals. Quite often, the use of the solvent is detectable by sniffing the document. Some documents have printing that is affected by the use of solvents and this effect will generally be seen very easily. UV light is probably the best means of detecting the stain left by a chemical used for an erasure. In some check-washing cases, there is no patent evidence that the check has been washed [24]. Comparison with other checks from the same check book may show some faintness of color in the washed check. Some security documents have printing that reacts to bleaching agents. This will make the erasure attempt patent. Examination with IR wavelengths may show some traces of the eradicated entries.

In many erasures, it is virtually impossible to decipher the original entries. It is sometimes possible to recover some of the entries by examining the embossing on the back of the document caused by the tip of the pen. It is important to note that when photocopies are examined, evidence of an erasure on the original may not have been reproduced on the copy.

Obliterations

An obliterated entry is obvious to the reader of a document. It may be done in desperation or at leisure at the time of writing. The former is more likely to result in a decipherment of the original entry since a different pen may be used.

Examinations with infrared reflectance (IRR) and infrared luminescence (IRL) are often successful in filtering the obliterating ink to reveal the original (see Figure 3). If the same or similar inks are used, then these techniques may not work. In this case, the FDE can examine the obliterated entry with high magnification and using an enlarged copy, go over the lines that comprise the obliteration. Whatever remains may constitute part or all of the

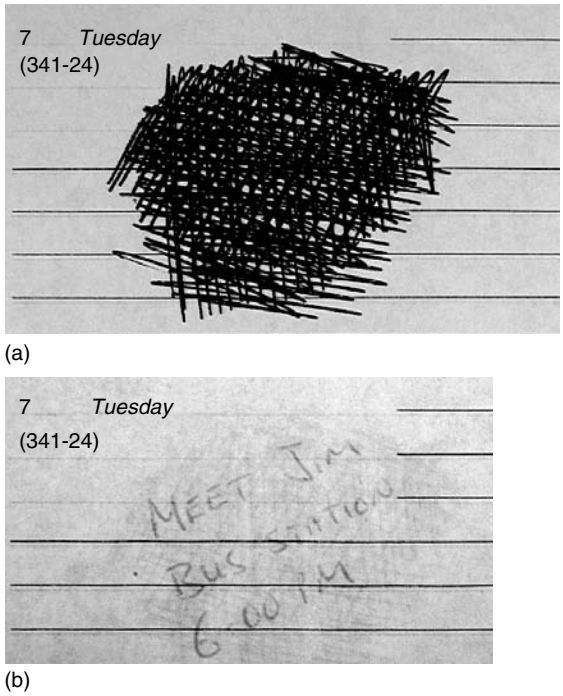

Figure 3 Decipherment of an obliterated entry. (a) Obliterated entry in a diary and (b) original entry deciphered using IRR [Reproduced with permission from Foster & Freeman.]

original entry. This requires some interpretation on the part of the examiner and the result may not be definitive.

A common form of obliteration is conducted with the use of the ubiquitous correction fluid. Sometimes, the obliteration is a cursory pass of the brush with the fluid. In other instances, the entry gets a severe pasting, which results in a thick coat of correction fluid. Examination with backlighting in the first instance is usually sufficient to reveal the obliterated entry. IR radiation and filters can be used to induce luminescence in the ink entry. This luminescence can be observed through the correction fluid. In circumstances where the correction fluid is exceptionally thick, substances such as petroleum ether or a xylene substitute can be used to remove some of the correction fluid [25]. A combination of techniques is generally required to reveal all or a portion of the obliterated entry.

In an examination of a photocopy, the FDE has to look for any evidence of obliterations. If a person carefully uses correction fluid, it may be impossible to tell on a photocopy. Some telltale signs are missing parts of lines or characters in the area of the obliteration. However, the FDE should not confuse normal dropouts caused by the photocopying process as evidence of obliteration.

Amphetamine

Introduction

The amphetamines represent a family of drugs that stimulate the central nervous system (CNS) and other parts of the body to produce euphoria and increased vigor and alertness. They are related chemically to the naturally occurring substance, ephedrine, which is found in *Ephedra* species. Related stimulants are also found in khat (*Catha edulis* grown in the horn of Africa and the Middle East, containing cathinone and other alkaloids), and mescaline. Mescaline is the active alkaloid in the peyote cactus (*Lophophora williamsii*) from Northern Mexico and Southern USA and other cactus species growing in subtropical and temperate areas of South America.

Pharmacologically, the amphetamines are all related to the hormone adrenaline (epinephrine) and the neurotransmitter noradrenaline (norepinephrine). Figure 1 illustrates the similarities of the naturally occurring stimulants ephedrine, cathinone, and mescaline as well as the hormones adrenaline and noradrenaline with amphetamine.

Some amphetamines are available legally, i.e., amphetamine for use in narcolepsy and attention deficit hyperactivity syndrome (ADHD); however, the majority of these drugs that are used in the community are from illegal sources. The amphetamines are produced in clandestine laboratories either from simple chemical precursors or from legally available drugs such as ephedrine and pseudoephedrine. The synthesis of designer drugs containing methylendioxy moiety is usually done using safrole (extracted from sassafras oils) as precursor.

Types of Amphetamines

Amphetamine, or sometimes known as *dex-amphetamine,* is the prototype drug in this class of drugs. Modifications on the benzene ring and nitrogen

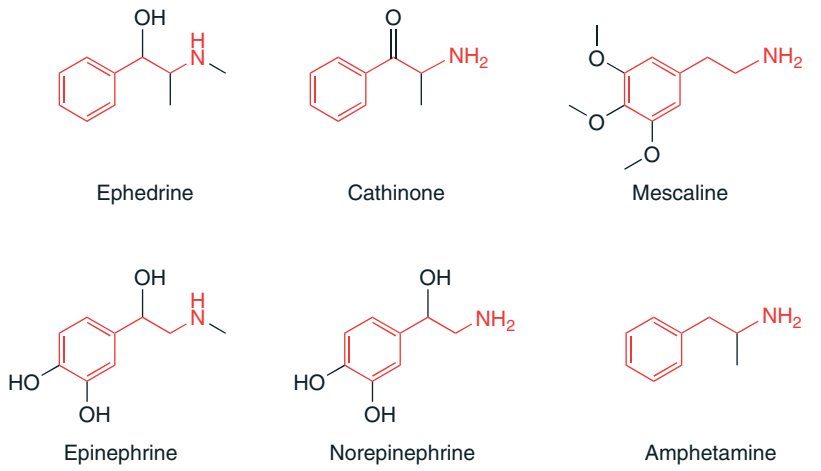

Figure 1 Chemical structures of selected stimulants and hormones

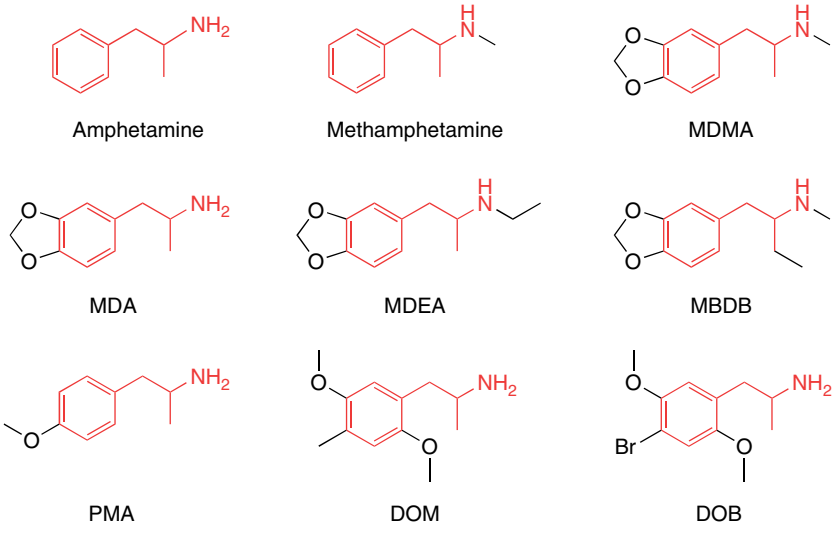

Figure 2 Chemical structures of selected stimulants. DOM, 4-methyl-2,5-dimethoxyamphetamine; DOB, 4-bromo-2,5-dimethoxy amphetamine; MDA, 3,4-methylenedioxyamphetamine; MDMA, 3,4-methylenedioxymethamphetamine; MDE, 3,4-methylenedioxyethylamphetamine; MBDB, N-methyl-benzodioxazoylbutanamine; PMA, 4-methoxyamphetamine

end have led to numerous "designer" stimulant drugs. The most common is methamphetamine (methylamphetamine or "speed"), which is the N-methylated form of amphetamine. Ring substitution with methylendioxy moiety leads to analogs including 3,4-methylenedioxy-methamphetamine (MDMA or ecstasy), 3,4-methylenedioxyamphetamine (MDA), 3,4-methylenedioxyamphetamine (MDE, or "eve"), or *N*-methyl-benzodioxazoylbutanamine (MBDB). Ring substitution with lipophilic groups (like methoxy groups) leads to analogs including 4-methoxyamphetamine (PMA), 4-methyl-2,5-dimethoxyamphetamine (DOM), or 4-bromo-2,5-dimethoxyamphetamine (DOB). Figure 2 illustrates the similarity in the chemical structures of few selected stimulants related to amphetamine.

Drugs with the dextro configuration (D) are more active than those with the levo (L) configuration.

For example, L-methamphetamine is less active than D-methamphetamine and is used as a decongestant in some countries (as L-desoxyephedrine), while the D-isomer is the abused form of the drug.

Abuse of Amphetamines

Amphetamines are arguably one of the most abused drugs. Amphetamine is the predominate member of this class abused in Western Europe while methamphetamine is the predominate member in Eastern Europe, Asia, Australia, and North America.

MDMA and related designer amphetamines are common in the night clubs worldwide due to their ability to promote empathy and a sense of well being. Ecstasy tablets are primarily composed of MDMA but can also contain other stimulants such as methamphetamine.

The United Nations Office on Drug Control (UNODC) estimates that approximately 34 million people consume amphetamines annually with 8 million consuming ecstasy [1]. The prevalence of use varies substantially from region to region and between types of amphetamines. However, the proportion of the population using the drug that is over 15 years of age generally ranges from about 1–4% with much higher numbers in younger males.

Amphetamines tablets come in several different forms, sizes, colors, and shapes [2]. Apart from the different appearances of the tablets, amphetamines can be used in different forms, as hydrochloride salt or as free base. The form used illustrates the common street names and the common way of intake of the drug. For example, methamphetamine used as hydrochloride salt is usually injected or taken orally and is known as *speed or ice*. When methamphetamine is used as a free base, it is often smoked and is known as *base or crystal meth*.

These products can be manufactured locally or imported through a criminal network. Low purity forms (powders and tablets) of methamphetamine are usually administered by snorting or injecting, and can be mixed with other drugs such as ketamine. A gluggy, pasty, or oily form is often brown or yellow due to the presence of iodine and other organic impurities, and crystal meth or ice is high purity, crystalline methamphetamine that comes in the form of large translucent/white crystals that are usually smoked or injected. Free base methamphetamine is required in higher doses compared to other forms and this in turn has a greater risk of harm and prospects of developing serious addiction [3].

Pharmacology and Disposition

Mechanism of Action and Effects

Amphetamines interact with noradrenaline- (norepinephrine-) and dopamine-containing nerves to either replace the monoamine neurotransmitter in the nerve ending and act as a false transmitter, or to facilitate the release of neurotransmitters from nerve endings. Mood and behavior can be affected by some amphetamines (e.g., MDMA) due to the release of serotonin at nerve endings in the brain. The sudden "rush" or "high" experienced with intravenous injections, or smoking, is caused by the sudden release of noradrenaline and related monoamines from nerve endings [4].

Amphetamines stimulate the heart and cause irregular rhythm. Increases in heart rate also occur. Amphetamines produce CNS effects such as movement disorders (locomotor activity) and can produce a stereotyped behavior. This behavior will manifest itself as repeated movement or agitation, unusual facial expressions or grimacing, pacing, grooming, etc. Overt aggression and a feeling of increased strength is also a frequent serious side effect of amphetamine use, particularly with repeated use.

Amphetamines can reduce fatigue but this is short-lived as tolerance sets in with repeated use leading to hypersomnolence. This is a serious risk factor in long-distance truck drivers using amphetamines to ward off the effects of long driving hours.

Chronic use of amphetamines can produce psychotic conditions, which is often associated with violent and irrational behavior.

Potency and Duration of Action

As one would expect, the various amphetamines have different potencies to cause an effect, and consequently each amphetamine is associated with a different range of common doses. These are tabulated in Table 1. Chronic abuse invariably involves higher doses than initiation doses in naïve users.

Depending on the dose and the type of amphetamine, the effects can last for at least one-half day and up to more than two days when higher

Table 1 Common doses for selected stimulants

Drug	Dose range (mg) [a]	Duration of action [b]	Common blood concentrations (mg l^{-1})[c]
Amphetamine	5–60	Half to one day	<0.2
Cathinone	50 or more	Several hours	<0.2
Ephedrine	to 240	Half day	up to 1
Methamphetamine	5 or more	Up to two days	<0.5
MDMA	50–150	Half to one day	<0.5
MDA	50–250	Half to one day	<0.5
MDE	50–250	Half to one day	<0.5
PMA	50–100	Half to one day	<0.5

MDA, 3,4-methylenedioxyamphetamine; MDMA, 3,4-methylenedioxymethamphetamine; MDE, 3,4-methylenedioxyethylamphetamine; PMA, 4-methoxyamphetamine

[a] Usual dose range

[b] Common duration of action (dependent on dose, pH of urine and a range of physiological factors)

[c] Common blood concentrations (after ingestion of usual dose)

doses are used or when excretion is reduced due to high acidity in the urine (Table 1). Acid urine can be caused by dietary influences or by the use of drugs that cause higher acidity.

The stimulant group of drugs, including legal stimulants and designer amphetamines, are generally well absorbed orally. This route tends to be the major route of administration. Peak concentrations of amphetamines are generally within 1 to 2 h postdose when taken orally.

Amphetamines are also injected intravenously, taken by nasal insufflation (snorting), or by smoking. Intravenous dosing provides the most efficient and quickest way of administering the drug. Amphetamines are smoked using a glass tube that is heated to volatilize the drug. Smoking or intravenous administration will produce much higher initial blood concentrations than oral administration.

Excretion

There are often substantial amounts of unchanged amphetamines excreted into urine. Hence urine is a useful screening specimen to determine the past use of these drugs.

Amphetamines are metabolized into substances that can be used to identify the type of amphetamine used, and if necessary targeted by analyses to increase the likelihood of detection. For example, amphetamine is hydroxylated on the α-carbon (carbon adjacent to ring) to norephedrine, which is in turn converted to benzoic acid.

Methamphetamine is metabolized to amphetamine (about 10%), which in turn is broken down further. MDMA is metabolized to another designer amphetamine, MDA, and to the dihydroxy metabolite (O-desmethylation). Consequently, for both methamphetamine and MDMA, the corresponding *N*-desmethyl metabolite is also targeted in the analyses. PMA is converted to the 4-hydroxy form and metabolized at the α-hydroxy to the corresponding norephedrine. Cathinone is metabolized by the oxidation of the keto group on the side chain to norephedrine and norpseudoephedrine.

The antiparkinson drug selegiline is metabolized to the weakly active L-isomer of methamphetamine [5]. The formation of amphetamines from legal substances applies to related drugs, e.g., fenethylline, clobenzorex, mefenorex, fenproporex, and benzphetamine. In these situations it will be necessary to use chiral assays to discriminate the isomers (dextro- or levo-) and/or other metabolites to determine if the source of the amphetamine is legal or illegal.

Toxicity

Life-threatening adverse reactions of amphetamines are well described. Initially, these can include agitation, fever, aggression, and violence, and can rapidly

lead to very high body temperatures, with elevated heart rate and blood pressure. Potentially fatal consequences of these effects can be rhabdomyolysis (liquefaction of muscles finally leading to disruptions in heart rhythm caused by hyperkalemia), intravascular coagulation, convulsions, profuse sweating, and hemorrhages in the heart and blood vessels.

Death resulting from excessive water consumption (caused by hyperthermia) following ingestion of ecstasy tablets at a nightclub presents another mode of death due to the use of amphetamines, particularly ecstasy-like amphetamines [6, 7]. PMA is a more toxic member, and while rarely seen has been linked to clusters of deaths [8, 9]. This may be caused by the phenotype of the enzyme CYP P450 2D6, which catalyzes the major metabolic step of PMA metabolism (*see* **Pharmacogenomics**). There is little correlation between concentration of amphetamines in blood and a likely toxic reaction [10]. Tolerance, route of administration, chronicity of use, and individual sensitivities regulate any unwanted responses to these dangerous drugs.

Prolonged use of amphetamines, particularly MDMA, cause long-lasting or even permanent nerve damage to dopamine- and serotonin-containing nerves in the brain leading to stereotyped behaviors and paranoid psychosis. Long-term use of amphetamines is also associated with damage of heart muscle that can manifest as cardiac arrhythmias leading to sudden death, although this may not be obvious in an external examination. Sudden death usually occurs only when preexisting heart disease is present or owing to brain hemorrhage that is induced by high blood pressure [11].

Interpretation of Results

As with other drugs of abuse seen in forensic cases, the interpretation of toxicology results of amphetamines requires a detailed understanding of the context in which the drug detection has occurred. This requires an understanding of the form of the drug used and its route of ingestion (e.g., intravenous or oral etc), whether the drug has been used in a continuing manner (e.g., acute or chronic use), and the circumstances of the case.

It would not be surprising to hear of a person suffering a "meltdown" at a night club (very high core body temperature) under the influence of MDMA or another designer amphetamine has been detected; however, such an adverse reaction does not occur in everyone using this drug even at blood concentrations reported of people exhibiting such toxicity.

Similarly, low concentrations of methamphetamine in long-distance truck drivers can lead to hypersomnolence and cause fatigue-based crashes after the strong stimulant effects of the drug have largely worn off, particularly in persons using the drug regularly. However, low concentrations may not have this effect in situations where single doses may have been used and no tolerance to the drug has developed.

Accordingly, drug concentration data in blood, and indeed other specimens, needs to be carefully evaluated based on the available circumstances, the known disposition of the drug, and of course on the actual detected amphetamine. It is equally true with amphetamine users as with other drug users that other drugs are often used concomitantly. These drugs may include other stimulants, cannabis, benzodiazepines, or even opiates. Multiple drug use can increase the risk of adverse reactions and toxicity. It is therefore essential that any drug screening encompasses a range of likely drugs (*see* **Postmortem Toxicology: Interpretation**).

Methods of Analysis

The class of drugs is readily detected by standard toxicology methods. Immunoassays are commonly used for initial testing since they require little or no sample preparation and are relatively cheap. Immunoassays are normally targeted to detect those members related to amphetamine (no substitution on the nitrogen including MDA) and those related to methamphetamine (N-substituted analogs including MDMA, MDE). These tests can be used on blood and urine and even oral fluid (saliva) [12, 13] (*see* **Toxicology: Initial Testing**; **Confirmation Testing: Toxicology**; **Oral Fluid Toxicology**).

In forensic matters confirmatory testing is usually conducted by gas chromatography followed by detection using mass spectrometry (GC–MS). Most of the amphetamines show poor mass spectral definition when underivatized, and hence it is common to chemically derivatize extracts with acetyl or perfluoracyl derivatives [14, 15]. More recently, liquid chromatography coupled to tandem mass spectrometry (LC–MS/MS) is being increasingly used as this

technique does not require chemical derivatization. Amphetamines are isolated from biological matrices either by liquid–liquid or by solid-phase extraction procedures [16, 17].

As mentioned above, some legal substances like selegiline or clobenzorex are metabolized to the weakly active L-isomer of methamphetamine. For differentiation of the intake of these substances from an illegal abuse of methamphetamine (D-isomer), chiral analysis is required. Methods for determination of isomer ratios have been described using GC–MS and LC–MS/MS. These techniques have been adapted for biological specimens such as blood, urine, saliva, and even hair [18–20] (*see* **Postmortem Toxicology: Laboratory Analysis**).

Amplified Fragment Length Polymorphism

Introduction

The tandemly repeated sequences of human genome, especially the hypervariable minisatellites, are suitable markers for forensic identification and population studies due to their highly polymorphic and multiallelic nature. Minisatellite loci are also known as *VNTRs*, a name that appropriately describes their structural conformation. When first used in forensic science, variation at VNTR loci was typically detected by restriction fragment length polymorphism (RFLP). Following the advent of the PCR, small VNTR loci analysed following PCR amplification were referred to as *amplified fragment length polymorphisms* (*ALFPs* or *AmpFLPs*). An example of an AmpFLP that was widely used in forensic science is HumD1S80 (pMCT118, GenBank accession number D28507). D1S80 is a VNTR locus located on chromosome 1p35–36 with a repeat unit of 16 bp [1, 2]. The number of repeats at D1S80 has been reported to vary from 13 to >50 [2]. The D1S80 minisatellite is a well-studied marker that has been used worldwide to differentiate genetic affinities among and between various populations [3, 4]. In forensic casework, AmpFLPs such as D1S80 have been successfully used to identify individuals [5, 6] and human remains [7] and also to investigate paternity [8]. Data on allele frequency distributions are necessary to support forensic analyses, so much of the population genetic data available emerged from forensic validation studies.

Analysis: Computer Network

Background

Criminals can use the Internet for a variety of purposes including distributed denial-of-service (DOS) attack, other attack or compromise of computer systems, identity theft, communication with accomplices, information gathering, illicit transfer of stolen intellectual property and/or contraband, and various forms of theft (services, goods, and funds). These activities can often be identified using network analysis. While media analysis is primarily concerned with the identification, retrieval, and recovery of data stored on a variety of media, network analysis is concerned with data transmitted from one computer to another (*see* **Computers**). The dominant networking protocol of the Internet is Internet Protocol (IP) and associated protocols are Transmission Control Protocol (TCP), and User Datagram Protocol (UDP). An excellent summary of these protocols is defined in Request For Comments (RFCs) 1180 [1]. TCP/IP works by encapsulating blocks of data into "packets". These packets have two parts: the "payload" or data portion; and the packet header, containing information needed by the TCP/IP itself, such as, source and destination IP addresses and port numbers. Owing to the nature of the TCP/IP protocol, there are several intermediaries (commonly known as *hops*) between the traffic source and its destination. This article identifies challenges to network analysis, common roles of compromised systems, and tools and techniques to conduct network analysis.

Challenges in Network Analysis

There are challenging aspects of network analysis, in addition to the challenges of media analysis. The principal challenges are as follows: data pertaining to an investigation is not located on one system but across multiple systems and attackers attempt to obfuscate the true source of network traffic. During preliminary stages of an investigation, the exact nature of the event may be unknown. In this case,

the investigator must consider any traffic that appears out of the ordinary.

Multiple Data Sources

Examiners usually cannot evaluate traffic in real time, but are limited to reviewing recorded traces of past activity. The examiner often must retrieve data from multiple sources, and attempt to reconstruct a plausible chain of events. The collection effort may include data from systems belonging to many different companies or organizations. In some instances, it may be necessary to obtain the cooperation of foreign governments if the network trail crosses national boundaries.

Lack of Collection Control. Network analysis is complicated by the fact that the examiner usually has little or no control over the way the data was initially collected. For example, different Internet service providers (ISPs) will have different equipment and logging mechanisms, and so the type and format of traffic logs will likely differ greatly. As a result, the examiner must deal with data in many formats including firewall logs; router logs; intrusion detection system (IDS) logs; network captures from network sniffers; binary, hexadecimal, or ASCII data formats; host-based logs (e.g., tcp wrappers, mail logs, telnet/ftp logs, system logs); and intruder network tools (e.g., attacker network captures, IP addresses of distributed DOS master servers). Logs created by similar products produced by different vendors are often dissimilar.

Incomplete Logs. Logging mechanisms are often configured poorly, disabled, or simply not capable of generating the detailed data desired. Some devices are capable of different levels of logging, and although capture of the desired information is possible, it may not be configured to do so. For example, many routers only log packets that are blocked. In the event of traffic of interest being passed, no record would exist in that router log. Owing to the large storage volume and performance impacts, many administrators enable detailed logging only when investigating a specific problem. In other cases, the device is not capable of logging the level of detail desired. A router's function is to forward the IP traffic, and its logs contain little or no insight about the protocols or data higher up in the network stack.

Falsified Logs. Any user with root (or administrative privileges) on a host has the potential to alter system logs. If an attacker has gained root privileges, logs may have been sanitized; that is, log entries may have been modified or deleted altogether. This is not an uncommon practice used to mask access to a compromised host. For example, the UNIX syslog program records user logins, including connections from other hosts. After gaining root privileges, an attacker could attempt to modify syslog (and possibly other logs) to remove relevant connections to the host. Similarly, an attacker who compromised a web server may attempt to erase records of network traffic from the server logs.

Source Address Obfuscation

Because of the way the TCP/IP protocol is implemented, we often cannot be certain that the source IP address of a monitored session is the true origin of the traffic in question. There are several techniques available to mask the true identity of the source host or make it difficult to actually locate the attacker.

Use of Open Access Points. With the proliferation of public Internet access points, many of them are used for nefarious purposes. These facilities can be public access points on a wired network as well as wireless access points (WAPs). While some control measures can be taken at these access points, many are left with minimal controls. Additionally, many WAP devices have minimal logging facilities and, in many cases, simple security measures (such as enabling encryption on the device) are not taken. Users can successfully connect from a distance, depending upon the location of the WAP device, the wireless card in the computer, external antenna usage, and intervening structural elements. Even WAP for home use are abused in this way, especially in areas where density is higher, like business districts, town houses, apartment buildings, and condominiums. Attackers can frequently change their IP addresses by utilizing multiple access points, making tracking the subject a difficult proposition.

IP Spoofing. IP spoofing is a technique in which an attacker sends traffic to a target while making it appear to have originated from a third party. This is common in DOS attacks, where there is no

need or desire to receive any response from the target. It is also used for network reconnaissance to mask the true source of probes. Determining the true origin of spoofed traffic requires tracing the path back through every intermediary router between destination and source, and may require the cooperation of multiple ISPs, telecom providers, and possibly foreign governments.

Proxy Servers and Anonymizer Services. Proxies are legitimately used by organizations to restrict access to needed Internet services while protecting the identity and security of internal hosts. The source address of traffic originating behind the proxy is replaced with that of the proxy. While a proxy server can provide the actual source address of the traffic, many are configured to hide this information. Identification of the true source host will require an examination of proxy server logs. Some proxies contain vulnerabilities or are poorly configured, resulting in use or control by unauthorized parties. Some proxies are actually networks, such as The Onion Routing (TOR) proxy, and have multiple entry and exit points, making tracing connections nearly impossible [2]. An anonymizer is a generic term used to describe some service that shields information about a user or a system. Anonymizer services act as proxies for common Internet services but provide additional functions, such as blocking of Hypertext Transfer Protocol (HTTP) cookie requests, providing false login credentials (pseudonyms), e-mail forwarding, and data encryption. Attackers can use such services to hinder identification.

Compromised Host Network. Attackers also mask their true origin by using a network of compromised hosts. In this method, the attacker never connects directly to his victim, but rather he uses one or more previously compromised hosts as intermediaries. In such cases, the source address of the attacking host is correct but the attacker is directing the attack from another host, and the intermediary host is simply used as a platform for the attack. To locate the true source of the attacker, the investigator must analyze the logs of one or more intermediary network systems, as the compromised system(s) logs may be altered or deleted. Attackers often share information on compromised hosts, so an attacker found to be currently using any given host may not be the one that originally gained access. A single compromised host may be used by multiple attackers at any given time. The discovery of many such hosts could cause the scope of an investigation to expand very rapidly.

Summary of Challenges

Certainly, the challenges listed are not all inclusive, but rather are designed to prompt the examiner to consider the types of problems that are encountered. Although there are many challenges, the situation is not hopeless. While the data provided by a single set of logs might be inadequate, data provided by multiple correlated logs may reveal the required information. For example, an attack on a web server leaves log traces on the web server, corporate firewall, and one or more intermediate routers. When malicious activity is ongoing, configuration changes to deployed systems will allow collection of additional information. Deployment of additional equipment or software tools on an appropriate network can collect relevant data. In most operating systems (OS) there are several logs that may record evidence of malicious activity. In any given incident, none, some, or all of these logs may have been modified. Not all attempts to modify logs are successful, and most modifications are easily detected. Many systems send log data to separate computer systems, which would store significant evidence for an examiner. The skill level of attackers varies widely such that even if some logs have been tampered with, useful information might still be obtained from other log files. The manner and level to which a compromised host has been modified may, in fact, help the examiner gauge the expertise, tools, and methods used by the attacker. Other systems may collect data about the attack and/or follow-on traffic, which the attacker is unable to manipulate, or else may be unaware.

Compromised Systems in Network Investigations

There are a number of ways that compromised systems may be used by an attacker, and understanding these uses is essential in order to use appropriate tools and methods to perform network analysis. The following paragraphs, although not a comprehensive list, provide concepts of how systems are used.

Backdoor/Trojan

A Trojan is a malicious program disguised as a benign application. Trojans usually provide a means for an attacker to access and/or control the compromised system. They are often used to harvest personal information (keystrokes, passwords, e-mail addresses, credit card info, etc.). Some Trojans send collected personal data to network locations accessible to the attacker. In order to protect access to a system, attackers often attempt to replace system files to hide files and processes on a system, making it difficult to identify the attacker's activities. In order to function, the Trojan (or the applications it installs) will generate network traffic.

Proxy Server

Compromised systems are often used as a proxy server or anonymizer, as described in the prior section. This allows the attacker to use a compromised system, instead of a commercial proxy or anonymizer, which may have records that could be obtained by legal authority. When used in this way, attacks or connections to other systems will show network traffic back to the compromised system. Each level of proxy provides another layer of anonymity to an attacker. Collecting and analyzing network traffic at a proxy server can identify the actual network information of an attacker.

Internet Relay Chat (IRC) Server

Internet Relay Chat (IRC) servers are systems providing both group communications (many to many) and individual communications (one to one) in discussion groups known as *channels*. They also provide the means to conduct data transfers via private messages. IRC is fully described in RFC 1459 [3]. IRC servers are relatively easy to set up and provide a simple effective solution for communications, which can even employ encryption. They are used to host distributed zombie or BOT (short for robot) networks because of the relative anonymity available. IRC servers are typically installed on victim machines. Network traffic analysis can identify the operator (attacker) of an IRC channel from BOT traffic data as well as gauge the size of the BOT network by enumerating the victims within a channel. Attackers also install an automated BOT client on compromised systems. The BOT can automatically send data, receive commands, and execute preconfigured actions. Figure 1 depicts a typical BOT network. Compromised hosts (victims) often include

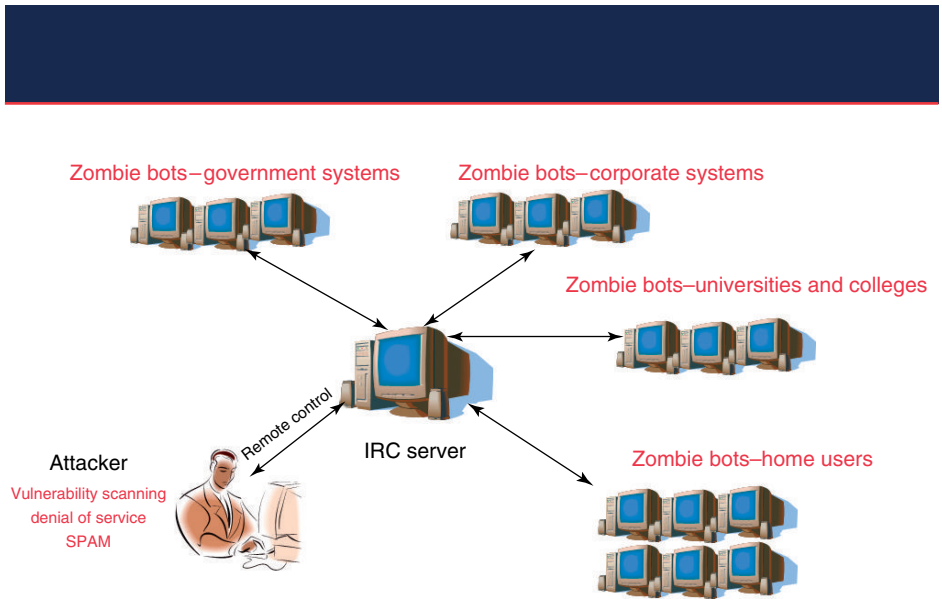

Figure 1 A typical IRC BOT Network

government, corporate, and university systems [4]. BOTs are used for activities that are easily automated such as vulnerability scanning, DOS, spam generation, etc. BOTs normally connect to an IRC server and report their status to an attacker "controlled" IRC channel. Automated processes controlled by an attacker can then connect to the IRC channel and direct the BOTs (individually or as a group) to perform specified actions, for example a distributed network DOS attack.

Web Server

Web servers use HTTP, which is one of the most prevalent application layer protocols on the Internet, used by millions of people daily while visiting various websites. HTTP can be used to provide static and dynamic content, or even to send and retrieve files like a File Transfer Protocol (FTP) server. HTTP is fully described in RFC 1945 [5]. Because HTTP is ubiquitous, it is normally allowed across different networks with little control or interference, and traffic volume may create problems when monitoring HTTP traffic. Attackers often host websites on compromised systems because of these attributes. However, since data would need to be retrieved from the sites, monitoring of traffic to a web server can disclose all systems connecting to it, and the types of connections can differentiate random visitors from an attacker.

Mail Server

Mail servers are used to distribute e-mail to users around the world. While there are several types of e-mail servers, most are compliant with Simple Mail Transfer Protocol (SMTP). SMTP is fully described in RFC 2821 [6]. Mail servers can be used to distribute mass mailing of advertising e-mails (often called *SPAM*) and malicious e-mails; however, most legitimate mail servers have some safeguards in place to preclude such abuse. An SMTP server that only sends e-mail requires little overhead and is often installed on victim systems. Analysis of the network traffic of such a server can identify control traffic to the SMTP server from the attacker.

FTP Server

FTP has been around since the early 1980s and is fully described in RFC 959 [7]. FTP was designed to enable systems to exchange files over TCP/IP networks. Today, attackers utilize compromised systems to operate FTP servers to host malicious code and large archives of illegally copyrighted software (commonly referred to as *warez*), music, and video content. Analysis of network traffic on an FTP server can identify control to the FTP server from the attacker.

Common Tools and Techniques

There are far too many tools and techniques that can be used to conduct network analysis to list them all in a brief article such as this. There are several detailed books and other resources that provide far more detailed information, which are listed in the last section of this article. Some of these provide case studies and sample data. A reduced set of tools and techniques is presented as an overview, and is by no means a complete enumeration of the types of techniques necessary for network analysis.

Tools

Examiners require tools that properly parse various file formats created by tools used in network analysis and investigation, store and retrieve data, and find correlations between the different data sources. Examiners also require knowledge and expertise in networks and networked systems. Examiners may need the ability to quickly modify existing tools (or create new tools) for analyzing unique file formats. Tools for performing network analysis and analysis of malicious binaries used in network attacks are subject to change over time. The following paragraph lists some functions/capabilities and tools that perform all or some of them that are used today.

Examiners can conduct static text analysis with the strings command (a utility built-in most Unix/Linux OS), the strings utility from Microsoft Sysinternals utilities [8], Hex Workshop [9], and WinHex [10]. For software disassembly and debugging, there are tools like IDA Pro [11] and OllyDbg [12]. For real-time OS monitoring, there are a number of UNIX utilities (free, top, sysstat, vmstat, lsof, etc.) and the Microsoft Sysinternals Utilities (such as regmon, filemon, procmon, and ProcessExplorer). For network monitoring, Snort [13] and Wireshark (formerly known as *Ethereal*) [14] are solid tools.

The use of virtual operating systems, using software such as VMWare [15] and Microsoft Virtual PC [16], is an excellent method for conducting multiple tests.

Network Traffic

Time is of the essence when obtaining network data and logs. Many ISPs maintain only logs necessary to support operational needs. For example, many ISPs utilize Dynamic Host Configuration Protocol (DHCP) to assign IP addresses to customer client systems, as there are often a limited number of IP addresses available. DHCP allows a provider to "reuse" an IP address for multiple systems. An explanation of DHCP can be found in RFC 2131 [17]. DHCP logs at a busy ISP may only be retained for days, or just hours, depending on the number of client connections and the ISPs IP address space. Router logs and other logs may simply be a rolling log that is limited by space, and thus may contain only the last several hours of connection data. Additionally, data stored on network servers by persons of interest can be moved, modified, or deleted should the attacker become aware of an investigation. It is essential to identify relevant networks and systems of interest, and initiate the process to have the ISP retain data until a formal legal order can be obtained from a court or other legal authority. In the United States, there are preservation requests that can be submitted to an ISP to retain such data for 90 days (which can be extended another 90 days) for investigative purposes [18].

In addition to logs, network traffic is often collected and stored in capture files. A common file format is the packet capture or "pcap" file format, used by many tools, such as TCPDump, based on libpcap [19]. Many other network capture formats exist and an examiner may need to be able to handle these other formats. Each captured packet includes a packet header followed by the raw captured bytes including the frame header, IP header, etc. The frame header type for the capture bytes is based on the "linktype" flag of the file header. This data in raw form is difficult to analyze as it is binary data and it is packet-based rather than session-based. Additionally, time is not stored the same way in all capture formats. In some formats, timestamps are assigned by the capture utility and is relative to the first packet. Time is often stored as a function of the operating system, and could be the number of seconds elapsed since midnight Coordinated Universal Time (UTC) of January 1, 1970, not counting leap seconds, or as the number of 100-ns intervals since January 1, 1601. However the raw network traffic does not have a time value other than dates/times that may be in the data portion of the packets. One can process the data with tools such as Snort to determine whether the capture reveals any known intrusion signatures. Sessions can be reassembled with other tools, such as Wireshark to extract session data such as an SMTP, FTP, or HTTP session. One must carefully document time/date offsets of systems from which data is collected, as well as time drift information (where available) in order to allow examiners to properly correlate data.

Examiners need to obtain information about the source of network events discovered by review of logs or network traffic data. An IP address can be resolved to a hostname using the "nslookup" or "host" command, and the hostname can also be resolved back to an IP address, using the same commands. Resolving a host in both directions provides a sanity check that may uncover domain name system (DNS) spoofing. An innovation which has recently become more widespread may complicate this procedure, known as *Dynamic DNS services*, which is described in RFC 2136 [20]. This allows systems without fixed IP addresses to utilize a fixed domain name. While not a new capability, it has become more widely available without cost and in an anonymous fashion. A "whois" query provides IP address block registration and domain name registration information. A "traceroute" provides information about the series of network connections between the source and destination system. Care must be taken, however, as traceroute and other active techniques are detectable by a knowledgeable target.

Peer-to-Peer (P2P) technologies are also utilized, not only to "chat" but also to share files. A simple P2P network directly connects one computer to another. In a more complex P2P network used for file sharing such as Kazaa, for example, users can search for files using a directory stored on a server. Most servers in this type of P2P network do not log the activity of users. The server identifies other computers where the file is available for download. The user's client can download files directly from another computer hosting the files desired. P2P networks are always changing as users connect and disconnect systems to the network. Analysis of logs maintained by the client software may provide information as to the location where files were downloaded. Additionally, network

traffic captures can readily identify connections made by the P2P client, although some clients can encrypt the data, the connection itself is visible.

Similar to P2P, a number of remote data storage techniques are available. These techniques use freely available services, such as GMail™ (Google's™ e-mail service) [21]. Using software clients, the user can specify a legitimate account at GMail, and utilize the e-mail account like a file system. This is not limited to GMail; however, it is a convenient example. One would have to conduct careful analysis of the HTTP traffic between the system and GMail and identify the nature of the traffic.

Binary Analysis

The root cause or catalyst for many network attacks today is malicious software or malware. Malware can exist in several forms – backdoor or key-logging Trojan; mass-mailing or self-propagating Worm, file-infecting, boot-sector, or macro virus; java applet or script; Active-X control; or other custom exploit. Peter Szor provided a comprehensive account of infection techniques, update procedures, and control capabilities for these and other classes of malware [22]. In many cases, network analysis directs an examiner to a suspicious executable or binary file on a system requiring evaluation to find leads to further an investigation. Binary analysis can be achieved using static and run-time analysis methodologies.

Static Analysis. Static analysis is the examination of a suspected binary without execution. It can extract human readable strings (i.e., e-mail addresses, IP addresses, registry keys, file names, usernames, hard-coded passwords, and application programming interface (API) calls) as an initial assessment to determine how a binary behaves when executed and clues to who created, authored, or controls the program. Figure 2 depicts an example of strings extracted from a sample binary file using a hex editor utility. Static analysis can also include disassembly and reverse engineering of malware. A disassembler is software used to recover object code from a binary executable. Object code is an intermediary format from source code, and is created by software compilers. Though

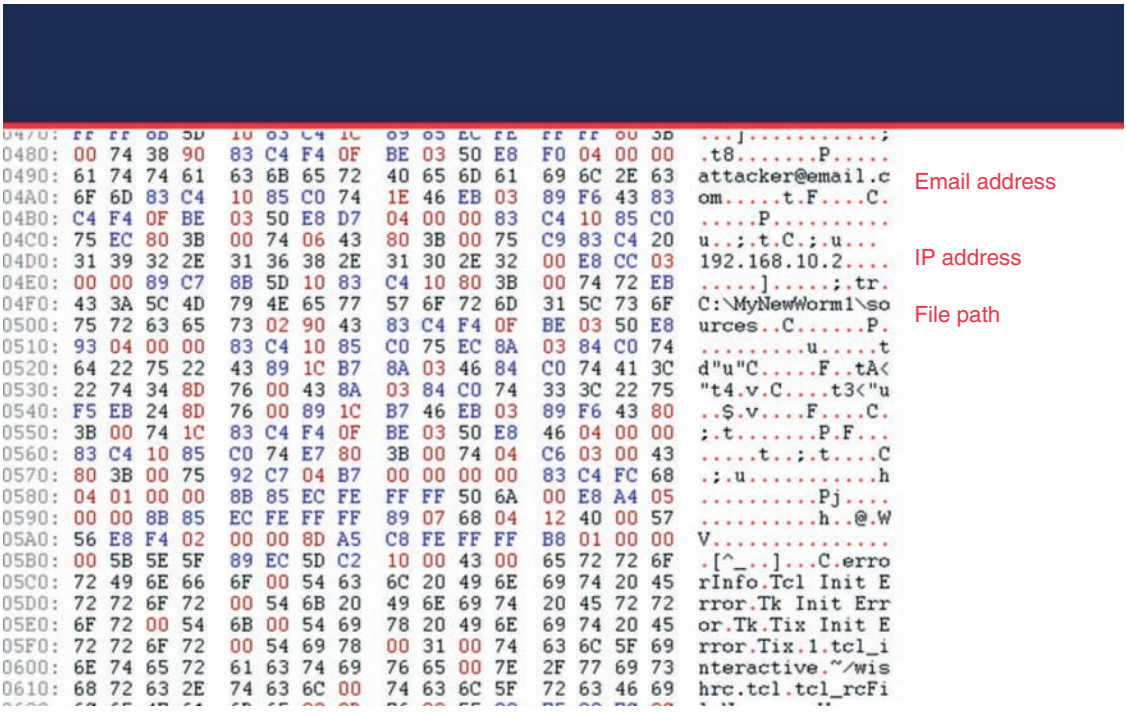

Figure 2 Example of strings extracted from malware

a very tedious process, disassembly is oftentimes a necessary process for forensic analysis of binary malicious code when source code is not available and the aforementioned strings analysis process proves not useful. Eilam details various reversing tools and disassembly techniques in his work [23].

Run-Time Analysis. Run-time analysis refers to the monitoring of the behavior of malware during execution. By behavior, we are referring to how the malware affects the OS and network during run-time. Malware will oftentimes delete and move existing files on a system, install or create new ones (i.e., Trojan key-logging files), or even make modifications to the system files like the Windows registry. Moreover, the tracking of newly opened network ports (i.e., Trojan backdoor) or data (i.e., passwords and credit card numbers) being surreptitiously exfiltrated from a system to an attacker across the network is critical when describing the behavior of malware. Microsoft Sysinternals hosts a suite of various tools for analyzing malware during run-time. In some cases, it may be necessary to analyze malware code and its memory contents while it is executing. Debuggers allow a malicious binary file to be monitored as each instruction is executed. An examiner may conduct "single-step" execution of malware one instruction at a time or set breakpoints at any time in order to view the values of code variables, registers, or memory locations. Debugging techniques enable the viewing of strings and data values that may have been otherwise encrypted, encoded, or obfuscated during static analysis.

Setting up an Analysis Environment. The presence of malicious binaries on a system is inherently unsafe. An examiner must give careful consideration to setting up a proper analysis environment for performing static and run-time analysis. The safest environment for such analysis is to establish an isolated or sandbox network. This enables malware to freely execute without fear of contaminating an actual network or sending traffic to the Internet. Virtual Machine software enables an emulated malware analysis environment to be created, saved, and refreshed in a quick and disposable fashion. An alternative solution involves creating and restoring malware analysis environments with incremental backup technology. This approach may be more viable if the malware is using antiemulation techniques, thus detecting if virtual machines, debuggers, or other techniques are being used.

Best Practices

Specified procedures, or protocols, for receipt, preparation, examination, analysis, and reporting of results should be in place. Adhering to a specified protocol/procedure will preclude mishandling, which could result in the scientific methodology being questioned in a legal proceeding. Additionally, data should be collected in a media-based methodology where possible, since media analysis may allow hidden, deleted, or altered data to be recovered during such analysis (*see* **Computers**). This recovered data may provide critical information to the examiner. In some cases, especially where critical servers are involved, it may not be possible to obtain complete disk images, and such cases should be documented carefully and thoroughly. Since network analysis normally requires examination of data from multiple sources, the examiner must use special consideration when performing correlation of data from these sources, as there could be time/date discrepancies, IP address changes due to network address translation or DHCP, etc. Additional important information required by the examiner would be network topology, system time deviation from a standard time for systems of interest, and actual configuration details of network devices such as firewalls, routers, and IDSs.

There are a number of excellent books and other publications that provide more detailed specific information on techniques for conducting e-mail, chat, file sharing, and other network based activities. A recent publication from the US National Institute of Standards and Technology (NIST) provides good overviews of these types of cases [24]. In addition to a solid explanation of typical investigative case scenarios (such as e-mail tracing, chat investigations, P2P networks, etc.), this document provides samples for a variety of legal requests under US Federal law. Other excellent resources (by no means a complete list) are Digital Evidence and Computer Crime [25], Handbook of Computer Crime Investigation [26], Windows Forensics and Incident Response [27], Computer Forensics: Incident Response Essentials [28], Incident Response: Computer Forensics (Second Edition) [29], Hacking Exposed: Computer Forensics [30], and WarDriving, Drive Detect and Defend: A Guide To Wireless Security [31].

Analysis: Neutron Activation

A Nondestructive Method

Neutron Activation Analysis (NAA), and variations such as Instrumental Nuclear Activation Analysis (INAA), Fast Neutron Activation Analysis (FNAA), and Epithermal Neutron Activation Analysis (ENAA) describe somewhat similar nondestructive methods for the analysis of concentrations of elements in small particles of trace evidence. NAA is a nuclear, as opposed to a chemical, spectrographic method of analysis. When the method first became popularized in the crime laboratory world of the United States in the 1960s. The high cost associated with conducting NAA examinations, as well as the discovery that the method performed poorly with some elements, caused it to fall somewhat from grace.

Also, as other less costly laboratory techniques suitable for the examination of minute specimens of trace evidence became available, NAA was effectively abandoned. When, early in the twenty-first century, the method began to be used in civil litigation through the services of some private and university-associated laboratories, NAA began to experience a modest revival.[a]

NAA is particularly an effective method for the analysis of bomb debris and explosives detection, gunshot residues and gunshot pellets, paint, and hair.

Basics of the Technique

NAA can determine the qualitative and quantitative elemental composition of a sample by bombarding the sample for a controlled period of time with an intense stream of nuclear particles, usually neutrons. Bombardment of a sample with neutrons will cause some of them to be absorbed by the nucleus of the bombarded atom. This bombardment ("neutron activation") causes an instability that produces radioactive species, or radionuclides, for about 70% of all elements.

The radioactive isotopes tend to return to a stable (nonradioactive) state over time. This process is called the *decay*, and the disintegration of the "unstable" atoms is accompanied by the emission of gamma rays – high-energy electromagnetic radiation. The gamma rays emitted by an activated sample are detected and measured by a gamma ray spectrometer, which indicates the energy and number of a given energy of each of the various rays being emitted. Thus, by comparing the data obtained with the data obtained from activating pure samples of the elements, the quantity of each element present in a specimen can be determined [1].

The energy of the gamma ray output is designated in million electron volts (Mev). The ability

of an atom's nucleus to capture bombarding neutrons also varies for each element. The probability that a stable nucleus will capture thermal neutrons is measured by its "cross section" and is expressed in "barns".

Some elements have low "barn" values, meaning that they capture thermal neutrons very reluctantly. An example of that is oxygen, whose "O" isotope has a cross section of only 0.0002 barn, which makes it virtually unusable for NAA. Cross sections of stable isotopes range from about 10^{-5} to 10^{5} barns. Higher barn values will be more sensitive in detecting elements. It is the combination of three values: half-life, decay energy (in Mev), and capture rate (in barns), which lies at the foundation of the NAA technique.

NAA, which was considered experimental for a long period, can today be considered a mature analytical technique that is being offered for forensic analyses in both criminal and civil cases by commercial as well as university-associated institutes.[b]

At the National Institute of Standards and Technology (NIST), INAA is used to detect and determine concentrations of up to 60 elements, derived from human as well as animal sources, along with specimens from botanical and geological sources.[c] In addition to forensic examinations of trace evidence samples that are of consequence to litigation, NAA/INAA are being applied to environmental studies to determine the source and nature of pollutants, the nature of biological tissues and fluids, the detection of impurities in pharmaceutical materials and food products, and for several analyses in nutritional epidemiological, industrial, as well as archeological studies.

End Notes

[a]The Federal Bureau of Investigation utilizes NAA for the examination of bomb and explosives debris, albeit sporadically.

Anthropology

Introduction

Forensic anthropology can be described as the analysis of human remains for the medicolegal purpose of establishing identity. It is a multi-disciplinary endeavor that applies the knowledge of biological anthropology and human osteology to cases where human remains are skeletonized, or where a detailed understanding of the growth and development, morphology, or reactive norms of the human body can assist other disciplines in positive identification. As such, it is perhaps best placed as a sub-discipline within the wider practice of forensic human identification, having applicability to both the living and the dead.

Anthropologists are routinely called upon to assist in the identification of individuals whose remains are severely decomposed, burned, disrupted, mutilated or otherwise rendered difficult to recognize. Their services have been of particular value in

three main areas: (i) investigations resulting from homicide, unexplained natural deaths, accidents, and mass fatalities; (ii) noncriminal events resulting in multiple deaths, e.g., arising from natural catastrophes; and (iii) war crimes investigations and genocide. However, the anthropologist may also be called upon to assist in the assessment of the living, providing confirmation of identifiers such as chronological age for the purposes of judicial accountability, immigration, or asylum status [1].

The context under which many anthropological cases are undertaken has changed during the last decade owing to a number of factors that have influenced not only on how anthropologists perform their job but also the type of jobs they are now requested to undertake. The twenty-first century has seen an increasing perception of risk involvement in mass fatality incidents including accidents, terrorist attacks, or natural disasters [2]. Terrorist activity resulting in mass fatalities, such as the September 11, 2001, bombing of the Twin Towers in New York, or the London bombings of July 7, 2005, has highlighted the requirement for national and international disaster victim identification (DVI) capability, and cemented the anthropologist's role as a significant component within the multi-disciplinary response facility. Thus, it may be argued that viewing the forensic anthropologist as someone who "deals with the analysis of human skeletal remains resulting from unexplained deaths" [3] is unrealistically restrictive given the multi-disciplinary nature of the demands of human identification in the twenty-first century.

Practitioners of forensic anthropology are specialists in human skeletal morphology, and are generally trained via human anatomy, physical or biological anthropology, or osteoarchaeology; professional accreditation is important in order to set professional entry standards, to monitor continuing professional development, and to oversee the maintenance of professional competence [4]. Practitioners may be registered with a suitable national organization, such as the American Association of Forensic Sciences (AAFS) in the US, or the Council for the Registration of Forensic Practitioners (CRFP) and the Forensic Science Society (FSS) in the UK.

Forensic Anthropology and Human Identification

The role of the forensic anthropologist focuses on applying detailed knowledge of the development, morphology, and variation of the human body as an aid to establishing, confirming, or indeed refuting personal identification. Four basic biological criteria form the basis of any primary identification: skeletal or developmental age, biological sex, living stature, and ancestry or racial affiliation [5]. These characteristics are supplemented by secondary traits, which include the following: body modifications [6]; evidence of surgical interventions [7], including scars and prosthetics; evidence of trauma; and chronic hard and soft tissue diseases that may leave characteristic macroscopic and microscopic lesions on surviving tissue [8]. Any of these additional factors can be of assistance when attempting to identify an individual and combinations of the above can be extremely useful when confirming identity. The anthropologist may also be called upon to advise on the manner of death, particularly in cases of skeletal trauma (blunt force, sharp force, or ballistic) or where physical processes such as burning, dismemberment, or explosive damage have disrupted the remains rendering quantification and identification problematical. They may also be called upon to corroborate estimations of the time elapsed since death (time-death interval) and assess taphonomic modification of human remains by taphonomic factors in the burial environment [9, 10].

The Stages of Forensic Human Identification

Is It Human? Differentiating Human from Nonhuman Bone

Frequently, bone is presented for identification from the sites of accidental discovery (i.e., stray surface finds, detritus from river, estuary or coastal contexts, or through excavation/construction work) or from the sites to which a presumption of violent or wrongful death may be attached through police intelligence. From a medicolegal standpoint, initially it is presumed that the remains are human and were deposited within a relevant timescale (i.e., 70 years before present in the UK or 50 years before present in the US). If they are determined to be human in origin,

and of recent deposition, then the forensic anthropologist applies the skills and techniques of skeletal analysis to establish or corroborate the presumptive identity of human remains. Thus, rapid determination of human or nonhuman origin is essential, both to determine whether a crime has been committed and to ensure that valuable police resources are not wasted investigating the disposal of nonhuman remains.

In practice, the anthropologist may not always be able to identify bone fragments to a particular species, but they should be able to determine whether they are human through macroscopic and/or microscopic evaluation depending on the elements of the skeleton presented for identification and the degree of fragmentation of the bones. Certain taxonomic groups may be difficult to differentiate because of similarities in overall structure, size, or bone quality; in general, the mammalian species with greatest likeness to those of humans can be found in larger mammals such as bears, deer, cows, pigs, and large dogs. Furthermore, skeletal remnants of smaller mammals and birds may be misidentified as fetal or juvenile human bones due to similarities in size and shape (Figure 1); perhaps more importantly, human fetal and juvenile bones may be misidentified as nonhuman due to the inexperience of the observer in working with such material.

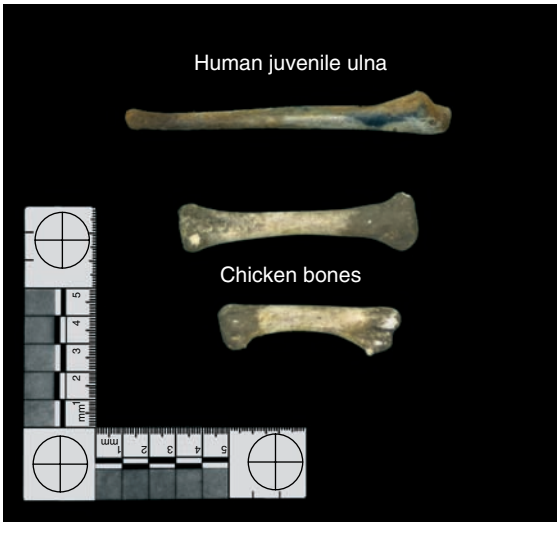

Figure 1 Comparison of human perinatal ulna with domestic chicken bones

Confusion primarily arises where only fragmentary bones exist, or the bones are charred, as morphological features are absent and cannot be used for identification. In cases where bone has been highly fragmented by trauma, postdepositional alteration, butchery/dismemberment, or burning, then identification through gross morphology alone may not always be possible. In such instances, the microscopic evaluation of bone histology [11], DNA analysis, [12], or immunological studies [13] may allow for taxonomic differentiation. Histological identification is predicated on the fact that different species both lay down bone and remodel it in different ways, the expression of which is dictated by functional demands (such as locomotion or body size) and the timing of major ontogenetic events set against lifespan. For instance, human bone displays tubular cellular structures that appear circular in cross section. These structures, known as *Haversian systems*, result from the remodeling of parallel layers that are deposited in a lamellar or concentric fashion to the cross-sectional axis of the bone; the extent of remodeling is proportional to the maturity of the bone.

Many animals, herbivores in particular, present a cellular structure made up of rectangular laminar plates, termed a *plexiform pattern*, which is only gradually replaced and overprinted by Haversian bone. Plexiform structures are a compromise between the requirements of structural rigidity (particularly, optimization for torsional forces) and the necessity for rapid bone formation and early maturation, resulting in large-diameter, thin-walled cross sections. The banding of osteonic units may also be used to differentiate human from nonhuman. While the presence of plexiform bone is a ready indication of nonhuman origin, it should be borne in mind that some animals present a combination of histological types (such as domestic and wild canids), which may make microscopic evaluation difficult. In such instances, the use of DNA analyses, immunoassay, or protein seriology may be more appropriate as a means of distinguishing between human and nonhuman bone. DNA (particularly, mitochondrial) can persist in bone for centuries, and recent studies have shown that highly repetitive DNA markers can be identified and used not only to determine human origin but also to identify individual species [12]. Similarly, specific coding regions (such as the mtDNA *cyt*-b gene) may be used to distinguish between taxa [14, 15].

Other discriminatory methods concentrate on the detection of species-specific proteins by utilizing the binding between an antibody and its antigen, a process known as *immunoassay*. Albumin is commonly used for detecting the origin of bone, as it is highly species specific, readily discriminates human from nonhuman bone, and can withstand high temperatures. Protein radioimmunoassays (pRIA) have also been used for discrimination, with some studies claiming 100% success rates in distinguishing human from nonhuman samples [13]. High levels of fragmentation, burning, and diagenic alteration by the burial environment adversely affect the discriminating abilities of these analytical methods [16].

Minimum Number of Individuals (MNI) Present

Accurate quantification of the number of individuals within an assemblage is the first stage of the individuation process. In cases of multiple burial of commingled remains, or fragmentation through explosive or thermal disruption, an accurate assessment of the minimum number of individuals (MNI) represented in an assemblage is paramount. However, quantification is compounded by the covarying factors of fragmentation and completeness. As a general rule, the more fragmented or disrupted the remains, the more difficult it will be to ensure full and accurate identification of the individual. Likewise, an individual represented by only a few bones of the skeleton will be more difficult to identify than one represented by a complete skeleton. As a consequence, there exists an inverse relationship between the degree of bone fragmentation and the number of individuals usually identified within an assemblage [17]; the competent anthropologist aims to reduce this identification bias through careful and detailed analysis of each and every fragment.

Quantification of MNI is based on a number of determinants, the most fundamental of which is nonduplication of skeletal parts. This requires accurate identification, seriation, and siding of all the bones or bone fragments present, with the proviso that there should be no duplication of skeletal elements if only a single individual is represented. For instance, the recovery of a frontal bone, right temporal bone, three to seven left ribs, a right femur, and two left humeral heads would indicate that at least two individuals are present due to the duplication of proximal humeri. It is, of course, entirely possible that 10 individuals are present as each recovered skeletal element could conceivably be derived from a different individual; determination of this would hinge on a variety of skeletal indicators coupled with an understanding of the context of skeletal recovery. Other skeletal markers that may assist in quantification include differing relative sizes of bones, differing stages of skeletal development, sex-discriminant markers, pathological conditions, or disjunction in color or state of preservation of the remains (the latter needs to be treated with some caution as bone color and preservation may differ within the same burial context). In general, such methods are prone to inaccuracy which has led to renewed interest in the methodology of quantification and sorting of commingled assemblages. New approaches that aim to be quantitative and more objective have been developed based on the recording of discrete anatomical zones [18], through the use of pair-wise maximum likelihood models, DNA analysis, or GIS-based (Geographical Information System) statistical models [19–21].

Sex Determination

Because most methods of age and stature determination are sex-dependant, determining the biological sex of an individual is the first component of individualized analysis. Like most primates, humans display a discrete pattern of morphological differentiation between males and females; this is termed *sexual dimorphism*. Some of these differences are associated with primary sexual characteristics of the reproductive system, which includes pelvic morphology, while others present a host of interrelated morphological, physiological, and behavioral features that become manifest with the onset of the hormonal surge at puberty. These are referred to as *secondary sexual features*.

In humans, secondary features manifest themselves in a variety of ways. Males, for example, tend to exhibit greater stature and body weight than females. They generally have more robust cranial and facial features, increased muscularity, greater strength, and speed. Females store more subcutaneous fat, while males have proportionately more muscle volume. Males have greater potential to develop muscle bulk and power output, while females have the potential to develop higher levels of stamina; this leads to definable differences in the form and

robusticity of their respective skeletons. Levels of sexual dimorphism can be affected by significant social phenomena including differential investment in parental effort, differential patterns of resource acquisition and utilization, and sexual division of labor [22–29]. For example, practices that are physically demanding may reduce sexual dimorphism if practiced equally between the sexes whereas they would tend to increase sexual dimorphism if practiced asymmetrically by one sex, with dimorphism arising as a consequence of divergence in muscular or skeletal robusticity. The level of sexual dimorphism exhibited by a population is thus a consequence of ecological, social, behavioral, dietary, and phylogenetic factors all finding varying degrees of expression. The result is that overall dimorphism represents a unique adaptation of the population to the environment, and is thus time, context, and population dependent [23, 26, 29–35].

As sexually dimorphic features are established during the adolescent growth spurt at puberty, juvenile remains must be assigned a sex with extreme caution; the remains of infants, children, and adolescents cannot be readily or accurately sexed on morphological grounds alone as primary and secondary sexual characters are yet to be established [36, 37]. While some success has been reported in the recognition of sex-discriminant characters in juvenile skeletons based on morphological assessment of the mandible and ilium [38–41] and the geometry of the developing cranium [42], these have yet to be shown to be sufficiently accurate for forensic purposes.

Sex assessment of adult skeletal remains is primarily based on a combination of size and shape differences between males and females (see Table 1). In general, these are most pronounced in the form of the bony pelvis, the cranial vault, and the mandible [5, 43], but are represented in most areas of the human skeleton to some degree [44]. Cranial characteristics (Figure 2a), such as larger brow ridges, increased sites of muscle attachment, pneumatized sinuses, rugose muscle entheses, and larger cheek bones and nasal apertures, are male characteristics linked to an extended period of facial growth, and the interaction between pituitary growth hormones and sex androgens. Shape-related, sexually dimorphic features of the pelvis (Figure 2b), such as the larger, more rectangular female pubic bone, the width of the greater sciatic notch, and the position and size of the acetabulum, result from differences between female and male hormone-induced growth patterns during adolescence. In general, the methods preferentially used in sex determination are morphologically (qualitatively) based and focus on the differentiation of cranial characters (the expression of the nuchal crest, mastoid process, glabella and supraorbital margin, and mental trigone) and pelvic morphology (greater sciatic notch, pubis morphology, and the sacroiliac articulation), although other characters such as variation in the ossification of the costal cartilages [45–47] have also been successful in sex discrimination (Figure 3). It is reported that accurate assignations of sex can exceed 95% from pelvis and skull, 90% from the pelvis and over 80% from the skull alone in the adult skeleton [48, 49]. However, these values should be considered optimal and context/population dependant.

However, quantitative methods have also been developed based on linear measurements of cranial and postcranial size variables. These have greater forensic preference as they are more readily scrutinized through statistical investigation, and as such, are not so heavily reliant on subjective evaluation (see [49]). Some of these utilize univariate discriminant functions to segregate male from female specimens around a predetermined sectioning point, while others employ multivariate discriminant functions including Mahalanobis distance and canonical variates analysis [49, 50, 52–65]. The linear measurements undertaken are primarily reflections of overall size and robusticity, and include measures of facial and cranial vault size (Table 2), humeral and femoral head size (Table 3), long bone lengths, and cross-sectional diameters of the appendicular elements. Computer-based multivariate programs have also been developed to facilitate the statistical discrimination of sex and ancestry measures in unknown-origin samples [66].

Age Determination

Determination of the chronological age of an individual is one of the more challenging areas of forensic anthropological enquiry, particularly once adulthood has been reached. In western society, it has become increasingly problematic to estimate the age of living individuals from visual examination let alone extrapolate this to the deceased. This difficulty can manifest itself in a number of ways with environmental stress,

Table 1 Morphological sex differences in the skull and bony pelvis[(a)]

Morphological trait	Male	Female
Skull		
Overall appearance	Large and rugged	Small and gracile
Supraorbital ridges	Prominent and rounded	Not prominent
Supraorbital margin	Rounded blunt margins	Thinner sharp margins
Orbital shape	Rectangular	Circular
Frontal profile	Sloping anteroposteriorly	Vertical
Frontal eminences	Bosses absent or not pronounced	Pronounced
Mastoid processes	Longer and more pneumatized	Short and small
Suprameatal crest	Extends as a bony crest past the auditory meatus	Root of zygoma does not continue past the auditory meatus
Parietal eminences	Bosses absent or not pronounced	Pronounced
Nuchal region	Muscle markings rugose and pronounced, nuchal crest with external hook may be present	Less rugose and pronounced. Protuberance not marked.
Palate	Larger, broader, tends to U shape	Small, tends to parabolic arc
Teeth	Large	Small
Mandibular symphysis	Pronounced trigonum mentale; projection of mental protuberance in midline with large mandibular tubercles	Small trigonum mentale; reduced projection of mental protuberance with small or absent mandibular tubercles
Mandibular profile	Squared and U-shaped	Narrow and more pointed
Mandibular ramus flexure	Present	Absent
Gonial flaring	Flaring present	Flaring absent
Gonial angle	More acute	More obtuse
Discriminant functions	DF > sectioning point (see Table 2)	DF < sectioning point (see Table 2)
Pelvis		
Pubic symphysis	Higher	Lower
Subpubic angle	Narrow V-shaped, acute angle	Wide U-shaped, obtuse angle
Subpubic concavity	Slight to no concavity	Concavity present
Ventral arc	Absent	Present as elevated ridge extending inferolaterally across ventral pubis
Medial ischiopubic ramus	Broad, flat and blunt. Slightly everted	Ridged, sharp edged, everted
Greater sciatic notch	Narrow and deep	Shallow and wide
Obturator foramen	Large and ovoid	Small and triangular
Acetabulum	Large, more laterally oriented	Small, more anteriorly oriented
Auricular surface	Depressed, wide	Raised, narrow
Preauricular sulcus	Not present or illusionary	Often present, well developed
Postauricular space	Narrow	Wide
Sacrum shape	Narrower, more curved, alae narrower than promontory	Wider, less curved, alae wider than promontory
Pelvic inlet shape	Heart shaped, narrow mediolaterally	Circular, elliptical, wide mediolaterally

poor diet, and lack of exercise leading to premature aging, or the use of cosmetic skin and hair products or plastic surgery to reduce the apparent signs of aging in adults. Visual aging of adolescents can also be rendered problematical by the use of adult styles of makeup, hair and clothing, and the adoption of more "mature" patterns of social behavior. Thus, there can be a considerable discrepancy between the perceived

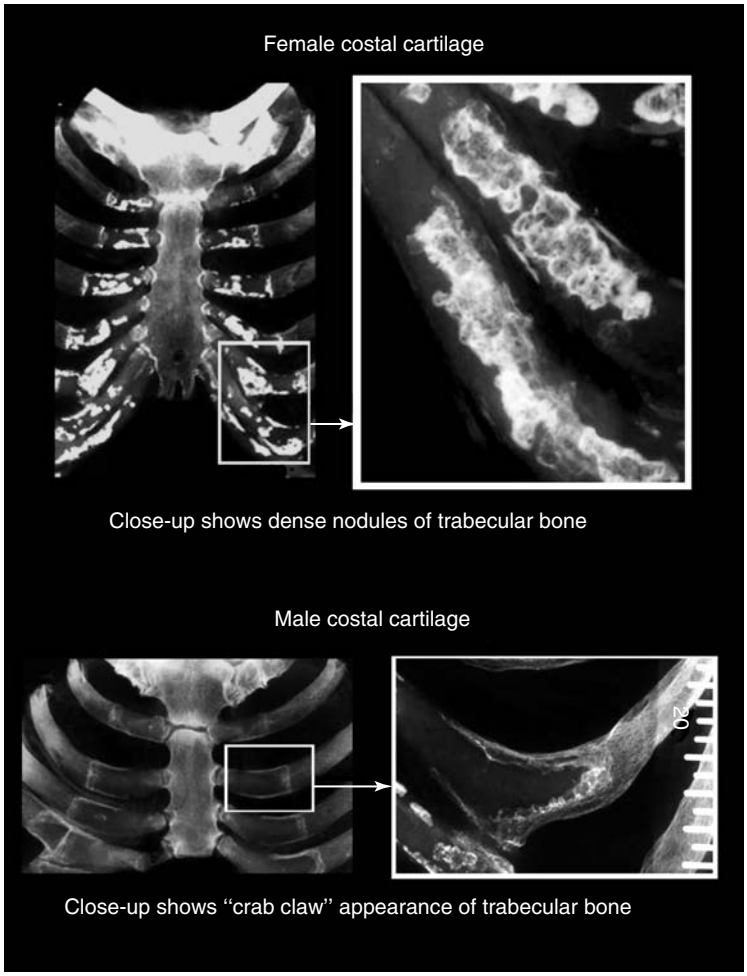

Figure 3 Sex differences in the ossification of costal cartilage

societal age of an individual and that stated on their official documentation.

Age studies have been used in a variety of situations including (i) identification of the individual as part of casework in both the living and the dead; (ii) study of the adequacy of growth of children in a population that is seen as an index of overall community health – poor growth is an indicator of unfavorable developmental conditions, diet or environmental stress; (iii) assessment of age-related social status milestones in life – coming of age, marriage, etc.; and (iv) construction of demographic profiles in an attempt to understand allochronic and/or diachronic patterning in mortality or funerary practices at the population level.

In biological terms, the aging process can be divided into three distinct phases: growth and development, equilibrium, and senescence. Natural variation in the timing and tempo of the aging process can lead to a divergence between biological (particularly skeletal) age and true or chronological age. As such, skeletal age should not be viewed as equivalent to chronological age at death. Skeletal age reflects the natural growth and development of the skeleton in response to diet, environment, and activity, rather than an absolute calendrical age; poor diet can be reflected in delayed maturation and growth yielding a "younger" skeletal age than real calendar years, and conversely, habitual activity, stress, or trauma can produce an aged, or 'older', skeleton than in reality.

This realization has profound bearing on many areas of inquiry with the effect that the criteria utilized to age an individual must be chosen and applied with care, caution, and understanding.

The developmental phase of aging (intrauterine to around 18 years of age) is largely under genetic and environmental influences, leading to well-understood and moderately predictable patterns and rates. During this phase, age determination is primarily based upon (i) well-understood and predictable rates for the mineralization, stages of crown and root formation, eruption and dehiscence of the dentition (Tables 4–6) [68–78]; (ii) timing of the appearance of primary and secondary ossification centers of the cranial and postcranial skeleton [36, 79]; (iii) the unification or fusion of the bones of the postcranial skeleton, which provides a reliable marker within relatively tight statistical margins (Table 7) [80–86]; (iv) correlation of the growth of individual cranial bones (pars basilaris, sphenoid, pars petrosa, tympanic ring, zygomatic, and maxilla) with gestational age [36, 79, 87]; and (v) correlation of developing long bone length against population-specific growth standards [88–94]. The latter method is relatively accurate in the intrauterine period, with fetal bone length closely linked to gestational age, but less accurate as developmental age increases because of the encroaching effects of environment and diet.

Once growth has ceased and skeletal and dental adulthood is reached, age determination becomes

Table 3 Metric determination of sex from selected measurements of the postcranial skeleton[a]

more difficult as many of the criteria used are reflections of skeletal deterioration and 'wear and tear', and as such they are less predictive, highly variable in expression, and socially mediated [95, 96]. Ages derived from adult skeletons should ideally be considered in broad age categories when using standard techniques, namely young adult (roughly 18–25 years), middle adult (25–45 years), or mature adult (45+ years). In particular, the generalized onset of skeletal maturity at its lower limit and the statistical range of full skeletal adulthood at its upper limit define the lower age bracket, while the upper bracket marks the cutoff point at which current techniques fail to discriminate age-related changes in a time-dependant or statistically significant manner as evidenced from known-age archaeological populations or casework.

In young adults, several components of the skeleton do not fully complete growth until late in the second or the third decade, and thus can be used with some degree of reliability in age determination. These components include the jugular growth plate of the skull, the vertebral segments of the sacrum, the ring epiphyses of the vertebral centra, epiphyses of the scapula and pelvis, the costal notches of the sternum, and the medial epiphysis of the clavicle (see Table 7). Age determination in mature individuals has focused on markers of skeletal senescence, the majority of which are functionally related degenerative changes. Mainly, these have utilized four avenues of investigation [97]: morphological changes in the pubic symphysis [98–103], degeneration of the auricular surface of the sacroiliac joint [104–108], degenerative change in the costochondral junctions of the ribs [57, 58, 109–114], and the degree of closure of the ecto and endocranial sutures [115], although the latter method is considered too imprecise for forensic use (see Table 8 for details of auricular, costal, and pubic methods). Advances in accurate age estimation for adult specimens have been made with the development of tooth crown and root translucency, and radiographic, microscopic or histochemical analysis of teeth or bone [111, 116–121]. While many of these techniques are still in their infancy, they have been shown to have some efficacy in current practice. In general, most adult aging methods have been shown to exhibit wide variation in the accuracy of the age ranges produced when compared to known-age samples. However, they may be useful when used in conjunction with the incidence of other age-related degenerative criteria such as osteoarthroses, osteophytosis, and osteopenia in order to make an informed judgment of overall age-related skeletal change, particularly in individuals between 40 and 60 years of age. It should be borne in mind that all of these techniques have been found to

be sex and context dependant, and prone to secular influences.

Stature

In the majority of cases, the calculation of the living height of an individual from skeletal remains is based on the fact that overall stature is correlated with long bone length assuming equality of body proportions; metric assessment allows the anthropologist to predict an individual's stature by regressing the lengths of individual limb segments. As body proportions vary by both race and sex (African-Americans, for example, have longer limb bones relative to height than US whites); thus, it is necessary to establish sex and race in order to use the correct regression formulae for the estimation of stature. The elements that are used to reconstruct individual stature include all of the major long bones (femur, tibia, fibula, humerus, radius, and ulna). The bones of the lower limb generally produce more accurate estimation of stature than those of the upper limb. A range of regression equations have been developed and are generally element and population specific; these include those of Badkur and Nath [122], Feldesman and Fountain [123], Genovés [124], Jantz *et al.* [125, 126], and Trotter and Gleser [127–131], amongst others [132–139].

Arguably the most accurate determination of stature (termed the *Fully Method*) is based on aggregated axial and paraxial measurements of the skeletal elements [140], which contribute to living height, but it is difficult to implement in many cases. The measurements comprise the height of the cranium, the total length of the vertebral column from C2 to L5, the anterior height of the first sacral vertebra, bicondylar length of the femur, the length of the tibia, and the height of the calcaneus and talus. Correction factors are applied for the missing soft tissue thicknesses and the method is obviously limited by the completeness of the skeleton under analysis [141, 142]. Estimation of living stature from fragmentary remains is generally considered too inaccurate and statistically inappropriate for forensic applications.

In addition to individualization, the reconstruction of stature and overall body size is routinely used to investigate secular change in archaeological populations through time [29, 138, 143–148]. Changes in stature tend to covary with changes in diet and calorific intake and are therefore potential indicators of periods of environmental or dietary stress, or conversely, of amelioration and excess. Depending on the pattern of expression, these changes may also reflect differential resource acquisition and utilization by sex or social group.

Ancestry or Ethnic Identity

The determination of ancestral or ethnic origin is one of the most problematical and contested areas of forensic and anthropological practice. Anthropologists are divided as to whether "races" actually exist, and most are in agreement that dividing the global population into three or four broad racial groups is not entirely justifiable on biological grounds alone [149–156]. The fundamental basis of the skeletal manifestation of "race" is predicated on the assumption that certain components of the body record evidence of ancestor-descendant relationships (phylogeny) with phenotypic similarity equating to genetic relatedness.

All modern humans share a relatively recent common African ancestor as suggested by the fossil

Table 7 Age estimation for adolescents and young adults from epiphyseal fusion of selected elements[(a)]

Element	Fusion	Age	
		Male	Female
Occipital	Fusion of sphenooccipital synchondrosis	13–18 years	11–16 years
	Closure of jugular growth plate	22–34 years	
Ethmoid	Ethmoid and vomer fuse	20–30 years	
Clavicle	Fusion of medial epiphysis	16–21 years, complete in all individuals by 29+ years	
	Fusion of lateral epiphysis	19–20 years	
Sternum	Sternebra 2 fuses to 3 and 4	11–16 years	
	Sternumebra 1 fuses to mesosternum	15–20 years	
	Sternum essentially complete	21+ years	
	All epiphyseal plaques in costal notches fused	25+ years	
	Xiphoid process commences fusion to mesosternum	40+ years	
Scapula	Coracoid and subcoracoid commence fusion to body	13–16 years	
	Coracoid and subcoracoid fused to body	15–17 years	
	Fusion of glenoid epihysis	17–18 years	
	Fusion of acromial and coracoid epiphysis complete	By 20 years	
	All epiphyses fused and adult form achieved	By 23 years	
Pelvis	Fusion of acetabulum	14–17 years	11–15 years
	Illiac crest commences fusion	17–20 years	
	Anterior iliac spine fused	By 20 years	
	Ischial and iliac crest fully fused	20–23 years	
Sacrum	Fusion between lateral elements and union of lower sacral segments	12–14 years	
	Sacrum complete	25+ years	
Humerus	Distal epiphysis fuses	12–17 years	11–15 years
	Medial epicondyle fuses	14–16 years	13–15 years
	Proximal epiphysis fuses	16–20 years	13–17 years
Radius	Proximal epiphysis fuses	14–17 years	11.5–13 years
	Distal epiphysis fuses	16–20 years	14–17 years

Table 8 Comparison of three methods of age at death assessment in the adult skeleton[a]

Method	Phase	Mean	SD	95% CI
Auricular surface (Buckberry and Chamberlain, 2002)		Males and females		
Aging from auricular surface change can be applied regardless of sex and ancestry [107]. Buckberry and Chamberlain (2002) adapted Lovejoy's [108] method of scoring from which they treated changes to the auricular surface as a series of independent variables. The surface is assessed for five traits: transverse organization (five stages), surface texture (five stages), microporosity (three stages), macroporosity (three stages), and morphology of the apex (three stages) using a descriptive scoring system. A composite score is obtained from the sum of each trait, from which an age estimate can be obtained.	I	17.3	1.5	16–19
	II	29.3	6.7	21–38
	III	37.7	13.1	16–65
	IV	51.4	14.5	29–81
	V	59.9	13.0	29–88
	VI	66.7	11.9	39–91
	VII	72.8	12.7	53–92
Rib phase (Iscan, Loth and Wright 1984 and 1985)		White male		
This method uses age-related changes associated with the costochondral junction of the fourth rib, which correspond broadly to age but vary by sex and ancestry. Phase changes are noted in the morphology of the rib end, surface contour, rim edge and contour. In general, the trend is from a nonporous billowed surface with rounded margins to one which becomes more porous, trending from V- to U-shape in contour, with thin walls and a degraded irregular margin.	1	17.3	0.5	17–18
	2	21.9	2.1	21–23

		White female		
Resulting age ranges show little overlap between age classes, leading Loth and Iscan (2000: 245) to describe the technique as "... the most consistently reliable method for the determination of age at death in the adult skeleton". Unfortunately, the efficacy of the method has not been adequately tested; what work has been done suggests the technique is most useful in the 40- to 49-year age ranges [114]. The technique was established using a small sample (108 white males and 83 white females) from Broward County, Florida; as a result, the predicted age ranges should be considered minimal estimates of unknown confidence intervals [5].	1	14.0	–	–

Pubic symphysis (Brooks and Suchey, 1990)		Male		
Age-related changes affecting the pubis have been recognized for many years [97, 98, 100, 103]. All methods perform poorly when tested on known-age samples outwith the demographic population on which the respective aging methods were established. For cases the Suchey–Brooks cast-based scoring system is considered most useful, although the statistical margins of age ranges for each phase are extremely large; in particular, these limit the accuracy of the technique when applied to individuals older than 30 years. The Suchey–Brooks method is based on a six-phase scoring system, which records a shift from pubic surface with billowed ridge and furrows to one of increasing granularity and to smoothing of the surface; the gradual formation of a ventral rampart; plateau formation at the dorsal margin; progressive lipping; the formation of bony outgrowths; and increasing irregularity and erosion.	1	18.5	2.1	15–23

[157–165] and archaeological records of early modern human morphology and behavior [166–169], coupled with assessments of African versus non-African genetic variability and phylogenetic relatedness [170–176]. This is corroborated by analyses of regional mtDNA relationships [177, 178], which root the mtDNA phylogeny firmly within Africa. Founder and maximum parsimony analysis indicates that all non-African populations are derived from a small founder population that most likely established itself to the West of the Indian subcontinent before bifurcating ca. 70 000 years ago into the two major divisional haplogroups, which segregate East Eurasia from West Eurasia. All subsequent human populations are ultimately derived from the African founder population, and share a common network of ancestor-descendant relationships; thus, all modern populations and "racial" groups are epiphenomena in the process of evolving and changing through admixture and hybridization, with any perceived morphological distinctions being the consequence of recent evolution. Consequently, the notion that modern humans can be classified into clear-cut subdivisions of monolithic racial origin groups is rejected by many anthropologists on both biological and ethical grounds [151]. While this standpoint may be true, it is clear that the human body does record phenotypic or genotypic traits that allow anthropologists to partition regional population groups [179].

In general, the most obvious ethnic differences in the living are either displayed in the face or the integumentary system, with the consequence that the skull is the most heavily studied skeletal element in "race" determination. Much of the early work focused on patterns of variation and the study of population movement, particularly in relation to archaeological "peoples", rather than individual discrimination that may be of use in a forensic context. Today, forensic anthropologists generally partition human cranial morphology into four primary skull morphotypes; whether these regional morphotypes equate to genetic or socially constructed "races" is a matter for continuing debate. The groups most commonly used are Caucasoid (including Europeans, Asians from the Indian subcontinent, North and East Africans, Arabs and Mediterraneans), Negroid (including West and southern Africans, and those of African descent such as African-Americans), Mongoloid (including southeast Asian and Palearctic Asiatics, and Native Americans), and Australoid (Australian Aborigines, Pacific Islanders, Fijians and Papuans).

Forensic assessment of ancestral association is carried out using both metric and morphological methods applied to both the cranial and postcranial skeletons [44, 51, 65, 67, 123, 180–186]. The principal cranial morphological differences between the groups are outlined in Table 9 (and see Figure 4) and it is clear that this type of analysis requires consistency and considerable experience observing and understanding skeletal variation between individuals, populations, and age groups. Metrical assessment of ancestry presents its own series of problems in determining morphological affinity, utilizing the main univariate or multivariate discriminant function analyses. Two recent computer-based multivariate methods have been developed on large database samples with the specific purpose of analyzing ancestry and partitioning an unknown specimen into pre-prescribed regional morphological groups. The FORDISC program [66] and CRANID [187] use metric measurements derived from archaeological/ethnographic crania, particularly the W.W. Howells dataset [188–190] or recent cases, in order to determine biological distance in an unknown-origin specimen. In practice, the strength of association of biological affinity is heavily influenced by the type of statistical contrasts used to discriminate between groups, and these programs need to be used with caution and a clear understanding of the underlying statistical and methodological principals.

Markers of Personal Identity

This supplementary set of characters differs from the first four primary factors (sex, age, stature, and ancestry) in that they are traits that are likely to be relatively unique to an individual, or that may be determined so with varying degrees of statistical certainty. They may be fixed characteristics under a high level of genetic control, or they may be subject to change during ontogeny through the addition, removal, or alteration of bodily tissues, and thus seen as phenotypically plastic in nature. Such characteristics may arise as a result of normal variation in development, through chance accident, or intentional modification, with the proviso that they are sufficiently discriminatory between individuals to act as markers of identity. These markers may include a suite of labile characteristics, which can aid in

Table 9 Craniofacial skeletal traits of four principal ancestral groups[a]

Morphology	Caucasoid	Negroid	Mongoloid	Australoid
Frontal profile	Sloping to upright profile	Sloping profile	Upright rounded profile	Sloping profile
Skull shape	Long	Long and low	Long	Short and high
Supraorbital ridges	Moderate-to-strong brow ridges with depressed glabella	Mild-to-moderate brow ridges	Little or no brow ridge expression	Massive brow ridges with glabellar expansion
Interborbital breadth	Narrow	Wide	Moderate	Wide
Face breadth	Narrow to wide	Narrow	Very wide	Wide
Face height	Medium to high	Low	High	Low
Cheek form	Receding malar region	Receding malar with some lateral projection	Strong anterior projection of malar (flat faced)	Strong lateral projection
Orbital shape	Angular orbits	Rectangular orbits	Round orbits	Rectangular orbits
Facial profile	Orthognathic	Pronounced prognathism	Moderate prognathism	Moderate prognathism
Nasal aperture	Narrow	Wide	Moderate	Very wide
Lower nasal margin	Prominent nasal spine with sharp (silled) nasal margin	Short nasal spine with smooth or guttered nasal base	Short nasal spine with sharp nasal margin	Guttering of nasal base
Nasal root	Steepled	Quonset hut	Tented	Steepled
Palate width	Narrow palate	Wide palate	Moderate palate	Very wide palate
Other characteristics	Prominent nose and chin. Deep canine fossa. Long pointed mastoid	Postbregmatic depression. Oblique gonial flare. Oblique posterior mastoid tubercle	Weak or absent canine fossa. Shoveled upper incisors	Marked occipital torus with no external occipital protruberance. Rocker-bottom jaw. Thick cranial vault bones

forensic individualization such as the uniqueness of skeletal or soft tissue structures, the pathological effects of disease or trauma, surgical intervention for medical or cosmetic purposes, or body modification by nonmedical personnel for aesthetic reasons. Such markers, whether assessed in combination or isolation, should provide a strong evidential basis for the recognition of individual identity.

In practice, anthropologists look for traits that set, for example, one Caucasian male, 25–35 years of age, of 170–175 cm living stature, apart from other missing persons that meet this common description. However, it is an important point to consider that while the fundamental parameters of age, sex, stature, and ancestral origin allow a reduction in potential matches, additional corroborative factors are only of value when preexisting comparative information is available. For example, the above case may show evidence that the male had suffered a broken left tibia that required surgical pining. While potentially individualizing, this information is limited in that it can only aid identification if suitable antemortem records exist to corroborate the match. In current practice, issues of identification are primarily addressed by individually sensitive biological markers such as DNA or fingerprints in preference to anthropological characteristics. However, in situations where such biological markers are unavailable (i.e., degradation of DNA in sea water), or where there is no potential of an antemortem match, then anthropological markers have utility. In cases where an assessment of personal identity fails to pinpoint a specific person, then facial reconstruction may be attempted in order to recreate the appearance of the unknown individual [191], which may then be matched against antemortem photographs of likely missing persons, if such exist.

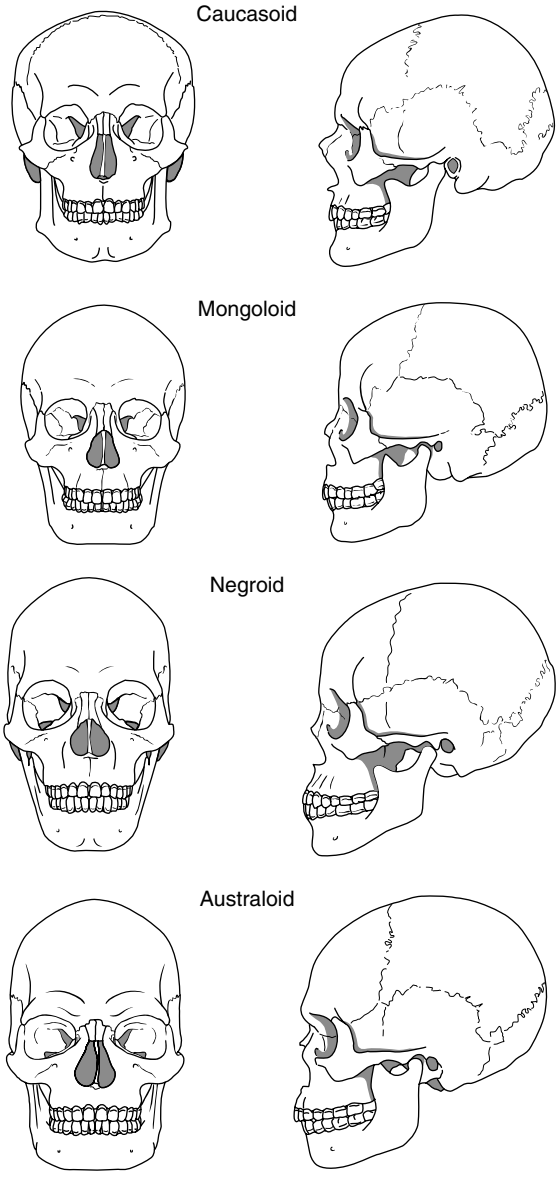

Figure 4 Frontal and lateral views of skulls showing ancestral group morphology [Reproduced with permission from Caroline Needham, University of Dundee.]

Individualizing Characteristics of Normal Human Variation. A number of soft and hard tissue structures have utility in cases of human identification, though in order to be of value such structures must not only be unique to the individual but must also remain stable over time.

Fingerprints or friction skin ridges are the most commonly used individualizing morphological structures. These are created during fetal development on the fingers, palms, toes, and feet. Friction skin ridge development is random, giving each finger or toe a unique set of surface shape characteristics; these are not considered to be genetically determined, and are therefore unique, probably even between identical twins [192].

The arborescent pattern of venous drainage and arterial supply is also thought to be individually unique. In particular, the pattern of epifascial veins superficially exposed at the dorsum of the hand and foot, the wrist, and the cubital fossa may have some utility in identification although this has yet to be statistically verified.

Palatal rugae are soft tissue ridges situated in the anterior part of the palatal mucosa on each side of the median palatal raphe and behind the incisive papilla. Rugae are useful in a forensic context in that they are somewhat protected from trauma by their intraoral location and are insulated from heat by the tongue and buccal fat pads. They have been suggested to be individually unique (even between twins) and minimally unaffected by factors of growth and development. The lengths of individual rugae have been demonstrated to change with age while shape remains largely stable. They have also been shown to resist the imposition of orthodontic treatment or the effects of antemortem tooth avulsion [193, 194].

Macrostructural and trabecular morphology of the sternum, the costochondral junctions, the lumbosacral spine, the pelvis, and skull are also considered to be highly individual. Areas of historical interest have included the size and shape of the frontal, paranasal and mastoid sinuses, endocranial vascular groove patterns, and ectocranial suture patterns [195–199]; in such cases, the comparison of morphological patterns by radiographic superimposition is generally used.

Pathological Conditions. The assessment of pathological variation or traumatic lesions may provide strong evidence as an aid to individuation. This can range from readily recognizable individualizing characteristics that may be known to or observed by informants, such as acne (which in extreme cases can cause significant scarring and skin discoloration), birthmarks, facial scar tissue, missing limbs, additional digits, or cleft palate, to characteristics that

may be cryptic during life such as degenerative joint disease or healed broken bones, the consequences of which may affect normal gait or mobility. The recognition of disease patterns may also assist in individuation, though in using such processes anthropologists are primarily looking at vectors that leave characteristic changes or lesions on the skeleton. The range of diseases that may be skeletally expressed includes trauma, congenital abnormalities (malformations produced by pathological changes during normal intrauterine development), circulatory disorders, joint diseases, infectious disease, diseases of the viscera, metabolic disease, endocrine disorders, hematological disorders, skeletal dysplasias, neoplastic disease, and various diseases and malformations of the dentition [200–202]. However, it is important to realize that not all disease processes leave skeletal lesions, and that any skeletal expression of a disease will be affected by the life stage (developmental age) of the individual concerned, the pathophysiology of the disease itself, and the duration for which the individual has been affected; as such, skeletal lesions of disease will only tend to be expressed in chronic rather than acute cases, and more often in adolescents or adults. They also have a continuum of appearance until they reach a stage of pathological stasis. Since similar skeletal lesions can be associated with different disease etiologies, any estimations based upon differential pathological diagnosis may be tenuous [203]; the difficulty involved in the diagnosis of pathological conditions from dry bone often requires the collaboration of anthropologists, physicians, and pathologists [204] to ensure accurate conclusions are reached.

Identification should never be based on the diagnosis of a pathological condition alone, although the presence of a condition can be useful as it may focus the list of possible identities where antemortem medical records are available. Furthermore, some pathological conditions are often more prevalent to a specific age group, sex or race, and may thus allow for the contextualization of remains of unknown-origin. For example, some disorders such as Legg–Calve–Perthes disease, osteochondritis dissecans, ankylosing spondylitis, or gout show a statistically higher and significant expression in males than females, and may assist in the determination of sex from skeletal remains.

Other distinctive pathological conditions of the skeleton may be due to infection from pathogenic bacteria and fungi, and many of the species involved have a distinct pattern of geographical and corporeal distribution, or more commonly affect a specific age range or sex. For example, hematogenous osteomyelitis is most commonly found in children and adolescents, with only 13% of reported cases involving adults [205] and presents four times more frequently in males [206]. Blastomycosis is caused by the inhalation of the fungus *Blastomyces dermatitidis*; it presents in a male-to-female ratio of at least 5 : 1 with a limited geographical dispersal. The disease is mainly limited to the cooler areas of the United States such as the Mississippi and Ohio valleys, the Mid-Atlantic states and North Carolina, as well as regions of Canada [207]. Hematological diseases such as sickle cell anemia (SCA) and thalassemia show striking differences in racial and geographical incidence, making their presence valuable for individualization of human remains. Since these disorders are present from birth and are associated with a high infant mortality rate [208], they are most frequently clinically observed in children. SCA predominantly affects Blacks of African descent, with a limited number of cases in Mediterranean populations such as Greece, Armenia, and southern Italy [208], whereas thalassemia has a complex geographical dispersal but is primarily found in Mediterranean regions, and is especially prevalent in those of Italian, Greek, and north African ancestry [207].

Trauma may also be a useful aid to individuation. Evidence of antemortem traumatic events may be left upon the skeleton following the decomposition process through the macroscopic recognition of antemortem fracture loci and/or skeletal scar tissue (the formation of a woven bone callus), or microscopically through the evaluation of hairline or cryptic (micro) fracture patterns. Traditionally, anthropologists have been of assistance in documenting and explaining traumatic patterning in relation to violent death through analyses of sharp force, blunt force, ballistic, or explosive trauma effects, the scope of which is outside the remit of this article (for discussion, see [209–212]). However, patterns of healed trauma can be useful in other ways. For example, the biological changes that occur in a postoperative context leave individualizing patterns within skeletal tissue, which continue for months and years, and can provide the anthropologist with a means of corroborating a presumptive identity, with the proviso that

sufficient antemortem clinical documentation exists in order to allow for comparison.

In such cases, the anthropologist is primarily looking at the effects of bone fracture. From a clinical and pathological perspective, a fracture is an interruption in the structural integrity of the bone, and may be variously present from a single crack, fissure, cortical break, dislocation, or bone avulsion, to a complete transverse break. Fractures occur through one (at least) of three mechanisms: (i) a single traumatic event with the application of excessive force; (ii) repeated stress; and (iii) abnormal weakening of the bone (this may arise through disease processes such as osteoporosis, osteogenesis imperfecta, rickets, or certain types of bone neoplasm). The cause of traumatic lesions can range from the accidental effects of crushes, trips or falls, to the consequence of deliberate action such as beatings, manual asphyxia, torture, suspension, electrocution, or the impact of ballistic projectiles or edged weapons. Traumatic lesions that occur antemortem will show evidence of callus formation and healing, and those which take place perimortem or postmortem will show no evidence of cellular recovery; consequently, it may be extremely difficult to distinguish between the two types of fracture in the perimortem and early postmortem periods.

Cultural Modifications. This class of evidence includes surgical interventions and body modifications. These may be undertaken by medically qualified personnel either for clinical or cosmetic purposes, or by the nonmedically trained for aesthetic reasons. Surgical intervention [7] includes surgical procedures such as amputation, orthopedic plating, breast augmentation, the insertion of cardiac pacemakers, or other foreign surgical devices such as staples or wiring (Figures 5 and 6) retained with the body. Some procedures, such as orthopedic joint replacements (Figure 7), require the implantation of prosthetics that may be individually numbered or carry manufacturer's identifying marks. Unfortunately, there are no universal stringent controls regarding the recording of these numbers; therefore, numbered prosthetics are only of use if the source of the prosthetic can be traced, or if specific matching evidence can be obtained, for example, in the form of radiographs. In addition to implantations, amputations can be easily recorded and can be of high value in an identification scenario in terms of reliability of evidence, as it is likely that informants may be aware of the loss of the body part. Scars resulting from surgery may aid in potential identification, particularly if they are in specific regions (for example

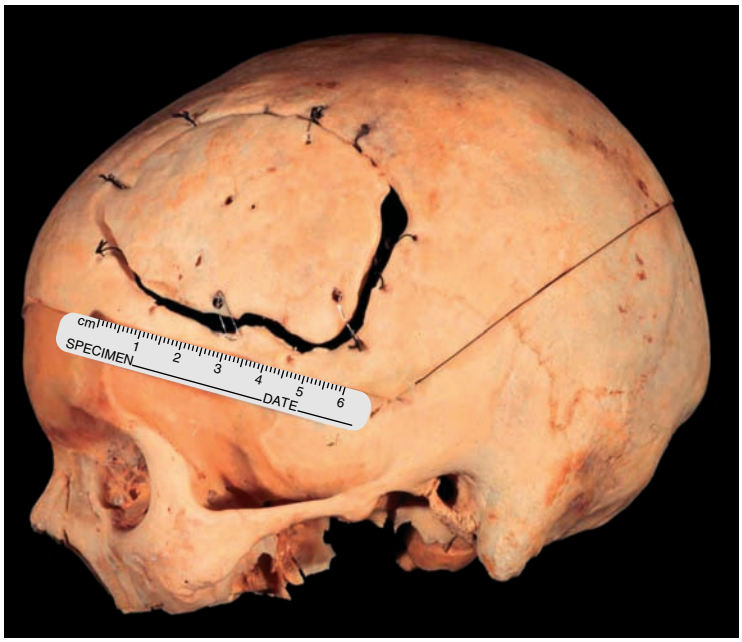

Figure 5 Surgical intervention to the cranium [Reproduced with permission from Michael Warren, University of Florida.]

Figure 6 Radiograph showing surgical artifacts of open-heart surgery

Figure 7 Radiograph showing surgical artifacts of stabilization of the proximal femur

resulting from appendectomies or caesarean sections) as they may guide an investigator toward a likely surgical specialist. The scale of surgical impact can also be important, with scarring and surgical interventions from major events such as car accidents less likely to be closely replicated between individuals, in addition to which most developed countries are likely to retain pre- and postoperative radiographs in such major trauma cases.

Body modification includes permanent and semipermanent tattooing, scarification, branding, cutting, subdermal implants (such as beads), or transdermal piercings such as rings, studs, or bars. There is a degree over overlap between surgical intervention and cosmetic body modification in that some of the more extreme types of alteration (tongue splitting, penile glans splitting, penilectomy, or osteogenic implants such as horns or crests) may involve anesthetics and utilize the services of a trained clinician. All of these classes of cultural/social modification or alteration may provide significant individualizing traits. While the increasing incidence of tattooing within the younger population can be viewed as limiting factors on their individualizing potential, those that contain personal information such as a name or badge of gang or clan membership, or that are extreme in expression or artistically unique, retain their individualizing value. Transdermal piercings including those to the earlobes, nipples, and genitals are now relatively common, but less common forms of alteration, including body sculpting or pocketing, are still relatively unique and likely to be memorable. Anthropologists must ensure that they have a current understanding of trends and developments in the techniques and social anthropology of body modifications (and the subcultural groups that adopt them), which may impact upon personalization of the human form.

Confirmation of Personal Identity

It is an important point to remember when considering the relative weighting attached to identification characteristics that while the fundamental four osteobiographical parameters of age, sex, stature, and ancestral origin allow a reduction in potential matches, additional corroborative factors are only of value when preexisting comparative information is available. As such, it may not always be possible to achieve a confirmed identity given insufficient

presumptive matches. To this end, we can define three categories of identity depending on the quality of the identification criteria utilized ([213] after [214]):

1. Positive or confirmed identity

This occurs when two sets of data are compared and enough specific markers found to conclude that the two sets of records were, in all probability, derived from the same individual. No irreconcilable differences should be noted. Unique markers may include DNA, fingerprints, dentition, and highly individualizing skeletal traits such as numbered surgical implants or radiographic superimposition of frontal sinus morphology.

2. Possible or presumptive identity

This occurs when several individual factors are considered, and although no single factor justifies the establishment of identity, the loadings or weightings attributed to the factors available are sufficient for a possible or presumptive ID. Such factors may include identifiable personal effects, visual recognition based on surviving soft tissues (facial form, body modifications, etc.), confirming osteobiographical data, skeletal pathologies, or other individualizing skeletal traits. In cases of BTB (believed to be), the principle of parsimony is invoked.

3. Exclusion

This arises when all the deceased in an identifiable category such as male or female have been identified, all surviving victims have been accounted for, and BTB have all been confirmed; those individuals who are unable to be matched to a list of presumptive identities are excluded from the identification. It is also possible to exclude with "absolute" certainty in certain cases, particularly where the remains of an unknown individual can be categorically excluded on the basis of an invariant or highly individualizing characteristic; for example, a set of unknown remains determined to be female and 18–25 years of age will clearly not be those of a missing 70-year-old male.

It is clear, therefore, that to limit the definition of forensic anthropology to the process of identification from the skeleton is outdated and inappropriate. The modern forensic anthropologist must be as comfortable working with the living as they are with the dead, and as familiar with the soft tissues as they are with the hard tissues of bones and teeth. It is a highly specialized area of expertise that requires thorough professional education and training.

Acknowledgment

The help and advice of Caroline Needham, Jennifer Randolph-Quinney, Christopher Rynn, and Caroline Wilkinson during the preparation of this manuscript was much appreciated and gratefully acknowledged.

Anthropology: Age Determination of Remains

Subadults

When dealing with the remains of infants, children, or adolescents, the evaluation of the length of bones and degree of fusion of epiphyses, along with the eruption and mineralization of teeth, can be performed in several manners [1–13].

Fetal and neonatal osteology allows one by looking at the degree of development of the fetus to determine time of gestation. In particular, dental formation may be very specific. The first signs of development can be seen at 6 weeks *in utero*. At 16 weeks, deciduous incisors begin to mineralize; at 26 weeks mineralization of the cusps begins for the first two deciduous molars; and at 30 weeks anterior dental mineralization is marked, and incisors have three-fifths of the crown completed, and the crypts of the second deciduous molars already have five mineralized cusps. In the completed fetus, the cusps of the deciduous molars are mineralized and form a closed circle, and one can see the mineralization of the tip of the first cusp of the first permanent molar.

Similar growth milestones exist for the dimensions of small bones, such as those constituting the skull (Figure 1).

From birth to adolescence, age is then easy to determine, both skeletally and dentally. The simple observation of flat bones such as those in the cranium can give important indications. Skeletons of newborns are thin and fragile, and the bones of the face are minute. During growth, cranial bones gradually

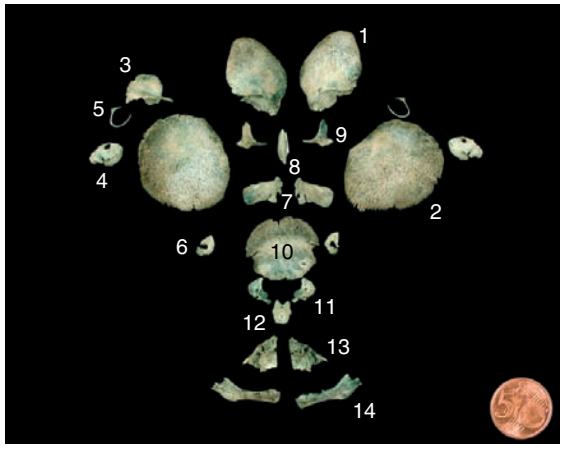

Figure 1 All the bones of a 5-week-old fetus: (1) frontal; (2) parietal; (3) squama of the temporal; (4) petrous portion of the temporal; (5) tympanic ring; (6) smaller wing of the sphenoid; (7) greater wing of the sphenoid; (8) vomer; (9) zygomatic; (10) occipital squama; (11) pars lateralis of the occipital; (12) pars basilaris of the occipital; (13) maxilla; and (14) hemimandible

Figure 2 Three crania in norma frontalis in different phases of growth. To the left a newborn (with no mandible); in the middle a 2-year-old child; and to the right a 10 year old

become thicker, particularly next to the sutures; the cranium quickly assumes adult proportions with a rapid growth of maxillae and mandible (Figure 2).

However, growth in the length of long bone diaphyses (Figure 3), together with the development of teeth, is a more precise indicator of growth.

Dental development and mineralization are perhaps the most precise indicators (Figure 4). Suffice it to say that teeth are less conditioned by environmental and pathological factors when compared to bone. Even when the teeth found are not *in situ* but are scattered, it is possible to achieve an accurate age by verifying the development. Macroscopic analysis

Figure 3 Metrical differences visible at different ages with these three femoral diaphyses: at the bottom a 6-month-old newborn; in the middle a 2-year-old; at the top an 8-year-old. Distal and proximal epiphyses have not been included. Long bones of the upper and lower limbs of infants are more or less of similar dimensions to adult metacarpals, but grow rapidly, so that at a certain length of the diaphysis one can obtain a corresponding age, with a margin error of 6–12 months

is generally insufficient and radiology should be performed in order to verify the exact extent of mineralization of roots.

In the skeleton of infants, long bone extremities (as well as other epiphyses – small "parts" of a bone, which will fuse during growth to the main portion of the same bone – Figure 5), where there is contact with growth cartilage, have a particularly beveled aspect.

Between 10 and 20 years of age, the fusion rates of epiphyses and the order in which they occur are especially useful. For example, proximal femur epiphyses fuse at 18 years of age, those of the iliac crest at 21, and those of the distal extremities of the humerus around 14 (Figure 6).

One should always keep in mind variations between different races. Studies have demonstrated that, for large epiphyses, there can be over two years' difference in age of fusion among different populations. Several years can go by between initial and complete fusion – this also could influence the error.

Adults

Determination of biological age in adult individuals is quite difficult and constitutes one of the most difficult tasks of forensic anthropology. Once dental and osseous development have occurred, very little remains on which one can accurately evaluate aging, if not pathology (arthrosis), degenerative changes,

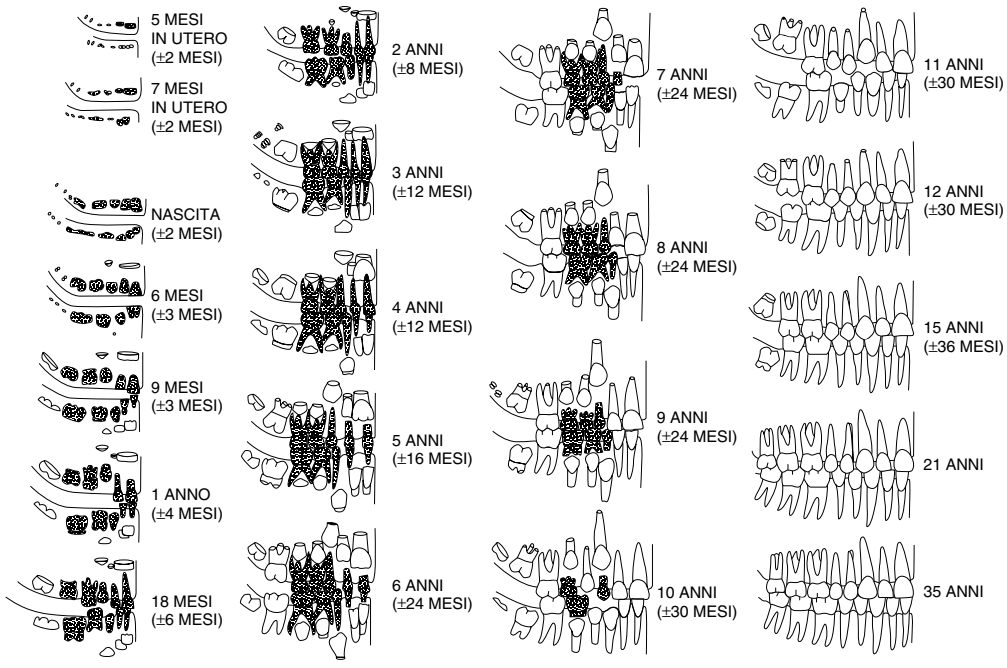

Figure 4 Diagram of dental development and corresponding age. The deciduous dentition is seen in gray and the permanent one in white

histological alterations, and chemical alterations of the components of bone and teeth.

General markers of old age do exist: osteoporosis, articular surface degeneration, osteophytes; however, these are severely influenced by pathology, nutrition, and interindividual variability.

Physical anthropology has established several methods for determining age in adults – macroscopic, microscopic, and biomolecular [14–77] (Figure 7), but most methods have error ranges, which encompass 10–15 years.

Macroscopic methods are the most important ones and consist principally in the degree of degeneration of selected articulations such as the pubic symphysis, osteochondral surface of the fourth rib, and auricular surface of the ilium. The rationale behind these anatomical sites is that they are articulations, which are equally stressed for all individuals, regardless of activity. Thus, they should reveal a degree of degeneration, which should be proportional only to the age and thus standardizable for aging procedures. Less reliable techniques are cranial bone suture analysis and radiological evaluation of bone rarefaction.

Pubic Symphysis

In young adults, the symphyseal surface of the pubic bones (i.e., the joint between the two pubic bones) has a billowed appearance, with deep and furrowed bone ridges running across the surface in parallel. As the person ages, the furrows gradually become filled and the surface becomes flatter and even. Around this surface, an oval outline is formed and an initial crest begins to form on the ventral margin. Then the surface starts to deteriorate. Numerous methods were devised for aging by pubic symphysis. The most acclaimed one, however, is the Suchey–Brookes method applicable to both male and female skeletons. This method divides the degenerative evolution into six stages, which correspond to mean age and age ranges. Phases are shown in Figure 8(a–f).

Fourth Rib

This method was developed by Iscan *et al.* and evaluates the profile of the osteochondral articulation of the rib, its depth, and the profile of the margin. With increase in age, the profile becomes more

Figure 5 Different phases of formation of the innominate bone. It consists of three portions (ileum, ischium, and pubis), which unite around the second year of life. Before adolescence, the innominate bone is made of three different bones: the ileum, whose principal nucleus of ossification appears at the second or third week of life *in utero*; the ischium, whose principal ossification nucleus appears at the fourth month *in utero*; and the pubis, which ossifies at around the fifth month *in utero*. The rami of ischium and pubis fuse at around 7–8 years of age. At 12 years of age, the cartilaginous strip, which separates the acetabulum from the three components, begins to ossify. Complete fusion occurs around 17 years of age. Other epiphyses of these bones, i.e., the iliac crest, the anterior superior iliac spine, and the ischiatic tuberosity, appear around puberty and fuse to the main body between 16 and 23 years of age. In the figure above one can see (1) ileum and ischium of a 5-month-old fetus; (2) ileum, ischium, and pubis of a 2-year-old child; (3) ileum, ischium, and pubis of a 11 year old where ischium and pubis are fused; (4) a 17 year old where the three main bones are fused but the lines of fusion are still partly visible within the acetabulum; (5 and 6) a 16–17 year old where the iliac crest has not yet fused to the rest of the ilium (note the billowing); (7) fusion of the iliac crest and ischiatic tuberosity has occurred; and (8) detail of the ischial tuberosity in fusion

irregular with margins, which go from a V form to a U form; depth increases and sternal insertion is more irregular (Figure 9a, b). These alterations are expressed in eight phases for males and females. One disadvantage of this method is that at times, with commingled remains, it is difficult to identify the fourth rib, or it may not be available.

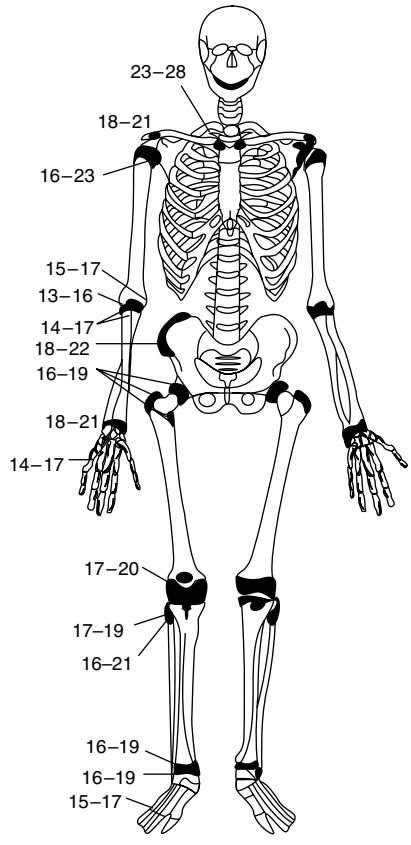

Figure 6 Diagram of a skeleton representing the age range of principal fusion events of the epiphyses with the respective diaphyses. One should always, however, keep in mind that these data are based on modern control populations, which belong to a specific race and social class, and therefore could be erroneous and at variation when applied on a different population

Auricular Surface

This method was devised by Lovejoy *et al.* in 1985 and is based, as for the pubic symphysis, on the degeneration, in eight phases, of the auricular surface of the ilium, according to the degeneration of the apex, the superior half of the surface, the inferior half, the retroauricular area, granulosity, density, and micro- and macroporosity of the surface.

Less accurate methods that involve the observation of suture closure both ecto and endocranial exist. These methods involve the evaluation of the degree of suture closure and give a score, which results in a specific age with a very large error range.

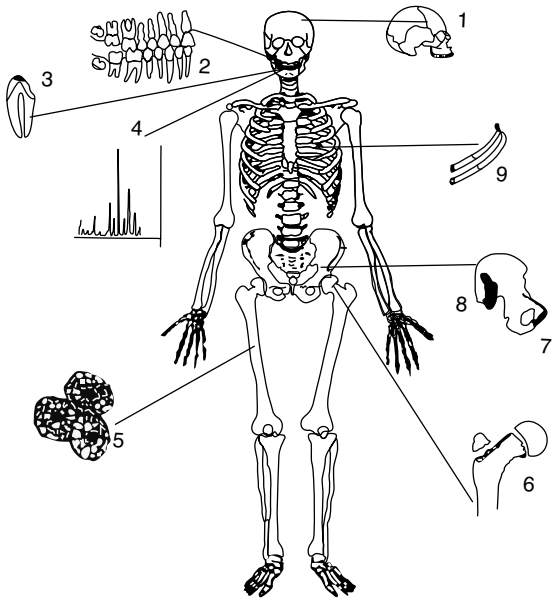

Figure 7 Schematic representation of various methods of aging adults: (1) cranial sutures; (2) third molar eruption; (3) dental transparency methods; (4) aminoacid racemization; (5) osteons; (6) fusion of last epiphyses to fuse; (7) pubic symphysis; and (8) auricular surface

Macroscopic alterations of teeth are also relevant. In particular, dentine translucency seems important – a variable that increases with age. As far as dental methods are concerned, the Lamendin is the most reliable among dental tests: it utilizes periodontal disease and translucency of root in monoradicular teeth throughout the following *formula*:

$$\text{Age} = (0.18P') + (0.42T') + 25.53 \qquad (1)$$

where $P' = P/L \times 100; T' = T/L \times 100; L$, teeth length; P, height of periodontosis; and T, height of root translucency.

The Lamendin test is considered by the literature the most accurate method of age estimation, especially between 40 and 60 years, but recent studies have demonstrated a variability in accordance with race and gender, requiring specific correction factors. It has, however, replaced the Gustafson–Johanson test, which is based on abrasion, secondary dentin deposition, periodontosis, root translucency, secondary cementum, root reabsorption, with a score from 0 to 3 for each element. However, new radiological methods, which study pulp chamber dimensions, are being introduced into the forensic scenario but still need testing.

Recently a "two-step procedure" has been developed for quickly achieving age: if the idea one has of the age of an individual by looking at the skeleton is that it is within the first three stages of the Suchey–Brookes pubic symphysis method, then this should be the method of choice. If the subject is classified in the last three phases, then one should switch to the Lamendin technique in order to assess age more accurately. Currently, age diagnosis at over 60 remains a problem.

Figure 8 (a–f) Appearances of the six different stages of the Suchey–Brookes method in which one can note the progressive alteration of the symphyseal surface. In order, fase I, much billlowing can be seen, average ages are expressed at 67% CI. phase I: in females 17–22, in males 16–21; phase II, reduction in billowing and a slight margin is beginning to form, females 20–30, males 20–27; phase III, billowing still visible, circumferential margin almost complete, females 23–39, males 22–35; phase IV complete margin, females 27–49, males 22–35; phase V, loss of billowing, degeneration starts, females 34–63, males 35–56; and phase VI alteration and degradation of the surface and margin, females 48–72, male 49–73

(a)

(b)

Figure 9 (a) The sternal end of a young fourth rib, where one can note the regular margin and round shape of the bottom. (b) The sternal end of an old fourth rib where one can note osteophytes, irregularity, and even the presence of calcified cartilage (yellow) at the margins

If macroscopic methods cannot be performed (for fragmentation, loss of the anatomical areas), one must then proceed to microscopic methods. The rationale behind the microscopic method is that since bone remodeling occurs constantly throughout life, an older bone will have more osteons and osteon fragments compared with a younger bone (Figures 10 and 11). Microscopic analysis of a bone section from long bone diaphyses can provide an age estimation throughout several methods, the most acclaimed being the Kerley–Ubelaker method [40], which counts the number of secondary osteons, of osteon fragments, and of primary osteons in a 100x microscopic field with a diameter of 1.62 mm; the method can be applied to tibial, femoral, and fibular diaphyses. The numbers are then inserted into an appropriate formula.

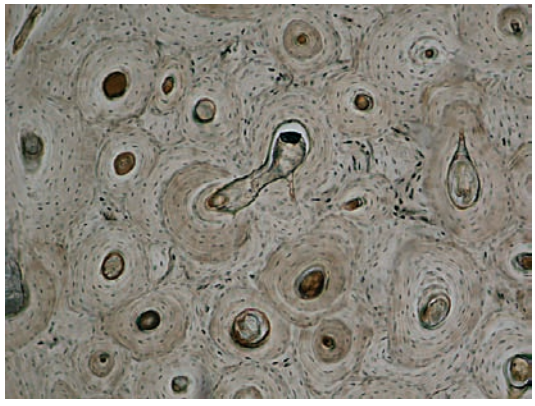

Figure 10 Bone section at a magnification of 100×: one can note, in this, thin section of femoral human bone and the presence of numerous osteons. The section belongs to an elderly individual

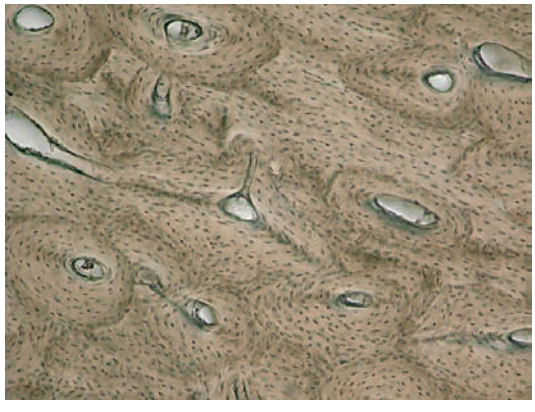

Figure 11 Similar section of a young individual. One can note the presence of a smaller concentration of osteons

Many other macroscopic and microscopic methods are available, among which are evaluation of the acetabulum and cementum annulation, respectively. These are, however, more difficult to apply and/or more costly, less user-friendly, or still need to be tested on larger populations.

Finally, there are also chemicophysical methods, which seem to yield a smaller error range. These are based on the racemization of aspartic acid. The aminoacids of which proteins are made of are present in nature in two stable forms: in the form of L-enantiomers and D-enantiomers. Living organisms synthesize proteins, which contain only L-aminoacids. In tissues such as teeth, D-aminoacids

will accumulate during life because of the racemization of L-aminoacids in the measure of about 0.1% every year. Levels of D-aminoacid seem to accumulate during life in a linear manner with age; thus, the evaluation of the L/D ratio is closely related to age. This technique requires the use of gas chromatography or high performance liquid chromatography (HPLC) and has already been tested on enamel, dentine, cartilage, and bone. The method, however, up to now, seems applicable only to relatively fresh teeth, and not on ancient or burnt material, is more expensive, and is more difficult to set up.

Finally, one should conclude the issue of aging adults with an invitation to caution, keeping in mind the large error ranges.

Anthropology: Aging the Living

The need to determine the age of living individuals constitutes a problem of increasing interest in our community, due to the progressively higher number of persons not in possession of any document of identity, who have immigrated illegally, and committed crimes, whose real age must be known in order to decide their imputability and whether they should be subject to trial as "of age" (e.g., 18 or more years of age). Many of these subjects actually do not know their real age; others, on the other hand, try lying about their real age in order not to go to an adult's prison. Judicial problems, which emerge, are aimed at determining whether the perpetrator of a more or less severe crime has reached "adult" age. This may be different in different countries; however, normally, the ages of 14, 16, 18, and 21 are the crucial thresholds for most American and European countries. The consequences are severe: if underage, the perpetrator will be brought to a juvenile prison, a much different environment with respect to a normal prison. Even in proceedings concerning adoption, it is sometimes important to assess age when no birth certificate is available.

Although such issues concern radiology, auxology, and pediatrics, they enter the realm of anthropology also since they deal with a classical anthropological domain such as aging. Aging has already been discussed in **Anthropology: Age Determination of Remains** with respect to human remains; however, the issue of aging the living deserves a specific section since usually more narrow error ranges are required – in other words, more accurate methods.

The anthropologist must learn to deal with concepts such as biological age, chronological age, skeletal age, and dental age. Chronological age is basically anagraphical age – the real age of a person. Biological age, on the other hand, is a statistical concept based on calculation of the degree of maturation of the body (e.g., sexual maturation), the skeletal system, or dentition. Thus, chronological age may not necessarily coincide with biological age, since they represent two completely different concepts. An expert witness, however, can only respond for biological age. An additional problem concerns race or ancestry. Even if progressive maturation of the skeletal and dental system follows a sequence, which is common to all individuals, different populations may reach different maturation stages at different times, and therefore at a different chronological age.

The evaluation of growth in individuals can be performed by the evaluation of anthropometric variables such as stature, weight, pubertal maturation, and bone and dental growth. Body development follows precise phases, which repeat themselves in the same manner for all individuals of the same sex, for the first 20 years of life. Somatic development, particularly dental and skeletal development, comprise well known and standardized stages. For this reason, it is preferable to choose to evaluate dental and skeletal development, by performing radiological exams on the person involved. And because of the specific legal requirements, aging has focused on those peculiar anatomical sites, which give more accurate results in the age ranges that are crucial to legal issues, such as the hand, wrist, and teeth. These methods not only allow one to give a rough estimate of age with a known error, but some, particularly the dental ones, may allow one to give the probability that the person has reached a certain age, for example, 18 years – which can be extremely useful for a judge who needs to know the entity of the risk he is taking. So, if a certain stage of development corresponds to a probability of having reached the 18th year of age, for example, of 90%, the judge will risk a "wrong" conviction only in 10% of cases.

In the last decade, forensic anthropology and forensic medicine, in general, have shown an increasing interest in this problem and in the reliability of methods for assessing biological age [1–13]. Among the methods most frequently used for skeletal assessment are those concerning the left hand wrist area, which can produce precise estimates up to the age of 16–17 years (Figures 1 and 2), at which time wrist maturation is complete in 90% of subjects. The development of teeth, and particularly of third molars, has been extensively studied for this purpose also.

A Study Group on Forensic Age Diagnostics has recently given guidelines and recommendations on this matter. It declares that in order to determine the age of living subjects, the assessment should include a physical examination, X ray of the hand and wrist, dental examination, and an orthopantomogram. computed tomography (CT) examination of the collar bones should be performed if the person is at least

Figure 1 X ray of the left hand of a 15-year-old individual. Notice how the epiphyses of phalanges, metacarpals, and ulna and radius are still unfused

Figure 2 X ray of the left hand of an 18-year-old individual. Notice how, with respect to the image in Figure 1, all epiphyses have fused

18 years old, since this is the only anatomical area, which will be able to give more precise information on the age range between 18 and 21.

A more difficult issue is aging living adult humans. This, once again, occurs in cases where individuals have no identity documents for the purpose of old-age pension or other civil acts. As has been said in the "aging human remains section", once maturation is complete, all one is left with are bone and dental degeneration. It is common experience that there are general markers of aging, such as wrinkles, white hair, posture etc., which, however, are not accurate due to the great interindividual variability. If the error range is large with human remains, where one can, however, attempt to look at pubic symphysis and other articular surfaces, perform osteon counts or look at dentine translucency, these methods are

not applicable in the live person. Some authors have suggested testing for amino acid racemization, although this implies performing a biopsy of the tooth. Other radiological methods, which observe the dimensions of the dental pulp chamber, are beginning to make their way; they, however, still need further testing.

Sometimes it is necessary to "age" pictures in order to provide reliable identikits of missing persons whose last picture may have been taken years before disappearing. It is, therefore, necessary to age that picture in order to perform the so-called face aging of photos. Aging process of photos has been carried out so far without a large-scale scientific approach. It is usually left to artists' subjective elaboration, although some researchers (few) are working toward the elaboration of software, which may use a slightly more scientific approach.

One of the main problems concerning the aging of living individuals represented in pictures is juvenile pornography. Once again, two-dimensional pornographic images can be the object of medicolegal/anthropological assessment. According to the country and legislation involved, the question frequently asked is the age of the child or adolescent (if, for example, under 10, 14, 16, or 18 years). This is a novel and very difficult aspect of age estimation, since facial and secondary sexual characteristics are extremely variable and do not necessarily represent chronological age. Since the late 1990s, in fact, authors have cautioned against the misuse of standard puberty stages, such as the Tanner ones, to estimate chronologic age. More scientific articles are stressing the differences in sexual maturation rates within different geographical areas. Pathologists, anthropologists, pediatricians, and gynecologists are really left with very little in order to fight juvenile pornography. In this sense, recent research in Europe is oriented toward the study of facial parameters, but is only at the beginning.

A great increase in diffusion of pedo-pornographic material has occurred in the last years, particularly due to the development of web technologies. Along with the technical progress, child pornography has increased proportionally. The misuse of the Internet as a (crime) weapon is a serious problem.

Technically, however, the difficulty lies in actually verifying whether the material is pedo-pornographic, i.e., if the subjects represented are – at present – below 18 (e.g., Italy, France, Canada, USA), 16 (e.g., Belgium, Switzerland, Netherlands, Great Britain) or 14 (e.g., Germany, Austria) years of age. Therefore, it often happens that specialists such as forensic pathologists, pediatricians, or anthropologist are called in by magistrates or the police in order to establish, on videotapes and photos, subject age. One of the most popular, but imprecise for these purposes, methods for age estimation is staging pubertal growth according to the Tanner criteria, utilized in clinical medicine to verify sexual maturation in adolescents; the Tanner method focuses on pubic hair and mammary glands in females, and on pubic hair, penis, and testicles in males. Use of Tanner staging for forensic purposes has been severely criticized. The author himself quotes that using the Tanner stages to estimate the probable chronological age is a "wholly illegitimate use of Tanner staging" and he wishes to "caution pediatricians and other physicians to refrain from providing "expert" testimony as to chronologic age based on Tanner staging ".

Great interindividual variability in sexual maturation is emphasized, bound to physiological and pathological factors, such as obesity, and to environmental influence. Another important limit is that Tanner staging focuses on clinical elements in order to establish which phase of sexual maturation the subjects have reached, not if the subject is of adult age. A further problem is that it is impossible to compare photographic staging with a complete medical examination, including inspection and palpation, since the method is applied to two-dimensional pictures. Furthermore, clues can be altered on pictures, e.g., by shaving the pubic or axillary hair. Dental eruption and development could be useful also; but frequently, detail of the images is not good enough to allow for analysis of dental outlines and features. Another method used in age diagnosis, not yet analyzed in depth, and apparently more subjective and disputable, is based on observation of facial traits. Morphological assessment of juvenile characters, however, may be extremely tricky. A more objective approach may be provided by facial metrics. However, research is at its initial stages.

Race or Ancestry

The word race seems to bring with it considerable discussion among biologists, sociologists, and even politicians and intellectuals. It can be criticized as being politically and biologically incorrect – and has been by many in the past decade. However, one cannot ignore that differences between populations do exist and that these may be fundamental for the identification of the victim of a crime. Thus, forensic anthropologists need to use "racial" traits in order to help investigating authorities.

So-called racial or ethnic characteristics can be considered as those differences that can be observed between populations and not among single individuals. Weight, for example, is extremely variable within a specific population; skin color and the type of hair may be less variable. From an evolutionary point of view, when a species lives in different environments, the best adapted genotypes are selected for survival. In the present sociocultural reality, thanks to the exchange of genetic heritage due to the increase in communication and acculturation, we have seen a progressive integration of different groups of populations – and it is therefore more difficult to distinguish specific racial groups. Ancestry is thus difficult to assess, since there is a large variation within races but also a great deal of overlapping between them. Nonetheless, the presence of concentrations of extreme expressions of some body traits can suggest affiliation with a particular major racial group.

The three main racial groups, easy to identify on human remains, are Caucasoids, Negroids, and Mongolids. Generally speaking, Caucasoids show high pigmentation variability, including dark skin and white skin types and red-haired subjects, thin and smooth hair, orthognathous profiles, and prominent chins, and height is often included within intermediate stages. Negroids show a variable coloring of skin from brown to black, dark hair and irises, variable height; the cranium is long, without prominent supraorbital reliefs, marked zygomas, alveolar prognathism, and receding chins. Mongolids have

yellow–brown skin color, dark and straight hair, variable height, high orbits, prominent zygomas, and shovel-shaped upper incisors.

Classical authors stress that an indication of racial affinity may be reached by metrical measurements of bone districts; the main measurements utilized in race diagnosis are the schelic index (lower limb length/height × 100), the nasal index (nasal width/nasal length × 100), morphological facial index (*nasio-gnathion* length/*zygion–zygion* length × 100), palate metrical analysis, and femural neck angle. These measurements show a high variability among different ethnic groups and change in conformity with geographical context. Prognathism (the forward jutting of the jaw) has an importance in determination of main racial groups. High degrees of prognathism are a common characteristic of Negroids, whereas low degrees of prognathism are observed in Mongolids. Histological analysis of skin in the case of putrefied and mummified remains provides some information on race, and has a great importance where skin color cannot be recognized, because of decomposition or conservative *postmortem* processes. Distribution of melanin pigments is also useful in remains where soft tissue residues are still present. Caucasoid and Negroid groups show a regular and continuous increase of the melanin stratum, whereas Mongolids have a typical melanin-flared disposition in the Malpighian stratum. Hair microscopic analysis also can be useful and used to distinguish between main races by observing its cross section: a round section is typical of Mongolids; oval sections of Caucasoids; and an elliptic section of Negroids (Figure 1).

Some information on race can also be reached throughout the analysis of bone and dental morphology. Caucasoid (White) crania tend to have receding cheek bones, which give a more pointed appearance

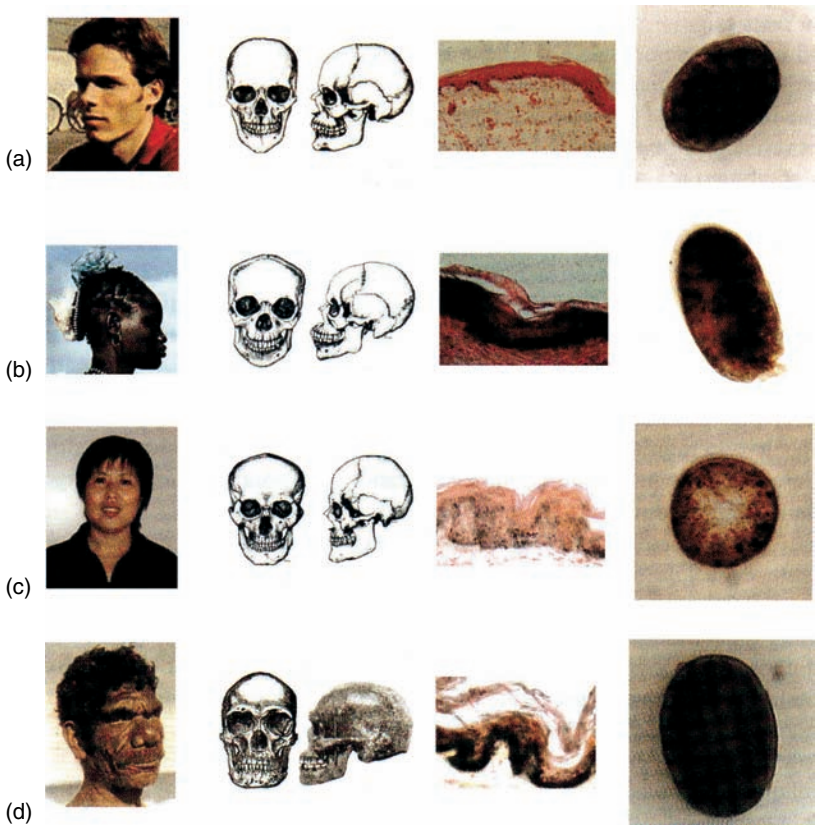

Figure 1 Each strip shows the appearance of face, cranium, skin histology, and hair microscopic section of the main ethnic groups in forensic anthropology: (a–d) Caucasoid, Negroid, Mongolid, and Australomelanesoid

Figure 2 (a) Cranium of a Caucasoid woman. (b) A Negroid woman. Notice the greater nasal aperture, absence of a nasal sill and more rectangular orbits in the Negroid

Figure 3 Lateral view of Caucasoid cranium (a) and Negroid cranium. (b) One can appreciate the marked prognathism in the Negroid

to the face. The nasal aperture is narrow and has a prominent and thick lower border (nasal sill) and a marked nasal spine. The palate is relatively narrow and the suture between maxilla and palatine bones seems to be curved. Negroids (Blacks) have more rectangular orbits. Nasal aperture is large and there is lack of a nasal sill; the nasal spine is absent or very small. The palate is wider and rectangular, and there is marked prognathism (Figures 2, 3a, b). This is the protrusion of the maxillary and mandibular region and can be evaluated via the "pencil test". This consists in trying to place the nasal sill, the mandibular symphysis, and the occlusal surface of the upper incisors on the same line. If one achieves this, then the cranium should be Caucasoid, if not, it is Negroid. Mongolids tend to have forward projecting malar bones. Nasal aperture has a slightly pointed lower margin. Orbits are circular. Facial flattening is also evident. A simple test for this is: position the cranium face up and balance a pencil across the nasal aperture; try to insert a finger between the maxillary bone and the pencil, if you can do it without moving the pencil it is probably Caucasoid, if not, it is Mongolid. Mongolids frequently have head-to-head occlusion of teeth.

Dental peculiarities may also indicate race. Diastemas (the space between the two central upper incisors) is more frequent among Negroids and

shovel-shaped incisors among Mongolids, although these are not exclusive traits.

Metric parameters of the cranium and other bones also may be helpful in determining race. The University of Tennessee has developed an interactive computer program called *Fordisc*, which performs a diagnosis of race from several cranial measures. The method is user-friendly but has some limits: the program compares the specific cranial measurements with a control sample taken from the US population. Its applicability in other parts of the world has only been partly tested. However, innumerous studies exist on racial variability of different parts of the skeleton, which are, year after year, building up information for the delicate problem of diagnosing ancestry from human remains [1–19].

Recently, researchers have focused not only on race but also on detecting signs of the country of provenance of that person. In fact, some radioisotopes typical to specific countries are stored in the bones of living individuals. The presence of such elements may be good indicators of whether that person spent a considerable time of his or her life in Eastern Europe as opposed to North Africa or other regions, for example. This represents a very interesting field whose developments may bring more information on the country of origin of an unidentified skeleton.

Stature

Height can be assessed by standardized mathematical formulae developed by several authors according to race and gender, and based mainly on long bone length, simply measured with an osteometric table (Figure 4). The bones most frequently used are femur, fibula, tibia, humerus, radius, and ulna. Formulae applied to each bone in different races are shown in Table 1.

Literature has also focused on the use of several other different bones, tested within different populations, as well as with equations including several bones [20–37].

Anomalies and Pathology

The more information one can obtain from the skeleton, the better for identification purposes. For example, dental work (*see* **Odontology**) and bone calluses can be fundamental in building a precise biological profile, which may lead to identification, just like tattoos and scars will be useful for well-preserved cadavers. Anthropologists are also very keen on recording nonmetric traits, which are anatomical anomalies, such as the presence of Wormian bones, metopic suture, or of double articular facets. Although these may be important in identifying the subject, if antemortem X rays show the presence of the same anomaly, they still do not have an extreme relevance in forensic anthropology, although they should always be recorded. The forensic anthropologist generally focuses on osteological signs, which give crucial details on the habits or health of a person. An important discipline in this sense is paleopathology [38]. This is the science that studies the signs of disease on skeletal remains and is very useful in telling us whether a person suffered from severe anemia, was lame because of an old bone fracture, or had tuberculosis. Below is a list of some disease categories detectable on bone, which may turn out useful for the biological profile.

Figure 4 An osteometric table to measure the length of bones – one of the classical anthropologist's main tools (along with sliding and spreading calipers)

Table 1 Main formulae for height estimation (from Trotter and Gleser) where F, T, H, R, Fi, and U are the maximum length expressed in centimeters for femur, tibia, humerus, radius, fibula, and ulna, respectively

	Femur	
	Males	Females
Caucasoids	$2.38 \times F + 61.41 \pm 3.27$	$2.47 \times F + 54.10 \pm 3.72$
Negroids	$2.11 \times F + 70.35 \pm 3.94$	$2.28 \times F + 59.76 \pm 3.41$
Mongolids	$2.15 \times F + 72.57 \pm 3.80$	
	Tibia	
Caucasoids	$2.52 \times T + 78.62 \pm 3.37$	$2.90 \times T + 61.53 \pm 3.66$
Negroids	$2.19 \times T + 86.02 \pm 3.78$	$2.45 \times T + 72.65 \pm 3.70$
Mongolids	$2.39 \times T + 81.45 \pm 3.27$	
	Humerus	
Caucasoids	$3.08 \times H + 70.45 \pm 4.05$	$3.36 \times H + 57.97 \pm 4.43$
Negroids	$3.26 \times H + 62.10 \pm 4.43$	$3.08 \times H + 64.67 \pm 4.25$
Mongolids	$2.68 \times H + 83.19 \pm 4.25$	
	Radius	
Caucasoids	$3.78 \times R + 79.01 \pm 4.32$	$4.74 \times R + 54.93 \pm 4.30$
Negroids	$3.42 \times R + 81.56 \pm 4.30$	$2.75 \times R + 94.51 \pm 5.05$
Mongolids	$3.54 \times R + 80.71 \pm 4.60$	
	Fibula	
Caucasoids	$2.68 \times Fi + 71.78 \pm 3.29$	$2.93 \times Fi + 59.61 \pm 3.57$
Negroids	$2.19 \times Fi + 85.65 \pm 4.08$	$2.49 \times Fi + 70.90 \pm 3.80$
Mongolids	$2.40 \times Fi + 80.56 \pm 3.24$	
	Ulna	
Caucasoids	$3.70 \times U + 74.05 \pm 4.32$	$4.27 \times U + 57.76 \pm 4.30$
Negroids	$3.26 \times U + 79.29 \pm 4.42$	$3.31 \times U + 75.38 \pm 4.83$
Mongolids	$3.48 \times U + 77.45 \pm 4.66$	

Figure 5 Amputation of first and second fingers of left hand

Figure 6 Signs of neurosurgery on the cranial vault of a young woman. One can notice the bone fragment originally removed probably to drain a hemorrhage and then reassembled to the rest of the cranium

Congenital disease: It is rare nowadays to see important congenital diseases on bone – examples are achondroplasia, cleft palates, and spina bifida. Trauma: aftermaths of amputations (Figures 5 and 6) or fractures (and therefore more or less recent calluses) along with prosthetic devices (Figure 7) are quite frequent, and it may be easy to determine

Figure 7 The presence of a prosthetic device in a left femur

the age of a particular fracture so that one can be more informed in determining when the incident happened. Degenerative disease/Arthrosis: Osteophytes (Figure 8) and/or any other proliferative reaction of articular surfaces, along with lytic reactions of bone, such as the presence of small depressions of the vertebra called *Schmorl's nodes*, may be indicative of discopathies or arthropathies to specific anatomical areas. Metabolic and neoplastic disease: bones and teeth can show signs of general stress (Figure 9), iron deficiency (Figure 10), scurvy, rickets, though rare. Moreover, metastatic bone lesions may sometimes be seen in individuals who had secondary cancer. Infectious disease: bone infections following bone trauma can be seen, such as osteomyelitis. More rarely, and in underdeveloped countries, syphilis, tuberculosis (Figure 11), or leprosy can leave specific signs on bones.

Figure 8 A lumbar vertebra with a marked osteophyte (a lip of bone growing upward from the vertebral body rim), indication of arthrosis

Figure 9 Enamel hypoplasia. These incisors and canines, which belong to a child (the teeth are still incomplete as the root is missing), show enamel hypoplasia, i.e., thin depression lines running across the width of the crown. This is a general stress marker, which shows that at some point a "systemic" incident (such as a severe disease) occurred that temporarily stopped dental growth

The disciplines of osteology, orthopedics and, in particular, paleopathology therefore supply a plethora of information on how to extrapolate disease, stress markers or simple anatomical anomalies, such as nonmetric traits, from human remains, which may be incredibly useful for building the biological profile and crucial for subsequent identification.

Figure 10 Cribra orbitalia. The fine porosity visible on the ceiling of the orbits is known as *cribra orbitalia*, a sign of severe anemia

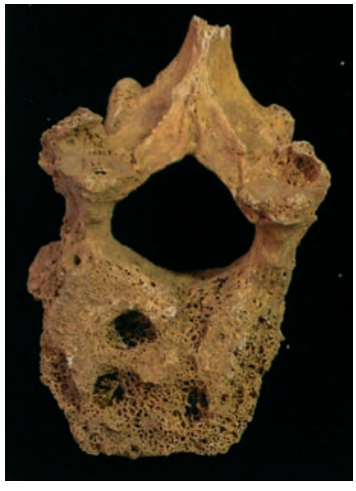

Figure 11 Thoracic vertebra bearing cavities due to tubercular abscesses, a clear sign of infection

Archaeology

Background

Archaeology is now becoming an increasingly familiar discipline in scenarios involving the search for and recovery of buried human remains [1], including the identification of mass graves and recovering victims [2]. The work has also been extended into nonhuman materials, for example, buried drugs, firearms, and stolen goods. Forensic archaeology is founded on the long development of "traditional" archaeology in the study, analysis and interpretation of buried soil formations, and in the use of electronic survey techniques. It requires a wide understanding of landscape mapping, natural geological phenomena, and the use of aerial photographic imagery. This thorough grounding in field archaeology is essential, as it brings with it an awareness of other disciplines that may need to be integrated as part of a recovery operation, for example, palynology (*see* **Palynology**), entomology (*see* **Entomology**), pedology (*see* **Soil: Forensic Analysis**), conservation, etc. Archaeology may also include additional specialisms in fields such as geophysical survey (e.g., ground-penetrating radar (GPR)) or physical anthropology (*see* **Anthropology**), but both these are usually considered individual fields of expertise in their own right.

Many archaeologists have completed some basic training in physical anthropology and will be familiar with which elements of the human skeleton are most useful for determining basic identification factors of age, sex, and stature, etc., and will therefore be able to take particular care in their recovery. This familiarity with hard tissue also usually extends to being able to distinguish between human and animal bone – an especially useful aspect of the discipline when it comes to assessing the significance of buried or concealed bone material discovered during construction work, gardening, house renovation, or surface remains handed in by dog walkers or other members of the public. Moreover, in forensic search scenarios where human remains may have become disarticulated, scavenged, or spread, the ability to determine this distinction *in situ* is both cost effective and time saving.

Forensic archaeology can be summarized as having input in criminal investigation in the following areas:

- Landscape analysis: the use of maps, aerial photographs, and shallow subsurface geophysical survey.
- Excavation: the recovery of buried individuals through excavation by understanding of stratigraphy and implementation of sampling, planning, and recording systems.
- Skeletal hard tissue: knowledge of skeletal components for determining individuality, and for distinguishing between human and animal materials.
- Associated environmental sciences: the value of soils, seeds, pollens, entomology, flora and fauna, etc., and their relevance in identifying habitats where incidents occurred.

The shift from "traditional" to forensic archaeology is not straightforward and requires a wide understanding of scene protocols, the evidential requirements of other specialists, and the nature of the legal constraints within which forensic work takes place. Recognition of the role of archaeology within criminal investigation has been a gradual process. There is often a popular misconception that "forensic" archaeology is predominantly concerned with historical or antiquarian matters such as the medical investigation of Egyptian mummies, the facial reconstruction of

ancient skulls, or analysis of the stomach contents of bog bodies. However, these simply involve the application of science (on occasions forensic science) to archaeological remains. "Forensic" archaeology, as with any other forensic discipline, is contemporary and pertains to matters of court; it normally involves working with police forces in the resolution of serious crime, usually murder. In fact many early police investigations searching for buried remains might best be described as archaeological scenarios, even although archaeologists were not involved. Archaeological input to crime investigation has been growing.

A number of fairly typical scenarios, illustrating the point at which archaeology may be utilized, and the archaeological methodologies involved, are outlined below. The majority involve locating clandestine burials and the recovery of victims, the elimination of areas where human remains are alleged to have been buried, or the occurrence of "stray" human material found, for example, during building operations. Within the context of mass graves, issues of genocide and human rights abuse are likely to be encountered, and the discipline has to address the types of evidence that may require recording. Mass grave work is relatively new in both the United States and the United Kingdom [1, 3].

Method

Contrary to some popular opinion, archaeology is not about finding objects. The discipline is largely concerned with locating specific buried remains and in recovering them in a manner that will include and maximize associated evidence, avoid contamination, and allow a process of reconstruction to take place. Archaeology is a destructive process and therefore unrepeatable; the key element is to ensure that an adequate record of the excavation is made. There are various strategies for ensuring that this is achieved, but there is no "by-the-book" method of approach. The method of each scenario has to be taken on its merits according to prevailing conditions and involves a minimum standard of process, record, and observation of strata. These factors are more complex in mass graves for which a number of standard operating procedures (SOPs) have been written [4].

There is often a general misunderstanding that ground subsurface is composed of an amorphous mixture of soils into which burials may be concealed, and from which they can be exhumed by coarse digging. This is far from the case: most shallow subsurface soils are composed of sequences of discrete layers (stratigraphy) representing different events in past time; these layers may be naturally formed, culturally formed, or a mixture of both. The key aspect of any archaeological intervention is an understanding of the nature and character of these soil layers. The layers may differ by virtue of color, physical property, geological character, or inclusion, and they may represent a range of different anthropogenic and natural processes (Figure 1). Archaeology is mostly about interpreting these layers, which can be created by a large range of activities, including construction, demolition, burning, cultivation, clearance, occupation, etc., or through natural formation processes. Successful interpretation of these layers enables an understanding of what occurred in a given place over time. In effect, interpreted correctly, these layers can be used to provide a statement of what went on in a particular place – it gives that location a context in which those events occurred. Moreover, because individual layers are superimposed, they also exhibit a local chronology – it is possible to show which is the earliest and which is the latest layer in that place – in effect providing a "snapshot" as well as a context for the layers in question. Any intervention into the ground, by clandestine burial or even by forensic investigation, will create a new set of layers within the existing context and add to the chronology of what was there before. These are the features with which the forensic archaeologist will need to be specifically concerned.

It makes no difference whether there are a few layers or a few hundred layers in any given location; and it makes no difference whether the layers are one thousand years old or a few days old – the principles of context and relative chronology remain exactly the same. In fact, even with recent criminal burials there are often layers that can be identified with specific events, such as the laying of terraces or patios, upcast from ditch clearance, minor building activity involving spreads of sand or other materials, even cultivation and manuring, or natural phenomena such as leaf fall. These events will be quite closely dateable, particular those aspects of construction work that require Local Authority permission or building consent. Dated layers that lie above and seal the grave are denoted as giving a *terminus ante quem* (time before which) for the date of the grave;

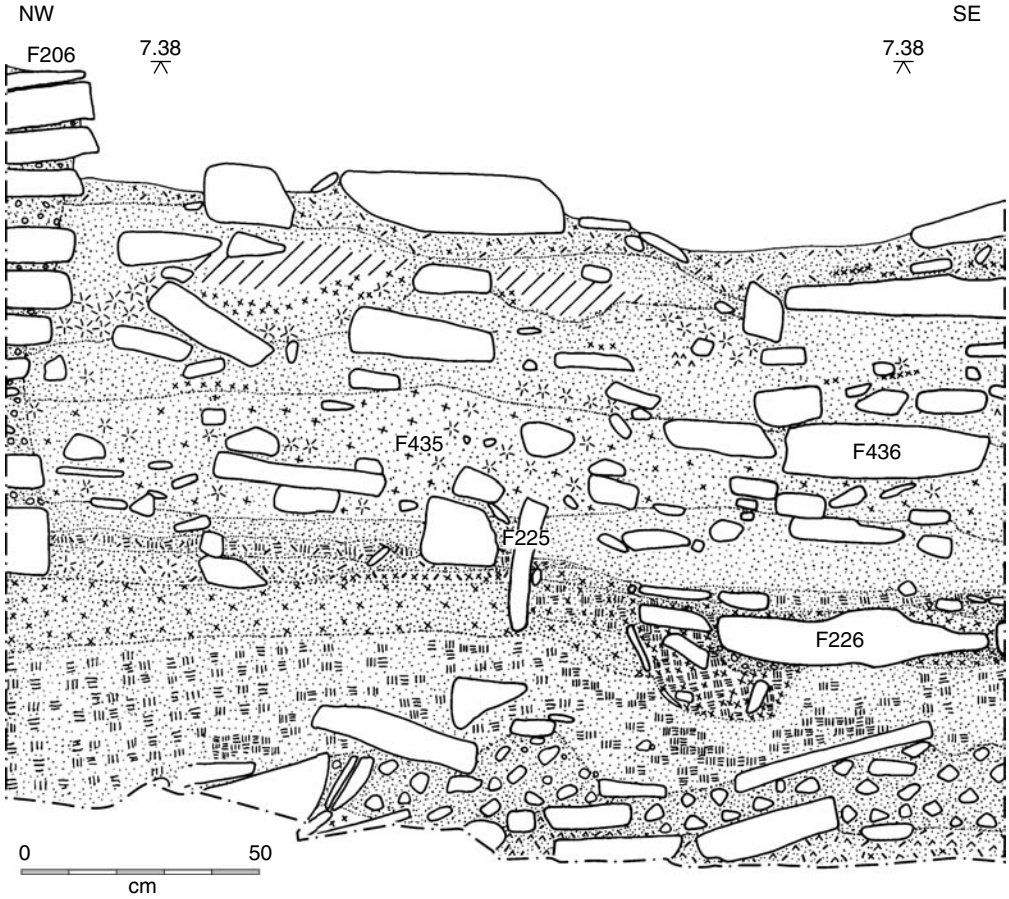

Figure 1 Illustration of different superimposed layers on an archaeological site

dated layers that are cut into by the grave can give a *terminus post quem* (time after which) for the date of the grave.

Stratigraphy

As the ground subsurface consists of a series of layers in varying degrees of complexity, any victim buried there is therefore contained within a fixed stratigraphic environment. The edges of any grave (i.e., the sides and base of the cutting made to create the grave, and the top after the grave has been filled in) effectively represent a sealed deposit in which the individual and any evidence pertaining to that individual is retained (Figure 2). It is best treated as a crime scene as it may contain evidence for the identity of the individual, the manner and cause of death and, depending on the layers above and below, the possible chronology of burial. Moreover (and less well recognized) is the fact that this deposit will also contain any evidence that may link the victim to an offender by virtue of traces of material (fibers, shoe marks, cigarette ends, etc.) or items added to the grave fill by the offender for concealment. It is of paramount importance that the integrity of that sealed deposit is recognized throughout the recovery operation; otherwise, not only will the validity of the evidence recovered (including material that may offer links with the offender) be suspect, but there will also be significant potential for contamination.

Many human remains are discovered during building work or land clearance, and there is an inevitable tendency for any bones to be removed

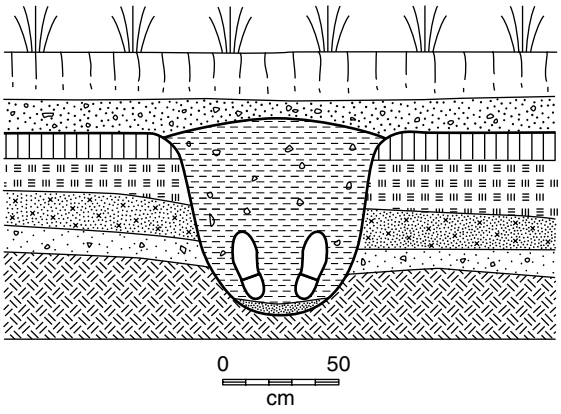

Figure 2 Reconstruction of the layers likely to surround a simple grave

for examination, usually to check if they are animal or human. By removing them from their layer, the integrity of the grave is effectively broken, their context is lost, and the chronology distorted. As a result, the material is largely unusable. However, the integrity of the grave can be maintained if the material is left exactly where it was found. The outline of the grave can be established by careful excavation and the contents removed appropriately. Case studies have shown that retaining the integrity of a burial can be important in a variety of practical situations: for example, if articulated remains are discovered during construction or drainage operations. By leaving them *in situ* an archaeological assessment of their stratigraphic context can be carried out and decisions can be made regarding whether the material is modern (and therefore of potential forensic interest) or ancient (and therefore of only archaeological or historic interest) before recovery commences.

As another example, there are sometimes incidents where human remains have been found partly buried; here it will be necessary to determine whether the remains were originally buried (i.e., by a third party) and may since have been exposed or scavenged, or have become buried (i.e., by a process of natural soil accumulation, hillwash, etc.). In the former, the matter may require criminal investigation, in the latter it may not. Any distinction between the two can be easily destroyed by clearing or exposing the remains by crime scene personnel, or by removal of the material, even in part, by the forensic pathologist. Retaining the integrity of the situation is critical to any understanding of what happened; hence the primary investigation and recovery is best carried out archaeologically.

Search

The initial search for missing persons assumes that the individuals concerned are alive in the first instance and may be missing because of medical or psychological conditions as much as to disorientation, abduction, or murder. The shift of search from a living to a deceased target is a gradual one and also necessitates a shift in the techniques deployed. In the United Kingdom, these techniques are listed and detailed in a comprehensive police advice manual [5]. This article is concerned only with searching for clandestine burials, which can involve the deployment of a range of specific techniques and an equally wide range of expert personnel (see also [6]). Most of these searches are highly planned and coordinated. Searches initially commence with noninvasive methods in order to target specific areas, to eliminate others, and to define search boundaries. The information (intelligence) that underpins this process may include a range of factors: offender and geographical profiling, witness accounts, last sightings, database statistics derived from similar scenarios (including disposal patterning), and the suspect's movements. General and specialized maps can be used to define access and feasibility of burial, aerial photographs may be commissioned, and appropriate areas can be defined. Aerial photography may be able to identify areas of disturbance from soil change, shadow, or crop mark, although on a scale much smaller than most archaeological features observed from the air, and in concealed rather than open locations.

All searches require some starting point or location of interest. Search is also about eliminating areas from the search, either because they are not considered feasible (e.g., open rocky ground) or because they have been searched without result. A search team should eliminate an area only if it can do so with a high degree of confidence. This level of confidence is achieved by using a sequence of search techniques, including complementary techniques. No one ever wants to find out that a burial was subsequently discovered in an area that had already been eliminated.

Once these "desktop" techniques have been concluded, target areas will be identified for more

detailed attention. These areas may consist of straightforward tracts of land, individual gardens, or specific, small points of interest identified from the air. Graves dug into the ground will invariably leave a trace, even years later. Ground disturbance is likely to have an effect on the surface vegetation, perhaps supporting stronger growth or different species or presenting different flowering times compared to the undisturbed surrounding ground. These are longer-term effects. In the shorter term, trampled vegetation and soil may be apparent, as will the local disposal of excess soil that is unable to fit back into the grave. There may also be a topographical effect in that eventual consolidation of the grave fill will cause a depression in the ground surface; this may later become exacerbated when the buried body collapses through the decay process. Both vegetational and topographical change may require skilled observation. Members of the public, so often photographed "helping" in many early enquiries, may unwittingly eliminate vulnerable evidence of this type.

The same effect of disturbance that can create vegetational and topographic change may also lead to the creation of a geophysical signature that differs from the surrounding, undisturbed ground. In effect, the search techniques used so far have been focused on identifying the disturbance caused by the grave, rather than the body lying within the grave. Archaeological geophysics (as opposed to geological or engineering geophysics) is particularly suited to work of this kind, as it shares the same requirements and sensitivity for identifying small, shallow subsurface targets [7, 8]. It does, however, require there to be a reasonable "background" of nondisturbed ground or of consistent geology in order for the grave to be picked up as being anomalous within that background. Even in wide open areas, geophysical techniques are pushed to their limits to detect grave-size targets, and this may become virtually impossible in many typical search environments, notably rear gardens that display various types of surface and are overgrown and cluttered with material both surface and buried that may interfere with the method.

Of the three main methods used in archaeology, resistivity and GPR are probably the most effective. Magnetometry, which is highly sensitive to local magnetic and ferrous effects, has been found to be less useful if only in view of the background "noise" present in many of the locations targeted. Resistivity is particularly useful in open landscapes such as lawns or areas of turned soil, but is likely to require data processing in order to enhance any anomalies detected. GPR, on the other hand, is better in confined spaces and has the ability to detect through dense surfaces. Thus, in contexts where patios, driveways, or swimming pools become targets of search, GPR is a helpful technique in being able to minimize heavy reinstatement costs. It also has the advantage of showing anomalies in "real time" and allows targeting of specific features as the survey progresses. However, there are now several software packages that allow all geophysical techniques to be processed and filtered as well as being converted into 3-D images, which allow the operator to maximize the data available.

It is important to stress that all geophysical survey methods have advantages and limitations. Electrical, magnetic, and electromagnetic techniques all respond to, or are affected by, different phenomena and the various systems are best used to complement each other rather than being used as individual options. For example, a grave in a particular soil environment might not be detected using resistivity, but may be picked up using magnetometry. Experimentation has emphasized the difficulty in detecting graves using geophysics, particularly soon after a burial has taken place. Equally, it can take a skilled and experienced operator to recognize the display effects of a burial evident in a radar scan depending on time since disposal. A key element here is the decay dynamics of the buried victim and its effect on detection methods. Features in traditional archaeology (such as pits, walls, ditches, etc.) tend to be inert, whereas a recently buried victim will undergo a process of decay, which ultimately (and under normal circumstances) will culminate in skeletonization. The speed and extent of this decay process and resulting effects (taphonomics) depend on numerous factors such as depth of burial, wrapping, wetness, temperature, soil environment, oxygen, bacteria, etc., and these in their turn may alter the efficacy of the various detection techniques available. In traditional archaeology, geophysical survey using resistance or magnetometry methods normally operates within 20 m × 20 m grids, allowing up to 10 grids to be covered in a working day taking measurements at 1 m intervals across the grid; in forensic work, readings are usually taken at 0.5 m intervals in order to ensure that any grave is

adequately sampled, and this will take commensurately longer.

The detection of likely targets either by geophysics, from the air, by fieldcraft, evidence of scavenging, or by observation of disturbed ground can then be tested by "ground truthing". This can entail trial trenching or, less invasively, the use of a cadaver dog. Cadaver dogs are trained to detect the scent of decaying human flesh but ideally require the ground to be "vented" first. This involves the handler piercing the ground in the suspect area often to a depth of around 0.6 m with a narrow metal probe in order to allow any scent to rise to the surface. Often the ground is vented with a series of holes, or in a line, which enables the handler to lead the dog into, and across, the suspect area downwind. If the dog responds in a particular place, further action can be taken. One option available is to become more invasive in order to be confident that no remains have been buried. For example, in a garden where a number of targets have been found by geophysics but have not been responded to by the dog, a mechanical excavator might be employed to strip away the topsoil. Used skillfully, machines have a valuable role to play in work of this kind. The use of a wide (toothless) ditching bucket can clear a garden down to undisturbed substrates in a matter of a few hours, allowing any disturbance to be investigated, usually by half-section. Given their destructive nature, machines are best used as a secondary rather than as a primary approach. Used primarily, they may destroy much evidence if any burial is present; used secondarily, they can achieve elimination of an area.

Probing can also be used, although this can have damaging effects on a buried victim. Used systematically, it may be possible to identify softer (disturbed) substrates from harder (undisturbed) substrates. This method can also be extended to the use of a corer, which will allow a column of earth to be removed in order to assess the nature of buried deposits. Both methods have destructive implications.

Any features discovered, by dog or other methods, can be excavated by hand, usually by half-section. This allows the excavator to identify the size, depth, and nature of the feature as rapidly as possible (there may be many features requiring investigation), as well as showing in section how the feature was infilled (Figure 3). If the feature turns out to be a grave, the nature of the infilling may be significant. During the half-section, spoil will be recovered either by contexts or (more likely) in arbitrary spits and retained in case the feature is found to contain human remains. In such an eventuality, the "search" process will have already interfaced with the recovery exercise: the likely extent and depth of the grave will be known, the nature of the infill identified, and the taphonomics established. Taphonomy is a relatively new area of study that can affect both search and recovery, and has been the subject of extensive focus [9, 10]. These factors will provide valuable information and guidance for the remainder of the recovery process. More significantly, both loss of evidence and the opportunity for contamination to have occurred will have been minimized.

Search exercises should be logged and produced in report form. This log should include times, dates, areas, methods, decisions made, and locations eliminated. In the event that no victim has been recovered, it provides an invaluable record for future "cold case" reviews in which new technologies and methods might be applied. Many older cases that now come under review with no such log, or even accurate record of where any "digging" took place, may need to be started from scratch.

Recovery

Excavation is normally geared in the first instance to identifying any grave outline, determining stratigraphic relationships between the grave fill and the surrounding ground, and setting up a recording regime. Fixed points need to be identified, and plans produced. In most, but not all, cases it may be preferable to half-section the grave in order to identify any particular pattern of infill in the exposed section. The section might, for example, show that a grave had been carefully backfilled with specific materials in order to minimize discovery. This might be used to demonstrate in court that the perpetrator was in a sound state of mind in disposing of the body, with resultant implications for motive and outcome. Most grave fills, however, are simple mixes of backfilled substrates and require excavating in numbered "spits" with spoil usually retained in sealed containers such as large plastic dustbins for later sieving. Graves often contain items deliberately concealed by the perpetrator, for example, soiled clothes or a weapon, as well as items conveniently discarded such as cigarette butts (useful for DNA) or newspaper (useful for dating).

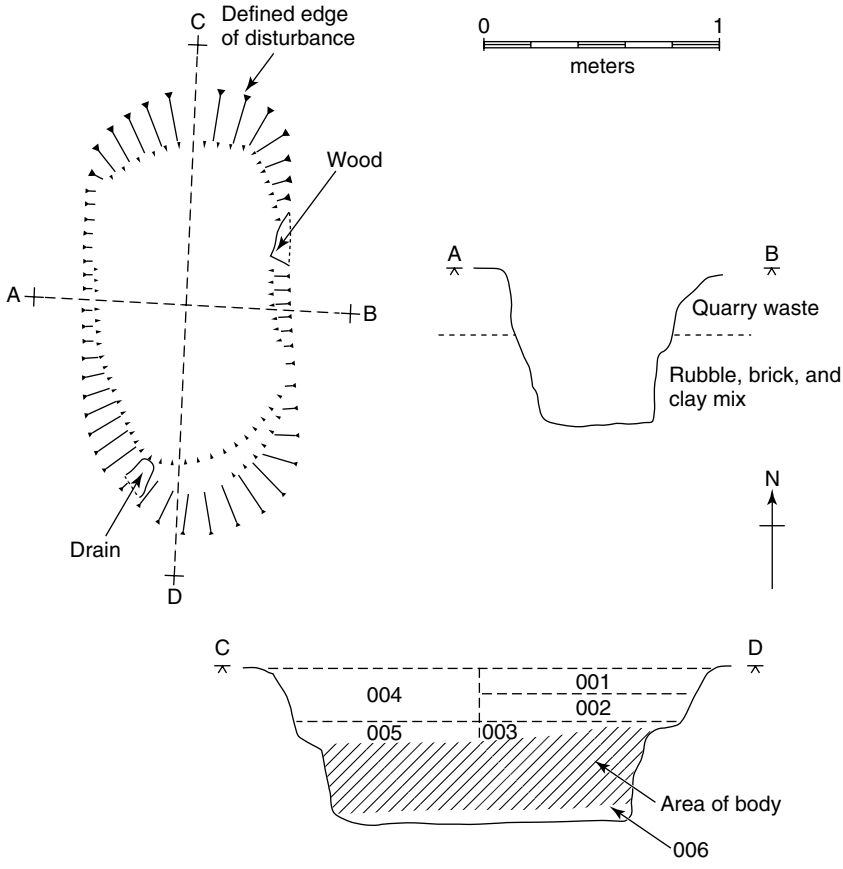

Figure 3 The half-sections and plan of a burial showing the layer numbering used

Forensic recovery is no different from any other type of archaeology in being destructive and therefore requiring the practitioner to excavate according to a research design in order to answer specific questions. Unlike traditional archaeology, however, these types of question tend to pertain to an individual event. The interrogation might consider how the grave was dug, what tools were used, whether it was excavated in a hurry or had been carefully prepared or even left open, whether it contained an unusual fill or any foreign material, or whether it contained material transferred from the offender into the fill. This is not conclusive evidence, but it can be used to develop further enquiries.

This type of evidence needs to be looked for and recovered as a matter of priority even if it entails excavating in unusual or unorthodox ways. Equally, the victim needs to be uncovered and removed in a manner that will retain any forensic evidence on the body itself, avoid contamination from nongrave contexts, and prevent any additional trauma to the body itself. This often has to be undertaken in confined, screened, or tented areas, sometimes in cellars or narrow gardens, and can present practical difficulties that have to be surmounted *ad hoc* in order to retain the integrity of the grave (above). Space permitting, access to the body may need to be facilitated by digging out a platform from the side of the grave in order that work on the body can take place at the same level. No matter how the job is done, at the end of the day the method undertaken needs to be able to recover essential data according to the highest possible standards in order for it to be presented in court and defended under cross-examination. Often this will need ingenuity and inventiveness, especially if a suspect is being held in custody with specific

time constraints. Irrespective of physical constraints, it is essential to produce basic archaeological records in both written and graphical terms.

Throughout this process, the archaeological work will need to be coordinated with the collection of other forms of evidence, for example, any necessary sampling for entomological or environmental purposes [11, 12]. The use of a stratigraphic methodology (real or in "spits") may allow such sampling to be coordinated in a manner that will allow all samples to be gathered within a common spatial framework, allowing for greater integrity of results.

Mass Graves

Opinions vary as to what constitutes a mass grave, but essentially it is one that contains numerous individuals, sometimes hundreds, and is usually the result of genocide or civil war, although they can result from the hurried consequence of natural disasters. Their excavation tends to fall into two types: the recovery of evidence in order to obtain convictions for war crimes, or the need to recover individuals in order to obtain personal identification and facilitate repatriation to families. Mass graves resulting from genocide or civil war are discussed here. They have occurred in several parts of the world, but most notably in Africa, the Balkans, and the Middle East. They can pose problems other than simply of scale, often through political interference, cultural differences, lack of appropriate facilities and equipment, and unfamiliarity with archaeological processes by those nominally responsible for excavation. Archaeologists and anthropologists may be part of a team but may not necessarily be in a position to exercise control over the way bodies are recovered and treated. They may need to devise minimum standards with which they are comfortable and which can be presented and defended in court.

Mass graves tend to be identified from the air, or located on the basis of witness accounts. Concealment is not necessarily a high priority in regions where the government itself has carried out atrocities, although some are very deliberately shielded from international gaze, for example, by redeposition of rubble. Witness accounts are probably the most important methods since the same witness(es) may also provide evidence of the people responsible. Trial trenching, usually by machine, can be used to refine the specific location. Geophysics remains a useful technique, but requires a large background area against which the anomaly caused by the grave is visible. Given that many areas around mass graves are known to be mined, this is not always feasible. However, once the grave has been found, geophysics may be able to provide information regarding density or nature of deposition within the grave itself.

Mass graves tend to be dug and infilled by machine. As such, they tend to be of characteristic width (typically around 3 m, which is the width of a large machine bucket) and have a ramp at one end. Tire tracks may still be evident on the surface and, if the grave was also an execution site, there may be cartridge cases and other material to be recorded at the grave edge. Many such graves may be over 2 m deep and will necessitate consideration of collapse and flooding during excavation. Other hazards may include live ordnance, or devices planted in the grave by perpetrators, and possibly local hostility. Only in some cases are the victims laid out individually or bagged. In some instances of genocide the bodies are carried to the grave in wagons and tipped in by machine causing a series of discrete depositions of contorted and intermingled remains. Some graves are secondary, i.e., the bodies have been removed from a primary grave, and therefore may contain evidence of the primary grave itself, or even of an original execution site. The process of moving human remains by machine inevitably causes some body parts to become detached; it may also entail differential states of decay between individual machine depositions within the grave. The net effect is that the archaeologist can be required to separate out tightly compressed individuals from each other, while at the same time identify soil change, record artifacts and belongings, identify evidence for abuse, and maintain a comprehensive system of recording.

Given the varied states of decay and disassociation of remains, recording a mass grave can require a high degree of anthropological knowledge. It will almost certainly require a system that can record in three dimensions and log data simultaneously. One software system, for example, allows for the taking of points on the main joints of each individual, thereby creating "stick-people" who can be viewed and rotated as appropriate on the computer screen. This method can sometimes assist the relocation of body parts to individuals. The nature of a mass grave is such that the individual victims are the key

"artifacts" and therefore bespoke recording proformas are likely to be required. Individuals are numbered uniquely, and this number should remain with each individual from excavation to mortuary, via autopsy and any other sampling (e.g., for DNA), through to eventual reburial. The same number will be used for clothing and any other associated material (e.g., jewellery) or objects that may support presumptive identification. Recording will also need to be made *in situ* of blindfolds, cable ties, and other evidence of abuse in case these become detached in the recovery process. Record will also need to be made of other materials within the grave, for example, artifacts such as projectiles or cartridge cases, botanical remains that may have been transferred with the victims, and soils or geological traces that may also provide links between graves and the point of execution. Tire marks and machine teeth marks within the grave itself may provide evidence of type of vehicle, or even the specific vehicle used.

Arson Investigation: Misconceptions and Mythology

Introduction

This article explores the development and promulgation of the "mythology" of arson investigation. There is no reason to believe that anyone ever set out to promulgate something that was not true. It is likely that many myths came about as a result of unwarranted generalizations.

Some myths arose because of intuitively "obvious deductions". The notion that gasoline burns hotter than wood is an appealing one, as is the notion that a narrow V-pattern indicates a "rapid fire". The problem is that the term "rapid" is never defined, thus making it impossible, in many cases, to actually design an experiment to test a specific hypothesis about the significance of a particular fire artifact. Even when an artifact can be shown to be of no value by direct evidence, resistance to change and a culture of "circular citations" can allow the myth to persist.

Many of the myths were gathered by the Law Enforcement Assistance Administration (LEAA) and published in *Arson and Arson Investigation: Survey*

and Assessment [1], and although they were reported with appropriate cautionary language, on many occasions the cautions were not heeded. And when the "indicators" were listed by what should have been the ultimate authority, the cautions were lost. No less an authority than the National Bureau of Standards (NBS then – now National Institute of Standards and Technology NIST) published the *Fire Investigation Handbook* [2], which stated that crazed glass meant rapid heating, shiny alligator blisters meant that a fire burned "faster than normal", and narrow V's indicate "fast-developing, hot fires".

In the 1980s, one American text after another referred to the NBS publication or to another publication that cited the myths published in the LEAA report. These circular citations continued in books still in print. Interestingly, many of the myths never gained much credibility in the United Kingdom because the major "go to" textbook, Cooke and Ide's *Principles of Fire Investigation* [3], either did not repeat the myths or provided an accurate interpretation of the significance of indicators such as crazing and spalling.

In 1985, when the National Fire Protection Association (NFPA) Standards Council became increasingly concerned about the validity of fire investigations, it appointed a Technical Committee to address the issue. Seven years later, the Committee and NFPA produced the first edition of NFPA 921, *Guide for Fire and Explosion Investigations.* There was, perhaps predictably, resistance to this from some fire investigators. If what was printed in that document were actually true, it meant that hundreds or thousands of accidental fires had been wrongly determined to be incendiary fires. No investigator wants to admit to the possibility that they had caused an innocent person to be wrongly convicted, or a family to be wrongly denied their life savings.

In 1998, the Technical Committee on Fire Investigations, in response to public pressure, removed the word "misconception" from the titles of several paragraphs in the chapter on pattern development in the optimistic but mistaken belief that previous editions of the document, which were still not accepted in many quarters, had relieved the profession of these misconceptions.

The myths are slowly dying out (or being "Dauberted" out), but there are still practitioners who use them today. Examples of the continued promulgation and application of the mythology since 2000 are presented, as is the debunking of the myths as set forward in NFPA 921.

The Development and Promulgation of Myths

It is a failure to address a serious problem concerning the training and education of fire investigators that causes the myths to persist. The purpose of this article is to discuss those myths and, to the extent possible, attempt to understand why they came into being, and why some of them still persist.

No single reason exists to explain why a myth develops. No reason exists to believe that any investigator deliberately set out to promulgate something that was not true. It is likely that most myths originated as a result of unwarranted generalizations. For example, an investigator might observe that in a garage fire, a pattern of spalling surrounds the remains of a gasoline container and makes an association of gasoline with spalling. The next time he sees spalled concrete, he infers that gasoline must have been involved.

Paul Kirk, one of the leading forensic scientists of his time, wrote in the first edition of *Fire Investigation* [4] on examining melted metals.

> Whenever any residues of molten metal are present at the fire scene, they will reliably establish a minimum temperature for the point of their fusion in the fire. The investigator may use this fact to advantage in many instances, because of the differences in effective temperature between simple wood fires and those in which extraneous fuel, such as accelerant is present [4].

To this day, investigators sometimes infer the presence of accelerants when they observe a melted aluminum threshold.

The notion that crazed glass indicates that the glass was rapidly heated was appealing enough that Brannigan, Bright, and Jason, three respected fire researchers at the National Bureau of Standards (now NIST), published it in the Fire Investigation Handbook [2] Some authors have declared that crazed glass is sufficiently useful that the size of the crazing cracks can indicate proximity to the area of origin [5].

It is the unchallenged publication and continued promulgation of myths that ensures their longevity. If an "arson school" decides to use a text containing

the mythology in its training courses, hundreds of investigators can be exposed to this false "gospel". Those who take few refresher courses, fail to keep up with the literature, and those who attend few meetings may never be exposed to updated ideas and new research.

Much of the mythology about fire investigation was collected by the Aerospace Corporation, under a contract to the LEAA in a 1977 booklet entitled *Arson and Arson Investigation: Survey and Assessment.* To their credit, the authors of this survey pointed out, "Although burn indicators are widely used to establish the causes of fires, they have received little or no scientific testing." They recommended, "a program of carefully planned scientific experiments be conducted to establish the reliability of currently used burn indicators. Of particular importance is the discovery of any circumstances which cause them to give false indications (of, say, a fire accelerant)." In a remarkably prescient statement, they added, "A primary objective of this testing would be to avert the formidable repercussions of a court ruling on the inadmissibility of burn indicators on the grounds that their scientific validity had not been established." Despite this prediction, serious challenges to the myths did not become common until NFPA 921 was published. Part of the reason for the acceptance of the mythology may be that no less an authority than the National Bureau of Standards gave its blessing to many of the myths. In Section 1.1 of the *Fire Investigation Handbook*, which two National Fire Academy staffers are credited with contributing, most of the myths from the LEAA report were reprinted without a single caution of the type found in the original survey report. Having the imprimatur of such an august body as NBS, fire investigators and textbook authors believed (incorrectly as it turns out, but who knew?) that the myths had been scientifically tested.

The LEAA study provides a good basis for the study of the myths of fire investigation. Here is the list from the survey.

Alligatoring effect:

Checking of charred wood, giving it the appearance of alligator skin. Large rolling blisters indicate rapid intense heat, while small flat alligatoring indicates long, low heat. (This myth was repeated in the *NBS Handbook.*)

Crazing of glass:

Formation of irregular cracks in glass due to rapid intense heat – possible fire accelerant. (This myth was repeated in the *NBS Handbook.*)

Depth of char:

Depth of burning of wood – used to determine length of burn and thereby locate the point of origin of the fire.

Line of demarcation:

Boundary between charred and uncharred material. On floors or rugs, a puddle-shaped line of demarcation is believed to indicate a liquid fire accelerant. In the cross section of wood, a sharp distinct line of demarcation indicates a rapid, intense fire. (This myth was repeated in the *NBS Handbook.*)

Sagged furniture springs:

Because of the heat required for furniture springs to collapse from their own weight (1150 °F) and because of the insulating effect of the upholstery, sagged springs are believed to be possible only in either a fire originating inside the cushions (as from a cigarette rolling between the cushions) or an external fire intensified by a fire accelerant.

Spalling:

Breaking off of pieces of the surface of concrete, cement or brick due to intense heat. Brown stains around the spall indicate the use of a fire accelerant [1].

In addition to the misconceptions listed in the LEAA report, the following myths have also been widely promulgated:

Fire load:

Knowing the energy content (as opposed to the energy release rate) of the fuels in a structure was believed to allow an investigator to calculate the damage that a "normal" fire should produce in a given time frame.

Low burning and holes in the floor:

Because heat rises, it was widely believed that burning on the floor, particularly under furniture, indicated its origin on the floor.

V-pattern angle:

The angle of a V-pattern was supposed to indicate the speed of the fire. (This myth was printed in the *NBS Handbook.*)

Time and temperature:

By estimating the speed of a fire, or establishing the temperature achieved by a fire, it was believed that an investigator could determine whether it was accelerated.

The Overarching Myth

Before the discussion of the individual indicators used to determine whether a fire behaved "normally", we first consider the myth that makes all the rest of the myths plausible. This is the notion that accelerated fires burn at a higher temperature than unaccelerated fires. It is true that accelerated fires burn with a higher heat release rate (*see* **Fire: Dynamics and Pattern Production**) but there is no measurable difference in temperature.

A corollary myth about accelerated fires is really about accidental fires. Accidental fires generally start small and slow. The myth is that even after a slow smoldering fire makes the transition to flaming combustion, it remains small and slow. This is simply false, as anyone who has watched a small cigarette fire on a piece of upholstered furniture can attest. After making the transition to flaming combustion, the sofa or chair can release sufficient energy to bring a room to flashover in less than 5 min [6].

Many of the myths about fire investigation were addressed in the first two editions (1992 and 1995) of NFPA 921. In the chapter on fire patterns, there were several paragraphs entitled "Misconceptions about … (char, spalling, V-patterns, inverted cone patterns)". While the Technical Committee felt it important to shine a spotlight on these myths, many in the fire investigation community railed against the notion that any investigator had ever harbored any misconceptions about anything. They insisted, and the committee acquiesced to a change in the 1998 edition, that section titles be changed to "Interpretation of …", as if removing the word "misconception" would remove the misconception.

Alligatoring

The *Fire Investigation Handbook* contains some useful information, but it starts out with a myth-filled chapter on how to determine origin and cause [2]. Chapter 1 of the *Handbook* states:

> In determining whether the fire was a slowly developing one or a rapidly developing one, the following indicators may be used: a) Alligatoring of wood – slow fires produce relatively flat alligatoring. Fast fires produce hump-backed shiny alligatoring.

The 1982 [7] International Fire Service Training Association (IFSTA) smanual unequivocally states:

> If alligatoring is large, deep, and shiny, the fire spread extremely rapidly. Large alligatoring should be considered an indication of the nearby presence of a flammable or combustible liquid.

Nowhere it is stated what is the difference between a "fast" fire and a "normal" fire. The lack of a definition of these subjective words not only renders the "indicators" of a fire's progress meaningless but also makes it nearly impossible to design an experiment that tests the indicator's usefulness. The U.S. Army's Field Manual 19–20, *Law Enforcement Investigations* [7] provides a slightly different interpretation of alligatoring when it states:

> When wood burns, it chars a pattern of cracks which looks like the scales on an alligator's back. The scales will be the smallest and the cracks the deepest where the fire has been burning the longest or the hottest. Most wood in structures char at the rate of 1 inch in depth per 40 to 45 minutes of burning at 1400° to 1600° Fahrenheit – the temperature of most house fires. *(Thus combining three misconceptions in a single paragraph!)*

O'Connor's *Practical Fire and Arson Investigation* [9] stated:

> Deep alligatoring (large rolling blisters) on an exposed wooden surface ordinarily indicates an intense, rapidly moving body of flame. This condition may be associated with the use of an accelerant.

The second edition of the book (1997) is far more cautious, the authors having apparently become aware if the new scientific understanding of this subject [10]. The newer text states:

> It has been suggested that the presence of large shiny blisters (alligator char) and the surface appearance

> of char, such as dullness, shininess or colors have some relation to the presence of liquid accelerant as the cause, but no scientific evidence substantiates this. The investigator is advised to be very cautious in using wood char appearance as an indicator of incendiarism.

They have not completely given up, however. The 1997 text shows a photo of "a heavy rolling char . . . caused by the rapid intense movement (extension) of heat and flame."

Randall Noon, in his 1995 *Engineering Analysis of Fires and Explosions*, wrote:

> In the same way that a hunting guide interprets signs and markers to follow a trail of game, a fire investigator looks for signs and markers which may lead to a point of origin. For example, a fast, very hot burn will produce shiny type wood charring with large alligatoring. A cooler, slower fire will produce alligatoring with smaller spacing and a duller appearing char.

Noon then goes on to explain "scientifically" why this should be so [11].

> As heat impinges on the piece of wood, the water in the surface material will evaporate and escape from the wood. The rapid loss of the water at the surface is also accompanied by a rapid loss of volume, the volume which the water formerly occupied. The wood surface then is in tension as the loss of water causes the wood to shrink. This is the reason why wood checks or cracks when exposed to high heat or simply dries out over time. Of course, if the heat is very intense, more of the water "cooks" out, and the cracking or alligatoring is more severe.

The scientific-sounding explanation, although groundless, is the kind of exposition in many books that repeat the myths and has enhanced their credibility and thus their longevity.

The final word on this and most other myths may be found in NFPA 921. Here is what it says about alligatoring:

> **6.5.5 Interpretation of Char.** The appearance of the char and cracks has been given meaning by the fire investigation community beyond what has been substantiated by controlled experimentation. It has been widely stated that the presence of large shiny blisters (alligator char) is proof that a liquid accelerant was present during the fire. This is a misconception. These types of blisters can be found in many different types of fires.
>
> There is no justification that the appearance of large, curved blisters is an exclusive indicator of an accelerated fire. Figure 6.5.5, showing boards exposed to the same fire, illustrates the variability of char blister.
>
> **6.5.5.1** It is sometimes claimed that the surface appearance of the char, such as dullness, shininess, or colors, has some relation to the use of a hydrocarbon accelerant or the rate of fire growth. There is no scientific evidence of such a correlation, and the investigator is advised not to claim indications of accelerant or fire growth rate on the basis of the appearance of the char alone.

The referenced figure is a photograph taken by Monty McGill, which was first shown in *Kirk's Fire Investigation, Second Edition*. It is the definitive evidence that debunks the myth of the shiny alligator. (In the United Kingdom, the term *"crocodiling"* is more widely used.) Figure 1 shows a fire damaged wood wall that exhibits three different kinds of alligatoring, all the result of exposure to the same fire.

Crazed Glass

The *NBS Handbook* stated, "Window glass fragments in large pieces with heavy smoke deposits usually indicate slowly developing fires. Crazed or irregular pieces with light smoke deposits indicate a rapid buildup of heat" [2]. Both statements are false, but crazing is our focus for now.

The Army's Field Manual, *Law Enforcement Investigations*, states, "As a general rule, glass that contains many cracks indicates a rapid heat buildup. Glass that is heavily stained indicates a slow, smoky fire" [8].

IFSTA's *Fire Cause Determination* [12] stated:

> A window with small crazing (minute cracking), and perhaps with light smoke accumulation, is probably near the point of origin, its condition suggesting intense and rapid heat buildup. Large crazing and a heavy smoke accumulation suggest slow heat buildup and remoteness from the point of origin.

The IFSTA manual may have been the source used in *Practical Fire and Arson Investigation*, [13, 14], which repeats the notion that crazing implies a "rapid and intense" heat buildup and that if the crazing is "small", it is close to the area of origin. A larger crazing pattern, on the other hand, "implies that it may have been located in an area some distance away

Figure 1 Burned wooden wall exhibiting char blisters (alligatoring) of different sizes and different levels of gloss, all as a result of exposure to the same fire

from the point of origin." The misconception about crazing follows an extensive discussion of the types of glass that an investigator may encounter, complete with softening points, chemical compositions and applications. The reader thus is led to believe that the writers know all about glass.

In a series of laboratory experiments conducted by the author, it was conclusively demonstrated that crazing is never caused by rapid heating and can only be caused by rapid cooling [15]. The glass shown in Figure 2 was heated slowly to about 500 °C (932 °F), and then treated with water. It was possible to actually "write" in the glass using a wet cotton swab.

It is interesting to note that crazing of glass as an indicator of rapid heating is a myth that never gained much credibility in the United Kingdom. This is almost certainly because in the United Kingdom, the most widely read fire investigation text, *Principles of Fire Investigation,* correctly identified "the appearance of many small conchoidal fractures on one surface of the glass", as being the result of rapid cooling from extinguishment water [3]. The authors of that text did not use the term "*crazing*". The absence of the crazing myth in the United Kingdom lends credence to the proposition that it is publication in apparently respectable texts that is

Figure 2 Author's initials written in crazed glass by applying water on a cotton swab to hot glass. The area of crazing at the lower left was caused by the application of water from a spray bottle

responsible for the perpetuation of the mythology of arson investigation.

Depth and Location of Char

In 1979, Aetna Life & Casualty [16] published a brochure-style handbook, authored by John Barracato, who was hired by Aetna after a long career as a fire investigator for the City of New York. This pamphlet espoused as many myths as any publication ever printed on the subject. On the subject of depth of char, the booklet entitled *fire . . . is it arson?* states:

> The speed at which a fire burns is an important indicator of its cause. A fire not involving accelerant (such as gasoline or other flammable liquid) burns at the rate of 3/4 inch per hour into pine wood. The investigator should ask the fire department how long and intensely the fire burned, then carefully inspect any charred wood to see if there is a reasonable correspondence between the length of time the fire burned and the degree of damage it caused.

Exactly this type of analysis was put forward in the case of *Commonwealth v. Han Tak Lee* [17]. The investigator in that case made the following observations:

(a) the fire burned for a total of 28 min;
(b) fire burns 1 in. in 45 min (note: this is a more commonly cited charring rate than Barracato's 3/4 in. h^{-1}); and
(c) 2 by 10 s, were completely consumed.

Therefore, the fire must have been accelerated because it would take 4.5 h to burn through a 2 by 10. This of course, assumed that the fire would only burn in one dimension, as opposed to attacking the wood from both sides. He estimated the time required to burn a 2 by 4 at 1 h 43 min at 1780 °F [17]. The investigator was misled by two myths, one is that the depth of char could be used to determine reliably the time of burning, and two is a uniquely-held belief that only one side of the wood would be attacked by the fire. If we assume, for the sake of argument, that fire burns 1 in. in 45 min, then it should take only 34 min to burn through a 1 1/2 in. piece of wood, assuming it is attacked from both sides. This investigator had both his premise and his implementation of that premise wrong. NFPA 921 unequivocally states that depth of char measurements should not be relied on to determine the duration of the burning [18].

Lines of Demarcation

This is one of the more complex myths in fire investigation because, in some instances, lines of demarcation can be used to tell exactly what happened, whereas in other instances, lines of demarcation are just lines. The threshold question is whether the compartment where the lines occur experienced full room involvement. Let us be clear. There are times when a fire pattern is so obviously caused by an ignitable liquid that further analysis truly is "the icing on the cake". Figure 3 shows just such a situation. Once a fire progresses to the full room, however, it is no longer valid to make a determination using visual clues alone, and there are some who maintain this should never be done. Sharp, continuous, irregular lines of demarcation between burned and unburned areas are frequently cited as evidence of the use of ignitable liquids. It is true that ignitable liquids can produce such patterns on carpeting, and many arson seminars include staged fires that are extinguished early, so that investigators can learn to recognize "pour patterns". What is not evident from these incipient test fires is what happens after the room becomes fully involved.

Lines of demarcation can occur for no apparent reason. The intensity of radiation falls off as the square of the distance from the source to the target, so at some point, perhaps a sharply defined point, insufficient energy exists to maintain combustion. This property, as well as the random nature of some burning, can result in sharp lines of demarcation. The fire pattern shown in Figure 4 is an example of one that is subject to misinterpretation. No ignitable liquids were used to set the test fire, yet there are "sharp continuous, irregular lines of demarcation

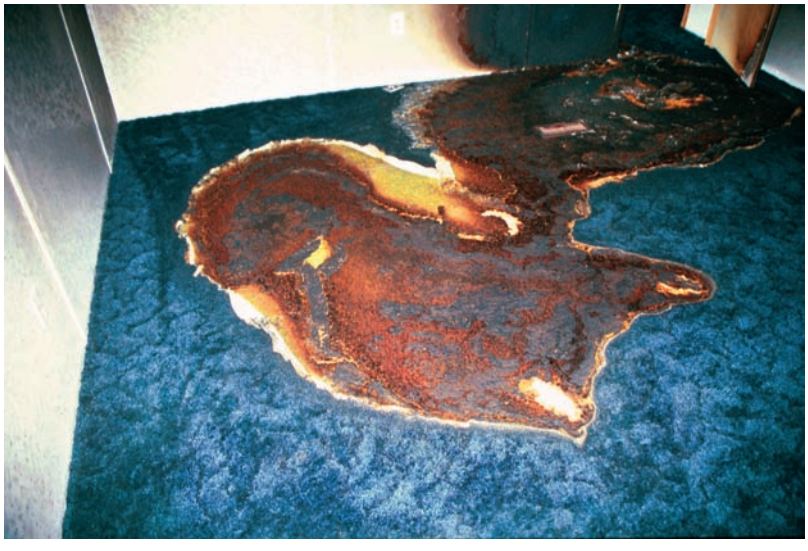

Figure 3 A rare case of an "obvious pour pattern". Only the carpet burned. There was no other fuel present. The carpet shows a "doughnut" pattern, and a sample of the carpet tested positive for the presence of a medium petroleum distillate

Figure 4 A hole in the floor and an irregular fire pattern produced by a test fire in which no ignitable liquids were used

between burned and unburned areas". There is even a hole burned through the floor, and there are still those who argue (incorrectly) that a fire will not burn downward without "help". A naïve person could be easily persuaded that this pattern was created by ignitable liquids burning on the floor. Illustrating the photograph with lines and labels makes it even more convincing, as shown in Figure 5.

Protection patterns can be produced by irregularly shaped pieces of gypsum drywall, which fall from the ceiling and provide protection to whatever floor they land upon. Clothing on the floor has also been known to produce alternating areas of exposure and protection. Figure 6 shows a protection pattern that might, if not carefully examined, be called a "*trail*". Such patterns are not uncommon in residences where the house is not tidy.

In a ground-breaking study of burn patterns caused by burning pools of gasoline and kerosene, Putorti demonstrated that even on wood and vinyl floors, the

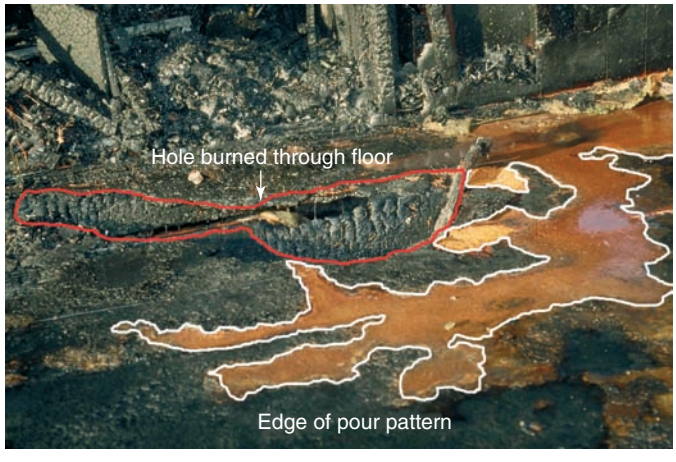

Figure 5 The same fire pattern seen in Figure 4, but annotated to show convincingly, albeit incorrectly, that the pattern was created by pouring ignitable liquid on the floor

Figure 6 "Trailer" pattern created by clearing a path through clothing on the floor of a mobile home burned in a test fire. Close examination of the edges of the pattern reveals the true nature of the sharp lines, but the pattern has the appearance of a trailer. The key to distinguishing real trailers lies in understanding that the unburned sides of the trail should have been burned in this fully involved compartment. Rather than trying to explain the burning, the investigator should explain the lack of burning. In this fire, the only valid explanation is that something protected the unburned areas

edges of the patterns produced are not necessarily sharp [19]. The only definitive pattern he found that could reliably be associated with the use of ignitable liquids was the "doughnut" pattern on carpeting, caused by protection at the center of the pattern by the presence of liquid fuel that had not yet evaporated.

Lines of demarcation in the cross section of charred wood have been cited since 1980 as an indicator of the speed of a fire. The *Fire Investigation Handbook* stated, "A distinct line between charred and uncharred portions indicates a rapidly developing fire. Lack of a distinct line usually indicates a slow cooking process, thus, a slowly developing fire" [20]. O'Connor [13] and O'Connor and Redsicker [14] both provide a diagram of a cross section of a piece of lumber showing a sharp line of demarcation indicating a rapid spread, and a gradual line of demarcation indicating a slow-burning fire. DeHaan [21] states, "One indicator that is more reliable [than the surface appearance of char] is the appearance of the charred wood in cross section. When a charred beam is cut crosswise, the gradation between the charred layer and the underlying undamaged wood is more gradual with a slowly developing fire." He then goes on to provide a perfectly reasoned analysis of why this should be so, but like O'Connor, provides neither data (though he also provides a drawing) nor a definition of what is meant by "sharp", "gradual", "fast", or "slow". DeHaan cautions that a fast-developing fire may or may not be accelerated. Nonetheless, this is the type of "data" that an investigator may use to incorrectly "eliminate" a smoking fire, since smoking fires are not "fast-developing". (Actually, once a smoldering fire started by a cigarette makes the transition to flaming combustion, the speed of fire growth is not distinguishable from a fire ignited by an open flame.)

Some of the more frequently debated sections of NFPA 921 deal with determinations made by observing lines of demarcation. While it is silent on the observation of cross sections, the document contains a whole section devoted to caution in the interpretation of burn patterns on the floor. NFPA 921 contains more cautions on this subject than on any other. The reason for the abundance of cautions on the subject of interpreting lines of demarcation is simple – the errors caused by this particular misinterpretation have been legion.

Sagged Furniture Springs

This myth has been subjected to different interpretations. The Aetna booklet f*ire ... is it arson?* [16] advised fire investigators to photograph furniture springs, "because their appearance can help the investigator to document the area of origin. Severely sagging springs can indicate that a flammable liquid was involved and created heat intense enough to cause the springs to sag" [22]. Carter, on the other hand, writing in *Arson Investigation* [23] stated that collapsing all or part of a coil spring showed the indication of a cigarette that caused the fire.

In the Han Tak Lee case, smoking in bed was ruled out because the bedsprings had lost their temper. Clearly, this is an area of much confusion. In 1989, Tobin and Monson, two Federal Bureau of Investigation (FBI) laboratory scientists, subjected furniture springs, both loaded and unloaded (with and without weights on them), to different fire conditions, and basically concluded that the condition of the springs is of little probative value in fire investigation [24]. DeHaan correctly states that varying degrees of spring damage can provide some insight into the progress of a fire, but cautions that the collapse of springs cannot be reliably used to determine whether a fire was incendiary [25]. NFPA 921 states that the value of analyzing the furniture springs is to compare the differences in the springs to other areas of the mattress, cushion, or frame. Comparative analysis of the springs can assist the investigator in developing hypotheses concerning the relative exposure to a particular heat source.

Spalling

There exists no more misunderstood and misused indicator than concrete spalling. It has been the pivotal "indicator" in many major fire cases, and has been the subject of numerous contentious articles in the *Fire and Arson Investigator*. To this day, arson cases are made on the basis of spalled concrete. Kennedy's *"Blue Book"* [26] had the following comments on spalling:

> Spalling caused by flammable liquids burning is usually found at low levels because the flammable liquid vapors are heavier than air and tend to go down.
>
> ... Regardless of the composition of the concrete or brick, the indicator is the spalled area or areas indicating the burning of accelerants ....
>
> ... The spalling temperatures are usually much higher than the temperatures found in the normal dwelling or commercial building fire. Therefore, we know that accelerants were used.

IFSTA's *Fire Cause Determination* [27] provided the following statement on spalling in 1982:

> Concrete floors and assemblies that have spalling should be examined closely. The spalling may be an indicator of the use of accelerants. If the accelerants had adequate time to soak in before ignition, the spalling will follow the flow pattern of the liquid. Spot spalling is not a clear indicator of the use of accelerants. Further, it is not unusual for spot spalling to result from severe fire exposure.

This semi-cautious language is typical of what has been written about spalling. Skeptics have always questioned the relationship between ignitable liquids and spalling. These include Harvey French in 1979, Fred Smith and Jack Mitchell in 1981, Bruce Ettling in 1984, Charles Midkiff in 1990, and Bernard Beland 1993. Some fire investigators simply ignored all these skeptics, and ploughed on with their case-making.

One of the largest insurance bad faith awards in Alabama history was the result of a fire investigator, who relied on a "trail of spalling" in addition to other "indicators" to conclude that the cause of the fire was arson. It did not help that the fire chief testified that he stood on the "trail" before the fire reached the basement. Nor was the court impressed with the shape of the "trail" when it learned that its shape resulted from the investigator shoveling a trail. When the slab was completely cleared, it was found that the entire slab had spalled, and no "trail" of any kind had ever existed [28].

Fire investigators have argued endlessly about the characteristics of an accelerant-induced spall versus a naturally occurring one. A brownish, or pinkish halo around the hole was thought to indicate the presence of burning hydrocarbons. Numerous slides and photos were exchanged, but in the end, the consensus was that the skeptics were right. It is actually quite simple to cause spalling without ignitable liquids. A stack of oak pallets ignited with newspaper on a concrete slab will almost invariably cause the explosive destruction of the surface through spalling. Even the most diehard defenders of spalling as an indicator of accelerant use would be unlikely to claim that the spalling shown in

Figure 7 Deep spalling on the ceiling of a parking garage

Figure 7 on the ceiling of a parking garage was the result of flammable liquids burning on the ceiling.

Cook and Ide [3] reported that the color change was probably the result of the dehydration of yellow colored hydrated iron oxides, which turned pink or reddish brown approximately at 300 °C.

Most of the writings on spalling today wishfully refer to misconceptions that were formerly held. NFPA 921 has, since its inception, warned about misinterpreting spalling. Overall, 921 states that the importance of spalling to the fire investigator lies in the documentation and analysis of a heat source.

Fuel Load

In one of the early attempts to bring a quantitative approach to the practice of fire investigation, French [29] described a method by which a fire investigator could determine whether the fire behaved in a "normal" manner. He described the process as follows:

> The heat energy production of fuels is extremely important to any competent fire investigator in determining fire load in the premises or equipment under investigation, again in respect to its potential in affecting temperature rise and spread and the time spectrum . . . .
>
> Fire load of any given space may be established by knowing the type of combustibles in storage, their calorific heat producing capacity in Btu's per lb., the total weight of the combustibles in storage, and the square-foot capacity of the space.
>
> The formula is as follows: multiply the calorific contents in Btu's per lb. by the total weight of the contents or materials in pounds. Then, divide the result by the area in square feet. The answer is fire load per square foot.
>
> National Bureau of Standards and American Standards as well as the National Fire Protection Association and British time/temperature curves are in general agreement as to what temperature rise may be expected in various occupancies, with known fire loads, particularly during the first two hours of combustion.
>
> For example, with sufficient oxygen to support continuing combustion, fires in buildings may be expected to attain 1000 to 1200 °F during the first 5 to 10 minutes, accelerating on the curve to approximately 1500 °F in the first half hour and with temperatures reaching the order of 1700 °F at one hour.

Carroll, writing in *Physical and Technical Aspects of Fire and Arson Investigation*, adopted a similar approach, but instead of fire load, he urged investigators to use the flame-spread index described earlier in his text [30]. The vaguely defined process was described in two paragraphs as follows:

> Using this flame spread index (available from Underwriters Laboratories, Inc.), a fire investigator can

determine the comparative rate of how fast a fire should or should not have spread under normal circumstances by comparing the burning rates of known fires and the standard ASTM (American Society of Testing and Materials) time/temperature fire exposure chart shown in Figure 10.

Figure 10 shows the temperature acquired as a function of time, which has been found to be the average temperature 8 feet off the floor.

Carroll also wrote, "By knowing the fire load of the building, i.e., the material available for the creation of heat, a reasonable approximation of the highest temperatures attained can be made and compared with temperatures to be expected had an accelerant been used."

Neither Carroll nor French understood that the "standard time/temperature curve" had nothing to do with the behavior of any fire. The standard time/temperature curve describes the way in which a furnace should be operated in order to compare the fire resistance of various building assemblies. Unfortunately, for many fire victims, including Han Tak Lee in Pennsylvania, this approach resulted in numerous determinations of a fire behaving "abnormally", and this in turn resulted in wrongful prosecutions and convictions.

This particular misconception about fire behavior did not receive as much acceptance as some of the other myths, possibly because it involved mathematics. There were enough practitioners using this "quantitative" approach; however, that the NFPA Technical Committee on Fire Investigations felt the need to address the issue in NFPA 921 in the chapter on basic fire science:

5.4.1 General. The term fuel load has been used to indicate the potential severity of a fire and has been expressed in terms of Btu (British thermal unit) or pounds of fuel per square foot of floor area. An example is provided in 5.4.1.1.

5.4.1.1 The Btus were expressed in wood equivalent based on 8000 Btu per pound. The fuel load was determined by weighing the fuel in a room and converting the weight of plastic to 2 pounds of wood using 16 000 Btu per pound as a value for plastic (1 pound of plastic equals 2 pounds of wood). The total Btus (or pounds of fuel) were divided by the area of the room floor. While this approach can be a measure of the total available if all the fuel burns, **it does not depict how fast the fire will develop once it starts.** *(Emphasis added).*

5.4.1.2 The rate of fire growth as determined by witness statements is highly subjective. Many times witnesses are reporting the fire growth from the time of discovery, which cannot be directly correlated to ignition time. The rate of fire growth is dependent on many factors besides fuel load, to include fuel configuration, compartment size, compartment properties, ventilation, ignition source, and first fuel ignited. The rate of fire growth as reported by witnesses is not reliable or supported independent evidence of an incendiary fire.

5.4.2 Heat Release Rate

5.4.2.1 Total fuel load in the room has no bearing on the rate of growth of a given fire in its preflashover phase. During this period of development, the rate of fire growth is determined by the heat release rate (HRR) from burning of individual fuel arrays. The HRR describes how the available energy is released. This quantity characterizes the power – energy released per unit time (Btu/sec or kilowatts) – and is a quantitative measure of the size of the fire. A generalized HRR curve can be characterized by an initial growth stage, a period of steady-state burning, and decay. The largest value of the HRR measured is defined as the peak heat release rate.

These values should only be considered as representative values for comparison purposes. Fuel items with the same function (e.g., sofas) can have significantly different HRRs. The actual heat released rate for a particular fuel item is best determined by test.

Despite this warning about fuel package variability, some allegedly scientific fire investigators insist on their right to estimate the HRR of an item of furniture, and then opine whether it will have sufficient radiant energy to ignite a nearby item. Usually the estimate is at the low end of the HRR scale, which may range from 500 to 2 500 kW for an armchair for example. The investigator then "deduces" that because the fire did spread, there must have been multiple points of origin.

Low Burning and Holes in the Floor

A common misconception is that because heat rises, fire burns up and out and will not burn downward unless it has "help".

In Carroll's [30] text, he discusses multiple low points and states, "The discovery of a low point should not be considered at the end of the search, since more than one low point may be discovered. This is particularly true in arson fires." He states further that, "Every effort should be made to determine whether multiple low spots are accidental or deliberate. If they have been set in an incendiary effort, these would be considered as evidence of arson."

Carroll states, "Significant differences in char depths at two different low points would indicate an accidental low point" [31]. If the low points or holes in the floor are all about equally charred, the use of multiple holes to indicate multiple points of origin could arguably be justified by referring to this treatise.

The IFSTA manual, *Fire Cause Determination*, espoused a similar misinterpretation when it stated, "Low levels of charring are good indicators of a flammable liquid having been used. For example, accidental fires are unlikely to burn the bottom edge of furniture or the bottom edge of the door" [32].

The Army's Field Manual [33] succinctly restates the popular myth

> Liquid accelerants leave evidence of low burn. That is, they show burning on the floor of the structure. A normal fire chars only the upper portion of a room. Floor damage in natural fires is usually limited to about 20% of the ceiling damage. Low burn, shown by complete charring of large areas of the floor or the baseboards, is not natural.
>
> Nor is fire burning downward natural. Fire burning downward is a prime indicator of the use of a flammable accelerant. Patterns burned in wood floors or holes in a floor may show that an accelerant was used.

Kirk [34] was one of several workers who disagreed with the notion that holes observed in a burned floor necessarily indicated the presence of an ignitable fluid. In 1969, he wrote:

> In many instances, the lowest burn is a floor surface or region directly under a floor. These points are sometimes difficult to evaluate and often lead to error in interpretation. For example, there is a hole burned in the floor in a region away from any walls or other objects that could carry a fire upward by providing fuel in the path of the flames. It is not uncommon for the investigator to assign the cause to the use of a flammable liquid. Such an interpretation is more often incorrect than otherwise. On a tight floor, it is always incorrect, unless holes or deep cracks are present. **Lacking such conditions, flammable liquids never carry fires downward.** (*Emphasis in the original*).

This important point was apparently lost by the investigator who testified that he was able to discern nine separate points of origin in the room shown in Figure 8. The ceiling and roof over this room were entirely consumed, but the investigator saw no connection between the holes burned in the floor. Numerous other myths were introduced in this 1989 criminal prosecution [17].

NFPA 921 has dealt with this myth in a straightforward admonition:

> **6.17.2.2**. Like other areas of low burning, holes in the floor can be produced by the presence of ignitable liquids, glowing embers, or the effects of flashover or full room involvement.

It is this warning in NFPA 921 that drew the ire of many fire investigators who believed they had been properly trained to recognize artifacts indicative of the use of liquid accelerants, even in fully involved compartments. There is no doubt that they had been trained, but that training had no validity.

The Angle of the "V"

The "V" angle myth has been published by many authors. It goes like this: The sides of a "normal" conical fire plume are angled 15° from vertical. The faster a fire burns, the slower it will spread laterally and the closer the angles will be to vertical. Conversely, the slower a fire burns the further the angle will tilt from vertical. Like most of the myths presented in this article, no scientific support exists for this myth; however, it is a deceptively appealing notion. The *NBS Fire Investigation Handbook* stated that the V-pattern should be examined to determine whether the fire was a slowly developing one or a rapidly developing one. Without defining rapid and slow, the intent was apparently to let the indicator do the defining [20]. The authors stated:

> Fire patterns – a wide or diffuse V pattern generally indicates a slowly developing fire. A narrow sharply defined V pattern generally indicates a fast developing, hot fire.

The U.S. Army's (1985) [8] *Field Manual* states:

> Fire burns up and out. It leaves a V-shaped char pattern on walls and vertical structures. A fire which is hot and fast at the point of origin will leave a sharp V pattern. A slow fire will produce a shallow V.

The new, allegedly updated, Army *Field Manual* [35] repeats the same misinformation.

Carroll [36] took a more quantitative approach, at least as far as the angles were concerned:

Figure 8 Fire pattern on a floor allegedly showing nine separate points of origin. The investigator also opined that 60 gallons of liquid accelerant were applied to the floor, though the laboratory tests all came back negative

> A normal fire, consuming wood, plastic or electrical insulation, would burn with a "V" pattern of approximately 30° measured vertically. If an accelerant was used, or if highly combustible material was involved, the "V" would be narrower as the temperature of the fire increased, due to the additional heat content of the accelerant or flammable liquid. This would cause a faster rise of heat and flame, resulting in a "V" pattern of approximately 10° depending on the heat flux generated by the accelerant.

Noon [11] devotes an entire section of his book to burning velocities and V patterns. This discussion is accompanied by equations to help the investigator determine the ratio of the upward burning rate to the lateral burning rate by finding the tangent of the angle of the V.

O'Connor [13] and O'Connor and Redsicker [14] repeat the story:

> The breadth or width of the V (also called the *funnel pattern*) is affected by (and hence, indicative of) the buildup, progression, speed and intensity of the fire. An intense rapidly moving fire produces a narrow the pattern whereas a slow, less intense fire produces a wide V pattern. The angles of the boundaries average between 10 and 15°.

In the third edition of *Kirk's Fire Investigation*, DeHaan urged caution in the interpretation of the pattern angles when he stated, "Although it is sometimes claimed that the more vertical the sides of the V, the faster the initial fire (and therefore the more suspicious), one can appreciate that the nature of any wall covering and conditions of ventilation have important effects on the shape of the pattern, and must be taken into account" [37]. By the fourth edition, he came right out and said, "The angle and width of the V are not dependent on the rapidity of ignition of the fuel" [38].

Since it was first published in 1992, NFPA 921 has contained a section on the interpretation of V patterns, and describes the equation of angles with speed as a "misconception". The current (2004) edition makes the following statement:

> **6.17.2.2.** The angle of the borders of the V pattern does not indicate the speed of fire growth; that is, a wide V. does not indicate a slowly growing fire, or a narrow V does not indicate a rapidly growing fire.

It is therefore surprising that when the U.S. Army revised their *Field Manual* in 2005 and stated that the revision contained information from NFPA, they would continue to include the V angle myth despite

the fact that NFPA 921 had disparaged this myth through five editions over 13 years.

Time and Temperature

A fire that burns "hotter than normal" or "faster than normal" is thought to indicate an accelerated fire. Actually, fire temperature and the perceived speed of the fire are not valid indicators of a fire's cause.

A major misconception underlying many false determinations of arson is that the temperature achieved by a particular fire can help an investigator to evaluate whether a fire was "normal" or "abnormal", with an abnormal fire being attributed to incendiary activity. Higher than "normal" temperatures indicate that a set fire is such an appealing notion that even Paul Kirk appeared to agree with the concept, as previously discussed. To this day, investigators sometimes infer the presence of accelerants when they observe a melted aluminum threshold.

Kennedy [39], discussing the melting of copper, wrote:

> Copper fuses at 1980 °F, which is very high. Therefore, if we find fused copper or beaded copper wires, we are immediately alerted because we have an unusually high temperature that must be explained. The normal burning of a structure would not cause temperatures in the 2000 °F range, which is necessary to fuse or melt copper.
>
> What could cause copper to fuse or melt? The burning of an accelerant such as flammable liquids, natural or LP gases or electrical shorts or arcing are some of the causes for "high heat" – meaning excessive temperatures.

Barracato [40] summed up the time and temperature equation as follows:

> Fires which burn through entire floor sections, destroy large support beams in a relatively short period of time, or melt articles located in the area of origin such as metal, copper, aluminum or glass, are unusual. It takes tremendous heat to cause such damage and unless there is a rational explanation for the heat buildup – for example, if the room was used to store a highly flammable material – it's very probable that the fire was intentional and an accelerant was used.

Carroll, as discussed previously under "fire load", presented the standard time/temperature curve from ASTM E119, *Standard Test Methods for Fire Tests of Building Construction and Materials*, and stated that it can be used as a basis in comparing the burning rates in structures. Carroll also stated, "if accelerant or other chemicals are present, temperatures can reach higher than on the standard fire curve" [41].

On the basis of the research that began in the late 1970s and continues until today, it is now well understood that there is no valid definition of "normal" fire spread and also that the ASTM time/ temperature curve has little relationship to the behavior of a "normal" fire.

In the second edition of *Kirl's Fire Investigation* [38], DeHaan somewhat moderated Paul Kirk's enthusiasm for interpreting melted metals, but still left readers with the suggestion that an abnormal fuel load, such as provided by an accelerant, will increase temperatures [42].

Although the third, fourth, and fifth editions of *Kirk's* include a discussion of the fact that gasoline burns at essentially the same temperature as wood, it still states that temperature can be used to determine the presence of "enhanced draft conditions or unusual fuel loads", when the data support only the former. Nonetheless, the modern text of *Kirk's* at least recognizes that increased ventilation causes increased temperatures.

NFPA 921, beginning with the first edition and continuing until today contains an admonition about placing too much stock in the perceived temperature of a fire. In the 2004 edition of the document, both temperature and speed of the fire are addressed, and investigators are warned to be cautious when interpreting temperature and speed. The following statement appears:

> **6.8.2.2** Wood and gasoline burn at essentially the same flame temperature. The turbulent diffusion flame temperatures of all hydrocarbon fuels (plastics and ignitable liquids) and cellulosic fuels are approximately the same, although the fuels release heat at different rates.

The speed at which a fire progresses is frequently used to imply that the fire is incendiary. While it is true that an accelerated fire burns faster than an unaccelerated fire, at least in its initial stages, serious caution is required when confronted with information about how rapidly a fire spread. Most observations about the "speed" of a fire are provided by eyewitnesses, but there have been reported instances of an investigator looking at a destroyed structure and by knowing the time from alarm to extinguishment,

opining that the amount of destruction could not have occurred in that timeframe unless the fire had "help". These conclusions are usually based on the misconception that the wood has a fixed burning rate, such as the often quoted "1 in. in 45 min".

A study by the editors of *Fire Findings*, published in 1995, revealed that witnesses might make very different observations about a fire, even if their sightings are only a few minutes apart [43]. This study, which involved the actual burning of a two-story house, resulted in the findings that fires may only appear to start rapidly and tended to dispel the widely held (but incorrect) belief that if a fire appears to start quickly, accelerants must have been involved. If an eyewitness only notes the existence of a fire at the point where it breaks out a window, the progress thereafter will be rapid indeed, regardless of the cause.

In the fifth edition of *Kirk's Fire Investigation*, DeHaan published a time/temperature curve for a fire in a "typical furnished room" with no accelerants that shows flashover occurring just 210 s (3.5 min) after ignition. This curve looks nothing at all like the "standard time/temperature curve" from the ASTM test method [21].

Thus, while it is true that accelerants tend to make fires burn more rapidly, a rapidly burning fire does not necessarily indicate the presence of accelerants.

Conclusion

Fire investigation involves the comparison of the investigator's "expectations" with his perception of the behavior of the fire. If those expectations are not properly "calibrated", the result will be numerous errors. In the seventeenth century, when the scientific community was first getting organized, it was understandable that misconceptions about fire, such as the phlogiston and caloric theories, should exist. What is surprising is that after three centuries of scientific examination of fire, myths have been added rather than dispelled.

Many of the myths have been taught to the individuals who are now in control of the fire investigation industry. These myths were promulgated by the National Fire Academy and by other entities involved in the training of fire investigators, and given the stamp of approval of one of the most prestigious and credible US government agencies. To date, the misinformation has not been officially repudiated or "recalled". While most responsible training organizations no longer teach the myths, there are still plenty of fire investigators who have not been back to school since it was learned scientifically that the "indicators of arson" that they learned were false. Further, the libraries of most fire investigators contain numerous texts that are filled with this misinformation. Even worse, there are still a few popular speakers and agencies training new investigators with the old mythology.

The sheer number of misconceptions and their widespread publication in learned and not-so-learned treatises indicate that fire investigation, as a profession, still has very far to go.

Asphyxia

Introduction

Asphyxia is a classical term in forensic medicine that has come to have varied definitions and meanings. Etymologically, asphyxia means "pulseless", but in common forensic usage it has come to denote deaths from the acute cerebral deprivation of oxygen. On this basis, asphyxia can be unambiguously defined as death from rapid cerebral anoxia or hypoxia. The concept of asphyxia, and more particularly whether asphyxial deaths have specific postmortem signs, has been extensively discussed in the literature and classical textbooks of forensic pathology. There are long-standing myths about asphyxia that continue to be difficult to dispel.

The first myth about asphyxia relates to a misunderstanding of what constitutes the nature of the asphyxia. Specifically, asphyxia is not a cause of death but rather a mechanism of death. On this basis, the opinion that "asphyxia" has occurred provides no specific medicolegal information, unless the cause of the asphyxia can be ascertained (e.g., strangulation). Thus, without specific knowledge about how the "asphyxia" has occurred, there is no medicolegal value to providing a diagnosis of asphyxia. This closely relates to the most important myth about asphyxial deaths: that there are diagnostic postmortem signs of asphyxia. It is now known that there are no specific gross or microscopic changes that will allow the determination of asphyxia as a mechanism

Table 1 Classification of rapid anoxial deaths

Mechanism	Classical terminology	Examples
Reduced oxygen tension in the respirable atmosphere	Environmental hypoxia	Rebreathing within a plastic bag sealed overhead
Obstruction of the mouth and nose	Upper airway obstruction	Choking; gagging; suffocation/smothering
Interference with the mechanics of breathing or chest compression	Positional asphyxia	Heavy load compressing chest wall and limiting respiratory excursion; acute ethanol intoxication with fall into posture causing hyperflexion of the neck; hogtying in prone position
Neck compression	Pressure on the neck	Strangulation; hanging; neck holds
Chemical inhibition of oxygen utilization for metabolism	Chemical anoxia	Cyanide and carbon monoxide poisoning

of death. The best that can be accomplished using present methods of forensic medicine is to determine the cause of asphyxiation from direct evidence at the autopsy and then infer that the mechanism of death was asphyxial. Otherwise, it is not possible to determine that a death is asphyxial without resorting to circumstantial information. The classical signs of asphyxia including cyanosis, fluidity of blood, and visceral congestion and petechiae have been thoroughly debunked and are now considered to be unreliable indicators of a rapid anoxial death.

Another important and persistent myth about rapid anoxial deaths relates to the pathogenesis and medicolegal significance of ocular petechiae. Although it was once believed that petechiae were caused by asphyxia, this is not supported by available evidence. It is now generally accepted that petechial hemorrhages of the conjunctivae and face are due to rupture of small blood vessels due to increased jugular venous pressure rather than due to a tissue effect of hypoxia. Thus, in the context of rapid anoxial deaths, ocular petechiae are most frequently observed in cases where the cause of hypoxia coincidentally involves impairment or obstruction to the venous return from the head (e.g., compression of the neck with jugular venous compression or chest compression with increased intrathoracic and central venous pressure). Ocular petechiae are best interpreted as an indication of a pathophysiological process that has resulted in impaired venous return from the head. Thus, petechiae are not sure evidence of "asphyxia". This is demonstrated in routine medicolegal autopsy practice, where one of the most frequent causes of ocular petechiae is sudden cardiac death from ischemic heart disease.

Overall, rapid anoxial deaths are best classified by considering the level at which oxygen supply is lost and therefore unavailable for metabolism (Table 1). The deficiency in oxygen may be due to reduced oxygen tension in the respirable atmosphere; obstruction of the mouth and nose; interference with the mechanics of breathing; pressure on the neck; and chemical inhibition of oxygen utilization for metabolism. Traditionally, the term *mechanical asphyxia* has included any mechanism that interferes with oxygen delivery to the brain by application of an external force on the body, or the action of gravity. In the case of pressure on the neck, the most frequent means by which cerebral anoxia occurs is through reduction in cerebral arterial perfusion due to compression of the carotid arteries.

Drowning is best viewed as a rapid anoxial death due to airway obstruction by water. However, other pathophysiologic effects also occur. Therefore, drowning is considered separately.

Upper Airway Obstruction

Partial or complete obstruction of the nose, mouth, or upper aerodigestive tract created by a physical barrier to airflow can result in rapid anoxial death. The physical barrier maybe fixed in position such as in the application of a gag over the mouth and

nose, or occlusion of the upper aerodigestive tract by physical material (e.g., foreign body placed in the mouth or bolus of food). The physical barrier may be transient such as in smothering and suffocation.

Postmortem determination that death has occurred from upper airway obstruction can be difficult unless the physical barrier is still *in situ*, or if injuries are sufficiently characteristic to infer that a physical barrier was present. Homicidal upper airway obstruction sometimes occurs in infants. This poses problems to detection since the paucity of autopsy findings can result in the misdiagnosis of sudden infant death syndrome.

Gagging

Gagging can be defined as obstruction of the mouth and/or nose by a fixed physical barrier that is held in place by tying (e.g., knotted rag) or adhesion (e.g., wide tape such as "duct tape"). At autopsy, the main findings of gagging relate to the nature of the gag, injuries produced by the gag, and the secondary effects of the gagging process. The nature of the gag is easy to ascertain if the gag is left *in situ*. However, if the gag has been removed (after death but before the autopsy), then the prior presence of a gag can only be inferred from the injuries, secondary effects of the gag, and circumstantial information.

Gags are generally fixed into position by tying to the head or adhesion to the skin, if the gag is a tape. The completeness of occlusion is determined by the range of the gag, i.e., if it covers both the mouth and nose. Sometimes the obstructing effects of the gag are complicated by the presence of a separate foreign body placed in the mouth (e.g., cloth or sock in the oral cavity with duct tape over the mouth), which may also be referred to as a *gag*. The absorptive properties of the gag (e.g., cloth) and the presence of an intraoral component may further cause the gag to swell, and obstruction of the airway may occur progressively rather than acutely. In addition, the tongue may be displaced into the posterior oropharynx, further compromising the airway. If an adhesive tape-type gag has been removed, residue can sometimes be collected from the skin to indicate that a gag was present.

Injuries produced by the gag relate to direct damage to the corners of the mouth and oral mucosa by compression of tissue by the gag. Sometimes there may be facial injuries radiating from the corners of the mouth.

The secondary effects of gagging include aspiration of gastric contents. Since the fixed barrier over the mouth inhibits expelling vomitus, the airway will become occluded and death will occur by airway obstruction. This is often the immediate cause of death in cases of gagging when the mouth is obstructed but the nose is open. However, great care must be used when determining if gastric contents in the air passages have resulted from true aspiration rather than transfer during movement of the body to the mortuary. The other main secondary effect of gagging is more contextual and situationally defined. Sometimes elderly people with ischemic and/or hypertensive heart disease die suddenly while gagged, but without complete occlusion of both the mouth and nose. These fatalities are usually due to sudden cardiac death from underlying heart disease that is exacerbated by gagging, rather than the obstructing effects of the gag itself.

Smothering and Suffocation

Smothering and suffocation may be used interchangeably and are best defined as rapid anoxial death by facial compression with external obstruction of the mouth and/or mouth by a nonfixed or transient barrier. Smothering and suffocation are often used to denote transient obstruction of the nose and mouth by hands and fingers, or the application of a soft object to compress the face and thereby obstruct the external air passages. However, suffocation is also sometimes used to denote the rapid anoxial death that results from the application of an enclosing barrier over the head, such as a sealed plastic bag. The main challenge in determining whether death has occurred from smothering or suffocation is that injuries to the mouth, nose, lips, and face that are specific and reliable indicators of facial compression are not consistently present. At the extremes of age or when there is a reduced level consciousness, smothering or suffocation can occur with no external marks. In contrast, in responsive and resistant people, the injuries to the face can be extensive and are often associated with other injuries. When findings are present, the injuries are typically abrasions or contusions centered on the nose and mouth, as well as lacerations on the inner surface of the labial mucosa. Another pitfall is the overlap in perimortem injuries caused by emergency

medical intervention such as intubation, which may cause focal injuries to the lips and face. This can be particularly problematic in infants and children.

The gross and microscopic findings in cases of smothering and suffocation are controversial. It has been claimed that hyperinflation of the lungs (presumably due to expiration against a closed airway), pulmonary hemorrhage, and interstitial pulmonary emphysema are highly correlated with smothering and suffocation. The evidence to support these claims is anecdotal and the specificity of these findings has not been established. The finding that has been most extensively studied is pulmonary hemorrhage. It is clear that extensive acute pulmonary hemorrhage can be observed in individual cases of smothering in infancy. However, it has also been shown that pulmonary hemorrhage is found in infants who die suddenly from natural causes. There is some evidence that sublethal smothering maybe correlated with hemosiderin-laden macrophages in the lung, leading to the inference that a prior episode of smothering causing pulmonary hemorrhage occurred.

Choking

Choking is obstruction of the upper aerodigestive tract by food. Choking is almost invariably associated with two factors: a predisposing condition or circumstance that results in impaired swallowing and a bolus of incompletely masticated food that has a sufficient diameter to occlude the lumen of the airway. The predisposing condition or circumstance is usually acute ethanol intoxication, neurodegenerative or neuromuscular disease, poor dental hygiene, or the rapid and poorly controlled ingestion of food. The foodstuffs that are frequently observed in cases of choking are usually firm, such as meat. The main pitfalls in the autopsy diagnosis of choking usually relate to the history. If emergency medical intervention has occurred, the bolus of food may have been removed and no trace may be found at autopsy. Alternatively, endotracheal intubation can displace the bolus further down into the trachea. In addition, it is important to differentiate among postmortem transfer of gastric contents from the stomach into the trachea, aspiration of gastric contents, and choking. In choking, the obstruction is a discrete piece of material that is firmly wedged into a narrow portion of the upper aerodigestive tract, typically the laryngeal aperture.

Positional Asphyxia

Positional asphyxia is rapid anoxial death that occurs as a result of external compression of the body or postural/gravitational effects on the body that impair breathing at the level of the neck or chest wall. The key to the determination of positional asphyxia is the history including information regarding the position of the body at the scene, since positional asphyxia cannot be ascertained purely from autopsy findings. Positional asphyxia can be arbitrarily divided into crush (traumatic), postural, and restraint asphyxia. These categories are classically defined and relate to the common circumstances of how the "positional" elements of the "positional asphyxia" arose, rather than representing fundamentally different entities. Other forms of positional asphyxia include oddities such as burking (e.g., homicidal chest compression by sitting on the chest and impairing breathing).

Crush Asphyxia

Crush or traumatic asphyxia occurs when the chest is compressed by large external forces such as a considerable weight, or when the chest is wedged into a tight space, thus preventing expansion during inspiration. In many cases of crush asphyxia, there is a well-demarcated line of florid congestion and petechiae that is cephalad (toward the head) to the main horizontal line of chest compression. The nature of the chest compression may be reflected in injuries to the chest wall such as bruising, abrasion, and rib fractures. However, in many cases, the compression is caused by a flat and broad surface so no chest wall injuries may occur. Crush asphyxia occurs frequently in industrial mishaps and in some road traffic fatalities.

Postural Asphyxia

Postural asphyxia occurs when the fixed gravitational posture of the body precludes breathing or respiratory air transmission. This is distinct from crush and restraint asphyxia due to the lack of an external force or agent actually inhibiting breathing. The most frequent underlying cause for postural asphyxia is acute ethanol intoxication. In this circumstance, the person collapses and becomes unconscious in a position that impairs breathing. The positions that are highly correlated with postural asphyxia are

neck hyperflexion, prone and head down positioning, wedging between furniture or other fixed structures, and complex positions that may indicate many different physical impediments to breathing. There are no distinct pathological findings related to postural asphyxia unless there is an element of direct injury to the neck or chest. The distribution of postmortem hypostasis often provides information on body position, but scene information and toxicological findings are key to the diagnosis.

Another specific form of postural asphyxia is hogtying in the prone position. In this circumstance, an individual's ankles and wrists are tied together behind the back and the person is placed with the body weight concentrated on the chest. This position impairs movement of the chest wall during inspiration and the ligature restraints inhibit a change of position. This form of postural asphyxia may be aggravated by gagging or preexisting cardiopulmonary disease such as ischemic heart disease. This form of postural asphyxia overlaps with restraint asphyxia.

Restraint Asphyxia

Restraint asphyxia is considered by many forensic pathologists as a variant of positional asphyxia that occurs during physical restraint by another party. This is a controversial area that has not reached a consensus, since there are often factors that complicate a precise understanding of the cause and mechanism of death in these cases. Despite the controversy, it is generally accepted that individuals who are restrained, typically in the *prone* position during a bout of agitation and/or bizarre behavior, can die suddenly and unexpectedly. It is not uniformly accepted that these cases are rapid anoxial deaths due solely to the restriction of breathing or other forms of mechanical interference with neck or chest. The majority of these cases occur in the context of excited delirium from acute decompensation of a chronic psychiatric illness or acute cocaine intoxication. Therefore, one of the competing hypotheses to explain these deaths is sudden cardiac arrhythmia related to the excited delirium. On a practical level, this often becomes a challenge in the individual case if there are injuries on the neck that could relate to neck compression.

In the typical case, an individual is restrained by law enforcement officers in the prone position. The individual usually manifests excited delirium with agitation, bizarre, inappropriate and often confrontational behavior, apparent great strength, and hyperthermia. The individual usually becomes unresponsive in the prone position after a violent struggle that may involve the deployment of pepper spray, a taser, or physical techniques aimed at subduing resistance. Clearly, it is important to differentiate death *during* restraint from death *by* restraint, but this is frequently impossible.

Pressure on the Neck

Rapid anoxial death often results from pressure applied to the neck. The different forms of neck compression are determined by the physical means of application of the pressure. The main challenge for the forensic pathologist is realizing that the pathology of neck compression is not entirely specific. Thus, the injuries that result from pressure on the neck reflect both the nature of the compressive force and the physical effects of the compression. For example, the types of internal damage from hanging and strangulation can be the same since both compress the neck, but the distribution of the findings and the precise nature of the skin injuries can be used to differentiate between hanging and strangulation. Furthermore, the postmortem diagnosis of neck compression has three well-defined pitfalls. First, the postmortem findings of neck compression form a spectrum from no or minimal injury to extensive or maximal injury, the former often providing a barrier to detecting subtle or concealed homicides by neck compression (i.e., the under-diagnosis pitfall resulting in "missing" cases). Second, internal injuries of neck compression can be mimicked by postmortem artifacts including hypostatic hemorrhages (i.e., the over-diagnosis pitfall resulting in "over-detecting" cases). Third, interpreting the medicolegal significance of postmortem findings of neck compression is entirely contextual, unlike many deaths by physical injury. For example, the autopsy findings in a case of hanging cannot always be differentiated from postmortem suspension of the body. Similarly, the injuries in cases of nonfatal and fatal strangulation are often the same. In these circumstances, determining the relevance of the autopsy findings to the cause of death relies on understanding the circumstances of the case and exclusion of other causes of death.

Table 2 Pathology of anterior neck compression

Site	Classical injury pattern	Pitfalls and emerging issues
Skin	Abrasions; contusions; ligature marks	Hypostatic hemorrhages mimic contusions; neck folds mimic ligature marks
Fat and muscle	Subcutaneous, intramuscular and myofascial hemorrhage	Hypostatic hemorrhages; dissection artifacts (requires dissection in avascular field)
Hyoid	Fractures (most involve greater cornua)	Infrequent in infants, children, and young women
Laryngeal cartilage	Fractures (most at the base of superior cornua)	More frequent than hyoid fractures
Laryngeal mucosa	Mucosal hemorrhage and intralaryngeal mucosal hemorrhage	Specificity not completely studied; frequently observed in nonviolent deaths
Pharynx	Intramural hemorrhage	Specificity not completely studied; identical to Prinsloo–Gordon hemorrhage
Carotid arteries	Intimal tears	Frequency not well studied

Pathology of Neck Compression

There are five cardinal postmortem signs or hallmarks of neck compression: ocular petechiae; injuries on the skin of the anterior neck; injuries to strap muscles and soft tissues of the neck; injuries of hyoid-larynx complex; and miscellaneous or variable findings (Table 2). However, these hallmarks cannot be considered as diagnostic criteria for neck compression. It seems that straightforward diagnostic criteria for the postmortem diagnosis of neck compression cannot be proposed because of the inherent variability of the processes involved.

Ocular petechiae are related to the compression of the jugular venous system with rupture of small mucosal blood vessels as described above (Figure 1). Injuries on the skin of the neck are often quite helpful in determining the nature of the neck compression (e.g., manual or ligature strangulation, or hanging). Internal injuries including strap muscle and soft tissue hemorrhages are often helpful in diagnosis, particularly if the cutaneous findings are minimal (Figure 2). Fractures of the hyoid bone or larynx occur in less than 50% of female victims of strangulation and are probably more frequent in male victims. The presence of such fractures is often viewed as good evidence of neck compression. The laryngeal cartilage is more often fractured than the hyoid bone. The most frequent fracture is situated at the base of the superior cornu of the thyroid cartilage. In addition, there are often mucosal hemorrhages in the larynx and pharynx. Hemorrhages and microfractures in the laryngeal cartilage have been reported but are not well studied. Intimal tears of the carotid arteries can be seen in some cases of neck compression.

Figure 1 *Ocular petechiae*. These hemorrhages are related to the compression of the jugular venous system with rupture of small mucosal blood vessels

Hanging

Hanging is rapid anoxial death from ligature compression of the neck with (or "accompanied by") suspension of the body. The pressure on the neck is caused by gravitational tension on the ligature. The

Figure 2 *Strap muscle hemorrhages*. These hemorrhages are related to the blunt injury (bruising) of the soft tissues of the neck by applied force

pathology of hanging is highly variable and it relates to several factors including the nature of the ligature, degree of suspension, and relative position of the ligature. The surface injury on the neck in hanging is largely related to the physical properties of the ligature. If the ligature is soft and broad (e.g., suicidal bedsheet hanging in jail) there may be no mark on the neck. If the ligature is narrow and rough (e.g., a braided rope), the ligature mark may be a deep abraded furrow with a corresponding woven pattern within the ligature mark (Figure 3). Mostly, the ligature mark is a well-demarcated curvilinear abrasion consisting of a continuous component and an intermittent or incomplete component that is angled toward the point of suspension. Typically, this is evident by a rising or sloping nature of the ligature mark on the side(s) of the neck, depending on the precise position of the ligature and the point of suspension. Intense pressure on the neck may result in protrusion and postmortem drying of the tongue and perimortem epistaxis. It is classically stated that the main difference between hanging and ligature strangulation

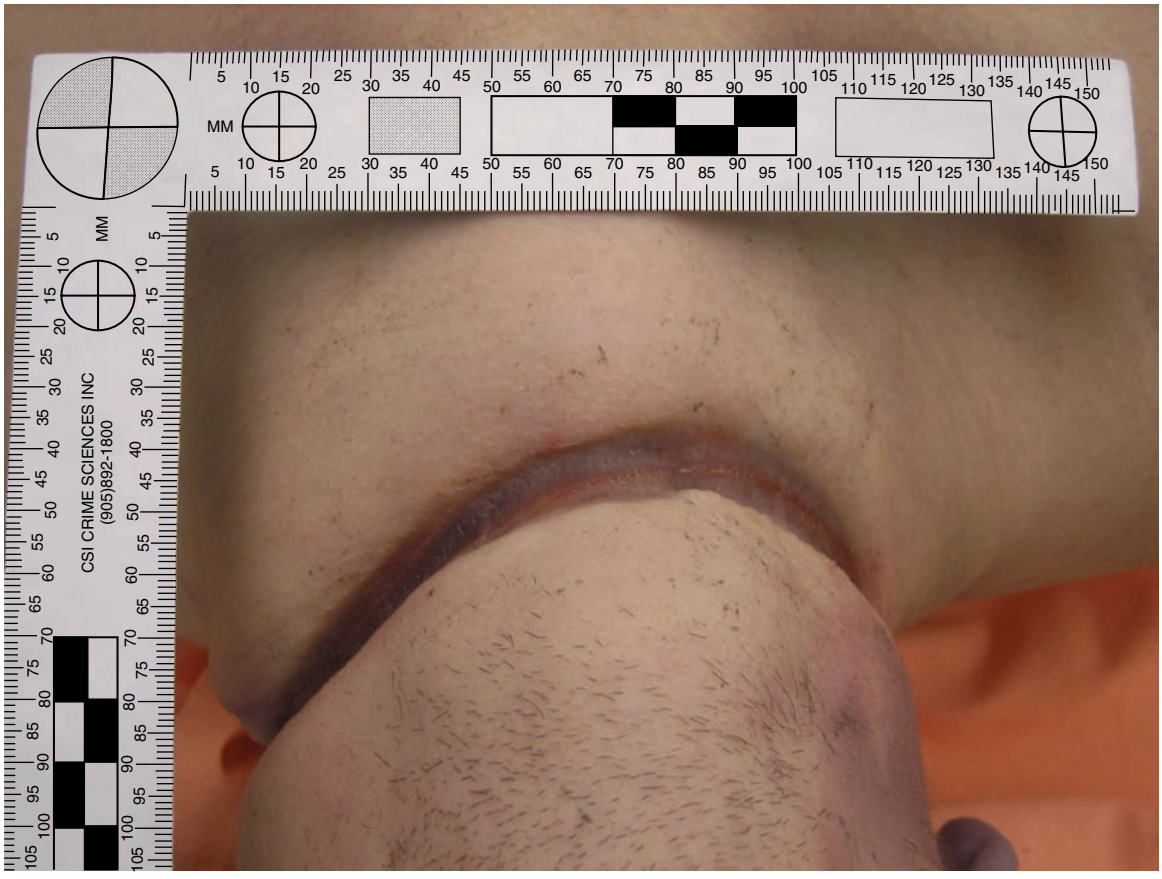

Figure 3 *Ligature mark in hanging*. The ligature mark is an indented abrasion or furrow caused by pressure applied to the skin by the weight of the body during suspension

is the horizontal nature of the ligature mark in the latter. However, this is an overstatement. Hanging may occur with relatively horizontal ligature mark, depending on the precise physical arrangements of the body and ligature. However, in general, ligature marks with hanging are typically not uniformly horizontal in orientation.

Internal injuries associated with hanging may range widely but are typically minimal. If subcutaneous or intramuscular hemorrhage is present, it is usually associated with the ligature mark, or is positioned over a prominence of the larynx or hyoid bone. Fractures of the hyoid and larynx may be detected and are often directly beneath a deeply indented ligature furrow or a knot.

Specific forensic variants of hanging include autoerotic hanging, atypical hanging with incomplete suspension, "long-drop" (or judicial) hanging, and so-called delayed hanging. In autoerotic hanging, hypoxia is induced by regulated neck compression (partial suspension by hanging, with release of the pressure on the neck by standing or kneeling) during masturbation. If the neck compression leads to unconsciousness, then the suspension may be accidentally fatal. In atypical or incomplete suspension hanging, there is often a physical process that results in neck compression by gravitational means that either involves a fixed surface or a ligature. For example, a toddler may be accidentally suspended in the drawstrings of a window blind. If there is complete suspension there may be florid ocular and facial petechiae. In "long-drop" (or judicial) hanging, there is often fracture of the upper cervical vertebra. Finally, if an individual is successfully resuscitated

from cardiopulmonary arrest after hanging, death may occur later as a delayed death following hanging. This is often observed in suicidal hangings in prison with immediate medical intervention. At autopsy, there may be no findings other than hypoxic–ischemic encephalopathy.

A rare occurrence is homicidal hanging. Homicidal hanging is often associated with incapacitating injury or intoxication, or other evidence of violence. Homicidal hanging must be differentiated from postmortem suspension of the body after strangulation, which is also rare.

Strangulation

Strangulation is pressure on the neck by the application of force using hands, a ligature, or other firm or unyielding material(s). Classically, strangulation has been subclassified by the mode of neck compression. Manual strangulation is pressure on the neck using hands, and ligature strangulation is neck compression achieved by application of a ligature around the neck. Other forms of strangulation include compression of the neck with an object (e.g., broom handle), appendage (e.g., foot, crux of elbow [sometimes called *mugging*]), or compression of the neck onto an immobile structure. Thus, the term *strangulation* has sometimes been used rather broadly. Furthermore, strangulation is complex and may involve more than one mode of compression. This is most frequently encountered with combined manual and ligature strangulation, when the hands are used to compress the neck and the collar of the victim's shirt is used as a ligature.

In general, the mode of strangulation is determined by the nature of injuries on the skin of the neck. In manual strangulation, the injuries are typically discoid bruises, abrasions, and sometimes small curvilinear (crescent-shaped) abrasions caused by fingernails. In ligature strangulation, there is typically a linear abrasion on the neck representing a ligature mark. Internally, the injuries are highly variable but often include strap muscle injuries. The least frequent classical injury is fracture of the hyoid bone.

One specific variant of strangulation is the neck hold or neck restraint. The context is usually restraint, sometimes by law enforcement officers or medical personnel. In addition, this can be observed in death during participation in martial arts including judo. In these cases, the neck hold is usually applied to restrain rather than kill, but death may occur. The autopsy findings are highly variable ranging from few findings to bilateral fractures of the superior cornua of the thyroid cartilage.

One popular concept associated with strangulation is sudden death associated with vasovagal inhibition or reflex cardiac arrest. It was once thought that compression of baroreceptors (carotid body) or irritation of the vagus nerve could cause sudden cardiac arrest. Although this mechanism of death from neck compression has some anecdotal support, it is probably better viewed as part of the folklore of forensic pathology rather than a robust concept based on scientific evidence.

Diagnostic Pitfalls

The main diagnostic pitfall in cases of neck compression relates to errors of overinterpretation and failure to use proper techniques when dissecting the anterior neck. It has been known for decades that the best approach to the internal examination of the neck is a layered bloodless dissection following venous decompression achieved by removal of the brain and evisceration of the thoracoabdominal organs. This ensures that no "hemorrhages" are created by extravasation of blood from congested blood vessels during soft tissue dissection. However, despite adequate technique, additional pitfalls can be encountered. If the body is in the prone position at the scene and postmortem hypostasis is well established in the neck, hypostatic hemorrhages may form and mimic bruising of strap muscles and soft tissue. Such "pseudobruises" are an important pitfall since the false diagnosis of strangulation can be made if the true nature of the "hemorrhages" are not identified. Another less frequent pitfall is misdiagnosis of the natural (synchondrotic) joints of the hyoid bone as fractures and mistaking triticeous cartilages for fractures of the superior cornua of the thyroid cartilage.

There are several open questions in the pathology of neck compression. These include the differentiation of hypostatic hemorrhages (pseudobruises) from "real" bruises, the combinatorial specificity of the "signs" of neck compression, the search for methods to detect "rapid anoxial deaths" in general, the incidence of hyoid–laryngeal fractures in neck compression, and the specificity of lesser well-known laryngeal findings in cases of neck compression.

Environmental Hypoxia

Oxygen desaturation of the respirable atmosphere may cause rapid anoxial death. This typically occurs by the utilization of oxygen in a closed space without regeneration of the oxygen supply, or displacement of oxygen by another gas. Confinement in a closed space with limited air supply may result in a reduction of oxygen tension due to respiration and replacement by carbon dioxide (environmental hypercapnia). In addition, the respirable atmosphere in a confined space may be saturated by another metabolically inert gas, usually a noble gas (e.g., argon, helium). Such gases have been called *asphyxiant gases*. There are no gross or microscopic postmortem findings that allow for the diagnosis of environmental hypoxia. The diagnosis is made by assessment of the scene and history and exclusionary findings at autopsy.

Chemical Anoxia

Anoxia may occur at the level of intermediary metabolism using oxygen. Thus, a blockage in either oxygen transport or oxygen utilization may cause anoxia at the tissue level. This occurs through chemical agents that poison specific metabolic steps that utilize oxygen. The most common anoxic poison is carbon monoxide. The high-affinity binding of carbon monoxide to hemoglobin (carboxyhemoglobin) results in the failure of oxygen transportation on hemoglobin and the deprivation of oxygen to tissues. Cyanide acts in a similar manner but binds to a cytochrome protein, thereby inhibiting energy production by the electron transport chain in the mitochondrion.

Carboxyhemoglobin imparts a bright cherry red color to blood and tissues at autopsy. Similarly, cyanide can cause pink–red discoloration of postmortem hypostasis. If cyanide is ingested (e.g., hydrocyanic acid), the gastric mucosa may have a bright red color and display acute hemorrhagic gastropathy. Deaths by carbon monoxide poisoning often occur from accidental or suicidal exposure to carbon monoxide as an exhaust gas from fuel combustion (e.g., automobile exhaust), or smoke produced in fires. Cyanide poisoning can occur by ingestion of cyanide usually in the context of homicide or suicide. Occasionally, cyanide poisoning may occur by the inhalation of cyanide in fire gases, since synthetic fibers and plastics may liberate cyanide upon combustion.

Conclusion

Asphyxial or rapid anoxial deaths are due to oxygen deprivation of the brain. The most common mechanisms of rapid anoxial deaths are mechanical, those that interfere with cerebral arterial perfusion, breathing, or airflow through the nose, mouth, or upper aerodigestive tract. Rapid anoxial deaths present technical challenges to the pathologist due to the nonspecificity of autopsy findings and the need to consider circumstantial information. Although some myths have been dispelled (e.g., the postmortem signs of asphyxia), there remain open questions that need to be addressed to provide a firmer evidence-based foundation and a more scientific approach to the postmortem diagnosis of rapid anoxial death.

Assault: Sexually Motivated

Introduction

Sexually motivated assault occurs in all countries and all jurisdictions. The legal, cultural, and societal definitions of sexually motivated assault vary widely. Table 1 shows the current legal definitions of certain types of sexual assault in England and Wales. However, wherever a claim of such an assault is made, it is essential to justice that appropriate medical assessment of both complainant and suspect is undertaken. Such an assessment may identify injuries and the appropriate interpretation of such injuries (or lack of them) is a key to assisting the judicial process. Above all, it must never be forgotten that the initial examination and assessment is only the first part

Table 1 Some definitions of certain types of sexual assault in England and Wales (Sexual Offences Act 2003)

1 **Rape**

(1) A person (A) commits an offence if –
  (a) he intentionally penetrates the vagina, anus or mouth of another person (B) with his penis,
  (b) (B) does not consent to the penetration, and
  (c) (A) does not reasonably believe that (B) consents.

(2) Whether a belief is reasonable is to be determined having regard to all the circumstances, including any steps (A) has taken to ascertain whether (B) consents.

(3) Sections 75 and 76 apply to an offence under this section. [These Sections apply to evidential and presumptive conclusions about consent]

(4) A person guilty of an offence under this section is liable, on conviction on indictment, to imprisonment for life.

Assault

2 **Assault by penetration**

(1) A person (A) commits an offence if –
  (a) he intentionally penetrates the vagina or anus of another person (B) with a part of his body or anything else,
  (b) the penetration is sexual,
  (c) (B) does not consent to the penetration, and
  (d) (A) does not reasonably believe that (B) consents.

(2) Whether a belief is reasonable is to be determined having regard to all the circumstances, including any steps (A) has taken to ascertain whether (B) consents.

(3) Sections 75 and 76 apply to an offence under this section.

(4) A person guilty of an offence under this section is liable, on conviction on indictment, to imprisonment for life.

3 **Sexual assault**

(1) A person (A) commits an offence if –
  (a) he intentionally touches another person (B),
  (b) the touching is sexual,
  (c) (B) does not consent to the touching, and
  (d) (A) does not reasonably believe that (B) consents.

(2) Whether a belief is reasonable is to be determined having regard to all the circumstances, including any steps (A) has taken to ascertain whether (B) consents.

(3) Sections 75 and 76 apply to an offence under this section.

(4) A person guilty of an offence under this section is liable –
  (a) on summary conviction, to imprisonment for a term not exceeding 6 months or a fine not exceeding the statutory maximum or both;
  (b) on conviction on indictment, to imprisonment for a term not exceeding 10 years.

of a process where the examinee requires specialist medical advice and perhaps treatment, after the examination for the alleged assault, and the capability must exist for appropriate medical, psychological, and social support.

In the United Kingdom most adult assessments are undertaken by forensic physicians, and for pediatric patients, joint examinations with a forensic physician and pediatrician are recommended. In other jurisdictions, examinations may be undertaken by other trained healthcare personnel as part of their workload (e.g., sexual assault nurse examiners and forensic pathologists) [1–3]. Such an assessment of both complainant and suspect must be independent, compassionate, impartial, and nonjudgmental. The medical examiners' role is to identify, collect, and

interpret medical information. It is up to the court to apply that evidence to the entirety of the case. Complaints of sexual assault may relate to recent or older events, sometimes from years ago. Allegations of historic abuse may be disclosed many years later. In some cases, therefore, examination of genitalia may have no relevance. The need for an examination in sexual cases must be clear, in order that inappropriate and unnecessary examinations are not undertaken.

Principles of Examination

The principles expressed here are those that are generally applicable worldwide. Some of those principles may be limited by financial considerations, but if these impact on dignity and impartiality such financial considerations should be regarded as professionally and legally unacceptable. It is appropriate that complainants and suspects should be examined by doctors (in the United Kingdom – generally forensic physicians) or healthcare professionals with specific forensic expertise and experience. The appropriate level of these are by no means agreed or adopted throughout the world [2]. The examinee should be able to choose the gender of the examiner. A minority of complainants are male [4]. Examiners of suspects and complainants need to abide by the principles of consent (including for examination, sample taking and production of reports for courts) and confidentiality (with regard to personal medical information that may be unrelated to the allegation). The examiner must be trained in and understand and be familiar with medical care, the retrieval of evidence, and the preservation and interpretation of evidence.

All examiners need to be familiar with the range and frequency of "normal" sexual practice – which may well be dictated by factors including country, culture, sexual orientation, ethnicity, and religion. In one British study, and in another study, 30% of males and 26% of females ($n = 11\,161$) had experienced penile vaginal intercourse before the age of 16 years [5] Other studies have examined incidence of practices in consensual settings and found for fellatio (penis placed in mouth, sexual stimulation by sucking plus ejaculation) an incidence of 55% (Evans) cunnilingus (female genitalia licked, sucked, or rubbed by lips or tongue) 66–72% [6] and anilingus (anus is licked, sucked, or rubbed by lips or tongue) perhaps 15% ($n = 526$) [7]. In nonconsensual settings the following incidences have been considered – fellatio 34% (male–male $n = 104$), and 78% (female–male $n = 1403$) [8], cunnilingus −22% ($n = 1403$) [8], and no data are available for anilingus.

Social factors may also result in altering sexual behavior and in cultures where alcohol and drugs are used widely, risky sexual behavior may be increased in both males and females [9]. Concerns regarding drug-facilitated sexual assault are clear [10]. The evidence shows that alcohol is the drug that is most commonly associated with sexual assault [11–13]. A clear understanding is required of the nature and the purpose of the examination, appropriate documentation of findings, the reasons for sampling, and the current appropriate methods of sampling.

Assessment and Sampling

The assessment of a complainant or suspect of sexual assault is divided into four main parts – the history taking, the clinical examination, sampling, and postassault management. The examiner should ensure that all these aspects are addressed. Subsequently, the examiner is required to produce a report of findings for the court and may then be asked to attend court to be questioned on, their procedures and the interpretation of their findings.

Table 2 summarizes the key considerations for an assessment in allegations of sexual assault.

Table 2 Key considerations for medical assessment – complainant and suspect

Need for immediate medical care (may override forensic needs)
Timing of the assessment (acute or historic allegation)
Location of the assessment (e.g., hospital, victim examination suite)
Medical examination
Introduction (nature and purpose explained)
Consent
History of the allegations (complainant and others)
Medical, gynecological, and sexual history (if relevant)
Drug and alcohol history (if relevant)
General clinical examination (developmental, height, weight, nongenital injuries, and condition of nails)
Anogenital examination
Sampling
Documentation (e.g., photographs and colposcopic images)
Chain of custody
Report writing and interpretation

Table 3 Specific relevant information from history

How was each injury sustained
Object or weapons used (e.g., sex aid, erect penis, fingernails, and bite)
When was the injury sustained
Has injury been treated
Any preexisting illnesses (e.g., skin disease and bleeding diathesis)
Any regular physical activity (e.g., contact sports)
Any regular medication (e.g., anticoagulants, steroids)
Handedness of complainant and suspect
Use of drugs and alcohol
Clothing worn

Documentation of injuries and forensic samples can assist in confirming, or otherwise, the nature of sexual acts alleged, the possible identification of an unknown assailant, and potential links with other offenses. Such information may assist in determining the consensuality or nonconsensuality of any sexual contact.

In taking a history, it is important to establish as much information as possible that allows proper interpretation of marks, injuries, or scars that may be identified on a complainant or suspect. Table 3 identifies key features, which may require determination, dependent on the allegations made.

Characteristics of any injury (anogenital or nongenital) need to be documented. Relevant characteristics that may be important are listed in Table 4. A consistent injury classification system should be used that is both reproducible and understandable to medical and lay individuals [14]. It is also important that examiners understand the limitations of interpretation – for example of bruise coloration [15, 16].

Table 4 Injury characteristics

Location
Pain, tenderness, reduced mobility
Type (e.g., bruise, incised wound, abrasion, and laceration)
Size
Shape
Color
Orientation
Age (if known)
Causation (if known)
Time recorded
Temporary nature of injury (is reexamination recommended after 24 h?)

Once sites of possible contact or injury have been recorded and documented clearly, the forensic swabs from the sites should be taken [17–20]. Standardized modular sampling kits, which contain all appropriate items for sampling should be used if available. These assure standardization and sterility. Forensic samples may include swabs from skin, vagina, anus, rectum, mouth, and elsewhere. Other biological samples of relevance may include hair, nails, blood, urine, and saliva. Disposable proctoscopes and specula should also be retained for forensic information following use.

All samples should be labeled with the date and time taken, the source of the swab (e.g., penile shaft), the examiner and the examinee name. Tamper-evident seals should be used and appropriate storage identified for the type of sample. A clear chain of custody of sample must be established.

It is important to consider taking samples from all parts of the body where contact may have occurred, as recovery of biological samples may assist the investigative process [21]. Types of contact may include (in addition to general injuries such as punches or grip marks) licking, kissing, sucking, biting, ejaculating, and penetrating. These sites of contact may be visible, but some may not be visible and additional techniques have been applied to identify extraneous substances (e.g., semen) on skin, with limited success [22]. Appropriate sampling of such sites can improve positive sample recovery assist in identification by DNA recovery [23, 24].

Findings associated with sexual contact

It is a common, but wrong assumption that sexual assault of any nature results in injury to the victim, whether adult or child [25]. Sexual assault (including rape) may often occur without any visible physical injury – genital or extragenital. Conversely, consensual sexual activity (sexual activity between consenting adults) may result in injury to the body and genitalia. Thus the presence or absence of injuries, in association with allegations of sexual assault do not necessarily indicate by themselves whether the particular activity was consensual or nonconsensual. It is important therefore to understand that medical findings alone cannot imply either consensuality or nonconsensuality but must be taken as part of the overall body of evidence if a case goes to court. The

presence or absence of findings can assist in supporting (or otherwise) accounts of what occurred.

A number of studies in adults have been published, which explore the type of injury seen and the frequency with which the injuries have been noted following clinical examination of complainants of sexual assault. Some of these are discussed here. The method of examination (e.g., the use of a colposcope) may increase the number of "positive" findings [26]. The incidence of nongenital injury is generally higher than the incidence of genital injury [25]. A study of 819 women presenting after sexual assault showed 52% had general body and 20% anogenital trauma. A total of 41% had no injury [27]. One study [28] documented injuries in 249 women, who alleged that they had been assaulted. Of these, 80 had sustained injuries and 169 had not. These injuries when present are shown in Table 5:

The authors of this study concluded that in sexual assault "Most women do not have visible genitoanal injuries. The risk of sustaining genitoanal injury during a sexual assault is higher among women without prior sexual intercourse experience and among women exposed to anal penetration. The severity of the assault is a poor predictor of genitoanal injury."

There are few data of the incidence and type of genital and nongenital injuries of females and males following consensual sexual activity. Consensual sexual activity has been shown to result in the full gamut of blunt trauma injuries and consequently bruises, abrasions, and lacerations to genital and nongenital sites may be present [29]. The severity and site of the injury varies according to many factors including the type of sexual activity, relative sizes of participants, position of participants, previous sexual activity, and intoxication of the participants. The accounts between two participants may differ substantially in the description of the degree of force used and the medical findings may add more weight to one account over the other. The same factors that may influence the degree and severity of injury and the anatomical site of the injury are the same as for nonconsensual activity and thus may include some or all the following – each of which may have differing influences at different times – age of the complainant, type of sexual activity, relative positions of the participants, previous sexual activity, and degree intoxication of either or both of the participants. Consensual insertion or attempts at insertion of a finger or fingers, penis, or any other object into the vagina may result in bruises, abrasions, and lacerations of the labia majora, labia minora, hymen, and posterior fourchette. Consensual digital vaginal penetration may result in accidental fingernail damage or injury to parts of the female genital tract, which may not be noticed by either party. Death has been reported following such injury during sexual contact [30]. The effect of tampon use on the appearance of the hymen has been studied. In 300 females, sexually active subjects (81%) were significantly more likely than tampon users and pad users to have "complete clefts" in the lower hymen between the 2 o'clock and 10 o'clock positions; tampon users were not significantly different from pad users (11% *versus* 5%) [31]; and vaginal injuries may result in bleeding. If penile vaginal penetration follows the digital vaginal penetration then it seems likely that any injury or bleeding may be exacerbated. Cases have been reported where consensual vaginal sexual activity resulted in injury causing bleeding which necessitated internal iliac artery ligation [30, 32, 33].

The incidence of injuries after consensual and nonconsensual sexual intercourse has recently been studied. Anogenital injuries occurring in adolescent females (13–17 years old) after consensual and nonconsensual sexual intercourse [34] were documented in a retrospective, matched case–control study to assess anogenital injuries in female adolescents

Table 5 Injuries after sexual assault[(a)]

Genitoanal injury	*n*	Yes (%)	No (%)
Penetration			
Anal	38	20 (52.6)	18 (47.4)
Vaginal	150	47 (31.3)	103 (68.7)
Attempted vaginal/anal	14	4 (28.6)	10 (71.4)
Digital/pawing of genitals	18	1 (5.6)	17 (94.4)
No recollection	29	8 (27.6)	21 (72.4)
Reported physical violence			
Grievous bodily harm/attempted strangulation	28	9 (32.1)	19 (67.9)
Actual bodily harm	46	11 (23.9)	35 (76.1)
Restrained	104	34 (32.7)	70 (67.3)
None	44	15 (34.1)	29 (65.9)
No recollection	16	5 (31.3)	11 (68.7)
No information	11	6 (54.5)	5 (45.5)

presenting to a nurse examiner clinic during a four-year study period. Adolescents were selected for inclusion in the study if they reported consensual sexual intercourse (CSI) and agreed to a medicolegal examination. Control subjects were victims of alleged sexual assault (nonconsensual sexual intercourse (NCSI)) matched to cases by age and prior sexual intercourse experience. Genital trauma was documented using colposcopy with nuclear staining and digital photography. Overall, 49% (25/51) of CSI subjects reported no prior sexual intercourse experience. CSI and NCSI were comparable in terms of race, time to physical examination, alcohol use, and frequency of genital injuries (73% *versus* 85%, $p = 0.069$). The mean number of documented anogenital injuries in CSI subjects was $1.9 + 1.5$. These injuries commonly involved the hymen, fossa navicularis, and posterior fourchette. NCSI subjects had a greater number of anogenital injuries ($2.6 + 2.0$; $p < 0.02$), typically involving the fossa navicularis, labia minora, and hymen. The most common type of injury in both groups was laceration (39% *versus* 41%); however, NCSI subjects had a greater incidence of anogenital abrasion, bruising, and edema ($p = 0.035$). The authors concluded "Anogenital trauma was documented in 73% of adolescent females after consensual sexual intercourse *versus* 85% of victims of sexual assault. The localized pattern and severity of anogenital injuries were significantly different when compared with victims of sexual assault, the presence of anogenital trauma suggests that penetration has occurred and implies nothing about consent".

Another study [35] reviewed adolescent complainants of sexual assault, comparing virgin and nonvirgin groups. About 224 patients with a mean age of 14.8 years were studied of which 81 were "virgins" and 97 had been sexually active prior to the assault. The virgin group took longer to present for examination than the nonvirgin group (90 h compared to 44 h). Of all clients, 51% had a nongenital injury. These tended to be minor. In the nonvirgin group 32% had a genital injury. In the virgin group, 53% had a genital injury, however only 32% had the type of genital injury that would leave permanent evidence of penetration (i.e., if examined more than several weeks later). Alcohol use prior to assault was common. The authors concluded "Genital and or body injuries are not routinely found in adolescents after an allegation of rape or sexual assault even when there has not been previous sexual experience. The absence of injury does not exclude the possibility of intercourse, whether with or without consent."

If children alone are considered, sexual abuse is rarely diagnosed on the basis of only physical examination or laboratory findings [36]. Even when the perpetrator admits to penetration of the child's genitalia, physical findings may be absent on examination [37–41]. Abuse may leave no physical evidence, and mucosal (skin or anal/rectal, vaginal surfaces) injuries often heal rapidly and completely [42–45]. Examination of the healing of hymenal injuries in prepubertal and pubertal girls shows that hymenal injuries in both groups healed rapidly and, with the exception of more extensive lacerations, left no evidence of previous injury [46]. Heger and colleagues have concluded from a review of over 2000 children that "research indicates that medical, social, and legal professionals have relied too heavily on the medical examination in diagnosing child sexual abuse. History from the child remains the single most important diagnostic feature in coming to the conclusion that a child has been sexually abused. Only 4% of all children referred for medical evaluation of sexual abuse have abnormal examinations at the time of evaluation. Even with a history of severe abuse such as vaginal or anal penetration, the rate of abnormal medical findings is only 5.5%" [47].

Anal intercourse is part of the normal sexual repertoire of many heterosexual and homosexual couples. Consensual anal intercourse may (in the same way as vaginal sex) be pain free and discomfort free and would not normally leave any residual injury. Repeated anal intercourse results in easier penetration over a period of time. Lubrication such as saliva or KY Jelly can be used to ease penetration.

Nonconsensual anal intercourse if done without force, with or without lubrication, and without physical resistance on the part of the person being penetrated may leave no residual injury and may be pain free. The effects of drugs and alcohol may make penetration easier [48]. In an individual who is otherwise used to anal intercourse no pain or discomfort may be experienced.

The likelihood of pain, or injury in nonconsensual anal intercourse may be increased (i) in someone who has not experienced anal intercourse, (ii) in the absence of lubrication, (iii) if force is used, and (iv) if there is great disparity between the size of the anus (which varies little in the adult) and the penis (which may vary a lot).

The types of injury that can be caused by forced anal intercourse are stretch injuries that damage the lining of the anal canal or the skin surrounding the anus (the perianal region). The stretching can cause damage to the blood vessels supplying the local tissues – and such damage to blood vessels can cause blood to leak out into the tissues resulting in bruises – or can tear the surface of the anal canal and the perianal region causing fissures, tears, or lacerations. Because of the nerve supply, such fissures, tears, or lacerations (the terms are used interchangeably), even if minor, can be exquisitely painful. The incidence of fissures in nonconsensual anal intercourse is uncertain as there are only a few studies that have explored these issues, and there is some overlap of definition of terms such as fissure, tear, or laceration. One study [49] found fissures in 16% of cases after anal intercourse. Another study found tears in 19 of 55 patients reporting anal contact. In both these studies patients were generally examined within 72 h of the incident. The incidence of bruising noted is considerably less and is reported as occurring in between 2 and 4% of cases. In no cases were major sphincter disruptions observed. Regarding repeated acts of anal penetration, study results conflict. A study of 129 heterosexual women who gave histories of anal intercourse showed no report of gross fecal incontinence [50] while another [51] found that although the anoreceptive males had lower resting anal canal pressures, there were no complaints of fecal incontinence; however, another study [52] found a significant increase in fecal incontinence or urgency. The term anal fissure refers to breaks or a tear in the skin around the anus. Fissures may be acute (i.e., developing and healing within a couple of weeks) caused by some form of trauma, or chronic (i.e., persistent and not healing) perhaps being initiated by trauma and prolonged by certain diseases or illnesses. Chronic constipation, requiring straining to defecate, associated with the passage of hard stool, is one cause of acute fissure development and defecation has been noted to cause a superficial abrasion of the anal verge [19]. Other causes of acute and chronic fissure include sexually transmitted disease, diarrhea, inflammatory bowel disease (e.g., Crohn's disease), and skin diseases. Another cause of the development of anal fissures is the passage of objects into the anal passage for sexual purposes, this may include items such as dildos or a penis. In the absence of repeated trauma, any fissures, tears, or lacerations would be expected to heal within two weeks or so and leave no residual marks.

Management Postassault

It is important that medical needs are appropriately attended to after an assault. The follow-up of a complainant may be essential, particularly when considering potential infectious complications (e.g., sexually transmitted infections (STI), hepatitis, and HIV). The usual ethical principles of consent and confidentiality apply, but these may be confounded, at least temporarily by other factors, such as drugs or alcohol or mental health considerations. The forensic physician must weigh up the priorities regarding medical care and forensic sampling and determine which, from the examinee's viewpoint is in their best interests. Treatment may involve screening for infection either in the community or in hospital, emergency contraception, and prophylaxis against STI, which may be a significant risk. Often, particularly in the case of HIV, specialist advice may need to be sought. It is essential that as much relevant information is supplied to the treating doctor as possible, so that an informed approach can be made [53]. Additionally, facilities should be in place for future medical, social, and psychological support.

Conclusions

Complaints of sexual assault are common. A forensic physician (or other appropriate healthcare professional) has a duty to undertake a full assessment in an appropriate nonjudgmental, impartial, and appropriate manner; false complaints do occur. Many investigating officers from police or other agencies may not be conversant with the needs and limits of medical forensic assessments.

The principles for examination of all complainants (and suspects) of sexual assault are clear. They require an understanding of medicine, anatomy, physiology, and science. The forensic physician must ensure that evidential findings are not over- or misinterpreted. The health of the individual being examined is paramount, forensic issues must be considered secondary to the well-being of the examinee. The examinee's best interests are served by a full and detailed history and examination with appropriate sample taking and clear and accurate documentation

of findings. The examiner should remember basic medical principles and ensure that the information they provide to the court is accurate and relevant and unbiased.

Autoerotic Deaths

Introduction

Deaths associated with sexual activity have been classified by homicide detectives as "death by sexual misadventure" [1], and by the research literature as "sexual fatalities" [2]. The term *sexual fatality* refers to *a broad array of deaths* that involve a sexual element (see Table 1).

This article focuses on sexual fatalities known as *autoerotic deaths*, which often require a postmortem behavioral analysis or psychological autopsy to assist the medical examiner. Autoerotic deaths are unanticipated deaths that occur while the victim is engaged in solitary sexual activity [3], most commonly masturbation [4]. Autoerotic deaths are most frequently caused by a failure of the "escape" mechanism the victim designed to stop his cerebral hypoxia immediately before unconsciousness.

The term *asphyxiophilia* has been used to describe sexual arousal to the state of oxygen deprivation [5]. It is not specifically listed in the Diagnostic and Statistical Manual of Mental Disorders, 4th ed.–Text Revision (DSM-IV-TR) under paraphilias; however, it could be classified as a "Paraphilia Not Otherwise Specified" [6]. Since this type of death is often associated with ligature strangulation and other forms of self-harm, there is the potential for the medical examiner to misidentify autoerotic deaths as suicides and homicides.

The medical examiner's goal is to classify deaths into one of the four categories or "modes": natural, accidental, suicide, or homicide (*NASH*) [7]. When a death cannot be immediately classified, it is often officially referred to as *undetermined*. Deaths that are associated with some element of sexual activity can occasionally present a confusing picture, resulting in a finding of an undetermined or "equivocal" death. An "equivocal death" is one in which the

Table 1 Examples of sexual fatalities [2]

• Myocardial infarction or stroke during coitus or masturbation
• Autoerotic asphyxiation
• Accidental asphyxiation by a partner
• Masochistic sexual practices involving electrocution or bondage

manner of death is questionable, or the circumstances surrounding the death are otherwise unclear [8]. Sexual fatalities in which the decedent was also using substances may be particularly difficult to classify [9]. Research has strongly suggested that the majority of autoerotic deaths are due to AEA [3].

Autoerotic Asphyxiation

AEA is the practice of self-induced strangulation, ostensibly for the purpose of enhancing the pleasure of masturbating [5, 10]. It has been reported that the hypoxia induced by the reduced cerebral blood flow may produce an altered or enhanced sexual experience [11]. Of critical importance is that the practitioner's intent is sexual pleasure, not suicide. Cases combining suicide with AEA have been reported, but are believed to be quite rare [2]. It has been estimated that AEA is responsible for approximately 500–1000 deaths annually in the United States [12, 13]. However, such estimates may be conservative, as cases of fatal AEA are subject to underreporting and misidentification. The majority of victims are Caucasian males [14].

Most deaths resulting from AEA are due to an accidental, unintended failure of a release mechanism in the apparatus designed to produce cerebral hypoxia [3, 15]. The physiological mechanisms observed in fatal AEA can be categorized into four basic processes (see Table 2).

Bilateral neck compression can quickly produce unconsciousness via the carotid sinus reflex. The carotid sinus reflex is triggered by continuous pressure on the carotid artery in the area of the carotid bifurcation. Stimulation of the carotid sinus reflex induces vascular hypotension and a reduced heart rate, which significantly reduces cerebral blood flow. Airway obstruction may result from gags, inhaled vomitus, plastic bags drawn tightly over the victim's head, or other forms of suffocation. AEA victims may also bind themselves tightly enough around the torso that chest expansion is greatly reduced, resulting in fatal hypoxia. Finally, inhaled chemicals such as amyl nitrite may displace or exclude the availability of oxygen in the lungs.

Table 2 Physiological mechanisms of fatal autoerotic asphyxiation [3, 15]

1. Neck compression
2. Airway obstruction
3. Chest compression
4. Oxygen deprivation

Table 3 Pathological findings in AEA [3]

- Petechial hemorrhages of conjunctiva, sclera, and face
- Pulmonary congestion
- Congestion of viscera
- Occasional thyroid cartilage fracture

On autopsy, several pathological findings are commonly found (see Table 3) [3]. These include petechial hemorrhages of the conjunctiva, sclera, and face. The viscera is often diffusely congested, and pulmonary congestion is common. There may occasionally be a fracture of the thyroid cartilage, depending upon the nature and placement of the neck ligature. However, fractured thyroid cartilage is more often associated with manual strangulation. The presence of seminal discharge has been described as unhelpful in distinguishing fatal AEA from other modes of death [4].

Criteria have been proposed to assist in the determination of the AEA death (see Table 4) [16]. There must be a physiologic mechanism present which the victim had used for sexual arousal. Evidence of solitary sexual activity and sexual fantasy aids should be present, such as pornography or sexually oriented props. There will often be evidence of prior autoerotic practice, either from findings at the scene, or from collateral interviews. Finally, there should be an absence of suicidal intent, which may require a comprehensive psychological autopsy (*see* **Psychological Autopsy**) [7, 8].

Other death scene findings have been described as pathognomonic for fatal AEA (see Table 5) [13]. The victim will often be either partially supported by the ground, or will otherwise have some structure nearby to stand on and alleviate neck compression. Neck ligatures, the most common method

Table 4 Proposed criteria for autoerotic death [16]

1. Physiologic mechanism for obtaining sexual arousal
2. Solitary sexual activity
3. Sexual fantasy aids (pornography, sex toys, and mirrors)
4. Prior autoerotic practice
5. Absence of suicidal intent

Table 5 Common findings in fatal AEA [13]

- Body partially supported by ground
- Ligature with self-rescue mechanism (slip knot, etc.)
- Bondage items and/or sexual masochistic behavior (genitals, nipples, etc.)
- Male wearing female attire
- Protective padding between ligature and body

for AEA, will have been designed by the victim to have some type of self-rescue mechanism. This may be a slip knot or an interconnection between ligatures.

Male victims of fatal AEA may be found wearing various pieces of female attire (cross-dressing), or bondage type attire such as leather, chains, and rubberized garments. Victims who practiced masochistic type sexual behaviors may show evidence of prior self-mutilation. Examination of the ligature often reveals the presence of protective padding between the ligature and the neck. This is done by the AEA practitioner to prevent tell tale neck abrasions and bruising.

AEA in Women

The extant research literature suggests that women victims of fatal AEA are far less frequent than men [17]. Thus, the body of research providing information about female autoerotic deaths is relatively small. It is believed that fatal AEA in women may have a less obvious presentation than in men [18]. This may be due to the fact that the majority of women in early studies did not employ sexual props, special clothing, or extra ligatures. AEA in women may be distinguished simply by evidence of solitary sexual activity, neck compression with a self-rescue mechanism, padding around the neck, and the absence of indicators of suicide or depression.

Women are more likely than men to employ only a simple ligature around the neck, which is controlled by body position movement [13]. Other methods described in cases of fatal AEA in women include suffocation by plastic bag over the head and inhalation of ether [19]. A case involving foreign body insertion has also been described [16]. Most of the research supports the finding that women may be less inclined than men to use pornography or fetishistic items during AEA. For this reason, the female autoerotic death scene may pose a greater challenge in distinguishing accidental death due to sexual misadventure from suicide and homicide.

Atypical Autoerotic Asphyxiation

While ligature strangulation about the neck is the most frequently reported method in fatal AEA, atypical cases may be encountered. Such cases may involve asphyxia due to inhalants, plastic bags, or suffocation due to a variety of forms of external compression of the thorax. Atypical cases of AEA have been defined on the basis of (i) the nature of the autoerotic activity, (ii) the cause of death, and (iii) the relationship between the two [20].

Atypical AEA leading to death is believed to account for about 10.3% of cases in the literature [14]. Atypical AEA fatalities can be classified into five broad categories: electrocution (3.7%), binding/overdressing/body wrapping (1.5%), foreign body insertion (1.2%), atypical asphyxia method (2.9%), and miscellaneous (1.0%) [14]. Table 6 lists some of the most commonly reported mechanisms of atypical AEA deaths.

Some cases may be atypical even when evidence of ligature strangulation is present. For example, the hypoxia induced may result in a fall and fatal head injury. Other causes may include aspiration, cardiovascular disease, and syncope due to inhalant use. Acute cerebral hypoxia may be produced by the inhalation of amyl and butyl nitrite, known colloquially as *poppers*. The use of other inhaled substances, such as N_2O, ether, and chloroform has also been described [4, 22].

The use of electrocution has been found to be the cause of death in some cases. Typically, the victim will have constructed a wiring device that draws on household current. The mechanism of death

Table 6 Mechanisms of death in atypical autoerotic fatalities [14, 21]

- Cardiovascular
- Electrocution
- Inhalants
- Suffocation from “binding”
- Hyperthermia
- Sepsis due to foreign body
- Hemorrhage

in such cases is often attributed to fatal cardiac arrhythmia, although respiratory arrest is also a possibility [23]. Cases have been reported involving electrocution of the genitals, nipples, and anal cavity [4, 15].

Binding

The sexual fetish known as *binding* or *body wrapping*, involves tightly wrapping the body in various materials such as leather, rubber, or plastic wrap. It is a relatively rare form of atypical AEA death, accounting for approximately 1.5% of published cases [24]. Besides suffocation due to thoracic compression, binding may lead to fatal hyperthermia when the body can no longer effectively thermoregulate with sweating because of the tightly-wrapped binding materials.

Aquaeroticum

Another rarely reported autoerotic phenomenon, aquaeroticum, involves asphyxia from submersion under water. Typically, the victim will engage in masturbation while submerged, either with or without bindings or other attire. For example, one reported case of a 25-year-old man described his homemade plastic body suit and complex bondage [25]. The victim was found submersed, tied underwater to a boat, and had been using a homemade diving apparatus for air supply. It was determined that his death resulted from a faulty air-supply device.

Breath Control Play

Breath control play is a term used by it's practitioners to describe the sexual practice of asphyxiation by strangulation or suffocation of one person by another during sexual intercourse [10]. Breath control play may be done in conjunction with other fetish activities. Cases of unintended homicide due to mutually consenting breath control play have been described [15]. Such cases have the potential to be misidentified as either a simple AEA fatality or as a sexual murder.

Asphyxial Games in Juveniles

In cases of autoasphyxiation in children and adolescents, the phenomenon of asphyxial games should be considered. Asphyxial games, while not new to the juvenile population, may be increasing in overall lethality. It has been hypothesized that this increased lethality may be due to the increasing use of ligature, playing the "game" alone, and a societal trend of "extreme" sports and activities among youth [26]. Some slang terms used by juveniles to describe asphyxial games are listed in Table 7. The goal of juvenile asphyxial games is to produce a euphoric hypoxia. Thus, asphyxial games in juveniles do not ordinarily have a sexual theme or purpose.

Table 7 Slang terms for asphyxial games [27]

- Space monkey
- Space cowboy
- The choking game
- Black hole
- Black out
- Flatlining
- Funky chicken
- Gasp
- Knock out
- Rising sun
- Tingling
- Suffocation roulette

The limited research available on juvenile asphyxial games suggests that the typical age range is 9–15 years, and the male to female ratio is approximately 2 : 1 [26]. Two general typologies of asphyxial game playing in juveniles have been proposed. One group is described as athletic, action-oriented, and being average to above average students. This group may turn to asphyxial games due to their thrill-seeking nature. The second group is described as a "subset of younger adolescents with anxiety and/or depression who, having a desire for drugs and alcohol... but limited access to such agents, turn to this kind of behavior as a substitute" [26].

Postmortem Behavioral Analysis and Psychological Autopsy

Many cases of autoerotic fatality require a comprehensive investigation consisting of (i) a thorough death scene investigation, (ii) a complete autopsy, (iii) toxicology, (iv) collateral interviews, (v) behavioral analysis, and (vi) a psychological

Table 8 Postmortem behavioral analysis

- Examination of neck
- Examination of ligatures, bindings, and restraints
- Careful analysis of release mechanism
- Decedent's attire
- Presence of sexual aids
- Evidence of prior autoerotic behavior
- Visual inspection of death scene
- Decedent's possessions
- Decedent's journals, emails, and writings
- Forensic analysis of decedent's personal computer
- Review of medical examiner's findings
- Toxicologic analyses
- Review of any relevant medical or psychiatric records
- Collateral interviews of decedent's family and social contacts

autopsy to determine the presence of suicidal intent [2–4, 7] (*see* **Psychological Autopsy**). The postmortem behavioral analysis requires gathering the decedent historical information from collateral sources, and analyzing this data in conjunction with the physical evidence from the death scene [2].

It is important to note that areas of the decedent's dwelling other than the death scene may have to be searched for the purpose of analyzing the decedent's possessions. Evidence of interest in and collection of autoerotic materials and pornography may be found in areas that are not readily visualized. Table 8 gives a list of important elements of the postmortem behavioral analysis.

Forensic computer analysis is a very helpful and often necessary part of the postmortem behavioral analysis. The victim's emails and Internet activity may reflect an interest in autoerotic activity. Websites explaining and promoting dangerous autoerotic activity currently abound on the Internet (e.g., http://www.zeroair.com) [27]. Over the past several years, there have been increasing reports of autoerotic fatalities that were directly associated with Internet use [28, 29].

During the behavioral reconstructive phase, it may be necessary for investigators to recreate complex bindings, knots, ligatures, or body positions in an effort to see if the decedent was physically capable of creating the mechanisms discovered at the death scene. Significant challenges to the investigation may arise. For example, cases of family members altering the death scene out of shame or impulse have been described [4]. In addition, cases in which suicide notes were actually part of a sexual fantasy may result in a mistaken conclusion of suicide [13].

Another challenge may involve decedents who are found with both hands bound. Such cases may easily be mistaken as "suspicious" for a homicide [30]. However, a thorough postmortem behavioral analysis which includes a reconstruction of the victim's position and bindings may resolve the case. A thorough postmortem behavioral analysis should focus on the presence or absence of certain key features of the death scene (see Table 9).

Investigators should attempt to find evidence of prior AEA experience in the deceased [3, 13] In addition to collateral interviews of the victim's social

Table 9 Key features of the autoerotic death scene [3, 4, 13]

Location	• Secluded, isolated • Bedroom, basement, and garage • Locked room
Victim position	• Partially supported by ground • Occasionally suspended • Suspension point within victim's reach • Genital area exposed • Victim's hand on or near genitals
Injurious agent	• Ligature • Electric current • Gag • Inhaled chemicals • Restrictive device or container
Self-Rescue mechanism	• Slip knot • Ability to stand erect to relieve pressure • Connection between ligatures • Knife
Bondage	• Ropes, chains • Handcuffs • Bondage of genitalia • Miscellaneous bindings
Masochism	• Injury inflicted on genitalia • Self-induced burns • Electrical wires • Insertion of sharp objects • Miscellaneous self-mutilation
Attire	• Nude or partially nude • Female clothing • Leather or rubber materials
Protective padding	• Between ligature and body surface
Sexual paraphernalia	• Pornographic literature, videos • Fetish items, female undergarments • Sexual devices (vibrators, dildos)

contacts, investigators should search for suspension point indentations or marks, suggesting prior use of ligature. Permanently affixed protective padding suggests prior experience with AEA. It has been reasoned that increasing complexity of the asphyxial mechanism, bindings, and sexual props suggests that the AEA practices have become more elaborate over time [4].

Automated Fingerprint Identification System

Introduction

Definition

Automated fingerprint identification system (AFIS) refers to a computer system developed in order to assist in establishing the identity of an individual through fingerprints. AFIS technology is used for forensic and nonforensic (other government uses and commercial) applications, but this article concentrates only on the forensic applications.

Early Fingerprint Classification

At the end of the nineteenth century, William Herschel and Henry Faulds set out the principles of the forensic use of fingerprints and fingermarks: the use of fingerprints and fingerprint collections for the identification of offenders and the use of fingermarks to establish a link between a crime scene or an object and an individual. In the literature, confusion exists between the term print and mark. We will use a uniform terminology: the finger dermatoglyphics and their standard rolled or flat inked or scanned impressions are named *fingerprints* while the recovered or lifted traces are named *fingermarks*. *Marks* is a preferred usage in many countries to designate impressions that, in other countries (primarily the United States and Canada) would be characterized as *latent* impressions. In criminal records, the standard impressions are collected using forms named 10-print cards (see Figure 1).

The first system of fingerprint classification was introduced by Juan Vucetich in Argentina in 1891. The development and practical application of dactyloscopy for forensic use became known in law enforcement after the publication of the first manual and a system of fingerprint classification by Francis Galton. This led to the acceptance of fingerprints in Great Britain. Then, in 1900, Edward Richard Henry modified the classification system of Galton, which became the most widely used system under the name of Galton–Henry. The volume of paper-based 10-print card collections increased progressively during the twentieth century and workability was maintained by increasing the sophistication of the classification system, leading to a trade-off between selectivity and reliability.

AFIS Technology

Development

With the advent of computers in the mid-1960s, work on the automation of fingerprint identification started. Manual searching of the 10-finger hard-copy card collections reached its limits, in terms of workload and efficiency. The USA and Japan concentrated on the automation of the high-volume 10-print work load, while France and the UK focused more on the automation of fingermark identification. After a decade of effort, digitization of the 10-print card and automatic extraction of minutiae became effective enough for the USA and UK to produce automatic fingerprint reader systems. This advancement eventually permitted the digitization of the 10-print cards, thus permitting the storage of the standard impressions and the demographic data of individuals (e.g., name, citizenship, and date of birth) in a computerized database [1, **Databases**].

Image Capture. Currently, flat-bed document scanners are used for the digitization of the 10-print cards, but the capture of standard impressions is also possible by applying and rolling the finger friction ridge skin directly on fingerprint live-scan equipment (*see* **Biometric Devices**). The fingermarks are captured from their initial support with digital cameras or are scanned from analog pictures. Image-processing techniques are then applied to segment each fingerprint of a 10-print card as an individual image and to enhance the image parameters. Finally, the images are stored as 256 gray-level (8-bit-GS) images at a resolution of 500 or 1000 pixels per inch (ppi) and compressed at a ratio of about 1 : 15 using wavelet-based algorithms such as wavelet scalar quantization (WSQ) or Joint Photographic Expert Group 2000 (JPEG2000 or JP2). The current international American National Standards Institute (ANSI)-Nattional Institute for Standards and Technology (NIST) fingerprint/fingermark image exchange file format stores JP2 8-bit-GS, 1000 ppi images.

Feature Extraction. In parallel to digitization, research has concentrated on classification. The first approaches translated the manual pattern

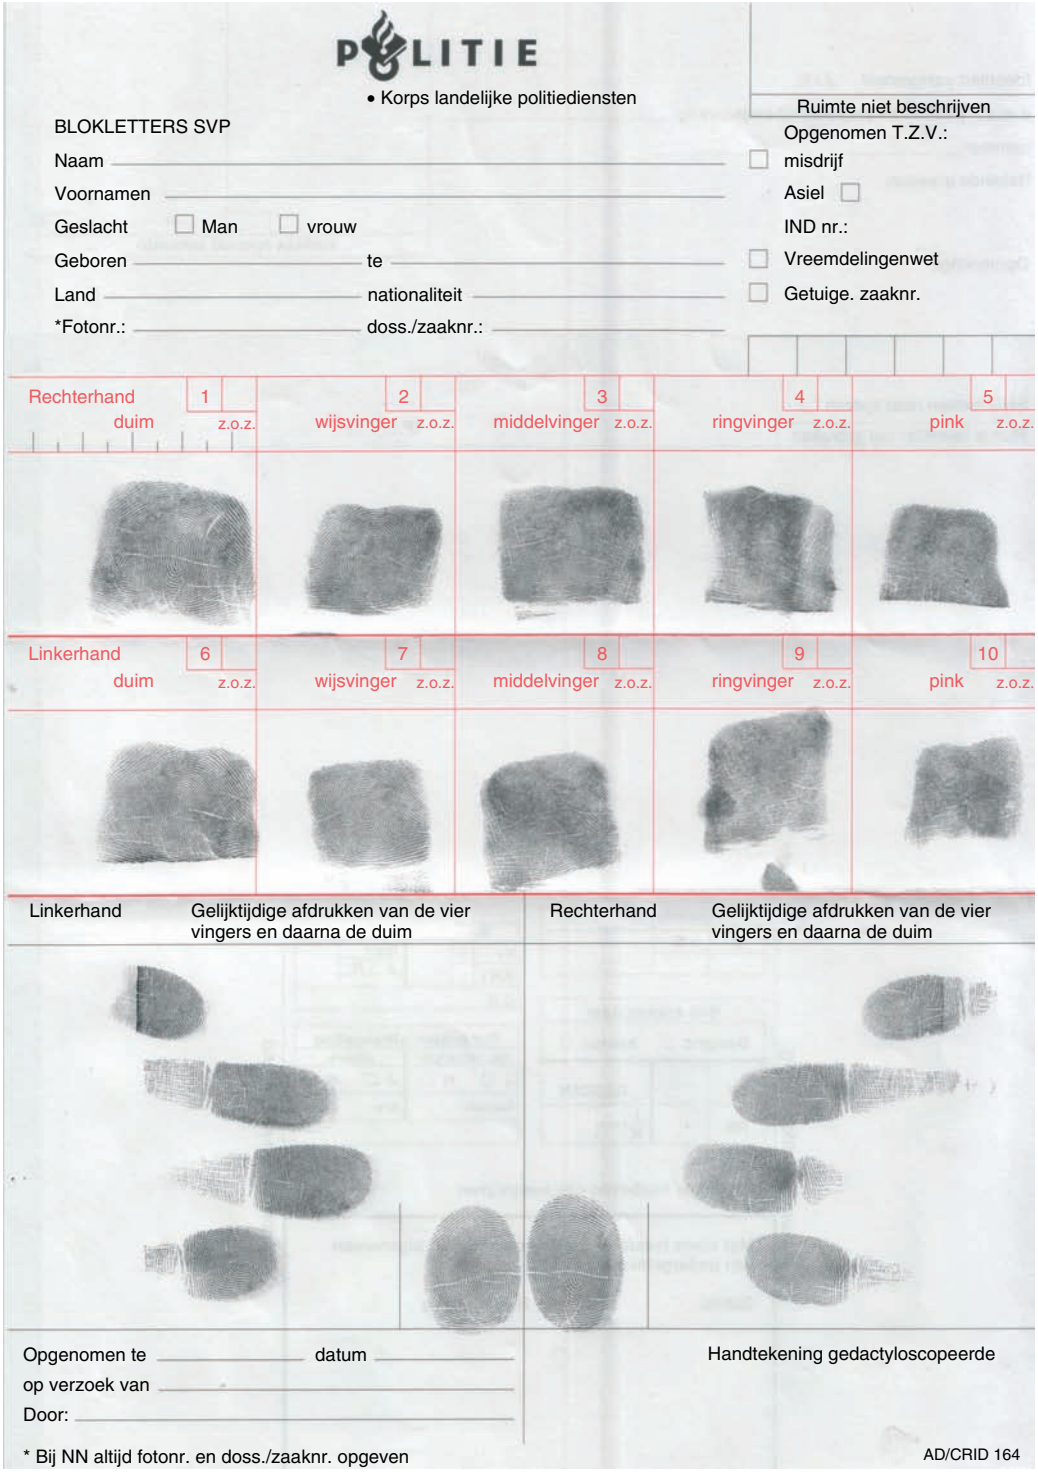

Figure 1 Example of 10-print card

classification into computer-friendly codes based on the shape of the papillary ridge flow; this shape is named *general pattern* and classified as first-level detail. This operation resulted in a potential elimination of the manual search and filing errors, but did not offset the original pattern type assignment errors [2]. Later, the fingerprint pattern classification was automated using the ridge direction matrix extracted from the fingerprint images. However, this suffered from the same type of assignment errors [3]. A solution was found with the more precise automatic minutiae detection and the comparison of minutiae configurations. Minutiae are points of termination (ridge ending) or bifurcation of the papillary ridges; they are also named *Galton points* and classified as second-level detail (see Figure 2a and b).

Current AFIS systems use the position (x and y coordinates) and the tail angle (θ) of the minutiae as the core components of comparison, followed by the use of extended characteristics of the minutiae such as their basic type (ridge ending or bifurcation), the ridge count between pairs of minutiae or the topology of the minutiae in combination with other features. The crucial elements in the success of this approach are the extreme typicality and robustness offered by the topology of the minutiae configurations and the development of robust image-processing techniques to enhance the papillary ridge structure and clarity.

The main stages of the feature extraction components consist in an orientation field estimation, by using information about local average directions of the ridges (gradient or ridge-valley algorithm), a ridge detection, by using either a thresholding algorithm given a gray-scale image, the ridge-valley algorithm, or a gray-level histogram decomposition, and a thinning of the ridges, by means of algorithms based on mathematical morphology [4]. These techniques allow for an accurate minutiae designation on high-quality fingerprint and fingermark images, as the ridges have well-defined frequency and orientation in local areas. On low-quality fingerprint and fingermark images, automatic minutiae designation remains a challenge and still does not equal the ability of human friction ridge examiners to designate the visible minutiae.

Feature Comparison. Numerous methods have been developed to automatically compare fingermark and fingerprint images; however, they can be classified into two approaches: the correlation-based and the structural feature-based comparison. The correlation-based comparison relies on global pattern matching; it consists in using translation and rotation to find the best superposition to compute the maximum correlation between two images. The structural feature-based comparison is based on the matching of extracted features; it consists in searching alignment between minutiae extracted from a fingermark

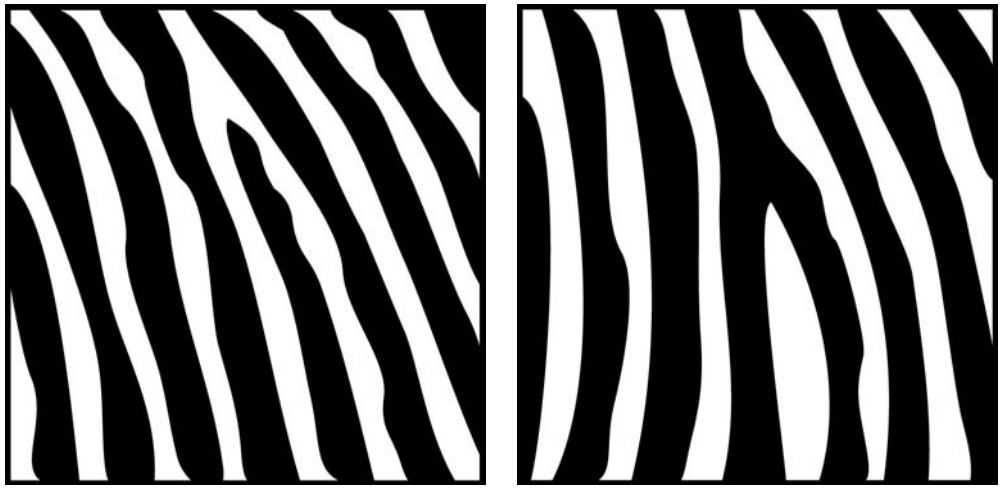

Figure 2 (a) Minutia or Galton point, basic type ridge ending. (b) Minutia or Galton point, basic type bifurcation

and a fingerprint image and in finding the maximum number of minutiae pairing. The structural feature-based approach is more robust but requires more computation than the correlation-based comparison. In general, the result of the comparison is expressed as a scalar number representing a statistical distance or a proximity index between a fingermark and a fingerprint [5].

Forensic AFIS systems exploit these two approaches to optimize their performance, but the problem remains complex. This difficulty is mainly due to the uncontrolled conditions of production of fingermarks during criminal activity and the large variability of different impressions of the same finger, named within-finger variability. The main factors responsible for this within-finger variability are the ridge skin condition, the transfer of information with loss from a complete three-dimensional pattern to a partial two-dimensional pattern, and the nonlinear distortions of the papillary ridges. These distortions result from the skin plasticity and from the movement of the finger during the production of the fingermark. These factors do not modify the topological relationships of the papillary ridges and of the minutiae configurations, but they modify the shape of the papillary ridge flow and the absolute distance between any pair of minutiae. The key to fingerprint features comparison is to exploit the topological invariance of the minutiae configurations despite the factors responsible for the within-finger variability. The current sophistication of the algorithms allows for state-of-the-art AFIS technologies to reach a false rejection rate (FRR) lower than 2% for a false acceptance rate (FAR) of 0.0001% in a task of identity verification comparing inked rolled fingerprints and partial fingermarks containing 15 paired minutiae.

Forensic Uses of AFIS Technology

AFIS technology was initially developed to assist the friction ridge examiners with computers in the process of verification of the identity of individuals through their fingerprints. This process consists in searching the 10 fingerprints of an individual in the database of standard impressions to verify if (s)he is already present in the database and, if present, to verify the rightness of his/her demographic data. AFIS technology has achieved enough maturity to offer an identity verification process, that is, virtually error-free from the technological point of view, although clerical mistakes in the database or in the running of the process can never be excluded.

In the 1990s, the semiautomatic processing of fingermarks was made possible by the improvement of both AFIS and computer technologies. Allying the manual minutiae extraction of the friction ridge examiners and the automatic comparison of the AFIS allowed the partial automation of forensic investigation and forensic intelligence using fingermarks. For forensic investigation, lists of potential sources for fingermarks could be produced automatically from the digitized 10-print card databases. For forensic intelligence, links between digitized fingermarks could be generated automatically.

In the 2000s, the improvement of the computer mass-storage, in terms of size and affordability, initiated the constitution of large-scale palmprint databases. It has allowed for an extension of the forensic investigation and forensic intelligence processes based on the use of palm marks. In most countries, the development of large-scale palmprint databases is an ongoing process.

Future Challenges for AFIS Technology in Forensic Science

Further Automation. Minutiae designation on low-quality fingerprint and fingermark images remains a computer-assisted process, combining the outstanding but subjective human pattern recognition ability and the more objective but also more limited computer ability. Both the human inconsistencies and the limits of the computer affect the performance of the feature extraction and, as a consequence, the performance of the forensic investigation and intelligence processes based on the use of finger- and palm-marks. Thus, a feature extraction process at once reliable and completely automated is desirable. Steps in this direction can be achieved not only by refining the minutiae extraction process but also by enriching the feature vector with other available, measurable, discriminatory, permanent, and robust features, like, e.g., the automatic count of the number of ridges between the minutiae.

Scalability and Interoperability. The scalability of the paper-based 10-print collections was limited by the necessary trade-off between selectivity and reliability imposed by manual classification systems, and the coexistence of several systems around the world

limited their interoperability at international level. The implementation of AFIS solved the problem of scalability for the national fingerprint databases but the interoperability problem remains as the first generations of AFIS incorporate feature vectors encoded using proprietary formats. Currently, the problem of interoperability between different types of AFIS is being solved partially by the widespread use of the ANSI-NIST biometric exchange file format, but the predominant use of proprietary formats for the feature vectors remains. This improvement opens a new challenge in terms of scalability, with the possibility to extend the interoperability of the AFIS at a global level.

Forensic Evaluation Based on AFIS Technology. Forensic evaluation of fingermarks and fingerprints consists mainly in the inference of identity of the source of a fingermark and a fingerprint. Currently, this task remains exclusively performed by friction ridge examiners. They apply the analysis, comparison, evaluation, verification (ACE-V) procedure and, in some countries, a numerical standard to substantiate three types of qualitative opinion: identification, exclusion, or inconclusive (*see* **Identification and Individualization**). As their evaluation is deterministic, friction ridge examiners also make an implicit use of their own subjective probabilities of the rarity of the features used for identification. They refine these subjective probabilities through training and experience.

In forensic research, the inference of identity of the source of a fingermark and a fingerprint is also envisaged, combining AFIS technology, digitized fingerprint, and fingermark databases as well as a scientific methodology; namely the likelihood ratio approach based on the Bayes theorem. This new approach aims to offer a uniform framework and a transparent methodology to the friction ridge examiners, and to assist them in producing a logical, testable, and quantitative evaluation of the fingerprint evidence [6, **Friction Ridge Examination (Fingerprints): Interpretation of**].

DIDIER MEUWLY

Automatism as a Defense to Crime

Automatism, from the Greek *automatismos* or self-action, refers to unconscious, involuntary behavior. The terms *automatism* and *unconsciousness* are sometimes used interchangeably. Either word has been used to mean that individuals have some degree of unawareness of their thoughts or behaviors. Automatism may be used as a defense against criminal responsibility, in essence to reduce culpability, based on the idea that a person cannot be held liable for actions that do not stem from full awareness of thoughts and behaviors.

In the case *People v Huey Newton* [1], the court held that "unconsciousness, when not self-induced say, as by voluntary intoxication, is a complete defense to a criminal act even though the defendant's acts seem very goal oriented". Lord Denning in *Bratty v Attorney General of Northern Ireland* [2] recognized two classes of automatism. The first class is a complete lack of consciousness and the second "an absence of control of the mind over actions". The latter applies to persons conscious of, but not in control of, their own actions.

The causes of automatism used in criminal defense include somnambulism [3], hypnotism [4], cerebral concussion, delerium from fever or drugs, diabetic shock [5], and epileptic blackouts [6, 7].

In American courts there has been no consistent interpretation of the automatism defense. Some courts have viewed automatism as a variation of the insanity defense, whereas other courts have accepted it as a complete affirmative defense. A great deal rests on the court's interpretation because an insanity defense usually results in hospitalization, whereas a successful strict affirmative defense results in acquittal [8].

In several cases in the United States, automatism has been considered a variation of the insanity defense (*see* **Insanity: Defense**). The Model Penal Code developed by the American Law Institute in 1962 and updated in 1981 defined the standard for the insanity defense as follows: "A person is not responsible for criminal conduct if at the time of such conduct, as a result of mental disease or mental defect, he lacks substantial capacity either to appreciate the criminality of his conduct or to conform his conduct to the requirements of law" [9].

In *People v Higgins* [10], Mr Higgins entered a plea of not guilty by reason of insanity contending that at the time of the offense he was "in the throes of an epileptic rage or furor, and consequently was laboring under such a defect of reason as not to know the nature of the quality of the act or that it was wrong". Mr Cooley, in a similar insanity defense application of automatism, presented evidence that at the time of committing the offense he was suffering from epilepsy and consequently was unaware of his actions [11]. The instructions to the jury in this case were "The law presumes every man sane until . . . the contrary is shown by the evidence; and, before the defendant can be excused on the ground of insanity, the Jury must believe from the evidence that the defendant was at the time of the killing without sufficient reason to know what he was doing, or had not sufficient reason to know right from wrong, or that, as a result of mental unsoundness, he had not then sufficient will power to govern his actions, by reason of some insane impulse which he could not resist or control". In these cases, the defense relies on the notion that a person's state of mind is incapable of knowing right from wrong, or if they know it, they have no volitional control over their behavior.

Other courts have recognized automatism as a complete affirmative defense, distinct from the insanity defense. The absence of a clear mental disease or defect, a requirement of the insanity defense in all jurisdictions, demands a different approach. The complete defense conceptualization is based on *actus reus*, the guilty act component of the two part test of criminality (the other being *mens rea*, guilty mind) must be voluntary. The Model Penal Code states that "A person is not guilty of an offense unless his liability is based on conduct which includes a voluntary act or the omission to perform an act of which he is physically capable." The code offers the following examples of involuntary acts: reflex or convulsion, bodily movement during unconsciousness or sleep, conduct during hypnosis or resulting from hypnotic suggestion, bodily movement that otherwise is not a product of the effort or determination of the actor, either conscious or habitual [9].

In *State v Caddell* [12], the Supreme Court of North Carolina stated that "the defenses of insanity and unconsciousness are not the same in nature, for unconsciousness at the time of the alleged criminal act need not be the result of a disease or defect of the mind; as a consequence, the two defenses are not the same in effect, for a defendant found not guilty by reason of unconsciousness, as distinct from insanity, is not subject to commitment to a hospital for the mentally ill". In *People v Newton* [13], the court stated that "unconsciousness is a complete defense that negates the defendant's capacity to commit any crime at all".

Likewise, a complete defense based on the absence of *mens rea* and on the inability to form some intent has been applied in court. This approach again differs from the insanity defense because it implies that an automatism is not the same as a mental disease or defect. In *People v Grant* [14], after the jury had rejected an insanity defense, the appellate court granted an epileptic defendant a remand to allow the jury to consider an automatism defense. Illustrative of the difficulty in clarifying *mens rea* in such defenses, the jury was allowed to consider prior actions as reflective of the degree of awareness of criminal behavior to impute the *mens rea* of the actual offense.

Regardless of the type of automatism defense, the insanity defense, which asserts a lack of knowing or volitional control of wrongful behavior, or a complete affirmative defense due to the absence of voluntary *actus reus* or *mens rea*, the court is challenged to determine the degree to which a person has access to and awareness of their thoughts and behaviors. Ultimately a judgment must be made as to whether the defendant had *enough* ability, along the continuum of awareness, to access into consciousness their criminal thoughts and behaviors. According to Candeub [15] "this judgment is crucial for determining culpability because only an actor who can be expected to consciously respond to reason can be morally and legally culpable". To simply offer that somnambulism, for example, is completely involuntary does not necessarily match the science. Somnambulism, and the behaviors associated with somnambulism, seems to be neither fully voluntary nor fully involuntary [16]. Thus, even defendants who following some otherwise criminal behavior due to somnambulism are able to later recall and discuss their intents and acts may be less culpable, or even lack complete culpability, if in the judgment of the court those intents and acts occurred outside the degree of awareness necessary for responsibility, *actus reus* or *mens rea*.

In the British system, a distinction is made between sane and insane automatism [8]. British courts use the *McNaughten* [17] standard for the insanity defense. The *McNaughten* standard states that, for a successful insanity defense, it must be proven that "at the time of committing the offense, the accused was laboring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing or if he did know it, that he did not know he was doing what was wrong". Within this context automatism is conceptualized as a "defect of reason", which may or may not be as a result of a "disease of the mind". If the "defect of reason" is a result of a "disease of the mind", it is defined as *insane automatism*, which meets the *McNaughten* standard. Consequently, an insanity defense is appropriate. If the "defect of reason" is not as a result of a "disease of the mind", it is considered a sane automatism, which may then serve as a complete defense and potential cause for acquittal.

The British system attempts to resolve the issue of degree of awareness of thoughts or actions through an understanding of the cause of the purported unawareness. If the trier of fact concludes that the degree of unawareness meets some minimal threshold, then the question becomes, "What caused the unawareness, a disease of the mind or not?" In *R v Sullivan* [18] Mr Sullivan contended that, while he had caused grievous bodily harm to the victim, he had done so while recovering from a minor epileptic seizure and that, therefore a defense of automatism was appropriate. The trial judge ruled that the defense was one of insanity not automatism. On appeal the House of Lords agreed, stating "if the effect of a disease was to impair those faculties so severely as to have the consequence that the accused did not know what he was doing, or, if he did, that he did not know that it was wrong, he was 'insane' in the legal sense. Accordingly, it did not matter whether the cause of the impairment was organic, as in epilepsy, or functional, or whether the impairment itself was permanent". The court further defined sane automatism as "temporary impairment of the mental faculties, not being self-induced by consuming drink or drugs, resulting from some external physical factor such as a blow to the head causing concussion or the administration of an anesthetic for therapeutic purposes".

Unfortunately, the Sullivan court's effort to interpret a disease of the mind as due either to internal factors or external factors only creates a subsequent problem. The argument that insane automatism is caused by internal factors and sane automatism by external factors is problematic. Consider, for example, the case of *R v Quick* [19] in which a diabetic in a hypoglycemic state injured an individual. The trial judge ruled that the appropriate defense was one of insanity. The Court of Appeals disagreed stating that it was a defense of "non-insane automatism, involuntary conduct which is not brought about by a disease of the mind but through other factors". The court considered it an "affront to common sense to regard a person as mad whose symptoms can be rectified by a lump of sugar".

Matters are further complicated because a judge may also consider the likelihood of recurrence of the criminal behavior as a factor in deciding whether the appropriate defense an insanity defense or a complete affirmative, that is, whether the appropriate disposition is hospitalization or acquittal. In *Bratty v Attorney General of Northern Ireland* [2], the court held that "any mental disorder which has

manifested itself in violence and is likely to recur is a disease of the mind. At any rate it is the sort of disease for which the person should be retained in hospital rather than be given an unqualified acquittal".

In summary, automatism, as a defense against criminal responsibility is problematic. Courts in both the United States and Britain have not had a consistent interpretation of the automatism defense.

Automatisms ***see*** Trauma Causation: Analysis of Automotive; Seizures: Behavioral

Autopsy

Historical Overview

Anatomical Dissection

The knowledge of the early history of human anatomy is scanty and the possibility to dissect human bodies varied greatly at times. Very early Indian medical literature indicates a knowledge of anatomy that may have been acquired by dissecting bodies of young children as the Hindu scriptures enjoined that bodies of persons more than two years old had to be burned [1].

The first known school of anatomy was in Alexandria around 320 B.C., where human dissections were carried out by famous anatomists, such as Herophilus of Chalcedon (335–280 B.C.) and Erasistratus of Iulis (c. 310–250 B.C.) to determine the normal structure of organs and the changes made by disease [2].

According to several reports, occasional "autopsies" were performed already in the twelfth and thirteenth centuries. The English chronicle by William of Malmesbury (c. 1080/1095-c.1143) mentions one ordered by the Norwegian King Sigurd Jorsalfar (1090–1130) in 1111, while stopping in Byzantium (present Istanbul) on his return from Jerusalem, to find out whether the cause of death of many of his followers had been liver damage by too strong wine [3].

In 1391, King John I of Aragon gave the University of Lérida in Spain the permission to dissect, once every 3 years, the body of a criminal. In Vienna the first anatomical dissection took place in 1404, in Prague somewhat later in 1460 and at the University of Paris in 1478 [4].

The first known postmortem examination on the American continent was performed in Hispaniola in 1533 and recorded by Fernandez de Oviedo in his General and Natural History of the Indies [5].

The publication of the great textbook of anatomy *De Humani Corporis Fabrica* in 1543 by Andreas Vesalius (1514–1564), the "father of anatomy", marked the beginning of an overthrow of traditional Galenic anatomy and theories, although it took more than 300 years until the new concepts of pathogenesis of diseases and cellular pathology started to take over from the old school of thought.

Medicolegal Autopsy

The application of medicine in the administration of justice began long before medicine started to develop into a modern science. The medicolegal investigation of deaths was introduced very early from the requirements of the judicial system as it was of interest to the society to know whether a person had died as a result of violence or due to natural causes. The oldest known instructions by the authorities about external examination of corpses have been found in China and dated to the Ching dynasty (~2000 B.C.). During Song dynasty (960–1279 A.D.), a decree enacted in 995 A.D., provided that a government official, though not a physician, had to investigate a violent or otherwise suspicious death within four hours. It is not known whether autopsies were ever performed in ancient China [6].

The earliest medicolegal autopsies took place in Italy, probably in the middle of the thirteenth century, at the University of Bologna. One was recorded by Guglielmo de Placentinus Saliceto, or by William of Saliceto (1210–1276 or 1277), a surgeon and a teacher, on the medical faculty there and is mentioned in his book *Surgery* [7]. Whether this really was an autopsy or just an external examination of the corpse, is questionable. Some authors have attributed the first medicolegal autopsy to Bartolomeo da Varignana, who, in addition to his professional and academic activities, served the municipality of Bologna in a medicolegal capacity. The public prosecutor had ordered an autopsy in 1302 in a case suspected of having died due to poisoning [8, 9].

According to O'Neill, medical historians have long agreed that the fundamental motive for the initiation of academic dissections in Western Europe was forensic. The decretals of Pope Innocent III contain several cases in which such examinations had provided the evidential basis for a papal verdict [8].

In Europe the principles of medicolegal investigation of deaths were developed on the basis of the criminal codes of the sixteenth century: the Bamberg Code in 1507, compiled by Johann Freiherr von Schwarzenberg and which was soon adopted by a number of other German states. These along with the best known criminal statutes in Europe, Constitutio Criminalis Carolina, the Caroline Code of 1532, obliged the courts to use medical expertise in certain medicolegal issues such as abortion, bodily harm, homicide, or medical malpractice.

The "father of the Swiss legal medicine" Felix Platter I (1536–1614) from Basle has been said to have performed more than 300 autopsies. In France the first medicolegal autopsy was performed by Ambroise Paré (1510–1590) in 1562. The autopsy of King Stephen Báthory of Poland in 1586 was probably the first one performed in the Eastern Europe [10].

Our knowledge about the old autopsy procedures is poor and, apart from a few exceptions, detailed written autopsy reports are relatively recent.

In addition to codification of the principles of medicolegal investigations, some countries went further providing detailed instructions as to the performance of medicolegal autopsy. By far the best example of this is the Austrian decree of 1855. The objective of medicolegal investigation of the deceased and the duty of medicolegal expert has probably never been defined with such brevity and clarity than in Section 1 of the Austrian decree. It is noteworthy that it is still valid legislation in Austria.

"The medicolegal examination of the deceased is of great importance and therefore it is an imperative duty of the expert, that the examination must be carried out with utmost accuracy, as very often, the honor, freedom, property, and life of the person accused of a criminal act, as well as the rule of law, depend upon it". (Authors' translation of Section 1 of the Austrian decree on medicolegal examination of corpses from January 28, 1855, Figure 1.)

The decree gives detailed instructions in 134 paragraphs for the performance of medicolegal autopsy. The Prussian edict of 1875 is similar but not as detailed as the Austrian one and both of them can, so far, be considered as the culminating point of legislation dealing with the performance of medicolegal autopsy.

Clinical Autopsy

Early attempts to solve medical problems through autopsies can be found already in the Middle Ages e.g., in the chronicle of Fra Salimbene. He referred in his description to one dissection performed by an unnamed Cremonese physician, of a victim of the malady that swept through the cities of Northern Italy in 1286. Similarly, victims of bubonic plague had been dissected in Perugia during the outbreak of an epidemic in 1348 [8].

Verordnung der Ministerien des Innern und der Justiz vom 28. Jänner 1855,

womit die Vorschrift für die Vornahme der gerichtlichen Todtenbeschau erlassen wird.

Die Ministerien des Innern und der Justiz finden für die Vornahme der gerichtlichen Todtenbeschau die nachstehende Vorschrift zu erlassen:

Erstes Hauptstück.

Von der gerichtlichen Todtenbeschau überhaupt.

§. 1.

Figure 1 Front-page of the Austrian decree on medicolegal investigation of corpses January 28, 1855

However, hospital or clinical autopsy became meaningful first after the introduction of modern concepts of pathogenesis of diseases by Carl von Rokitansky (1804–1878) and cellular pathology by Rudolf Virchow (1821–1902).

Gradually in the beginning of the nineteenth century increased attention was paid to the actual autopsy technique. In 1846 Rudolf Virchow, then prosecutor in Berlin, insisted on regularity, method, and definitive technique. The classical techniques, which are still in use today are, more or less modifications of those introduced by Rokitansky (organs are dissected *in situ*), Virchow (organs are removed one by one), Ghon (thoracic and cervical organs, abdominal organs, and urogenital system are removed as organ blocks) and Letulle (cervical, thoracic, abdominal, and pelvic organs are removed as one organ block), among others [11].

In 1872 Francis Delafield's *A Handbook of Post-mortem Examination and Morbid Anatomy* was published in New York and German and English editions of Rudolf Virchow's book on autopsy technique were published in 1876.

The Present Autopsy

There is considerable variation in the types and standards of medicolegal systems throughout the world from nonexistent to well-functioning organizations with sophisticated autopsy practices. Generally the lack of forensic and medicolegal services is a characteristic of developing countries, usually including a poor judiciary and educational system, but the awareness of the importance of high standard medicolegal autopsy for the protection of individual rights varies a lot even in industrialized countries due to historical and/or political reasons.

Most countries have not provided laws to regulate the actual performance of medicolegal autopsies. There exist both international recommendations and national guidelines by the competent authorities or professional bodies such as the Royal College of Pathologists in the United Kingdom or minimum standards by individual forensic institutes.

Various international bodies have been interested in achieving harmonized and internationally recognized rules concerning the performance of medicolegal autopsies. In Europe the "Sevilla Working Party on the Harmonization and Standardization of Forensic Medicine (SWP)" was established in 1985 by Professor Luis Frontela Carrerras of Seville, Spain, carrying out groundwork and collaborating with the Council of Europe to create minimum standards for autopsy protocols. The Minnesota Lawyers International Human Rights Committee had taken the initiative to draft international standards for the investigation of suspicious deaths, including autopsy. In May 1989, UN Economic and Social Council adopted in its resolution 1989/1965 "the Principles on the Effective Prevention and Investigation of Extralegal, Arbitrary, and Summary Executions", which had been created by cooperation with intergovernmental and nongovernmental organizations. In 1991, the General Assembly of the United Nations endorsed the Model Autopsy Protocol of the United Nations. SWP's work was continued by the European Council of Legal Medicine (ECLM), whose document "Harmonisation of the Performance of the Medicolegal Autopsy" was adopted by the General Assembly in London in 1995 and which largely served as basis for the Pan European, Council of Europe – Recommendation No. R (99) 3 On the Harmonisation of Medico-Legal Autopsy Rules and Its Explanatory Memorandum, which was adopted by the Committee of Ministers in February 1999 [12].

In spite of the invention of new medical imaging techniques such as computed tomography (CT), multislice computed tomography (MSCT), or magnetic

resonance imaging (MRI) clinical autopsy has been shown to have maintained its clinical, educational, and epidemiological value and remained an essential factor in the quality assurance of medical care [13]. In spite of this, there has been a progressive decline in autopsy rates in recent decades in most industrialized countries on all continents [14–16].

In 1971, the Joint Commission on Accreditation of Hospitals (JCAH) in the United States ended its requirement for minimum rates of autopsy for certification. Until then, a mandatory 20% autopsy rate had been required for accreditation of postgraduate training. The idea had been that each institution should set its own rate but the dropped requirement seems to have had a negative impact on autopsy rates and, according to an estimate, the national autopsy rate of nonforensic deaths may have fallen roughly to 5% [17].

There are several reasons for this decline and the emphasis of contributing factors varies according to the country. Clinicians may be too reliant on the new diagnostic techniques and poorly motivated to obtain consent from the relatives to perform an autopsy. Pathologists are less enthusiastic, and owing to low autopsy rates, less experienced to perform autopsies and this task is often delegated to inexperienced trainees. Further factors that probably have contributed to the decline of autopsies are fear of malpractice litigation, if errors in clinical judgment are detected, and cost-cutting pressures, when autopsies do not produce income [18, 19].

Objectives of Autopsy

Autopsy is a detailed systematic external and internal examination of a corpse carried out by a pathologist or one or more medicolegal experts to ascertain the underlying and possible contributing causes of death and, depending on the jurisdiction, also the manner of death. Before the pathologist can begin the examination, he must be sure that he has been authorized to perform the autopsy on that particular body. As infection risks are common in mortuary and autopsy may involve also other risks, such as electrical, chemical, and radiological hazards, these must be assessed and necessary health and safety precautions taken. The autopsy and all ancillary investigations must be carried out in compliance with the relevant legislation and possible national guidelines in a manner consistent with medical ethics and respecting the dignity of the deceased.

An autopsy is performed to achieve one or more of the following objectives:

- to identify or record characteristics that may assist in identifying the deceased;
- to determine the cause of death or, in the newborn, whether live birth occurred;
- to determine the mode of dying and time of death, where necessary and possible;
- to demonstrate all external and internal abnormalities, malformations, and diseases;
- to detect, describe, and record any external and internal injuries;
- to obtain samples for any ancillary investigations;
- to obtain photographs or retain samples for evidential or teaching use;
- to provide a full written report and expert interpretation of the findings; and
- to restore the body to the best possible cosmetic condition before the release.

In addition to the anatomical dissection, there are basically two main types of autopsy and, although in principle, a single standard should be applicable to all autopsy examinations, this is not the case in practice, owing to different traditions and structures in education of medical specialists and wide variation in autopsy practices, from partial autopsy to full examination of all body cavities including ancillary investigations such as histology of all major organs, depending on the country and jurisdiction.

The clinical or hospital autopsy must, in most jurisdictions, be consented by the deceased person, before death, or the next of kin after death. It is usually performed to investigate details of a known disease process, e.g., the exact type or spread of a malignant disease or the effectiveness of therapy. It can also be performed for medical audit or research purposes.

The medicolegal or forensic autopsy necessitates, owing to legal issues involved, the highest possible standards of practice. It is ordered by the competent legal authority (a coroner, a medical examiner, a procurator fiscal, a magistrate, a judge, or the police) to investigate sudden unexpected, suspicious, unnatural, or criminal deaths. Also unidentified bodies or deaths occurring in special circumstances such as deaths in police custody or during imprisonment are often subjected to a medicolegal autopsy. In most

jurisdictions, permission of the next of kin is not required [20–22].

Autopsy Techniques

The basic technique of autopsy has remained the same since 1850s but various imaging techniques such as CT, MSCT, MRI, percutaneous needle biopsies, or endoscopic techniques have been applied, either for preautopsy screening purposes, or as so called "*minimally invasive autopsy*" if full autopsy is not possible.

Both clinical and medicolegal autopsy may involve different strategies and techniques depending on the questions they are expected to answer and pediatric autopsy technique is generally somewhat different from the one in adults. The Royal College of Pathologists (the United Kingdom) has published a set of Guidelines on Autopsy Practice and scenarios for specific types of death, to facilitate the improvement of the standards of autopsy performance and reporting [23].

The scope of medicolegal autopsy is often broader than that of clinical autopsy, with special emphasis on all information concerning the circumstances of death, often necessitating a visit to and investigation of the scene of death. Both types of autopsies should consist of full external and internal examination of the body including the dissection and investigation of all three body cavities.

The External Examination

In medicolegal autopsy, the examination of the clothing is often an essential part of the external examination, whereas in clinical autopsy it is generally not.

The description of the body includes age, sex, build, height, ethnic group and weight, nutritional state, color of the skin as well as other characteristics of the deceased including color of irises and sclerae, presence or absence of petechiae; color, length, density and distribution of hair, or any abnormalities such as scars or tattoos. All injuries must be described in detail, measured, and photographed. Postmortem changes relating to rigor mortis, hypostasis, and decomposition should be described in detail. The examination should be carried out carefully and systematically and include head, neck, trunk, upper and lower extremities, and the back and description of all body orifices.

The Internal Examination

The state of body cavities includes the description of the presence of gas (pneumothorax), fluids (effusions or exudates), or foreign bodies and the measurement of their volume, appearance of the internal surfaces, and anatomical boundaries as well as location and external appearance of organs.

The classical autopsy techniques vary mainly in the order in which the organs are removed. All organs have to be dissected, the outer appearance as well as the cut surfaces described and weights recorded. The hollow organs have to be opened and their content described and measured. All relevant vessels, arteries and veins as well as ducts have to be dissected. All abnormalities must be described by location and size.

Ancillary Investigations

Many pathological processes are not visible to the naked eye, therefore, postmortem histology is necessary and of great value, not only in confirming but also for excluding any pathological changes in a cause of death investigation. As a rule, complete histological examination of all major organs is considered an essential part of every postmortem and this principle has been adopted by many guidelines.

The need for other ancillary investigations depends on whether the cause of death has been established with the necessary degree of certainty, and if not, additional samples may have to be taken for toxicological or other investigations such as bacteriology and virology. For toxicology this may include peripheral blood, vitreous humor, cerebrospinal fluid, bile, hair samples, or other relevant tissues. Depending on jurisdiction, whenever the results of ancillary investigations are subject to a criminal investigation and may be used as evidence in a court of law, it may be necessary to prove that there has been an unbroken chain of evidence from sampling through tests to trial. Also possible restrictions owing to national legislation must be considered, when retaining tissues at autopsy.

Sometimes special procedures and modifications of normal dissection techniques are necessary. Imaging techniques or conventional X-ray should be performed before autopsy, if there is suspicion of e.g., air embolism, nonaccidental injury in children, or a

death involving firearms or explosives. Where neck trauma is suspected, the brain and the organs of the chest cavity have to be removed prior to the dissection of the neck, to drain the blood from the area to avoid artifactual bleeding. Postoperative autopsies may present various problems with medicolegal implications, such as complications of anesthesia, surgical intervention, or postoperative care. However, detailed description of these special dissection procedures and techniques is beyond the scope of this presentation.

Autopsy Report

The report is an essential part of the autopsy, but its structure may vary according to the type of autopsy and sometimes may be limited to a list of postmortem diagnoses and conclusions as to the causes of death in the case of a hospital autopsy.

Medicolegal autopsy reports are usually more detailed and structured consisting of a preamble with personal particulars of the deceased, with the date, time, and place of the autopsy as well as the personal data and qualifications of the pathologist and other relevant information to the circumstances concerning the autopsy, summary of the background information about the deceased, findings of the external, internal and supplementary investigations as well as commentary and conclusions with the causes of death and also manner of death depending on the jurisdiction (usually within noncoronial/medical examiner type of medicolegal systems). The report should be unambiguous, comprehensive, and intelligible also to the nonmedical reader. In addition to the factual, positive and negative gross, microscopical and analytical findings, the pathologist should conclude with a discussion of the significance of the findings. Where the findings are of uncertain nature and there are several competing causes, the pathologist should try to give an opinion as to their probability.

Autoradiograph

Introduction

In the founding 'DNA fingerprinting' technique developed by Sir Alec Jeffreys [1, 2], restriction fragment length polymorphism (RFLP) techniques were used to isolate highly polymorphic minisatellite loci. The DNA fragments produced by restriction endocnuclease digestion were electrophoresed on agarose gels and then transferred to a nitrocellulose or nylon membrane via Southern blotting [3]. Following immobilization to the membrane (by UV fixation for example), an oligonucleotide probe was attached and then labeled with a radioisotope, commonly ^{32}P. Autoradiography was the process used for visualization. The radioactive object (in this case, the labeled probe hybridized to the DNA fragments in the membrane that were themselves produced through RFLP analysis) is placed in contact with high-speed X-ray film. The energy released from the decay products of the radioisotope is absorbed by the silver halide grains in the film emulsion to form a latent image. A chemical development process amplifies the latent image and renders it visible on the film [4]. This technique was time consuming and involved the use of hazardous radioactive reagents and has been superseded by contemporary PCR-based fluorescent detection methods.

Battered Child Syndrome

Introduction

The battered child syndrome is a clinical concept that was first enunciated by Kempe and coworkers in 1962 [1]. The term was used to describe the classic physical findings in children who have experienced severe abuse, often in the hands of adult caretakers. In the years following Kempe's work, the existence of the battered child syndrome was validated by several researchers [2]. A form of the syndrome, which involves life threatening head trauma to very young children, is now known as the shaken baby syndrome (*see* **Shaken Baby Syndrome**).

There have been recent attempts to expand the scope of the battered child syndrome beyond Kempe's classic description of physical abuse to include other forms of severe child maltreatment, such as emotional and verbal abuse. However, such attempts remain controversial [3]. In no other area has the reputation of the syndrome grown than in the legal arena where it has been applied in two broad ways. First, in response to the work of Kempe and his colleagues, there has been greater awareness of child abuse that has led to the promulgation of more stringent child protection laws. Now in many jurisdictions in the world, it is a serious crime to physically abuse children. As a result, prosecutors often use the battered child syndrome to convict perpetrators of severe child physical abuse. An increased awareness of the consequences of the syndrome has also resulted in mandatory child abuse reporting laws that are now in place in all 50 states of the United States (US) of America, including the District of Columbia (DC).

The second legal ramification is that the syndrome has been offered as a justification for parricide by some children accused of murdering their parents [3].

This review covers the origin of the battered child syndrome, its common features, detection, management, and legal implications.

Historical Perspective

The problem of child abuse has plagued mankind since ancient times. For many centuries, maltreatment of children was widely practiced and readily

condoned. Child maltreatment was often rationalized as an effective means of discipline. It was also envisioned as an indispensable tool required for adequate education of children. In addition, in the medieval ages, physical discipline of children was utilized to appease the gods or cast out evil spirits. It was not until the late sixteenth century that some scholars started to write in protest of such maltreatment of children [4]. By the nineteenth century, there was a growing movement in the western world aimed at drawing governmental attention to the plight of the abused child. This led to the adoption of a "Children's charter" by President Hoover in 1930. The aim of this charter was to make every child "wiser, safer, better, and happier", as well as to protect children from "abuse, neglect, exploitation, or moral hazard" [4].

The existence of severe, unexplained, physical injuries in children was long recognized before Kempe and his colleagues published their paper. For example, in 1946, Caffey [5] described a series of cases in which the affected children suffered subdural hematoma (blood in one of the coverings of the brain) and fractures of the long bones. He concluded that although these injuries were traumatic in nature, the mechanism by which they occurred was "obscure". Despite the suspicion that children who presented with unexplained physical injuries might be victims of abuse, physicians were reluctant to get involved and almost never confronted parents when children presented with suspicious injuries. Public interest in the matter was aroused in 1955 by the work of Wooley and Evans [6] who pointed out that some x-ray findings in children with physical injuries were intentional in nature. Later on, Altman and Smith [7] suggested that traumatic injury in some children might have been caused by parents or older siblings. The work of Kempe and colleagues led to greater governmental efforts to protect children from serious physical abuse. This resulted in the enactment of mandatory child abuse reporting laws that have now been adopted by all the states in the United States of America.

Definition

The battered child syndrome is a severe and often fatal form of child physical abuse. In the US, child abuse is defined by the Child Abuse Prevention and Treatment Act (CAPTA) of 1974 as "Any recent act or failure to act on the part of a parent or caretaker which results in death, serious physical or emotional harm, sexual abuse or exploitation, or an act or failure to act which presents an imminent risk of serious harm" to a child under the age of 18 [8]. Kempe and colleagues defined the battered child syndrome as "a clinical condition in young children who have received serious physical abuse, generally from a parent or foster parents" [1]. Kempe and coworkers seemed to suggest that such injuries were the product only of an intentional act. However, Terr and colleagues (as reflected in the US act mentioned earlier) explained that child battering might also result from "an act of carelessness on the part of the parent or guardian" [9].

Prevalence

There are no reliable data that specifically address the prevalence of battered child syndrome as a condition separate from child abuse. However, if the scope is broadened to include all forms of child maltreatment, in the US, according to the National Child Abuse and Neglect Data System (NCANDS) [10], 16.5 children per 1000 were found to be victims of abuse in 2005. Child neglect was the most common form of abuse. Physical abuse, which accounted for 16.6% of all reported cases of abuse, was the second most common form of child abuse. According to the Public Health Agency (PHA) of Canada [11], the rate of substantiated Child Maltreatment was 21.71 per 1000 in 2003, of which 10% involved physical harm. In England, 24 children in every 10 000 were abused in 2001, of which 7300 were victims of physical abuse [12]. According to the United Nations (UN) Secretary General's report on violence against children published in October 2006, about 80–98% of children suffer some form of physical punishment at home, a third of which is severe enough to result in permanent physical impairments. It can thus be inferred from the data presented above that child physical abuse is a serious worldwide problem [13].

Common Features

Kempe and his colleagues reported that the presentation of the battered child syndrome varies depending

on the severity of the physical injury to the child. In mild cases, the condition can be overlooked because the injuries are often subtle [1]. Severe cases are associated with life threatening injuries. The most common manifestations of the condition include skull fracture and subdural hematoma as well as multiple fractures usually involving the long bones. Subdural hematoma, which may occur with or without skull fracture, is the most common cause of death in battered children [1, 14]. Other common injuries found in battered children include, skin lesions such as abrasions, bruises, lacerations, welts, scalds, and major burns [15–17]. Occasionally, battering may involve suffocation, drowning, gunshot wound, stabbing, or poisoning with harmful chemicals and fumes [13, 16]. Smith and Hanson [18] reported in 1974 that in a sample of 134 battered children, 47% presented with intracranial and intraocular hemorrhages (bleeding into the brain and the substance of the eye), 42% had recent or healed fractures while 38% had other injuries such as burns and scalds. In children who present with fractures, the most commonly involved bones are the skull, ribs, the humerus (upper arm bone), femur (bone in the thigh), and the tibia (leg bone) [15, 16].

Another common feature of battered child syndrome is that a large majority of affected children show evidence of neglect, such as failure to thrive or growth retardation (delayed or interrupted child growth). They often appear unkempt, malnourished, and deprived. In one sample, 16% of battered children had experienced neglect, while about 17% were previously hospitalized for failure to thrive [16]. One study reported that 30% of battered children have been exposed to some form of physical or emotional neglect [2].

Finally, in a few cases, the battered children may present with nonspecific medical complications such as fever, anemia, and seizures [14, 15, 17].

Risk Factors for Victimization

Although battered child syndrome can occur at any age, it has been more commonly identified and described in younger children. Several authors report that the most common age when battered child syndrome is suspected is usually sometime between the second and third birthday [1, 14, 17]. Under most circumstances, the affected child might have suffered for several months or years before the abuse is suspected or confirmed. Although some authors report that males are more frequently battered than females, some other studies suggests that there is no sex differentiation in its prevalence [4, 13, 18]. The race distribution of battered child syndrome also varies depending on the study. Some studies report that battered child syndrome is more common in nonwhite (mainly black and Hispanic) children, while other studies suggest a higher prevalence in Caucasian children [4]. There are also studies that report no racial difference in the occurrence of battered child syndrome. Low birth weight babies and children with developmental delay are generally more likely to be battered. In addition, battered children have been reported to have an increased incidence of birth defects including spinal bifida, hydrocephalus, encephalocele, and congenital dislocation of the hips [16].

Battered children are often perceived as difficult to cater for, stubborn, or demanding. They are also less likely to wake up during the night. They are generally “excitable” and “lively” with a tendency to become tired during the day [16]. Affected children may have siblings who also have experienced some form of maltreatment [16, 17].

Profile of the Perpetrator

Available evidence suggests that biological parents are more likely to engage in serious physical maltreatment of children than other caretakers [1, 17]. Other common perpetrators include adoptive parents, stepparents, and foster parents. Siblings, other relatives, and baby sitters are also frequent abusers of children. It is unusual for a stranger to physically assault children because the degree of injury sustained by the children often indicate a close relationship with the perpetrator [19]. In the US, according to NCANDS, one or both parents were involved in 78.9% of child abuse fatalities in 2004 while nonparent caretakers were involved in 10.7% of cases [10].

Both males and females can be perpetrators of battered child syndrome. Some of the older studies suggested that women are more likely to be involved in fatal incidents involving very young children. These findings have been attributed to the fact that women are more intricately involved in the day-to-day care of children. This then increases the possibility that frustrations related to perceived

difficulties or inadequacies in their care of these children often resulting in violent behavior directed at the children [20]. More recent data suggest that fathers and other male caretakers are more likely to be involved in fatal cases of battered child syndrome.

Perpetrators of battered child syndrome are more likely to be young adults, usually in their early to mid 20s [10]. Majority of perpetrators are either high school graduates or high school dropouts. However, battered child syndrome has been reported even in families with highly educated parents. There is no clear racial majority amongst perpetrators of battered child syndrome. There is some indication that perpetrators of battered child syndrome have a higher incidence of psychiatric disorders than the general public. The most commonly implicated psychiatric disorders include mood disorders such as depression and bipolar disorder, psychotic illnesses such as schizophrenia. Often times, the perpetrators are experiencing significant stress in their own personal lives that they then act out on the affected child. They may perceive the child as "illegitimate" or they may attack the child in response to a perception of rejection by the other parent [17].

Detection and Diagnosis

The detection of battered child syndrome requires a high index of suspicion. It might go unsuspected for a long time in cases involving subtle injuries. It should be suspected when a child presents with serious physical injuries that are inconsistent with the explanation provided by the parent or caretaker. It should also be suspected when there is a delay between the time the injury occurred and when medical help is sought for the child [21].

Most cases of battered child syndrome are usually seen for the first time in the emergency room or the office of the family physician or pediatrician. The physician who has first encounter with the child should take a detailed history including a description, by the involved parent or caretaker of the cause of the injury. The history should be "elicited in a nonaccusatory manner" [22]. The parent should generally be interviewed separately from the child whenever possible. Where possible, the physician should obtain collateral information from other members of the family. The involved parent often blames the child or some other persons that live in the same household for the injury. The perpetrator could also explain that the injury is the result of some preexisting medical condition. In some cases, the perpetrator may report that the injury was accidental and explain that they never meant to cause harm to the child. Some may justify their actions by saying that parents have the right to discipline a child in any manner so as to get them to conform to rules [21].

When an accidental cause is given for the injury, the involved parent or caretaker may report that the child accidentally fell from a bed, couch, swing, or countertop. In one instance, I was told by a man suspected of battering his 4-month-old baby to death that the injuries occurred when he accidentally dropped the child after bumping into a doorpost. These accidental falls are often used to explain injuries such as fractures, dislocation, head trauma, and skin lesions. However, given that these falls occur from short distances, the degree of damage done to the child is usually inconsistent with the proposed mechanism of the accident. This is because a lot of these falls occur from distances of about 4 feet or less, while it has been estimated that a fall has to occur from at least 20 feet for it to cause fatal injuries to a child. An alternative accidental explanation for the cause of serious head injury to battered children is that the injury occurred while the perpetrator was gently tossing the child in a playful manner. However it has been shown by some studies that a greater amount of force is required to cause serious injury to a child than is generated during such play. In cases of burn injury, the perpetrator may explain that the injuries resulted from an accidental splash of some hot fluid such as water or that the child accidentally fell in the bathtub. Such claims are often contradicted by the fact that most of the burns are symmetrical and do not show the usual splash marks that would be expected if a child accidentally falls in the bathtub. Also, the severity of the burns is often inconsistent with the mechanism of the burn as proposed by the perpetrator [21].

The involved parent or caretaker could also blame other adults in the house for causing the injury to the child. In such cases, it is often very important to determine who was the last person seen with the child as this would give a clue as to the real perpetrator of the crime. Occasionally, other children (such as the child's siblings) may be blamed for causing the injury to the affected child. In such cases, there is

often a need to establish whether the accused child has the physical capability of causing such injuries to the affected child [21].

The first step in confirming suspected cases of battered child syndrome is to obtain a thorough physical examination, with clear documentation of findings by a trained pediatrician. Physical examination may reveal evidence of previous physical abuse such as skin lesions in different stages of healing. The location of the skin lesions may suggest ongoing physical abuse. Accidental injuries to children often involve the exposed parts of the body such as the shin, knee, and elbow. When injuries affect "protected" parts of the body such as the buttocks, thighs and torso, physical abuse should be suspected. Often times, the pattern of the skin lesions may suggest physical abuse. For example, bruises may show the mark of belts, cords, or other objects used to inflict the injury. Physical examination should also include a specialized examination of the eyes called fundoscopy. This examination helps to establish the presence of retinal hemorrhage (ruptured blood vessels inside the eye) that strongly suggests that the child has been battered [1, 22].

Finally, an x-ray examination of the whole body is usually required to establish the diagnosis of battered child syndrome. This may reveal fractures, usually of the long bones, in different stages of healing. This is the hallmark of the condition as it is indicative of repeated nonaccidental traumatic injury. The most common fractures that have been associated with battered child syndrome include fractures affecting the metaphysis of long bones, posterior rib, scapular, spinous process, and sternum [1, 15, 22].

There are some medical conditions that need to be excluded before the diagnosis of battered child syndrome can be confirmed. These conditions include inherited blood conditions, inherited or acquired skin lesions, infectious skin lesions, congenital metabolic abnormalities, congenital insensitivity to pain, and accidental trauma [22].

Management

The initial goal in the management of battered child syndrome is to terminate the suspected abuse and to prevent further harm to the child. To this end, the first step is to attend to the medical needs of the child. If the child has life threatening injuries such as subdural hematoma and fractures, immediate hospitalization for acute treatment is a must. Failure to urgently address these injuries could result in fatalities. When the child's injuries are minor and nonlife threatening, there is a need to determine whether it is safe for the child to return home with the parents. This decision often requires some collaboration with child protective service agencies. As such, after addressing the child's medical needs, the next step is to report suspected cases to the appropriate governmental agency responsible for investigating and prosecuting child abuse. In the US, all 50 states and the DC have mandatory reporting laws that require professionals (doctors, nurses, social workers, teachers, lawyers, etc.) and other childcare providers to report every suspected case of child abuse to law enforcement agencies. It should be noted that what constitutes child abuse varies from one jurisdiction to another. For this reason, reporting a suspected case of battered child syndrome does not imply guilt until adequate investigation by law enforcement and conviction of the alleged perpetrator in a court of law. Generally, any professional that makes a report in good faith is protected by law from claims of breach of confidentiality or other civil damages though rules may vary with jurisdiction [1, 22].

In most cases, it is unsafe for the children to go back home since the suspected perpetrator is a parent. When such is the case, the child is usually admitted to the hospital for further medical management and to gather more information about the nature and extent of the suspected abuse. Occasionally, there may be a need for child protective services to obtain emergency temporary custody to ensure that the child does not return home with the suspected caretaker.

Once admitted to the hospital, the treatment of battered children requires an interdisciplinary approach. There is often a need to involve different medical specialties, depending on the variation and severity of the injury sustained by the child. Neurosurgical involvement is indicated in cases involving serious head injury, while an orthopedic surgeon would be needed if the child has multiple fractures. Pediatricians or family physicians should handle most of the more general medical care of the child. Social workers and child psychologists should be involved in providing parental counselling, communication with various agencies, and individual therapy for the child. Even after the child has been treated and ready to be

discharged, caution should be exercised, as a premature return of the child to his or her parents' parents, could result in retaliatory abuse that may ultimately be fatal. Sometimes there may be a need to place these children with relatives or in foster care pending the outcome of criminal investigations [1, 22].

Prognosis

According to Kempe and Helfer [23] the prognosis of battered child syndrome depends on the severity of the child's injuries and the "type and quality of intervention" provided once the diagnosis is made. The outcome is generally more positive if the child's medical needs are immediately addressed and if the child is protected from further maltreatment. Permanent brain damage may occur in children with severe head injury. This in turn could lead to mental retardation or poor intellectual/educational performance as the child becomes older. Inadequately attended fractures may result in permanent deformities. The emotional damage resulting from repeated abuse could cause permanent psychic scarring, with the result being a child who has difficulties having empathetic feelings for others. The child's prognosis is often improved when the parents are willing to seek therapy for themselves and the child.

Legal Implications

There are three important legal implications of the battered child syndrome in the US.

1. The battered child syndrome has become a useful tool for law enforcement agencies in the prosecution of suspected cases of serious child physical abuse. This is because the disorder has classical features that are well understood. Moreover, it can be easily documented with physical examination and radiographic evaluations, thus providing strong evidence in court for successful prosecution of suspected perpetrators. Prosecution of suspected cases often require expert testimony. The medical expert testimony is usually needed to show that the affected child did indeed suffer from battered child syndrome. Such expert testimony can be contentious especially when the expert reaches an opinion based on prior nonaccidental physical injuries. This issue was addressed in the US Supreme Court case of *Estelle v McGuire* (1990) [24]. In that case, the Court found that expert testimony based on prior non- accidental injuries did not violate the due process rights of the defendant.
2. Physicians who fail to report suspected cases of battered child syndrome may be successfully sued for medical malpractice. The first case involving such claims was *Landeros v. Flood* [25], a 1976 Supreme Court of California case. In that case, a suit was brought against an emergency room physician who discharged a child to the care of an abusive parent despite evidence that the child was a victim of abuse. The California Supreme Court concluded that contrary to the ruling of a lower court, the child had a claim, since another physician discovered the abuse the next time the child was taken to the emergency room for similar complaints. In a more recent case, *Cooper Clinic v. Barnes* [26], the Arkansas Supreme Court reversed a jury's decision to award $2.5 million to a father for a doctor's failure to report possible abuse by the parents. The jury's decision was overturned because the case was brought against the clinic and not the doctor. The Arkansas mandatory reporting law identified specific individuals who are required to report cases of abuse, but not institutions.
3. The battered child syndrome has been proffered as a defense in some cases of parricide. Most of the cases involved have been contested only at the state level. The US Supreme Court has yet to address the issue of the battered child syndrome as a credible self-defense theory for the murder of a parent by a child. In some of the state cases mentioned above, the argument often involves the admissibility of expert testimony on the battered child syndrome. In the first of such cases, *Jahnke v. State* [3, 27], the trial court's decision to bar expert testimony on past abuse as an explanation for self-defense was upheld by the Wyoming Supreme Court. In another case, *State v. Nemeth* [28] the Ohio Supreme Court found that although there was some controversy involving the use of the battered child syndrome as self-defense justification for parricide, expert testimony should be allowed. More recently, the Minnesota Supreme Court ruled, in *State v. MacLennan* [29, 30], that the admission of

expert testimony should be limited to general description of the syndrome and not on whether the child actually suffers from the condition (*see* ***Daubert v. Merrell Dow Pharmaceuticals***).

Summary

The battered child syndrome is an extreme and often fatal form of child physical abuse. The hallmarks of the condition are well established and most physicians should easily recognize it. A high index of suspicion is often required in cases involving minor injuries. Prompt report to the relevant investigative authority and prevention of further maltreatment of the child is very important once the diagnosis is made. Some of the legal ramifications of the battered child syndrome include prosecution of suspected perpetrators, civil litigation due to failure to report, and its use as justification for a self-defense theory in cases of parricide.

SYLVESTER SMARTY

Battered Spouse Syndrome

The legal concept of battered woman syndrome (BWS) evolved from Walker's [1] initial description and is used in the defense of individuals who kill an abusive partner. Walker defined *BWS* as having three major components: a specific "cycle of violence", learned helplessness, and typical psychological sequelae. The "cycle of violence" begins with the "tension" phase, in which tension builds in the abusive partner. Second is the acute battering incident that serves to rid the aggressor of his built-up tension. Following the acute aggression phase is the "honeymoon" or "contrite" stage during which the batterer shows remorse for the aggression. This ends when the tension phase renews. Walker [1, 2] also theorized BWS as encompassing learned helplessness behavior, suggesting that the victim becomes more passive as she sees fewer solutions to her abusive situation. Finally, Walker noted several common psychological characteristics of battered women, including low self-esteem, guilt, denial of feelings of terror and anger, and traditionalist attitudes regarding gender roles, among others.

Since Walker's publications, systematic studies of the effects of battering on women have been done (e.g., [3]); however, Walker's theory continues to largely inform legal cases concerning battered women. Currently, the more inclusive phrase "battered s*pouse* syndrome" is sometimes used in an effort to recognize the occurrence of woman on man, woman on woman, and man on man intimate partner abuse (see e.g., [4]) (*see also* **Aggression: Gender Differences in**).

Legal Use of Battered Woman Syndrome

Initially, BWS evidence was used to support temporary insanity defenses and was successful in obtaining some acquittals. One of the first and most well known of these cases is the "burning bed" (*Michigan v Hughes*, 1977). In this case, Francine Hughes was physically, verbally, and sexually abused by her husband. After attempts to leave and divorce him failed, she set fire to the bed in which he was sleeping, killing him. She was found not guilty by reason of insanity based on BWS evidence [5].

Because most battered women fail to meet the cognitive impairment criterion needed for defenses of temporary insanity, BWS is now rarely used as part of an insanity defense. Instead, BWS has been used as an adjunct to self-defense claims [6]. Often, the killing does not occur in the course of an acute battering episode. In these cases, BWS has provided a "bridge" between the context of the killing and claim of self-defense. Walker's [1, 2] theory suggests that women perceive imminent danger, even when she is not actively incurring physical abuse. Battered women are said to be able to "read" their abuser and discern danger even when physical violence is not occurring. This aspect of BWS legitimizes a battered woman's killing as a form of self-defense when she kills outside of an acute battering episode [1, 2, 7]. In the context of self-defense, testimony regarding BWS is used to increase the credibility of an individual's claims of abuse and to support the reasonableness of the woman's actions [8]. These aims can be met via witness and defendant testimony regarding the abuse. They are also met using experts who testify regarding BWS.

Admissibility and Effect of BWS Testimony

As of 1996, all states had admitted testimony of BWS in some form [9]. When expert testimony regarding BWS has been rejected it has typically been on grounds that (i) it is irrelevant to claims of self-defense, (ii) it is unnecessary in aiding jurors to understand the situation of battered women, (iii) it is not well-supported by the scientific community, or (iv) its probative value is outweighed by its potentially prejudicial effects [8].

In the 1990s, public dismay was expressed regarding the "abuse excuse" [10, 11]. This largely stemmed from the still-present perception that women who kill their abusers are often "let go" without repercussion for their actions. In reality, most battered women who kill plead guilty to or are convicted at trial of serious charges, often murder or manslaughter, and serve significant time in prison [8]. In an examination of 100 battered women who killed their spouses Ewing found that nine plead guilty to charges of murder, manslaughter, or criminally negligent homicide. In 28

cases, the women were not sentenced to jail because of acquittal, findings of not guilty by reason of insanity or dropped charges. The remaining 63 women went to trial and were found guilty of charges ranging from reckless homicide to first-degree murder.

Concerns Regarding the Legal Use of Battered Woman Syndrome

The first problem surrounding BWS evidence is its questionable fit within self-defense doctrine. Self-defense implies, among other elements, that the individual believes he or she is in imminent danger of sustaining bodily harm. The fear of imminent danger must be reasonable, in that a "rational" individual would also perceive imminent harm [12]. Many women kill their spouses outside an acute battering incident but use "cycle of violence" and learned helplessness theories to fit their actions into the self-defense paradigm. The legitimacy of using BWS to bolster claims of self-defense has been questioned and fears of stretching self-defense doctrine immeasurably have been raised (e.g., [7]). Ewing [8] suggests an alternative to continuously broaden the scope of self-defense to include incidents of battered spouses who kill. He proposes the "psychological self-defense", in which the use of deadly force would be legitimate in cases where an individual acts to protect his or her psychological well-being. Ewing's theory purports that a reasonable person could discern imminent risk from her history of interactions with the abuser. If recognized by the courts, the psychological self-defense would preserve the spirit of self-defense laws but allow for the context of the battered woman's actions to be presented in the court.

Second, concerns have been voiced that BWS is more advocacy than science. Some experts testify regarding BWS in cases that clearly are outside the realm of self-defense, thus, misapplying the syndrome and stretching their credibility as experts [9]. In other words, while intimate partner abuse should be recognized by the courts, it should not come at the expense of "good science."

Third, similar to other syndromes (e.g., rape trauma syndrome and homosexual panic) the validity of BWS has been challenged on the basis that its presentation lacks specificity; moreover, research has not supported the notion that battering causes a unified set of symptoms in the majority of women. Legally, the theories of learned helplessness and the "cycle of violence" proposed by Walker are the most recognized and utilized aspects of BWS [13]. Many researchers deny that there is sufficient evidence that battered women experience the three stages she proposes (e.g., [7]). Several others (e.g., [7]) have questioned Walker's methodology in studying the effects of battering. Moreover, Walker's own data showed that 62% of battered women's relationships did not include the entire "cycle of violence" [9].

Similarly, researchers have disputed the occurrence of learned helplessness, emphasizing that many battered women use physical, verbal, and legal means to escape abuse [7, 9]. Further, killing one's abusive partner is in direct opposition with learned helplessness. Research has also shown that battered individuals present with varied symptoms, some of which directly oppose or are not specified under Walker's characterization of BWS. Because of the varied presentation of battered women, some have even argued that BWS does not meet the definition of a "syndrome" [6].

Finally, in most states, decisions regarding the admissibility of scientific evidence and expert testimony are based on the criteria set forth in the United States Supreme Court decision in *Daubert et al. versus Merrell Dow Pharmaceuticals, Inc.* (1993). *Daubert et al.* sets forth that, in order to be admissible in court, scientific evidence must be: (i) amenable to and have been scientifically tested, (ii) subject to peer review, (iii) have a known error rate, (iv) have limits regarding its definition, and (v) have widespread acceptance within the relevant scientific community. While BWS has been the subject of research and peer review, it lacks definitional specificity and is not widely accepted (in a unified form) by the scientific community. Thus, the appropriateness of presenting BWS evidence in court is questionable.

Conclusion

BWS describes the characteristics of some abused women and is often used to support claims of self-defense when individuals kill an abusive partner. Currently, courts rely heavily on Walker's conceptualization of BWS; however, many challenges have been made to this definition. It has been argued that BWS lacks definitional specificity and that it is inadequate to describe most battered women. BWS has

also been challenged on the grounds that it should not be used to support claims of self-defense and that it is not *Daubert*-worthy.

Battered Woman Syndrome *see* Battered Spouse Syndrome

Battered Woman's Reality

Battered Women's Syndrome: Woman's Reality

Some 20 years ago in *Zecevic v DPP*, a judge of the highest Australian court stated that the question to be asked in determining if an individual acted in self-defense was "whether the accused believed upon reasonable grounds that it was necessary in self-defense to do what he did" [1]. In looking at the judicial outcomes for battered women who killed a violent partner in Australia over the past two decades, it is evident that they often confront a legal system that anticipates the factual paradigm of a male–male confrontation, and a court that is accustomed to interpreting "reasonable grounds" in terms of a "barroom brawl" scenario and not within a context of domestic violence antecedents.

Why Expert Evidence is Necessary

The term "*domestic violence*" can underestimate seriousness and criminality of violence within the home (*see also* **Battered Spouse Syndrome**). "Domestic" can imply private or relatively unimportant in contrast to the "real" world outside the home. This is further illustrated by the words used by some judges as umbrella labels to describe in their judgments the assaults against a woman that her defense had presented in arguing for self-defense or provocation. Phrases such as "problems of a marriage", "domestic dispute", "difficult relationship", "domestic argument", "matrimonial discord", and "stormy" relationship tend to trivialize the violent antecedents and neutralize the role of perpetrator by allocating responsibility to both parties [2].

Consequently, in most of the Australian cases in which battered women have been acquitted to date, the homicide took place immediately (as defined in seconds) after their partner assaulted them [3]. There

are exceptions such as the acquittal of a defendant who shot her violent partner in the back. Her defense team argued that the shooting was a preemptive strike by using the state of Queensland's code definition of an assault: one can be defending oneself against "situations in which violence is merely threatened as long as there is actually or apparently a present ability to implement the threat . . ." [4]. Critically (and atypically), the judge had instructed the jury that the assault that the accused was defending herself against was the general nature of the relationship and all of the threats made toward her over an extended time period.

Accordingly, the view is held by some that the current Code provisions in Australian jurisdictions should be able to incorporate the context of long-term domestic violence without law reform but that "many solicitors, judges, and/or juries do not possess the requisite knowledge of the dynamics of domestic violence to be in any position to judge the availability of the defense generally and its applicability in the particular case" [5]. Thus, expert evidence is necessary to properly convey the social reality of the battered woman [6].

Expert evidence can serve another purpose. Direct questioning, fact-finding, and impartial/impersonal communication styles come at the expense of a more trusting and sensitive environment in which the women can feel safe when telling their stories. Beside aboriginality or immigrant status, both gender and the reality of living in a violent relationship can make such a style of lawyering and adjudication riddled with problems for the battered woman. She often lacks the self-confidence to present what society defines as credibility. The expert can not only help judges and jurors to learn more about the violent antecedents in the specific case but also by substantiating her evidence, the battered woman's testimony may be seen as more credible.

The main way that such expert testimony has been introduced in courts has been through raising or introducing battered woman syndrome (BWS). However, this psychologizing of women's experiences has not been without its detractors in Australia.

Objections to BWS Evidence

Some are concerned that BWS is constructed as a psychological affliction, which "affects the way you perceive things" [7]. The woman's individual state of mind and the medically explicable "irrationality" of her actions are the focus of medical and psychological testimony. Instead of explaining her action as the result of rational self-preservation decision-making, BWS presents the killing as a decision made from a state of "learned helplessness" or dependency [8].

In Australia this has been even more the case with an emphasis on the abnormality or the subjective aspect of BWS as compared to Canada where BWS evidence has been adduced to explain the objective component of self-defense – why a particular accused's response was ordinary or reasonable given the circumstances of violence the woman had survived [9].

Another concern is the potential risk that a formal or informal test of the "reasonable battered woman" will evolve that categorizes the effects of domestic violence into the traits of a singular personality type. This makes it even more difficult for courts to interpret and understand the actions of battered women whose personalities deviate somewhat from this stereotype; those who were not passive in their relationship and/or those who fought back, and/or had sought outside help. For that reason, current descriptions and applications of the syndrome have been criticized for isolating gender as a category of analysis and determinant of behavior while ignoring other systems of power and identity.

Specifically, there is concern that BWS denies that for many, the experience of being a woman, and in particular a battered woman, is incomplete without incorporating their experiences of race, religion, or class. For instance, BWS has not usually covered the particularities of being a battered Torres Strait Island woman or Aboriginal woman. The possible divergence of an indigenous woman's experiences from the stereotype of the dependent, irrational battered woman is evident, particularly with regard to their roles as "heads of households, responsible for the financial and the emotional survival of their families as primary kin-keepers" [10]. As a result, many do not conform to a psychological profile of dependency and passivity.

Perhaps then the critical question is not whether expert evidence is necessary, but the nature of the expertise and evidence. As discussed next, it is possible to use people, either from the "coalface" or academics, who do not syndromize but situationalize [11].[a] The main obstacle in using battered woman's reality BWR is the incompatibility of a traditionally

male dominated court and the acceptance of refuge workers and other nonmedicos or nonscientists as expert witnesses (*see* **Alcohol: Behavioral and Medical Effects**).

One Australian jurisdiction, Victoria has made significant reforms to its Crimes Act (1958) in 2005, clearing a pathway for evidence of family violence and its effects.[b] In other jurisdictions the admission of evidence about domestic violence is left to the magistrate or judge. Since expert testimony is generally only admitted if the subject contains material beyond the ken of the jury, the use of the label "syndrome" may be critical for admissibility.

Battered Woman's Reality (BWR) Evidence

Having nonpsychologizing experts explain the experience of living in domestic violence can assist the jury and the judge in understanding what is reasonable behavior in a domestic violence situation. Diversity of responses to ongoing violence is emphasized with the aim neither to further reinforce stereotypes of women as helpless or passive nor to pathologize their action.

The expert's report may commence with a section on domestic violence in general. The situational expert explains that the domestic violence ending in death more often contains alcohol abuse, death threats, threats with weapons, more severe battery, and sexual violence toward the woman [12–15]. She/he describes the effects of living under the constant threat of violence, categorizing the violence and its impact as "battered woman's reality." If relevant to the particular facts, the court learns that these homicides are usually preceded by an unusual incident: something done by the male that is outside his customary repertoire of violence. He may either have threatened the children's lives, began to sexually assault one or more of the children, or the mother might have just learned about the latter. This has been referred to as "*the turning point*". Something occurs that simply extends beyond the boundaries of what the woman is accustomed to [16].

Then, from a scrutiny of all pertinent records of interview, the expert report can focus on the case at hand, highlighting the pertinent background variables such as a history of childhood abuse, battering increasing in severity over time, intermittent periods of contrition and relative "peace" in the relationship, sexual abuse, death threats, and a precipitating event.

The expert may also be able to discern and label violent behavior by the batterer that has not been named as such by the defendant. For example, in one case, in the records of interview with the police and with the solicitor, the woman was asked specific questions about antecedent abuse.

"Were you hit?"

"Was your husband physically violent toward you?"

She responded "no" to these and other direct questions. The expert though identified a pattern of ongoing physical violence inflicted by the deceased. In the transcript of an interview with her lawyer, the defendant had mentioned that when she slept later than her partner, he squeezed her breasts and nipples so hard that it brought tears to her face. In addition, it was not uncommon for him to jump on her as she lay on the bed. These were not actions that the defendant labeled as hitting or bashing. In part, that is owing to the language and the different images that specific words such as "violent" conjure for different people, which is why screening questions need to be designed very carefully. And, in part, it can be attributed to one of the effects of ongoing violence. It may become so normative that its victims trivialize or normalize it to the point of invisibility. Thus, the situational expert may penetrate the family system's denial, naming not only some physical acts as violence but also emotional, economic, and sexual patterns of control.

How the Situational Expert Addresses the Issue of Immediacy Answering the Question, "How Can It be Self-Defense if He was Asleep or Passed Out?"

The BWR expert discusses how the woman's action was preemptive, explaining that if she did try to defend herself seconds after the violent partner had attacked, she would probably end up seriously injured or dead. Such an "immediate" response is not reasonable behaviour for someone who is, in all likelihood, neither as strong nor aggressive, not as skilled in assault, ans particularly a person who has been beaten down (externally and internally) usually for an extended period of time. Further, immediacy implies that there is one discrete precipitating incident. The expert explains that such a construction is . . .

> . . . (W)holly inappropriate because the danger that women who are habitually and seriously abused face

> is not so much embodied in a single attack as in the day to day experience of living under continuous threat [17].

Additionally, through describing the dynamics of domestic violence, the expert can help the court to understand that for the battered woman, the threat may have felt immediate. The violence is often erratic and therefore unpredictable. This unpredictability can be conducive to feelings of terror – simply not knowing when the batterer will attack.

How the Situational Expert Responds to the Issue of "No Other Recourse" Answering the Question, "Why didn't She Just Leave?"

The situational expert explains that for a battered woman, leaving the relationship may not be easy. It seems that the worse the violence inflicted, the harder it is for many to comprehend the woman's inertia or her return. Yet paradoxically, the worse the violence, the greater her inability to leave. The BWR evidence may equate the violent home with a political hostage context; most people can understand that the more serious the psychological and physical brutality, the greater the capacity of the captors to exert control. The expert shows that these controlling behaviors are often evolutionary and insidious. Disempowerment is perpetuated through humiliation and degradation and the woman's increased shame and isolation. The latter is often at least in part the consequence of the violent partner's exertion of social control – forcing the woman to cut her ties with family and friends.

Further, leaving the relationship does not necessarily mean the violence stops. In fact, leaving can place her life in more danger as the male feels his power is threatened. Accordingly, one fourth of the intimate partner homicides in Australia from 1989 to 2002 involved estranged couples; in 84% males were the perpetrators [18].

How the BWR Expert Explains the Woman's Motives and Emotions to the Court as a Normal Response to the Situation, Answering the Question, "Why is not She Remorseful?"

One less visible barrier to the battered woman's use of self-defense may be her lack of what are considered as "reasonable" emotions such as remorse that accompany or follow the homicide. It has been argued that self-defense may not in fact be appropriate for all battered women who kill since in some instances they may have an affect that does not correlate with the "reasonable subjective state of mind" to accompany an act of self-defense [19]. However, an argument that seeks "reasonable" motivation and affect fails to understand the unique dynamics of domestic violence and the intricacies of the relationship between the abuser and his "hostage" (*see* **Stockholm Syndrome**).

The BWR expert explains that if a political hostage killed his captor after enduring years of emotional and mental torture and terror, most people would accept that it would be "reasonable" for the hostage to be experiencing a wide gamut of emotions at the time of killing. Self-preservation and the desire for freedom and safety could easily be accompanied by a bonding with the perpetrator, anger, vindictiveness, and revenge.

In conclusion, this article offers a fact-based alternative to psychodynamic-based expert testimony that assists the trier of fact not through theories related to behavior syndromes but through background information that places conduct in a factually appropriate context.

PATRICIA EASTEAL

Bayesian Networks

Introduction

Forensic literature has pointed out the utility of methods that deal with formal analysis of inference and decision making [1]. Notably, it has been underlined that complex frameworks of circumstances, situations involving many variables, require a logical assistance [2]. Methods of formal reasoning have been proposed to assist the forensic scientist to understand all of the dependencies that may exist among different aspects of the evidence [3]. Graphical models, in a probabilistic environment (i.e., conducted through the use of a formalism known as *Bayesian networks* (*BNs*)) provide a valuable aid for representing relationships among characteristics in situations of uncertainty. They assist the user not only in describing a complex problem and communicating information about its structure but also in calculating the effect of knowing the truth of one proposition or piece of evidence on the plausibility of others. Moreover, the graphical nature of such models facilitates the formal discussion and clarification of probabilistic arguments [4].

Bayesian Networks

Definition

A BN is a compact model representation for reasoning under uncertainty that formally combine elements of graph and probability theory. BNs allowing their user to define a pictorial representation of assumed probabilistic relationships among a set of variables,[a] deemed to be relevant for a particular inferential problem.

In a BN, random variables are represented by nodes,[b] whereas directed edges (arcs) are used to express assumed relationships among the nodes. Both nodes and edges are combined in order to form a directed acyclic graph (DAG), or a digraph for short. Assuming discrete variables, the strength of the relationship between the variables is quantified by conditional probability distributions associated with each node: for a variable B with parents $A_1, \ldots, A_n$, there is a conditional node probability table $\Pr(B|A_1, \ldots, A_n)$, whereas a table containing unconditional probabilities $\Pr(A)$ is assigned to a

variable A that has no parents. If the conditional relationships implied by the structure of a BN hold for a set of variables $A_1, \ldots, A_n$, then the joint probability distribution $\Pr(A_1, \ldots, A_n)$ is given by the product of all specified conditional probabilities:

$$\Pr(A_1, \ldots, A_n) = \prod_i \Pr(A_i \mid \text{par}(A_i)) \qquad (1)$$

where par(A_i) represents the set of parental variables of A_i. Equation 1 is called the *chain rule* for BNs [5, 6] and formally defines what a BN means: a representation of the joint probability distribution for all the variables. An example is presented at the end of next section.

Structure

For the building of BNs, it is important to remind that they do not represent the flow of information, but serve as a direct representation of a part of the real world [6]. This means that through the use of a BN, a human expert can graphically and numerically articulate his subjective (not arbitrarily) view of a real world system. Therefore, the task of modeling as well as a model that is obtained as a result of this process will principally be influenced by both, the properties and the experts' individual view, perception, and ultimately, extent of understanding, of a domain of interest. As Lindley [7] wrote:

> A model is merely your reflection of reality and, like probability, it describes neither you nor the world, but only a relationship between you and that world. It is unsound to refer to the true model.

Even if the finding of an appropriate representation of a case under examination seems to be, to some extent, an art form, note that it can be guided by scientific and logical considerations.

The basic building blocks of Bayesian nets are the three possible elementary connections among three nodes A, B, and C (see Figure 1).

Such a pictorial scheme allows the scientist to directly translate qualitative information into dependence relations among variables under specified circumstances, specifying the relevance of the variables in the context of the case.

It is necessary to examine the properties implied by the structures. This would mean that it is required to observe concepts such as *d*-separation properties,

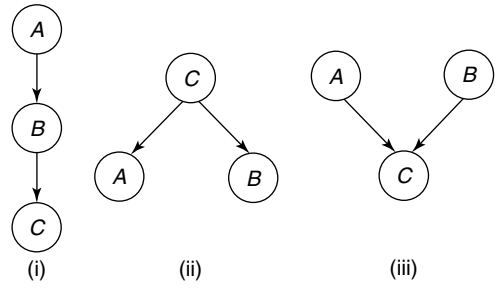

Figure 1 Basic connections in Bayesian networks: (i) serial, (ii) diverging, and (iii) converging connection

that stands in close relation to the notions of dependence and (conditional) independence. The point is that by drawing a certain graphical structure whatsoever, we will automatically be encoding such concepts in our representation. This is why we should be aware of their significance, and, furthermore, we are required to provide justifications for them, if we would like to argue for the appropriateness of the structure we propose.

d-separation, where *d* denotes directional, is a graphical criterion [8] that designates the blocking (or stopping) of the flow of information (or of dependencies) between variables that are connected through a sequence of arcs independent from the direction of the arrows (a chain). Consider this concept in case of the three basic connections presented in Figure 1.

- In serial and diverging connections, a path is said to be d-separated if the middle variable is instantiated.[c] In a serial connection, let A be the proposition that the suspect is the offender, B the proposition that the blood stain found on the crime scene comes from the suspect, and C that the suspect's blood sample and the blood stain from the crime scene share the same DNA profile. Then A is relevant for B and B for C but, given B, the cause of the presence of blood could be different from A. Therefore, evidence may be transmitted unless the state of B is known. Diverging connection is appropriate when we judge that knowledge of the truthstate of a certain event A provides relevant information for another event B and that knowledge of the truthstate of a third event C, which is relevant for both A and B, screens off A from B. For example, let C be the suspect who has been in contact with the victim, A the bloodstain on the suspect's clothes that

comes from the victim, and B the bloodstain on the victim that comes from the suspect. Evidence may be thus transmitted unless the state of C is known.

- In converging connections, a path is called *d-separated* as long as the intermediate variable, or one of its descendants, has not received evidence. For opening the chain, it is not necessary that the intermediate variable is instantiated. For example, let A be the proposition that the suspect is the offender and B the proposition that the bloodstain found on the scene of the crime comes from the offender: knowledge that one of these events occurred would not provide information about the occurrence of the other, but if it is true that C (the blood stain found on the crime scene comes from the suspect), then A and B become related. Converging connections in Bayesian nets are particularly important, because they represent a very common pattern of reasoning: conditional dependence or explaining away [9]. C has been observed; then if A is observed, it explains the observation of C. There is no longer the need to invoke other 'causes'.

Stated otherwise, if two variables in a network are d-separated, then changes in the value (known in the context as *truthstate*) of one variable will have no impact on the truthstate of the other variable. If two variables are not d-separated, they are called *d-connected* [6].

Consider the chain rule in case of the three basic sequential connections that are possible in BNs (see again Figure 1). For a path from A to C via B, as shown in Figure 1(i), $\Pr(A, B, C) = \Pr(A) \cdot \Pr(B|A) \cdot \Pr(C|A, B)$ can be reduced to $\Pr(A, B, C) = \Pr(A) \cdot \Pr(B|A) \cdot \Pr(C|B)$. For a diverging connection, the joint probability can be written as $\Pr(C, A, B) = \Pr(C) \cdot \Pr(A|C) \cdot \Pr(B|C)$, whereas in a converging connection it would be $\Pr(A, B, C) = \Pr(A) \cdot \Pr(B) \cdot \Pr(C|A, B)$.

Reasoning

It can be further explored how to use a BN to reason about the domain. In particular, when we observe a new information (a state of a variable in the net is instantiated), it is of interest to observe its effect on other nodes (i.e., query nodes). This process is called *inference* and it is relied to the computation of posterior probability distributions for these query nodes (*see* **Evidence Interpretation: a Logical Approach**).

Given that BNs offer a representation of probability distributions over variables, this imply that any set of variable can be instantiated and their effect of other variables can be measured as schematically presented in Figure 2. For the sake of illustration, the terms *cause* and *effect* are introduced to describe a simple two-nodes BN: cause → effect.

- The cause 'produces' the effect, i.e., knowing that the cause happened, it can be foreseen that the effect will occur or might probably occur, too. This is a predictive line of reasoning. For example, given that the suspect is the source of the stain (say, a binary variable S with states true instantiated), even before any laboratory tests have been performed, the probability of a match between the stain's DNA profile and the suspect's profile (say, variable E) increase (note that if S is known, then the probability of E is just given by the specified probability $\Pr(E \mid S)$ in the conditional probability table relates to node E). Note that this estimate represents the numerator of the likelihood ratio. By the instantiation of state false of variable S, scientists obtain the denominator of the likelihood ratio (*see* **Case Assessment and Interpretation**).
- The effect does not "produce" the cause, but knowing that the effect occurred, one may infer that the cause probably occurred. This is a line of reasoning against the causal direction that can also be termed *diagnostic*. For example, given that the test shows a match between the stain's DNA profile and the suspect's profile, then the belief that the suspect is the source of the stain is updated. If E is known, probability of S is updated *via* Bayes' theorem.

Bayesian Networks in Judicial and Forensic Context

There are different ways in which BNs are used as a modeling technique. Legal scholars focus on BNs as a means for structuring cases as a whole, whereas forensic scientists concentrate primarily on the evaluation of selected issues that pertain to scientific evidence. Many studies with an emphasis on legal applications thus rely on graphical models as a method for the retrospective analysis of complex and historically important causes 'célèbres', such as the Collins case [10], the Sacco and Vanzetti case [11], the Omar Raddad case [12], or the O.J. Simpson case [13]. Another contribution proposes BNs to clarify fallacious arguments [14].

Forensic applications of BNs [1] range from offender profiling [2], single [15, 16] and complex [3, 17, 18] configurations of different kinds of trace evidence as well as inference problems involving the results of DNA analysis. The latter is an important category that covers studies focusing on small quantities of DNA [19], cross-transfer evidence [20], relatedness testing with or without missing data on relevant individuals [21, 22], or mixed stains [23, 24]. Interest has also been focused on case preassessment where the role of the forensic scientist consists of assessing the value of the expected results, prior to laboratory examination [1, 25]. BNs evaluate the probability of possible outcomes in various cases together with their respective weight.

These conceptual and practical studies represent a relatively rich variety of inferential topics. The reported works jointly support the idea that graphical probability models can substantially improve the evaluation of likelihood ratios used for the assessment of scientific evidence. In particular, they allow their user to engage in probabilistic analysis of much higher complexity than what would be possible through traditional approaches that mostly rely on rather rigid, purely arithmetic developments.

In many applications, the size of problems to be analyzed using BNs may be important; scientists are seeking ways to reduce the complexity of model building. Object-oriented Bayesian networks (OOBNs) [26] facilitate hierarchical construction utilizing small modular networks (network fragments) as building blocks. Examples of such models are presented in [24, 27, 28].

What about the Numerical Specification?

If we cannot get any numbers, the method should be rejected? Note that numbers are not of primary importance; as mentioned by de Finetti, "a rough qualitative appreciation of probabilities is sufficient and worthy for practical purposes" [29]. In fact, reasoning with graphical models is about clarifying one's thinking.

Operationally, an abstraction of quantitative BNs, the so-called qualitative probabilistic networks, (QPNs), and sensitivity analysis can be used for inference purposes. In the former, qualitative relationships are used instead of numerical relations, and allow the user to rapidly gain an idea as to the qualitative effect a variable may have on another. On some occasions, this information may be entirely sufficient; on other occasions it may represent a valuable preliminary information before more sophisticated methods will be employed for eliciting probabilities[d] [31]. In the latter, information about the effect that one variable (or the joint effect that two or more variables) may have on a second is studied. Such indications may be helpful for deciding on the relative importance of efforts needed for the elicitation of some probabilities.

Forensic examples of such analysis are presented and discussed in [1, 32, 33].

What about the Decision-Making Process?

As mentioned earlier, BNs provide a coherent environment in which beliefs about target variables can be reevaluated in the light of newly acquired evidence. This constitutes a fundamental prerequisite for decision making under uncertainty. In fact, inference and decision are connected because the results of the former are the point of departure of the latter [34]. BNs can be extended to incorporate basic ingredients necessary to perform Bayesian decision analysis, that is, decision and utility nodes, representing actions available to the scientists and values for possible consequences of these actions, respectively [6]. Forensic examples of this approach are presented in [35–37].

Conclusions

BNs are a widely applicable formalism for a concise representation of uncertain relationships among variables of interest in a domain (in this case, forensic

science). They provide assistance and support in the rigorous evaluation of evidence according to the laws of probability, which guarantee rationality in reasoning under uncertainty.

BNs take an important part in forensic science practice and research, notably as

- a cognitive tool for the structuring and logical guiding of mental processes;
- a coherent inferential concept for drawing inferences to hypotheses based on evidence;
- a flexible and dynamic approach allowing knowledge to be transparently revised upon newly acquired information.

End Notes

[a.] Literature often refers to causal relationship.
[b.] Nodes represents random variables, where the random variable may be either discrete, with a finite set of mutually exclusive states which themselves can be categorical, discrete or continuous.
[c.] A variable is called *instantiated* if its state is changed from unknown to known.
[d.] Often the conditional distributions include parameters that are unknown and must be estimated from data. This technique is called *parameter learning*. A forensic example is given by [30].

Behavioral Science Evidence

Consideration for the relationship between individual differences, conduct, and culpability has existed since before recorded history. Throughout most of early history, human beings lived in extended family groups or tribes with no formal law, as we know it today. These tribal groups developed folkrights or customs for dealing with unmistakable differences between the individual members of the group. For example, if a man "fell out of his senses or wits and killed someone", his kinsmen were expected to compensate the victim [1]. People recognized what we today consider mental illness and physical handicaps. Often the mentally ill were regarded as having special powers. At other times, as appropriate, the mentally and physically disabled were given special dispensations and others in the group assumed their responsibilities and obligations.

In the eleventh century, major attempts were made to organize tribal and folk groups into nations. This is always a difficult undertaking. Tribes, by whatever name, are controlled by people generally known to

all of the members. Like a family, social dynamics can be worked out face-to-face; there is no need for formal law; and each member can be taken as a unique individual and treated accordingly. While tribes vary considerably, and some can be totalitarian and even belligerent, most people feel comfortable in small social networks, where they can plead their own case and find unique acceptance. For this reason, much of the world is still at best made up of alliances between local groups. Often these folkgroups or clans unite in religious or nationalistic factions, and these factions both impose some form of discipline and authority, while often also engaging in feuds or warfare against each other.

Great Britain attempted its first serious transition from tribalhood to nationhood following the Norman Conquest in 1066. It was a slow process, and it was not until the Magna Carta or "Great Charter" in 1215 that anyone really started to think about government under a rule of law. Henry de Bracton was born about the time the charter took effect, and went on to become perhaps the greatest single influence on modern law. Bracton was a priest – there were no lawyers or law schools at that time – and he soon became a judge and legal scholar.

Having studied folk customs, Bracton understood that law had to recognize individual differences and their impact on culpability. Bracton introduced the legal term *mens rea*. Law, Bracton reasoned, involved two components. The first is physical and considers questions such as whether a person actually did the act that, for example, defines a crime. The second is mental; *mens* being the mind or intellect, and *rea* being the answerability or accountability [2].

Bracton shaped a sophisticated body of legal thought that is still influential today [3, 4]. Special measures were taken for those who could not participate in their defense, parents were warned to take care of and treat leniently their "evildoer" offspring, and at least one court acquitted a defendant who had committed his crime under the influence of an improper prescription ordered by his physician.

Nevertheless, this was a balanced justice. Children and those suffering from a mental disease (what we would call today a *psychosis* that reaches the legal test of insanity) or mental defect (for example, mental retardation) were accountable for their *Torts* [5]. Torts are civil breaches of interpersonal conduct. The mentally ill can and occasionally do commit torts, and the law in most jurisdictions still holds them or their guardians accountable for the consequences.

Despite all these sophisticated legal provisions, most people were fully accountable for their conduct. Conduct is the fixed legal standards that specify what people should and should not do. The legal requirements that govern conduct did and still do provide tremendous latitude in individual behavior, but virtually all nations have laws that specify what is and what is not acceptable conduct. For this limited number of actions that are illegal, there is very little flexibility except for the special responsibility exception formalized by Bracton.

Folkway, on the other hand, did contain provisions for individual difference; a way to provide dispensations based upon the individual and the circumstances. Modern nations, working to create a society under law, could not ignore this need for and tradition of special dispensations. However, in the British courts and those of most nations to this day, findings of fact are restricted *only* to whether the accused did or did not commit the act that defines a legal offense. In fact, in many nations including England, the burden of proof, whether nation must prove guilt or the accused prove innocence, rests with the accused, though the burden of proving sanity may shift back to the prosecution, once the accused makes a prima facie case that he was insane.

The granting of special dispensation was reserved as an unyielding prerogative of royalty. Thus, in England and elsewhere, a defendant is first tried and found guilty of a criminal act. The guilty party must then appeal for royal dispensation based upon their individuality and circumstances. While this may seem complicated, it was consistent with folkways that left such matters to elders or other leaders of the tribe. Royalty was determined to retain the power of dispensation because it is one of the greatest powers in governance. Used wisely, it can demonstrate fairness, further respect, and earn undying gratitude.

Some royalty grant audiences during which dispensations are pleaded and awarded; usually with witnesses to the largess. This, however, can become a time consuming process, and in England the duty was delegated, except in high-profile political situations, to a court of chancery. A special court with a strong religious influence, chancery's legacy can be seen today in the American court of equity. These no longer involve a separate court, but regular courts

can convene in equity and deal with matters that reach beyond the letter of the law.

Insanity

Insanity is not a medical or psychiatric term. Insanity is a *legal* concept and must be determined as a question of fact. The cornerstone legal definition was formulated in England in 1843, and draws directly from Bracton. M'Naghten's Rule stemmed from Queen Victoria's outrage with a "not guilty" verdict in the case of Daniel M'Naghten, debate in both houses of Parliament, and a joint meeting of the high justices and the House of Lords. The Rule holds that "to establish a defense on the grounds of insanity, it must be clearly proved that, at the time of committing the act, the party accused was laboring under such a defect of reason, from disease of the mind, as *not to know the nature and quality of the act he was doing, or if he did know it, that he did not know he was doing wrong"* [6].

Since M'Naghten, attempts have been made to alter the law to make it easier or more difficult to enter a successful insanity defense. On the heels of M'Naghten, the Massachusetts Court added what came to be known as the "*irresistible impulse*" *test*, whereby an accused should be found not guilty if the jury determined he was irresistibly driven to committing the crime by the mental disease or defect of which he suffered [7]. In 1954, the US federal courts adopted the Durham Standard [8] also known as the "*product*" *test*. The Court held that neither M'Naghten nor the irresistible impulse test provided satisfactory criteria for determining sanity. The *Durham* court stated that "a defendant is not criminally responsible if his unlawful act was the "product" of mental disease or defect".

Durham presented a number of problems. The new test made it much easier to be found not guilty by reason of insanity. On the other hand, the test also provided for indefinite commitment in a mental hospital, and defendant Durham ended up spending more time behind bars than if he had been found guilty of the crime.

Finally, in 1981, John W. Hinckley, Jr. was found legally insane at his trial for attempting to assassinate President Ronald Reagan, an act by which Hinckley sought to impress actress Jodie Foster. The public saw Hinckley as an indolent self-indulgent drifter from a wealthy family. In response Congress enacted the Insanity Defense Reform Act of 1984 [9] that returned to Bracton's roots; producing a new definition requiring that at the time of the commission of the acts constituting the offense, the defendant, *as a result of severe mental disease or defect, was unable to appreciate the nature and quality or the wrongfulness of his acts.* Mental disease or defect would not otherwise constitute a defense, and the burden of proving the defense of insanity by clear and convincing evidence rested with the defendant.

Not all jurisdictions follow the US federal standard, and a few, including the state of New Hampshire, still have an irresistible impulse test on the books. Regardless of the test, however, jury verdicts reflect a societal consensus that the folkviews upon which Bracton based his legal formulations continue to this day. Nevertheless, insanity is not a simple issue (*see* **Insanity: Defense**; **Temporary Insanity**; **Treatment, Mandated: Mental Health**; **Treatment, Right to Refuse: Mental Health**; **Sex Offenders: Treatment of**).

Diminished Responsibility

When the United States declared their independence and sought to create a nation of their own, they faced a unique problem. The colonies rejected the monarchy, and were adamant about the separation of church and state. In fact, they even distrusted their own government and devised a set of checks and balances that restrained central power. This effectively precluded the delegation of dispensations to a monarchy or to a religious power. Faced with this problem, the new nation turned back to history and, as in early folkgroups, delegated the responsibility for special dispensations to the people who should best know and understand the parties in litigation: a jury of their peers.

No longer would justice require a two-step process with a trial for findings of the fact and a chancery to consider mental state and motive. The trial court would now address both. This required a completely new definition of laws; specifying not only the physical act(s), which define the violation of conduct, but specific adverbs to indicate required mental states.

The obvious examples are crimes that contain in their definition mental qualifications, such as "deliberate", "intentional", "wanton", and "premeditated".

Societies include these adverbs in their legislation not just to express their belief that the acts are unusually heinous, but to indicate that to meet the *legal* definition of such a crime, and therefore be subject to punishment for committing the crime, the perpetrator must meet both the *physical* requirement of committing the specified act or omission and must have possessed the requisite *mental* state during the events leading to and during the act or omission.

These expanded definitions, which invite behavioral evidence, are often referred to as *opening the door to "diminished capacity" defenses*. However, just as with insanity, if the defendant fails to satisfy the mental state requirements of the law, the law is simply not applicable. Although it is true that the added language involves states of mind, the states of mind and motives considered in an insanity defense, as opposed to other legal situations, are qualitatively different.

An insane defendant is accorded a unique status and could, for example, be institutionalized. The only way to hold a sane defendant accountable is to charge her with the correct crime in the first place. This may require, for example, reducing a charge from murder to manslaughter. This was effectively what a court of chancery did in retrospect. In the United States, however, matching the charge to both the physical and mental requirements of the law falls entirely within the trial court action. Moreover, while American criminal law, in particular, contains state of mind adverbs, mental state also plays a role in many civil causes of action. For example, the tort of "intentional infliction of emotional harm" requires specific intent – a direct correspondence between state of mind and the wording of the law. An insane person, on the other hand, is assumed to suffer from a disease or defect that deprives them of the capacity to conform to the law.

Virtually all litigation in any nation still requires consideration of both the physical and mental aspects of the alleged conduct. In most jurisdictions other than the United States, however, the mental aspects are still left to sovereigns or religious officials [10]. Therefore, if you look at the editors and contributors to the major international academic journals on law and behavior [11], virtually all are based in the United States or Canada. Other academic experts in this particular field also tend to have been educated or originally lived in North America.

The Judiciary

Most disputes involve *versions* of reality, much as with memory and belief, which must typically be accepted as narrative rather than historical truth. Only rarely do courts have access to the physical evidence necessary to reconcile beliefs to a single, certain, truth. Science may be the business of truth, but law is the business of justice. It is the acceptance of a quality of justice – respect for the court and its procedures – rather than any objective verifiable standard of truth, which determines whether the citizens of a nation resolve their disputes through law or through the shedding of blood in the streets.

The kings of Bracton's time recognized this or learned in blood the lessons of unjust rulership. Courts today, and particularly those that must go to the heart of justice that always rests in human individuality and motive, also understand that justice can never be entirely separated from public sentiment. The term *forensic* derives from the *forum* or arena of public debate – places like the courts in which matters of broad public concern are openly debated, exchanged, weighed, and assessed.

In earlier days, people came to view the court when it was the only public activity in town. Today, they follow trials on television. Certainly public debate can inspire bad ideas as well as good, but one of the strengths of open societies is their marketplace of ideas. Courts air a wide range of behaviors from exemplary to outrageous. Societies define their standards through every individual's constant measurement of their conduct against all other examples of human behavior including that of criminals, and generally arrive at a reasonable balance. While jurors define justice in a particular case through their verdicts, societies define justice through their debate of verdicts, by acting upon their conclusions as future jurors, and as they did in response to the Hinckley verdict.

The Judiciary, of which the trial courts are one part, is the branch of government most responsible for assuring stability and continuity of conduct, expectations, and social structure. The levels of appeal built into the judicial system, and the accumulation of common law – the past precedents that shape future holdings – provide a buffer against societal fads and the passions of the moment. Nevertheless, as Bracton recognized, law must gradually evolve with the evolution of societal convictions. If law does not heed

evolving public sentiment, triers of fact override the letter of the law through what is known in the legal vernacular as *jury nullification* [12–20].

As we saw in the post-Hinckley example, law related to any given area waxes and wanes in response to current beliefs. The public, and appropriately so, is generally willing to consider new information and scientific theories. Shifts in the law often occur in response to new or "novel" theories; particularly theories of human behavior. Justice operates in a social context, and in the 1960s the American public was heavily impacted by psychoanalysis with its view of the unconscious and therefore on limitations in individual responsibility. Over the past several decades, psychoanalytic therapy has been supplanted by cognitive behavioral therapies that maximize rather than minimize individual responsibility [21].

The impact of the evolution of "novel" scientific theories can be seen through the use of the legal research tool known as *case congregation analysis* [22]. In each case congregation, disputes progress along a path shaped not only by science but also by social fears and broad national political forces. Often, but not always, science prevails. Clearly, there can be no doubt that resolution of underlying scientific issues is a prerequisite to settlement of a complete legal case congregation, notwithstanding the reality that early cases are typically tried well before the scientific issues have been fully delineated, much less resolved. However, achievement of a national consensus on a seemingly scientific issue often turns out to require a social consensus on moral or cost/benefit issues, which transcend science [23].

Science

Although law is the province of justice, science should be the province of truth. The law has steadily moved toward requiring higher standards of proof and procedure in scientific expert testimony (*see* ***Daubert v. Merrell Dow Pharmaceuticals***; ***General Electric v. Joiner***; ***Kumho Tire v. Carmichael***; ***Weisgram v. Marley***).

In *Daubert* [24], the most recent major US Supreme Court case to address the standards for expert scientific testimony, the issue of fact in dispute was whether the drug Bendectin was a teratogen. Accepted scientific procedures have been established to determine whether a substance causes birth defects. However, science is not simply a set of accepted facts. Science is a *process* through which empirical truth is sought using scientific methods, adversarial debate, and peer review. In *Daubert*, the US Supreme Court focused upon scientific debate and just how the reasoning and methodology underlying evidence and testimony can be established as scientifically valid, as well as how best to determine whether that reasoning or methodology can be properly applied to the facts in dispute.

In some instances, the facts at issue in a given trial can be addressed through behavioral science expert testimony on the basis of scientific standards applicable to the best of the hard sciences (*see* **Deception: Truth Serum**). Typically, however, behavioral science experts testify about factual issues that are less comparable to those addressed by the physical sciences. In the vernacular of the field, the task is frequently to help "separate the mad from bad or the lazy from the crazy". It is not true that physical science operates in a judicial context any less influenced by issues of policy and societal pressures. Both behavioral and physical sciences cases are subject to these pressures, and their case congregations – the course of cases over time, which address a given issue of fact – reflect the evolution of public consensus. The distinction is that the physical sciences lend themselves more easily to methodologies that eventually yield scientific conclusions.

Nevertheless, the behavioral sciences appropriately address issues of fact intrinsic to the law. The law, and particularly the structure of law in the United States, is about individual differences. Questions of motive and state of mind are, by definition, unique to a given person at a specific time. Science can determine that a given drug is or is not a teratogen, and that scientific conclusion applies to that drug in any future litigation. Behavioral science expert testimony typically addresses issues of fact that relate to the conduct of a unique individual, at a given time and place, under a particular set of circumstances.

The behavioral sciences do follow scientific methodologies, but the application of a given methodology varies with the question being asked. The challenge is to match the correct methodology to the question being asked by the trier of fact. Behavioral science experts typically bring to a jury experience and expertise in assessing individuals. Triers of fact weigh that experience and look to

conclusions grounded in experience and training. Therefore, a proposal to introduce behavioral science expert testimony generally raises a question not of admissibility, but of credibility [25] (*see* **Expert Opinion in Court: a Comparison of Approaches**).

It is often suggested that the fact that two or more behavioral scientists can testify in the same case with opposite opinions is proof that behavioral science is not really a science at all. It is just as frequent that physical scientists testify with opposing positions, particularly in cases that are early in a case congregation sequence. Being a scientist is not about knowing the answers, but about following a systematic process to find the right answer to the question at hand.

Scientists, like the population at large, view the world through their own perspectives and biases. The rules of science are designed so that other scientists can detect and refute premature or flawed conclusions. As long as scientists follow the rules of science, the search for truth is built into the structure of the discipline. Science, in this respect, is no less adversarial than law.

In most physical sciences, replication is both a goal and proof that a finding has been scientifically established. This does not apply to behavioral case assessments. Under law, every person is unique. The fact that the vast majority of other people may fit a particular pattern is irrelevant if there is any chance that the person being evaluated may be an exception. The reality that behavioral experts do not always agree often reflects nothing more than one expert arguing the rule, and another the exception.

Expert Testimony

In a country such as the United States, where motive and mindset are integral to the facts that must be addressed by the jury at trial, behavioral science testimony is by far the most frequent form of expert testimony. Because it is so routine, and often the expert witnesses are government employees or others already working within the justice system, exact figures are unknown. Estimates suggest that from 30 to 60% of all expert testimony involves issues of motive or mental state.

The relationship between an expert and her attorney/client also follows a set of well-established rules. Experts must be objective to assist the trier of fact. Experts cannot accept contingent fees based on the outcome of a case. Their job is not to formulate trial strategy, which is the job of counsel who is bound by rules of privilege that may limit the type and amount of information that can be shared even with the expert. The topic is beyond the scope of this article, and an expert should conduct the research necessary to master the rules and art of expert witness practice.

As a general rule, expert witnesses testify only at trial. Appeals courts address questions of law and usually all questions of fact are resolved at trial and not revisited on appeal (*see* **Expert Opinion: Appeal v. Trial**). Moreover, experts usually testify about, but do not tell the trier of fact, the answer to the ultimate issue upon which the case turns. For example, if the case turns on whether a defendant is or is not legally insane, an expert may assist the jury to understand the mental state and functioning of the defendant; but will not be asked to state a conclusion as to whether the particular defendants actually is insane. This should be left to the trier of fact (*see* **Ultimate Issue Evidence by Experts**).

The legal system works when the people upon whom the system depends do their job.

Prerogatives of the Trier of Fact

Just who is or is not telling the truth in a legal situation in which the facts at issue are material to the outcome of the case is a question of fact usually left to the trier of fact – the jury or in some instances a judge. The judiciary is very reluctant to take such decisions away from the trier of fact, and therefore does not permit expert testimony to substitute for a party taking the stand for direct assessment by a jury. Similarly, although science has clearly demonstrated that eyewitnesses may provide the most unreliable forms of evidence, we leave their evaluation to the jury and even make it difficult (depending upon jurisdiction) to provide expert testimony on the reliability of eyewitness testimony [26] (*see* **Eyewitness Testimony**; **Eyewitness Lineups: Identification from**).

For the same reason, the courts generally do not allow admission of the results of lie detector tests or other new high-technology deception technologies [27]. Not only are they of questionable scientific accuracy, they are limited by the same human memory constraints as hypnosis and truth serums (*see*

Deception: Detection of; **Deception: Detection of and Brain Imaging**).

"Truth serum" and hypnosis evidence also impinge upon the prerogatives of the finder of fact, and for this reason alone have been held inadmissible as legal evidence (*see* **Deception: Truth Serum**; **Hypnosis and Memory**).

Issues and Controversies

The behavioral sciences, and related disciplines including psychopharmacology, are advancing at a progressive rate and today bear little resemblance to where they were fifty or even thirty years ago. The emphasis today is upon evidence-based practice, and the scientific literature in the field now holds its own against the standards of medicine and the hard sciences (*see* **Psychopathology: Terms and Trends**; for recent developments in psychopharmacology, *see* **Psychopharmacology**; **Psychopharmacology: Child and Adolescent**).

During recent years, crime novels, movies, and television have featured advanced forensic sciences as well as behavioral science methodologies such as profile and syndrome identification. While the imitation is flattering, most of the content is pure fiction. The glamor and unfortunately too much of the substance and its application to routine law enforcement is vastly overrated. Moreover, much of the fiction is based upon outdated information and practices that have been discredited or are no longer followed (*see*, in particular, **Profiles: Psychological and Behavioral**; **Syndromes: Psychological**).

Courts devote considerable attention to issues of child custody (*see, for example,* **Visitation Rights**; **Parenting: Assessment of Capacity**; **Battered Child Syndrome**; **Children: as Witnesses**) and capacity (*see*, for example, **Capacity Assessment**; **Capacity to Stand Trial**).

Elder affairs have also moved into the courthouse, with issues ranging from protection to guardianship (*see*, for example, **Guardianships of Adults**; **Capacity for Independent Living**; **Elder Abuse: Policy**; **Elder Abuse: Risk**).

Risk assessment (*see*, in particular, **Homicide: Multiple (Behavior)**; **Risk Assessment: Patient and Detainee**; **Duty to Warn**), and threat assessment (*see*, for example, **Threat Assessment: School**; **Threat Assessment: Workplace**; **Violence Risk Assessment for Mental Health Professionals**) are specialties that have made significant advancements in recent years (*see* **Dangerousness: Risk of**).

Malingering (*see*, for example, **Malingering: Forensic Evaluations**), persuasion and undue influence (*see*, for example, **Interrogation**; **Confessions: Evidentiary Reliability of**; **Capacity to Waive Miranda Rights**), Jury dynamics (*see* **Jury Dynamics**) and the structure of justice itself (*see*, for example, **Therapeutic Jurisprudence**; **Mental Health Courts**) are topics of increasing relevance.

Even the conceptualization of mental health diagnosis and classification has ongoing relevance to the functioning of the judicial system. The *Diagnostic and Statistical Manual of Mental Disorders* [28], that in turn shapes the *International Classification of Diseases* [29], is at a point that is comparable to where birth defects were 30 years ago. Developed as research tools and containing a disclaimer that the classifications "may not be wholly relevant to legal judgments . . . that take into account such issues as individual responsibility, disability determinations, and competency", these references are widely used as a catalog of "scientific" entities that can be used to either strengthen a defense or assert a cause of action.

The classifications, however, are of limited legal utility, and counsel as well as experts should learn how to prevent their abuse. Nevertheless, the structures and definitions in these volumes serve the same purpose that a compendium of birth defects accomplished prior to the development of large-scale gene mapping technologies – it defines research and testing populations upon which basic science research can be performed, thus hopefully helping to transform behavioral sciences from clinical to more empirical specialties.

In the meantime, efforts to shift and realign definitions of behavioral conditions have become controversial and contentious. The ramifications are not simply academic. As examples, consider addiction and posttraumatic stress disorder. Addiction (*see,* for example, **Alcohol: Use, Abuse, Tolerance, and Dependency**; **Addictions**; **Substance Abuse**) has been defined (here simplified for purposes of illustration) as taking a drug and undergoing withdrawal upon its discontinuation, or alternatively as taking a drug, going successfully through withdrawal, and then returning to use of the drug. The distinction is significant. The first definition can include almost anyone, while the second is far more restrictive and

selective. Their alternative application in a legal context can change the outcome of the litigation.

Similarly, a wide range of definitions of posttraumatic stress disorder (PTSD) has been proposed and is being debated (*see* **Posttraumatic Stress Disorder**). At one end of the continuum, the condition is a rare anomaly. Most people are strengthened by life and mastery of adversity, while a small number, perhaps for genetic reasons, are susceptible to PTSD. At the opposite end of the continuum, virtually everyone meets the criteria for a PTSD diagnosis at some point in their life; and everyone with the diagnosis might then have a cause of action against someone else for creating the condition.

"Novel" behavioral theories also have had a tendency to create both "victims" and causes of action [30] (*see*, for example, **Syndromes: Psychological**; **Deception: Truth Serum**). Typically, these proposed conditions are advanced during a period of social change, anxiety, and as a seeming means of righting some historic wrong. They usually run a course in which an individualized argument has occasionally been successful in the past. A novel theory is then advanced to lend scientific respectability to the concept. The theory is introduced in litigation, unsuccessful until a landmark case brings the "science" to public attention. Following the publicity and the controversy that it engenders, successful cases rise sharply until overuse become apparent and a concerted effort is made by the opposition to discredit the theory. Once discredited, as demonstrated repeatedly through case congregation analysis, the rate of successful applications of the theory drops precipitously until successful cases reach the pretheory level. Often public outrage calls for the banning of such theories as "junk science". However, it is the abuse of the scientific imprimatur that must be discredited, and once a behavioral theory is discredited, it ceases to be used. Lack of success is more effective than legal prohibition at ending impropriety.

Conclusions

Human beings have understood and accommodated the relationship between individual differences, conduct, and culpability since before recorded history. Henry de Bracton, building on this foundation in the thirteenth century, created a modern judiciary that could unite disparate clans into a nation under law. Bracton also reasoned that law involved two components: the physical fact of whether a person committed a crime, and a corresponding requirement of mental accountability. The prerogative of granting dispensations on the basis of mental accountability was reserved for kings and religious officials until the United States rejected royal and religious rule, and enacted laws that transferred behavioral dispensations to trial juries. Behavioral evidence now accounts for the single largest category of expert testimony in the United States, and the academic literature on the topic is followed worldwide.

Insanity is not a medical or psychiatric term; it is a *legal* concept that must be determined as a question of fact. The behavioral sciences today bear little resemblance to where they were 50 or even 30 years ago. Questions of motive and state of mind are, by definition, unique to a given person at a specific time. The task of an expert witness is to assist the trier of fact. The reality that the vast majority of people may fit a particular pattern is irrelevant, if there is any chance that the person being evaluated may be an exception. The fact that behavioral experts may disagree often, reflects nothing more than one expert arguing the rule, and another the exception.

"Novel" behavioral theories and classifications have had a tendency to create both "victims" and causes of action. Typically, these proposed conditions are advanced during a period of social change, anxiety, and as a seeming means of righting some historic wrong. Case congregations provide a vivid record of shifts and corrections in the judicial process. Most problems are self-correcting, given an open forum and a public, both willing to accept new ideas in its effort to do the right thing, and also able to recognize mistakes.

[21] Cognitive Therapy proper was developed in the 1960s by psychiatrist Aaron T. Beck as a treatment for depression. Later elaborated and expanded by his daughter, psychologist Judith S. Beck, the approached has been found applicable to the broad range of psychological disorders that are not overwhelmingly biological in origin. Beck, J.S. (1995). *Cognitive Therapy: Basics and Beyond*, Guilford Press, New York. Salkovskis, P.M. (ed) (1996) *Frontiers of Cognitive Therapy*, Guilford Press, New York; Beck later expanded the application of his theory to the treatment of anger, hostility and violence in his *Prisoners of Hate* (New York: HarperCollins, 1999). Today, the benefits of cognitive therapy are so widely recognized that in England, physicians are required to receive training in the technique as part of their clinical preparation. Behavior therapy has very little relationship to American behaviorism, but instead grew out of the tradition of British behaviorism which was far more cognitive, and came out of the discovery that patient symptoms often persisted because the patient had made inaccurate interpretations of the meaning of their behaviors or adopted counterproductive behaviors while trying to cure their initial complaint. In both Cognitive and Behavioral Therapy, the patient is taught, through structured exercises, to correctly interpret events and sensations, and adopt effective behaviors.

CARL N. EDWARDS

Behavioral Toxicology

Introduction

The ability of drugs to affect behavioral changes is arguably one of the most common issues confronting forensic practitioners investigating violent crimes. This has as much to do with the frequency of their use by sections of the community as to their often profound adverse effects on humans.

The risks of violent death including homicide and suicide are associated with the use of alcohol or illicit drug including those people living with drug-using persons but who themselves do not abuse alcohol or drugs [1, 2].

Drugs of most concern include alcohol, all of the amphetamine class of drugs, cocaine, the benzodiazepines and the hallucinogens such as ketamine and PCP, although many other drugs can have profound behavioral effects directly or can modify the behavioral effects of other drugs.

National household surveys on drug use conducted in the United States indicate that about 10 and 6% of males and females respectively have used illicit drugs in the previous month. This is mainly cannabis followed by cocaine [3]. The prevalence of drugs capable of causing behavioral changes is significant [4]. In victims of homicide, the most common is alcohol followed by the benzodiazepines, opiates, and stimulant drugs.

This article explores the notion of behavioral toxicity and its relevance to forensic medicine and provides some of the most common examples to illustrate the significance of this phenomenon.

What is Behavioral Toxicity?

This is a term used to define changes in behavior that impact adversely on rational thought and actions that may predispose to violence or other behaviors and have been caused by the effects of chemical substances. Most typically, these substances are illicit drugs, but this can also be caused by the inhalation of volatile substances, e.g., petroleum products, solvents, etc., the use of natural products that contain psychoactive compounds, or the misuse of prescribed medications (Table 1). The net effect of these behaviors is the association with criminal acts.

Table 1 Common drugs causing behavioral toxicity

Drug or drug class	Relative risk of behavioral toxicity
Alcohol	Moderate
Amphetamines	High
Anabolic steroids	Low to moderate
Benzodiazepines	Low to moderate
Cannabis	Low to moderate
Cocaine	High
LSD	Low to moderate
Mescaline	Low to moderate
PCP and ketamine	Moderate to high
Psilocin/Psilocybin	Low to moderate
Volatile substances (hydrocarbons, etc)	Moderate

This phenomenon is illustrated by excessive alcohol consumption, in which a person becomes disinhibited leading to an outburst of aggression following an argument resulting in harm to another person. While the actions cannot be blamed on the drug itself, the drug has modified the person's behavior to increase the propensity to violence and often also the severity of the violence. This is a well-known association with excessive alcohol use; however, with some drugs (e.g., benzodiazepines) changes in behavior are not so predictable.

Mechanisms of Action

Chemical substances may act on receptors in brain or bind to membranes affecting cellular functions in the brain modifying normal nerve function. The transmission of signals by nerves involves the use of chemicals known as *neurotransmitters*. These neurotransmitters include substances such as norepinephrine (noradrenaline), serotonin (5-hydroxy tryptamine or 5-HT), dopamine, *N*-methyl-D-aspartic acid (NMDA), and gamma-aminobutyric acid (GABA).

Interference in the actions of neurotransmitters can occur by blocking the effects of these substances on receptors located on adjacent tissue (postsynaptic sites) or the nerve ending itself (presynaptic sites) or by modifying the release, reuptake, or metabolism of these substances. For example, cocaine inhibits the reuptake of norepinephrine and dopamine and thereby effectively prolongs the effects of released neurotransmitter. Reuptake is essentially a process to recycle neurotransmitters in which active processes

exist within nerve terminals to reabsorb released neurotransmitter. Amphetamines can increase the amount of neurotransmitter released by the nerve ending thereby increasing the actions of the nerve impulse.

Benzodiazepines block the effects of released GABA. The binding of the benzodiazepine on this receptor has the net effect of increasing the movement of chloride through ion channels in membranes. This process reduces the stimulation of areas in the brain involved in regulating a range of behaviors and physiological functions including those involving emotions and memory.

Some drugs increase the actions of the neurotransmitter by inhibiting the enzyme responsible for metabolizing excess neurotransmitter, monoamine oxidase (e.g., the antidepressants moclobemide, phenylzine, etc).

Alcohol

Alcohol, or more accurately termed as *ethanol*, is by the far the most common drug affecting behavior. Alcohol is a complex drug in terms of its mechanism of action. It is a central nervous system (CNS) depressant and acts to depress various functions in the brain and the nervous systems generally. It resembles the volatile anesthetics such as chloroform, ether, and the modern halogenated anesthetics. Alcohol not only affects membrane function nonspecifically but also affects a number of excitatory and inhibitory amino acid transmitters such as GABA, glutamate, dopamine, and serotonin (5-HT).

Blood ethanol concentrations (BAC) in excess of 0.02% adversely affect coordination skills and cognitive function. These symptoms become quite obvious at BAC 0.1%, causing slurred speech, unsteadiness on the feet, poor judgment, and decision making. Disinhibition is most apparent over 0.1% BAC and is associated with aggression and with loud and outrageous behavior, risk taking, and criminal activity (*see* **Alcohol**) [5].

Amphetamines and Cocaine

This group of strong stimulants include (dex) amphetamine, methamphetamine, and the designer amphetamines such as 3,4-methylenedioxy-metham phetamine (ecstasy, (MDMA)),3,4-methylenedioxy-amphetamine (eve, (MDA)), **N-methyl-benzodio xazoyl-butanamine** (MBDB) and *p*-methoxy-amphe tamine (PMA). They all act as strong stimulants of the CNS and depending on the drug elevate heart rate, they increase anxiety, improve mood, and reduce the effects of fatigue. Ecstasy and some of the other designer amphetamines increase empathy and are often used in nightclubs to increase socialization. Owing to the stimulatory effects of these drugs on the CNS, persons become agitated and talkative. Other behavioral manifestations of strong stimulants include rapid or confused speech and aggressive behavior.

Persons driving motor vehicles using these strong stimulants display less vigilance and are less able to properly respond to multiple inputs (i.e., display impaired divided attention tasks). These drivers are also likely to drift out of the lane of travel, show erratic driving, and are associated with high speed collisions [6].

Prolonged use of amphetamines and cocaine can cause long-lasting or even permanent damage to dopamine- and serotonin-containing nerves in the brain leading to stereotyped behaviors and psychoses [7].

Consequently, it should be of no surprise that these drugs are associated with violence, particularly assault occasioning harm including homicides (*see* **Cocaine**; **Amphetamine**) [8].

Anabolic Steroids

Anabolic steroids are the drugs related to the male sex hormone testosterone and have androgenic activity, or an ability to increase muscle mass and tone. Numerous drugs are available in this group, mostly illicit, as solutions for injection, although some are taken orally. These steroids include stanozolol, nandrolone, methenolone, metandienone, oxymetholone, tenbolone, etc.

These drugs can be taken as small doses of two or more steroids, larger doses in cycles lasting one to three months, or as ever increasing doses as demanded. The net effect is a larger buildup of muscle mass compared to a drugfree situation for a given amount of body building.

A well-recognized side-effect associated with the use of anabolic steroids is the appearance of

mood disorders, irritability, and aggression. Controlled studies in athletes show a significant number of steroid users reporting major mood disorders, including mania, hypomania, and major depression. Psychoses, delusions, aggressive, and violent behavior are also strongly associated with active steroid users. Reports of fits of anger, assault, attempted murder are also linked to steroid use [9].

Personality profiles of men using anabolic steroids also show enhanced physical and verbal aggression and disinhibition [10].

Hallucinogens

Hallucinogens produce an altered perception of reality and include lysergic acid diethylamide (LSD), often sold as "trips" or "tabs". LSD users are often confused and exhibit illogical actions and may result in bizarre behaviors and paranoid delusions.

Phencyclidine (PCP) and its analogs thienyl cyclohexyl piperidine (TCP), phenyl cyclohexylpyrrolidine (PHP), phenyl cyclopentyl piperidine (PCPP), and cyclohexamine (PCE) produce an altered conscious state leading to hallucinations, dysphoria, symptoms of dissociation, and distortion of visual and other sensory signals. PCP shows some actions similar to LSD. Ketamine shares similar properties with PCP and is used widely by veterinary surgeons.

PCP is sold as a powder, flakes, or a liquid. In any of these forms, it can be impregnated in tobacco or cannabis cigarettes, or leaf material. Street doses of PCP range from 1 to 10 mg. Ketamine is sold as solutions for injection, powder, or tablet form. Ketamine is also commonly cut with other illicit drugs such as amphetamine, cocaine, and heroin.

Users of PCP can experience acute psychotic episodes leading to reckless and dangerous actions and it is not surprising that this drug is also associated with violence and dissociated behavior. In some persons, excessive PCP can lead to lethargy/stupor, acute brain syndrome, or even coma; however, surprisingly many can be alert and oriented [11].

Other common hallucinogens include the plant alkaloid mescaline and active ingredient in "magic mushrooms" psilocin/psilocybin. These substances produce physiological and psychological changes including anxiety, compulsive movements, and antisocial behavior (*see* **Poisons: Detection of Naturally Occurring Poisons**).

Benzodiazepines

Benzodiazepines are a large class of minor tranquilizers that are legally available, but are abused either by themselves or in combination with other drugs, often alcohol, amphetamines, and heroin. They include alprazolam, clonazepam, diazepam, flunitrazepam, and temazepam. The drugs sedate and reduce anxiety and in sufficient doses produce unsteady gait, slurred speech, and disorientation. They often affect retention of events while under the influence of the drugs, e.g., cause anterograde amnesia.

Benzodiazepines have adverse effects on driving skills through impairment of psychomotor and cognitive skills such as increased reaction times, poor lane control and poor lane tracking, and impaired divided attention tasks.

In some subjects, disinhibition may be observed with the excessive use of the drug either alone or in combination with other CNS active drugs. Alcohol is a common associated drug that intensifies these behavioral changes. Disinhibition of normal control mechanisms results in aggression and bizarre behavioral changes. These reactions, although not common, can produce disturbing changes when benzodiazepines are abused. In extreme cases, subjects may not have any conscious control over their actions (*see* **Benzodiazepines**).

Psychoses

Aggression can occur even without the direct effects of drugs, particularly in psychiatrically disturbed persons. Several psychotic disorders, including schizophrenia, may be associated with symptoms of acute agitation and aggression. Cannabis intoxication can also cause acute psychotic episodes.

Drug treatment can play an important role in the management of agitated persons. The most commonly used are the conventional antipsychotics and benzodiazepines, often by injection to achieve rapid results.

Tolerance and Withdrawal

Users of essentially all of the drugs mentioned previously will exhibit tolerance, or neuroadaptation if the drugs are used regularly. This applies particularly to the amphetamines and cocaine, although users of cannabis and other CNS depressants can also show

significant signs of drug dependence and tolerance if the drugs are constantly being misused. Chronic use of alcohol will also lead to dependence and tolerance.

Tolerance occurs as the human body becomes accustomed to the pharmacological and physiological effects of the drug causing drug users to compensate by consuming larger amounts of drug. They will consume doses several fold higher during their active phase than when they first started using the drug. Tolerance can occur after days to weeks of use.

Drug-dependent persons will by definition not only exhibit drug-seeking behavior but will also show signs of withdrawal following drug abstinence. Withdrawal symptoms can often be more profound than the direct effects of drug. For strong stimulants, abstinence symptoms are often severe and will be associated with behavioral changes. This includes fatigue (hypersomnolence or rebound fatigue following excessive stimulation of the CNS), depression, and suicidal behavior. Paranoid psychoses and other mood disorders can occur and can be particularly troublesome.

OLAF H. DRUMMER

Benzodiazepines

Introduction

Benzodiazepines are a large class of drugs widely prescribed for the treatment of a variety of conditions ranging from sleep disorders, anxiety, muscle tension to some forms of epilepsy. The best known members include Normison, Valium, and Xanax. They are among the most prescribed drugs in the western world.

The benzodiazepines are widely abused, either by themselves or in combination with alcohol, cannabis, and the opiate-like drugs (opioids). Indeed the benzodiazepines are second to alcohol in the prevalence of misuse and subsequently are often detected in a range of forensic cases. The benzodiazepines are classified as central nervous system (CNS) depressants as are alcohol, barbiturates, and the opioids.

The degrees to which benzodiazepines are associated with illicit or nonprescribed use depend on the availability of licit and illicit supplies in particular jurisdictions. Most commonly the drugs are obtained legally through medical practitioners. Persons using more than the prescribed dose or using the drug in a nonprescribed manner (misuse) are often the subject of forensic investigations.

This article provides an overview of the most common members of this class of drugs, their mode of action, pharmacological effects, pharmacokinetics, and applications relevant to forensic science.

Types of Benzodiazepines and Their Medical Applications

Over 50 benzodiazepines are known worldwide although most countries may have only 10–20 of these registered for legal use. The prototype benzodiazepine is chlordiazepoxide of which analogs such as diazepam, nordiazepam, temazepam, and oxazepam are commonly available worldwide. Other analogs include bromazepam, flurazepam, and lorazepam. Clonazepam, flunitrazepam, and nitrazepam are 7-nitro substituted analogs that possess slightly modified properties. Further three-ring variants include alprazolam, estazolam, midazolam, and triazolam. These three-ring analogs are also frequently very potent benzodiazepines requiring much lower doses than the older analogs and are also metabolized by the body through different pathways (see Table 1).

Benzodiazepines are best described pharmacologically as minor tranquilizers, that is they sedate and relax and are used to treat insomnia and various forms of anxiety, including generalized anxiety disorder. Their applications in medicine are often determined by their duration of action.

Members of this class that are short acting tend to be used as hypnotics (induce sleep). The short action is necessary to prevent persons feeling drowsy after a sleep. The half-life, or time taken for the blood concentration to halve for hypnotics tends to be under 12 h, and is often much shorter. The shorter acting benzodiazepines (e.g., midazolam) are also used as induction agents for general anesthesia in some forms of day surgery such as endoscopies.

The longer acting analogs such as diazepam, alprazolam, etc. are used to treat various forms of anxiety and are often prescribed in conjunction with other conditions associated with mood changes, such as depression and psychoses. Posttraumatic stress, obsessive compulsive disorders, and panic attacks associated with phobias can be treated with long acting benzodiazepines. Many of these disorders can lead to significant physiological and behavioral changes often seen in forensic cases. The longer acting benzodiazepines, particularly diazepam, are also used to treat anxiety associated with alcohol withdrawal and muscle spasm, and some are used in the management of some epileptic conditions and to treat seizures following head trauma in intensive care settings [1].

Pharmacology and Pharmacokinetics

Mechanism of Action

Benzodiazepines, like many drugs interact with specific sites, known as *receptors* that result in a cascade of actions ultimately manifesting as the desired action. Benzodiazepines bind to receptors in the brain that increases the affinity of the neurotransmitter gamma-amino-butyric acid (GABA). This interaction increases the chloride (an electrolyte) transport

Table 1 Medical uses and properties of common benzodiazepines[(a)]

Benzodiazepines	Applications	Relative potency[(b)]	Relative half-life
Alprazolam	Sedative	Moderate	Moderate
Chlordiazepoxide	Sedative	Low	Long
Clonazepam	Anticonvulsant, sedative	Moderate	Moderate-long
Diazepam	Sedative, anticonvulsant, relaxant	Moderate	Long
Estazolam	Sedative	High	Moderate
Flunitrazepam	Hypnotic	High	Moderate
Flurazepam	Sedative	Moderate	Long
Lorazepam	Sedative, hypnotic	Moderate to high	Moderate
Midazolam	Sedative, hypnotic	Moderate to high	Short
Nitrazepam	Hypnotic	Moderate	Short to moderate
Oxazepam	Hypnotic	Low	Short
Prazepam	Sedative	Low	Long
Temazepam	Hypnotic	Low	Moderate

[(a)] Most common uses, although there will be some variation from country to country
[(b)] Relates to both the commonly prescribed dose and the associated blood/serum concentrations

Table 2 Route of metabolism and target analytes

Prototype benzodiazepine	Examples	Fate and target substance[a]
Alprazolam	Etizolam, midazolam, triazolam	1-Hydroxy-metabolite
Clobazam	Prototype only	Desalkyl-clobazam
Diazepam	Chlordiazepoxide, clorazepate, pinazepam	Nordiazepam, temazepam, oxazepam
	Temazepam	Temazepam, oxazepam
	Oxazepam	Oxazepam
Flunitrazepam	clonazepam, nimitazepam, nitrazepam	7-Amino metabolite
Flurazepam	Prototype only	Desalkyl-flurazepam

[a] Selected benzodiazepines or metabolites are listed in the order they are metabolized

through ion channels and reducing the arousal of the cortical and limbic systems in the CNS. This is a simplified explanation of their actions, but helps explain the overall effects of these drugs, and how other drugs can modify this response.

Some benzodiazepines and unrelated drugs with similar properties (e.g., zolpidem, zopiclone, zaleplon) bind at subtypes of these receptors causing slightly different effects. Some anesthetics (e.g., propofol) and some anticonvulsants bind at adjacent sites to the benzodiazepine receptor and exert their actions by mediating conformational changes at this receptor. Other drugs cause changes to interconnected receptor systems that ultimately affect the activity of this receptor. These include ethanol, some antidepressants, and the narcotic analgesics (opioids). These drugs therefore modify or even enhance the activity of benzodiazepines when consumed together.

Pharmacokinetics and Metabolism

As the preceding section on the medical applications of benzodiazepines demonstrated that the members of this large class of drugs have widely differing pharmacokinetic properties. As expected, the longer half-life members are detectable in biological specimens for longer than the shorter acting drugs.

Diazepam, arguably the most commonly used benzodiazepine in the world has a half-life of over one day. This means that it is likely to be present in detectable amounts in tissues such as blood for at least a few days since last use. This is accentuated since its major (and active) metabolite; nordiazepam has an even longer half-life (about four days). Diazepam and nordiazepam can therefore be detected in biological specimens for about two weeks depending on the dose administered and the sensitivity of the analytical method.

In contrast, midazolam has a half-life of a few to several hours and will only be measurable for about one to two days since last use. Table 1 summarizes the pharmacokinetic half-life of several examples.

The metabolism of benzodiazepines is essential to understand when considering their actions and their duration of action and detectability in various specimens. Nordiazepam is the major metabolite of diazepam and also of a number of other benzodiazepines. Table 2 illustrates some of the more common examples of benzodiazepines and their corresponding major metabolites.

The related drugs zolpidem, zopiclone, and zaleplon have different pathways of metabolism because they do not have the benzodiazepine-type structure. Zolpidem is converted to carboxy-metabolites that can be targeted in urine. The other members tend not to have metabolites that can be readily targeted for analysis.

Behavioral Effects and Drug Associated Crimes

Benzodiazepines in normal prescribed doses can in addition to their sedative and anxiolytic effects reduce cognitive performance and produce short term memory loss (anterograde amnesia).

Short term memory loss is common and is often seen in patients given a benzodiazepine for a minor procedure. This loss of memory may be partial in that persons do not recollect all what has happened while under the influence of a drug, and/or the recollection is not entirely accurate. Cognition (ability to think and reason) is adversely affected by benzodiazepines and is particularly significant for persons on higher doses or those using longer acting drugs [2].

Not all benzodiazepines produce the same degree of adverse effects. For example, the nonbenzodiazepine hypnotics zolpidem and zaleplon produce

less behavioral changes than the benzodiazepines. Clobazam is also less sedating than the conventional benzodiazepines such as those based on diazepam or alprazolam.

When some benzodiazepines are misused or mixed with other drugs affecting the CNS disinhibitory effects can manifest such as aggressive behavior, mania, and depersonalization. These symptoms are sometimes termed paradoxical since they are seemingly not expected for sedative drugs [3]. These symptoms are more likely in persons vulnerable to psychiatric disorders such as borderline personality disorder. The benzodiazepines most linked to these effects are alprazolam, clonazepam, flunitrazepam, and midazolam.

Benzodiazepines are used in drug-facilitated crimes not only for their sedative actions but also to induce amnesia and hence victims will have poor recall of subsequent events, e.g., following a sexual assault (*see* **Drug-Facilitated Sexual Assault** for further details).

The benzodiazepines are also one of the more common drugs associated with impaired driving. This is due to their sedative effects reducing speed and accuracy of hand-eye movements and other psychomotor tasks required for safe driving. The sedative actions also reduce vigilance and responsiveness to driving situations. Alcohol invariably increases impairment even at blood concentrations of 50 mg per 100 ml of blood (*see* **Drug-Impaired Driving** for further details).

Dependence and Tolerance

As for almost all drugs regular use of benzodiazepines leads to an adaptation to many of the pharmacological effects. Unwanted day-time sedation, memory deficits, residual effects on other cognitive and psychomotor functions are attenuated with long term use. In some situations, particularly when the drugs are abused increasing doses are used to offset the developing tolerance. Some users take several tablets at once far above normal prescribed doses.

Subjects who use benzodiazepines for weeks to months will develop a dependence that leads to drug seeking behavior and signs of withdrawal during abstinence. These symptoms include anxiety, insomnia, restlessness, and a range of behavioral changes. Benzodiazepines enhance the effects of heroin and cocaine, and reduce the impact of withdrawal symptoms of these drugs [4].

Toxicity

The more severe symptoms of benzodiazepines are not as life threatening than other drugs, e.g., alcohol, cocaine, amphetamines, and opiates; however, misuse of benzodiazepines can be life threatening.

An overdose of benzodiazepines typically causes unsteady gait, somnolence, slurred speech, and substantial cognitive deficits. Coma is common.

Most of the benzodiazepines are capable of causing death although this occurs rarely in the absence of other contributing factors, such as respiratory or heart disease. Most commonly, benzodiazepines reported as causing death are alprazolam, diazepam, flunitrazepam, flurazepam, nitrazepam, temazepam, and triazolam.

In many cases presentations are mixed drug ingestions with other CNS depressant drugs such as alcohol and the opiate class of drugs such as heroin, oxycodone, methadone, and morphine.

Interpretation of Results

As with almost all drugs there is little correlation between the blood concentration of benzodiazepines and the response. However, it is still useful to measure the blood concentration of benzodiazepine in specific cases since the concentration provides a guide as to the amount used and possible time since last use.

Prolonged or inappropriate storage can cause some loss of benzodiazepines (and their metabolites). This means that specimens should be kept as cold as physically feasible during transportation and storage. It is strongly recommended to store specimens frozen ($-20\,^{\circ}C$ or lower) even if blood is collected in tubes containing preservative (fluoride/oxalate).

In postmortem settings, benzodiazepines concentrations in blood and tissues remain relatively static since there is little postmortem drug redistribution within the body; however, prolonged exposure to the elements can result in loss of some benzodiazepines, e.g., temazepam and diazepam. The 7-nitrobenzodiazepines are unstable postmortem and convert to their respective 7-amino metabolites. These metabolites can be successfully targeted in such cases.

Table 3 Common analytical techniques for the measurement of benzodiazepines

Screening (initial testing)	Confirmatory testing
Immunoassay (e.g., ELISA[a], CEDIA[b], EMIT[c], TDx[d]) [6]	GC[e] (e.g., ECD[f] detector) [7] GC-MS(MS) [8]
HPLC[g] (UV, DAD[h], etc.) [9]	LC-MS(MS) [10]
GC (various detectors) [11]	
TLC[i] (urine only) [12]	

Table shows some examples of analytical methods.
[a] ELISA: enzyme linked immunosorbent assay
[b] CEDIA: cloned enzyme donor immunoassay
[c] EMIT: enzyme linked immunoassay technique
[d] TDx: fluorescent polarization assay
[e] GC: gas chromatography
[f] ECD: electron capture detector
[g] HPLC: high-performance liquid chromatography
[h] DAD: photodiode array or multiwavelength detection
[i] TLC: thin layer chromatography

Methods of Analysis

Initial Testing

Most clinical and forensic laboratories test for the presence of the class of benzodiazepines in the initial phase of their investigations. These immunoassays are effective for the more common members particularly the lower potency members that have relatively high concentrations in fluids, e.g. diazepam, temazepam, oxazepam, alprazolam. However, they will detect most of the class providing the concentration is sufficient [5] (see Table 3).

This technique using commercial kits enables all members of the class to be detected; however, owing to their differing immunoreactivities the sensitivity to different benzodiazepines and their metabolites vary, and for some may be quite poor. This applies particularly to the more potent members, e.g., lorazepam, triazolam, clonazepam etc.

Initial tests are commonly conducted in urine since the concentration of the benzodiazepine or its metabolite is often much higher than blood. However, immunoassays designed for blood/plasma, or even oral fluid, are commercially available. An example of this is the enzyme linked immunosorbent assay (ELISA).

When a class test is positive further (confirmation) tests are required to detect the benzodiazepine (or its metabolite) that is causing this positive response (*see* **Toxicology: Initial Testing** for further details).

Confirmation Testing

The definitive confirmation method in forensic toxicology is mass spectrometry. This can either be gas chromatography mass spectrometry (GC-MS) or liquid chromatography-mass spectrometry (LC-MS). LC-MS or tandem LC-MS methods are now dominating the measurement for this class of drugs due to its very high sensitivity and specificity and requires very little or no chemical modification to permit chromatographic analysis (see Table 3).

Depending on the specimen and the drug the target benzodiazepine (or metabolite) varies. For example, nordiazepam is the main target metabolite for diazepam and a range of other benzodiazepines metabolized to nordiazepam (e.g., chlordiazepoxide, clorazepate, pinazepam etc.).

In blood and most other specimens the parent drug is the target analyte; however, in urine, a metabolite is often the target. For diazepam, drugs metabolized to nordiazepam, and for temazepam, the most common metabolite is oxazepam and the oxazepam glucuronide. The 7-amino and 7-acetamido metabolites are the main metabolites for the 7-nitro benzodiazepines. The 1-hydroxy metabolite is the target for the tri-ring analogs alprazolam, etizolam, midazolam, and triazolam.

See **Confirmation Testing: Toxicology** for further details.

Best Evidence Rule

The best evidence rule is a judicial construct that has its origin in the common law of England. Its meaning is not widely understood by many forensic experts, who are likely to suggest that the "best evidence rule" provides that only the most probative – or the "best" – physical and original documentary evidence is admissible in court. This view contains at least two misunderstandings of the evidentiary principle. First, the rule does not apply to most forms of physical evidence. Second, the rule's name is a misnomer; it does not specify that only the "best" evidence of a fact must be produced.

First, the best evidence rule is a narrow principle. It applies only to writings, X rays, films, videotapes, photographs, motion pictures, and recordings, but is applicable only when the *content* of the evidence is sought to be established [1]. If it is not the content of a document, but only the fact of its execution or transmission that is sought to be established, the best evidence rule does not apply. It also does not apply to other forms of physical evidence [2]. Second, the rule would be more appropriately called *the original evidence* rule in that it expresses merely a preference for the original. In any case, where the content of a writing is sought to be established, the original document must be provided to the court. However, the rule can also be satisfied if a witness can satisfactorily account for the absence of the original document; if the reason for not producing the original is believed by the judge, then a foundation has been laid for the use of secondary evidence. In that event, a copy of the original, or even oral testimony of its content, can be admitted to prove the

content of the writing and the best evidence rule is satisfied [3].

There are two different circumstances in which the best evidence rule applies typically. The first is where one seeks to prove a legal event that can only be demonstrated by a writing. This applies to divorce decrees, deeds to property, a last will and testament, a contract between two or more parties, or other documents containing a legally operative document – a document that creates, alters, or destroys legal relationships. The content of these documents requires that the original be produced, or its absence satisfactorily explained.

A second courtroom scenario wherein the best evidence rule applies is where a witness's sole knowledge of an event comes from what is contained in a writing. The witness is aware of certain facts because he read about their occurrence in a document – a situation where the witness may be said to lack "personal knowledge," as lawyers are likely to argue. In that case, too, the original writing is required, if it is available. Only in the event of unavailability will a reasonable substitute be admitted.

The rule is also relaxed when it comes to proving the content of voluminous writings, recordings, or other evidentiary material, which cannot be conveniently examined in court. In that case, the material may be testified to in the form of a chart, summary, or calculation, provided access to the originals has been provided to the opposing party prior to trial [4].

Some more technical aspects of the best evidence rule are the responsibility of lawyers and usually do not affect expert witness testimony.

Biological Agents

Introduction

The term *biological agent* (*bioagent*) refers to *pests and pathogens*, and/or their products that can be used for criminal, terrorist, or warfare purposes. Generally, these are organisms or toxins that are not only microscopic in nature but also include visible

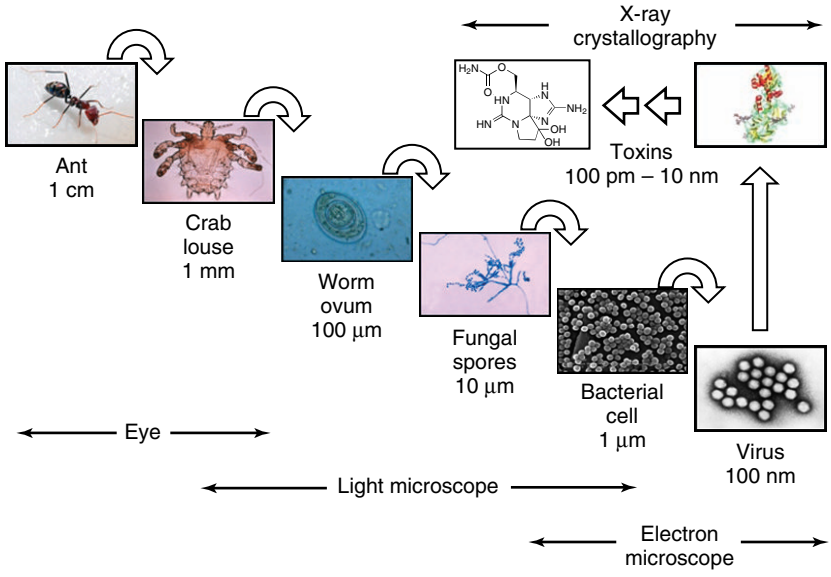

Figure 1 The relative size of biological agents and type of microscopy required to visualize them

organisms such as insects, worms, fungi, and plants. Figure 1 demonstrates the relative size of the different types of biological agents. Most biological agents have the potential to cause disease.

The manner in which biological agents are used or released is classified into four categories. Biowarfare refers to the *military use of biological agents*. Bioterrorism is the use, or threatened use, of biological agents by illicit organizations or individuals to intimidate or coerce a government, civilian population or persons, to further political or social objectives. The term *biocrime* refers to the *use, or threatened use*, of biological agents to further individual objectives. Examples of biocrimes include acts such as the deliberate infection or intoxication of individuals with intent to harm, incapacitate, or intimidate. The last category is bioaccident, which is the unintentional release of a biological agent. Depending on the incident, bioaccidents may be deemed as criminal acts if an accidental release is linked to illegal activities such as smuggling or illegal importation of goods. A good example of the latter is the citrus canker outbreak that occurred in Australia in 2004, which was alleged to have resulted from the illegal importation of plant material [1]. All categories have the potential to cause harm, create fear, generate social unrest, and/or restrict civil liberty. This article concentrates on the use of biological agents in acts of bioterrorism and intentional biocrimes.

Potential targets of bioterrorism and biocrime include humans, animals, and plants, however under a broader definition, ecological targets such as natural forests and marine parks, and industrial targets such as sewage plants and water distribution systems can also be included. Naturally, acts imposed upon human targets impose most fear, whereas those targeted toward agricultural plants and animals are likely to have the greatest economic impact. The release of biological agents may be overt, such as the anthrax letter attacks in the United States in 2001 [2, 3], or covert, such as the deliberate contamination of salad bars and salad dressing with *Salmonella* serotype Typhimurium by the Rajneeshee cult in the United States in 1984 [4].

Recognizing Bioterrorism and Biocrime

Acts of bioterrorism and biocrime can be difficult to detect and investigate. Covert acts have the potential to go unnoticed or be attributed to natural outbreaks. In general, the longer it takes to detect the act, the more complicated the ensuing investigation. A good example of this is the acts of bioterrorism conducted by the Aum Shinrikyo cult in Japan in 1993. The

Aum Shinrikyo cult is primarily remembered for the sarin attack on the Tokyo subway system in 1995; however, this cult had been experimenting with a number of biological agents including Ebola virus, botulism toxin and *Bacillus anthracis* for many years prior [4–6]. On a number of occasions in 1993 the cult aerosolized liquid suspensions of anthrax spores and cells over Tokyo [3, 7]. These releases remained unnoticed until after the sarin attack in 1995 and only emerged following the testimony of cult members and subsequent retrospective investigation. The investigation confirmed that the agent used was the *B. anthracis* Sterne 34F2 strain, a nonpathogenic strain used for the vaccination of animals against anthrax [6]. In this instance, the release had little potential to cause human illness; nevertheless, it demonstrates the possibility that a bioterrorist act could remain undetected for a number of years. Conversely, it is important that natural outbreaks are not attributed to acts of bioterrorism. The global severe acute respiratory syndrome (SARS) outbreak in 2003 [8] and the outbreak of West Nile virus in the United States in 1999 [9] are good examples of outbreaks that could have been falsely attributed to acts of bioterrorism.

The most common acts of bioterrorism and biocrime are hoaxes. The number of hoax incidents that followed the real anthrax letters of 2001 threatened to overwhelm emergency services across the globe; in the United States alone more than 15 000 anthrax hoaxes were made in the following 12 months [10]. Repeat offenders are common with one example of an individual in the United States who sent over 700 threatening letters containing white powder [10]. While hoaxsters cause no physical harm, they do cause considerable stress to their victims, contribute to a national climate of paranoia, cause disruption to services, and unnecessarily burden emergency services. The cost to governments and businesses is staggering. The main threat posed by hoaxes is that they provide a cloak under which real threats may be hidden [11].

Biological Agents as Weapons

There are many organisms and toxins that can be used as biological agents. These include pathogenic fungi, bacteria, rickettsiae, and viruses, as well as toxins from bacteria, fungi, plants, and venoms from animals. The biological agents listed in Table 1 are the core list recommended by the Australia Group for export control. The list assists countries within the Australia Group alliance to ensure that exports comply with the Biological and Toxins Weapons Convention of 1972 (http://www.opbw.org) and, although representative of many of the dangerous biological agents, it is far from exhaustive. Biological agents are designed to cause incapacitation (e.g., salmonellosis, cholera, and brucellosis) or inflict casualties (e.g., anthrax, plague, smallpox, and botulism). Most biological agents can be acquired from the environment and can be cultivated without highly specialized equipment by individuals with limited technical skills. This is particularly true for many fungi and bacteria. Viruses and rickettsiae are more difficult to cultivate and generally require more specialized equipment and technical skills. Venoms can be milked directly from animals, whereas toxins from plants, bacteria, and fungi generally require methods for cultivation and/or purification.

The effectiveness of any biological attack is dependant on the type of agent, the manner in which it is prepared, the method of delivery, and the location of delivery, as well as numerous climatic factors such as wind velocity, wind direction, humidity, temperature, degree of cloud cover, and rainfall [12]. The susceptibility of the host, and the presentation and lethality of disease is dependant on the route of exposure. For example, studies in mice show that ricin has an inhalational LD_{50} of $3-5\,\mu g\,kg^{-1}$ with death at 60 h, a subcutaneous LD_{50} of $24\,\mu g\,kg^{-1}$ with death at 100 h, and an oral LD_{50} of $20\,mg\,kg^{-1}$ with death at 85 h [13] (*Note*: the LD_{50} is the dose of toxin that causes death in 50% of victims.) Ricin can produce severe-to-fatal injury by contact with the eyes, but dermal exposure has little apparent toxicity [13]. Similarly, inhalational anthrax is dependant upon the deposition of spores in the lower airways. The estimated LD_{50} for *B. anthracis* is 2500–55 000 inhaled spores [2, 3]. Since only particles in the $0.5-5\,\mu m$ size range efficiently deposit in the lower airways when inhaled, crude preparations of anthrax powders and aerosolized suspensions are largely inefficient in causing inhalational anthrax (Figure 2). The so-called *weapons grade anthrax* contains purified spore-bearing particles $<5\,\mu m$ in size, treated with chemicals to minimize static and maximize dispersion [2, 3]. The preparation of weapons grade anthrax requires advanced biotechnical capabilities.

Table 1 Australia Group core list of biological agents for export control (July 2006) (http://www.australiagroup.net/en/biological_agents.html)

Viruses

1. Chikungunya virus
2. Congo–Crimean hemorrhagic fever virus
3. Dengue fever virus
4. Eastern equine encephalitis virus
5. Ebola virus
6. Hantaan virus
7. Junin virus
8. Lassa fever virus
9. Lymphocytic choriomeningitis virus
10. Machupo virus
11. Marburg virus
12. Monkey pox virus
13. Rift valley fever virus
14. Tick-borne encephalitis virus (Russian spring–summer encephalitis virus)
15. Variola virus (Smallpox)
16. Venezuelan equine encephalitis virus
17. Western equine encephalitis virus
18. White pox
19. Yellow fever virus
20. Japanese encephalitis virus
21. Kyasanur Forest virus
22. Louping ill virus
23. Murray valley encephalitis virus
24. Omsk hemorrhagic fever virus
25. Oropouche virus
26. Powassan virus
27. Rocio virus
28. St Louis encephalitis virus
29. Hendra virus (Equine morbillivirus)
30. South American hemorrhagic fever virus (Sabia, Flexal, and Guanarito)
31. Pulmonary and Renal syndrome-hemorrhagic fever viruses (Seoul, Dobrava, Puumala, and Sin Nombre)
32. Nipah virus

Genetic elements and genetically modified organisms

1. Genetic elements that contain nucleic acid sequences associated with the pathogenicity of any of the microorganisms in the list
2. Genetic elements that contain nucleic acid sequences coding for any of the toxins in the list, or their subunits
3. Genetically modified organisms that contain nucleic acid sequences associated with the pathogenicity of any of the microorganisms in the list
4. Genetically modified organisms that contain nucleic acid sequences for any of the toxins in the list or for their subunits

Rickettsiae

1. *Coxiella burnetti*
2. *Bartonella quintana* (*Rochalimea qunitana*, *Rickettsia quintana*)
3. *Rickettsia prowasecki*
4. *Rickettsia rickettsii*

Bacteria

1. *Bacillus anthracis*
2. *Brucella abortus*
3. *Brucella melitensis*
4. *Brucella suis*
5. *Chlamydia psittaci*
6. *Clostridium botulinum*
7. *Francisella tularensis*
8. *Burkholderia mallei* (*Pseudomonas mallei*)
9. *Burkholderia pseudomallei* (*Pseudomonas pseudomallei*)
10. *Salmonella* Typhi
11. *Shigella dysentaeriae*
12. *Vibrio cholerae*
13. *Yersinia pestis*
14. *Clostridium perfrigens*, epsilon toxin-producing types
15. Enterohemorrhagic *Escherichia coli*, serotype 0157 and other verotoxin producing serotypes

Fungi

1. Coccidioides immitis
2. Coccidioides posadasii

Toxins (and subunits thereof)

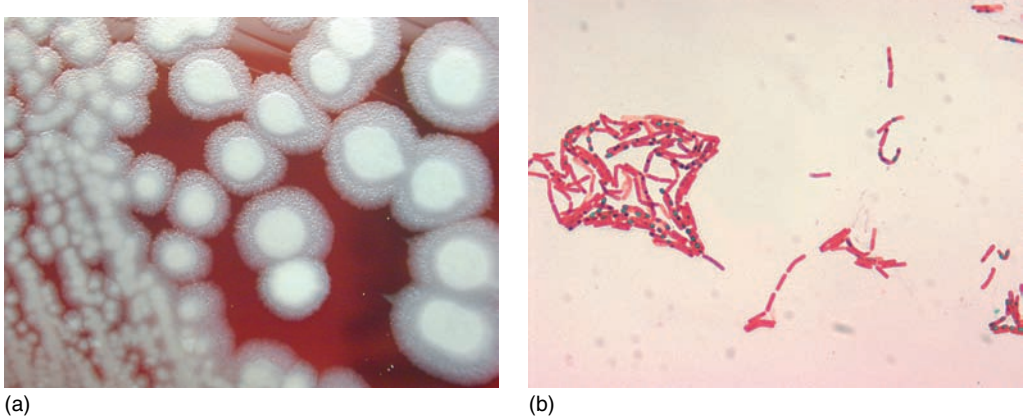
1. Botulism toxins
2. *Clostridium perfrigens* toxins
3. Conotoxin
4. Ricin
5. Saxitoxin
6. Shiga toxin
7. *Staphylococcus aureus* toxins
8. Tetrodotoxin
9. Verotoxin and shigalike ribosome inactivating proteins
10. Mycrocystin (Cyanginosin)
11. Aflatoxin
12. Abrin
13. Cholera toxin
14. Diacetoxyscirpenol toxin
15. T-2 toxin
16. HT-2 toxin
17. Modecin toxin
18. Volkensis toxin
19. Viscumin toxin

Figure 2 Scanning electron micrograph of anthrax spores (CDC PHIL Image 2266–Courtesy of Laura Rose)

When considering the type of agent that might be used for a biological attack, the mode of delivery and the scale of the attack should be considered. The biological agents that cause salmonella and cholera are more likely to be used for small-scale food and waterborne attacks, whereas those that cause anthrax and tularemia are more likely to be used for large-scale airborne dispersal. Smallpox and pneumonic plague are highly contagious, so person-to-person dispersal should be considered. *Yersinia pestis*, the etiological agent of plague, also has the potential to be used for a large-scale airborne attack while Variola virus, the causative agent of smallpox, is unlikely to be used in this manner because of the complexities involved with cultivating large quantities of agent. Similarly, ricin can be delivered *via* aerosol but is inefficient in comparison to *B. anthracis*; tonnes of purified ricin are needed to have the same impact as kilograms of weapons grade *B. anthracis* spores [7]. Ricin would be more effective for small-scale air, food, and waterborne attacks or *via* direct injection. Botulism toxin is the most toxic substance known. The lethal dose for an adult is estimated to be 0.09–0.15 μg intravenously or intramuscularly, 0.7–0.9 μg inhalationally, and 70 μg orally [14]. Since its lethal dose is in the order of hundreds to thousands times less than ricin, botulism toxin would be better suited to large-scale dispersal. The significance of botulism toxin as a bioweapon is demonstrated by the fact that Iraq chose to weaponize more botulism toxin than any other of its known agents. After the 1991 Persian Gulf war, Iraq admitted to the United Nations inspection teams to having produced 19 000 l of concentrated botulism toxin, more than is required to kill the entire human population by inhalation [14].

The Detection of Biological Agents

Unlike acts of terrorism involving chemical or radiological agents, the investigation of acts of bioterrorism or biocrimes is hampered by the lack of real-time detectors for the identification of biological agents. This provides a significant gap in the ability of first responders to determine risk when tasked with the initial investigation of potential biological releases. The technologies used for biological identification have not kept pace with those used for chemical and radiological identification. In part, this is because of the variety, complexity, and large size of toxins and organisms, but it is also due to the high level of sensitivity that is required for biological detection and identification. For example, the lethal dose for sarin is estimated as 1700 mg for a 70-kg man [15], which is approximately 7.3×10^{21} molecules,



whereas the infectious dose for tularemia is as few as 10 cells [16].

Historically, the common procedures used for the identification of pathogens and toxins require the capture, concentration, and/or amplification of the biological agent. Culture, genetic tests, and immunological assays may all be used to achieve this. Culture is still the gold standard for pathogen identification, but generally requires a minimum of 24–48 h (Figure 3a). Biological staining and microscopy can provide results within minutes; however, these procedures are labor intensive, largely insensitive, and require considerable skill in the performance of techniques and the interpretation of results (Figure 3b). Immunofluorescence microscopy has demonstrated merit as a tool to assist the rapid diagnosis of melioidosis; however, its sensitivity in comparison to culture is poor [17]. Its application outside of a laboratory setting is unlikely.

Immunoassays

To date, immunoassays provide the fastest biological detection technology that is commercially available with most able to provide results within 5–15 min. Most immunoassays use an antibody-mediated capture of their target antigens in lateral flow, enzyme-linked immunosorbent assay (ELISA) or magnetic bead-type formats. Typically, detection and identification is by means of specific antibodies that are covalently bound with visible or fluorescent dyes or with enzymes that generate visible or chemiluminescent reaction products. Tests range in sensitivity and reliability from simple colorimetric handheld tickets through to the more complex portable fluorescence detectors and the laboratory-based ELISA plate readers [18–23] (Figure 4). The specificity of these technologies can be quite variable. Cross-reactivity with related species and/or nonpathogenic variants of the target species is not uncommon and is the main cause of false positives. Conversely, some immunoassays are specific for one or a few forms of the target and therefore have the potential for false negatives. The botulism toxin is an excellent example of the latter; with seven known immunologically different forms (and subvariants) there are no commercial immunological assays that provide detection for all forms of the toxin. Sensitivity can also be an issue, but most immunoassays are developed to be within, or close to, the infectious or lethal dose.

The major downfall of immunoassay technologies is that they are currently limited to one or a few targets in each test. A requirement to test for multiple targets can take hours if the tests cannot be performed in parallel. Notwithstanding that, immunoassay technologies have been developed to detect multiple targets [24, 25]. Some have been adapted for field detection as portable automated pods [26], but these are yet to receive widespread evaluation and acceptance. The hybridization of immunoassay and flow cytometry technologies provides yet another

(a) (b)

Figure 3 (a) Anthrax colonies on blood agar (CDC PHIL Image 1897–Courtesy of Larry Stauffer, Oregon State Public Health Laboratory). (b) Spore stain of anthrax (CDC PHIL Image 1896–Courtesy of Larry Stauffer, Oregon State Public Health Laboratory)

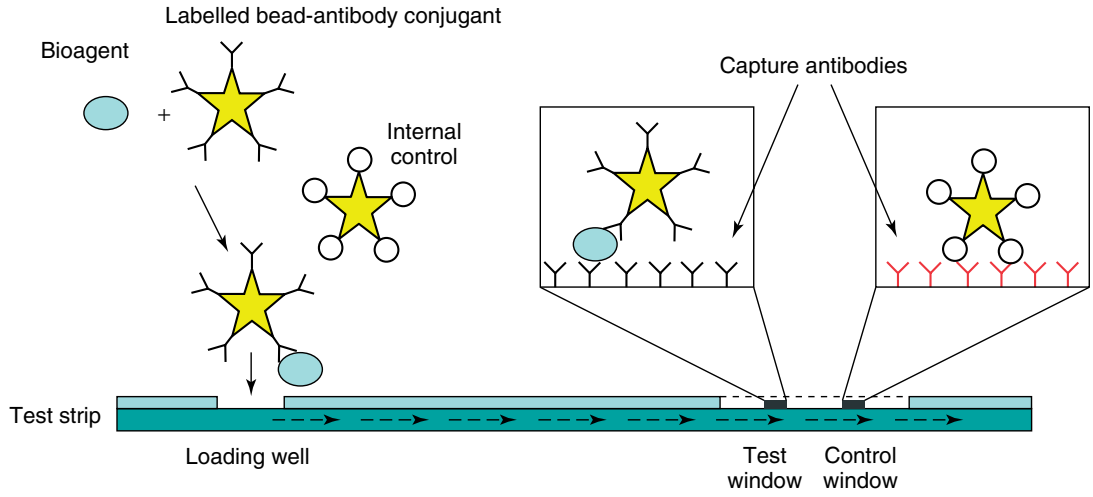


Figure 4 Lateral flow immunoassays

interesting technology that can provide quantitative assessment of multiple agents in a single sample [27]. Assays of this nature have great potential as field units, but currently still require complex and lengthy procedures in order to prepare samples for analysis.

Genetic Assays

Genetic techniques such as the polymerase chain reaction (PCR) and microarrays provide the exquisite sensitivity required for the detection of biological agents in the field and those samples submitted to the laboratory [28, 29].

Real-Time PCR. To date, real-time polymerase chain reaction (RT-PCR) technology has shown the greatest application for the genetic detection and identification of biological agents. RT-PCR combines amplification with simultaneous detection. It is based on the change in fluorescence in the PCR reaction tube, which is proportional to the amplified product. RT-PCR is as sensitive as traditional PCR, but less prone to false positives through contamination because the reaction tubes need not be opened for analysis. In addition, RT-PCR provides a mechanism through which an accurate quantitation of the target can be performed.

Most laboratory-based RT-PCR machines provide results within 90 min and use PCR tube or 96-well plate formats. The LightCycler (Roche Diagnostics GmbH, Mannheim, Germany), which uses capillaries, provides much faster thermal cycling but can be difficult to load and handle. The ruggedized advanced pathogen identification device (RAPID) (Idaho Technology, Salt Lake City, Utah) integrates the LightCycler technology but in a ruggedized portable format designed for field use. The SmartCycler (Cepheid, Sunnyvale, California), also designed for field use, uses a thin plastic capillary tube. The tube is much easier to load and manipulate than the capillaries used for the LightCycler and its design provides very rapid heat exchange allowing the completion of 40 PCR cycles within 15 min. An improved version of the SmartCycler, called the *GeneXpert system* (Cepheid, Sunnyvale, California), integrates the design of the SmartCycler but in a disposable test cartridge format that automates extraction, PCR setup, thermal cycling, and detection. Although portable, the RAPID, SmartCycler and GeneXpert systems, are still quite large and are best deployed in the field *via* a vehicle. The RAZOR thermal cycler (Idaho Technology, Salt Lake City, Utah), about the size and weight of a small car battery, is deployable by hand. In this system, amplification is performed inside wells within a thin flexible plastic pouch, which is slotted into the machine.

One of the major disadvantages of RT-PCR is the inability to multiplex numerous targets. Current technologies either run concurrent reactions for several different targets or multiplex only a few targets.

Multiplexing RT-PCR is technically complex because of the difficulties associated with predicting the interactions that take place among multiple primers, probes, target DNA, and amplified products. In addition, the technology is currently restrained by the number of fluorophores that can be analyzed simultaneously; presently, it is restricted to a maximum of five fluorophores. Another major disadvantage is the time, cost, and labor required to prepare samples for RT-PCR analysis. RT-PCR can be significantly inhibited by contaminants in the sample. Reliability and reproducibility is dependant upon the purification of the nucleic acid target away from potential inhibitors. The automation of extraction reduces the manpower required to process specimens but not necessarily the time. The hybridization of automated extraction and RT-PCR, such as used in the GeneXpert system, considerably simplifies the analysis process.

Microarrays. Typical microarrays consist of a bank of nucleic acid probes bound to the surface of a glass slide. Typical microarrays require a full working day or longer to complete. The advantage of microarrays is that the technology allows the simultaneous analyzes of hundreds to thousands of targets. Their application to diagnostic microbiology is potentially revolutionary [30]. Traditional microarray technology is lengthy, complex, and technically difficult. The integration of automation and software processing has largely removed human involvement into many of the repetitive tasks involved in the processing and interpretation of microarrays. Nevertheless, the traditional process is lengthy and ill-suited to field detection. However, the combination of nucleic acid amplification, lateral flow chromatography, and microarray technologies provides a novel platform from which microarrays can be developed for field deployment [31, 32]. This technology provides the versatility of multiplexing, with an unparalleled specificity afforded by combining amplification and hybridization technologies in series, while providing a level of sensitivity down to one or a few targets. Through miniaturization, automation, and improvements in nucleic acid preparation and amplification, it is likely this technology will be developed for real-time detection.

Real-Time Early Warning Biodetection Systems. A number of early warning systems have been developed for the real-time detection of bioaerosols. The most simple of the systems use light scattering for the detection of particles as they pass through a light beam and the natural fluorescence of biological molecules when energized with ultraviolet light (UV); the biological agent warning sensor (BAWS) [33], VeroTect sensor [34] and biological agent real-time sensor (BARTS) [35] are examples of these systems. These are true real-time sensors. As the particle passes through the UV light, beam light scatter is recorded enabling the determination of the particles shape and size. The presence of a biological particle is then confirmed from the emission spectrum; particles containing the amino acid tryptophan emit a characteristic fluorescence at 325 nm. Since all biological agents have proteins, all types of biological agents are detected. These systems are fully automated with continuous sampling and concurrent analysis, and are able to provide quantitative results. The downside is that the technology is unable to distinguish naturally occurring nonpathogenic organisms from pathogenic agents.

The more complex systems collect and concentrate airborne particles into a liquid sample that are then analyzed by genetic and/or immunoassays. Current technologies are not real time. The autonomous pathogen detection system (APDS) is an example of this type of technology, utilizing a combination of multiplexed immunoassay flow cytometry and then PCR on positives for the detection and identification of aerosols [26, 36]. The combination of immunoassay and PCR virtually eliminates the chance of false positives. The APDS is fully automated, continuously cycling between sampling and analysis. Although highly discriminatory, this technology is still comparatively slow, requiring a minimum of 20 min per analysis.

Emerging Real-Time Biodetection Technologies. A host of new technologies are being developed that have been reviewed elsewhere [23, 26, 33, 37–42]. Many of these are hybrids of existing technologies that improve specificity, sensitivity and speed, and/or automate and miniaturize processes. Most are not real-time processors. Two particularly interesting technologies that are true real-time processors are the microcantilever transducers and nanowire detectors. Both these technologies have theoretical and practical sensitivities down to a single target, can run in real time, can be designed to target any species, and can be multiplexed to detect multiple targets. Further,

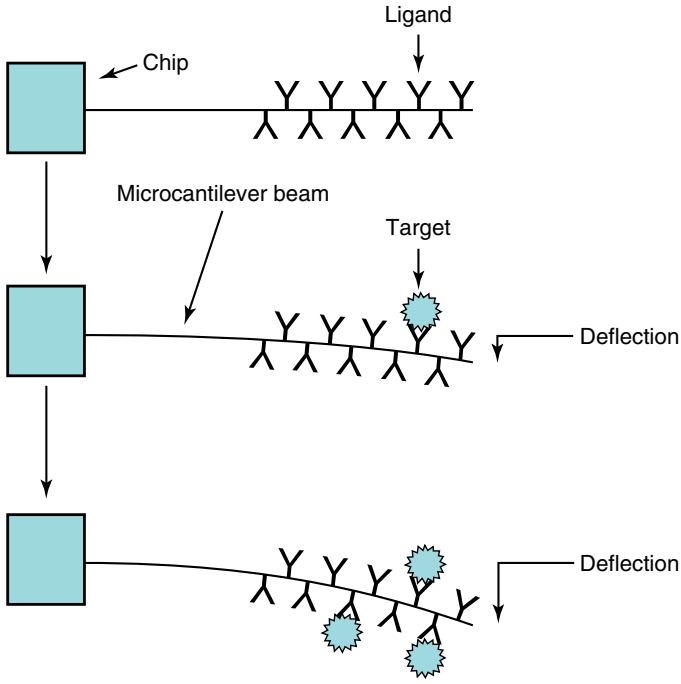

Figure 5 Microcantilever technology

both technologies are good for both chemical and biological targets, which can be detected simultaneously. A microcantilever is a minute cantilever beam that is coated with a ligand that is specific for a target molecule [26, 37, 38, 43, 44] (Figure 5). Any ligand can be used. Typical ligands include chelating agents, lectins, antibodies and antibody fragments, and aptamers and peptides. The binding of target particles to the beam causes deflection of the beam and changes the vibrational frequency within the beam. As more target binds the deflection, change in the vibrational frequency increases, thereby providing a mechanism for both the detection and quantitation of the target. Nanowire detectors work on a similar principle. A nanowire is a microscopic wire coated with a ligand. A change in resistance within the wire occurs as a consequence of a biorecognition event [26, 37, 38] (Figure 6). The level of resistance changes as more target binds, once again providing both detection and quantitation of the target. Since the microcantilevers and nanowires can be coated with affinity molecules for any target (biological or chemical), the opportunity for parallel sensing of multiple targets is enormous.

The Microbiological Investigation of Bioterrorism and Biocrime

The microbiological component of the forensic investigation has the potential to assist the investigation considerably, by providing information about the suspect(s), the source of the biological agent, the methods used to prepare the biological agent, the type of laboratory that was used, the potential location of the laboratory, and an estimate of the period over which the biological agent was prepared. Combined, this information can suggest opportunity and motive, thereby providing assistance to all the fundamental questions behind a successful criminal investigation; who, what, how, where, when, and why.

The first stage of the microbiological investigation is to locate the source of biological agent, determine the extent of contamination, and trace the movements of the agent. Standard microbiological techniques such as culture and viable counts are useful in this endeavor. In the investigation of the 2001 anthrax attack in the United States, these simple techniques were used to locate the letters and trace the time and vicinity in which the letters were posted

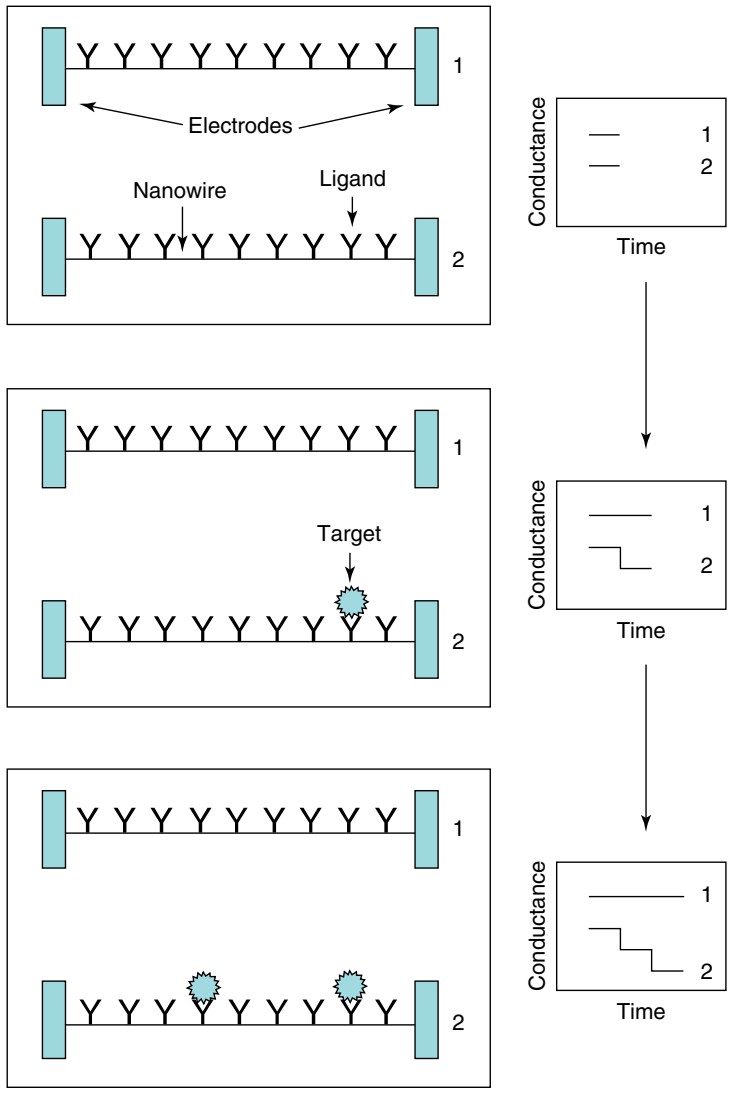

Figure 6 Nanowire technology

[45]. The next critical stage in the microbiological investigation is the identification and characterization of the biological agent. A myriad of cultural, physical, genetic, biochemical, enzymatic, proteomic, lipomic, and metabolic profiling procedures are available that can assist with the species and strain identification of the agent and should aim to provide the highest level of characterization as possible. Identifying the strain and establishing its identity at the site of the attack and other locations of interest allow police investigators to establish links between attacks and between the attack and the perpetrator [46–52]. The identity of the strain may also be used to trace the attack strain to isolate from culture collections, laboratories, organizations, natural outbreaks, or particular geographical regions.

Chemical and microscopic analysis of the original sample can provide a great deal of information about the manufacturing process. Traces of agar indicate that the agent was harvested from culture plates. Chemical analyses can indicate the type of culture medium that was used [53–56]. This can be

related back to a commercial source of the medium and potentially even back to a particular batch of medium. Stable isotopes of a number of elements like carbon, nitrogen, strontium, and lead provide an independent mechanism through which media can be traced [53–55, 57, 58]. The ratio of stable isotopes is directly linked to their geographical region of origin. This has shown great forensic utility for tracing the origins of illicit drugs such as heroin and cocaine, as well as to determine the authenticity of plant-derived food products [59, 60]. In this respect, stable isotope ratios have great application to the tracing of the biological agents such as ricin, abrin, and venoms that are extracted from plants and animals. Although the geographical origin of components within culture media may not necessarily relate to the geographical location at which the agent was cultured, it can be related back to the type of medium, the commercial source of the medium and potentially even the specific batch of medium, thereby indirectly providing evidence for the geographical location of the laboratory in which the biological agent was manufactured [53–55, 57, 58]. Isotopes of hydrogen and oxygen also show geographical influence (Figure 7). As components of water, these can be used as natural tracers to provide direct evidence for the location of the water source used by the laboratory during the manufacture of the biological agent [57, 61]. ^{14}C bomb-pulse dating can provide information about the date of manufacture of the biological agent within a precision of 1–2 years (postnuclear bomb, i.e., 1950 AD) [62, 63]. This can provide information about whether the biological agent has been manufactured recently or not, and if not, from where the biological agent may have been sourced.

Electron microscopy can be used to determine the purity and level of refinement of the biological agent, thereby providing important information about the manufacturing processes. The level of purity, degree of refinement, and presence of flow enhancers is evidence of intent by the perpetrator to prepare a weaponized agent. Chemical analysis for solvents, detergents, stabilizers, flocculants, and preservatives can provide additional information about the process used to manufacture the biological agent [49, 51, 65].

When examined as a whole, the results from these investigations provide a comprehensive profile of the perpetrator and the facilities used to manufacture the agent. It provides evidence for the time and vicinity of release of the agent, the source of the biological agent, the date of manufacture, the geographical location of the manufacturing facility and the manufacturing process. In turn, this provides information about the level of sophistication of the laboratory involved; whether it is likely to be a low-tech clandestine "back yard" laboratory or a well-funded high-tech laboratory. Speculations as to the type and sophistication of the laboratory, as well as the manufacturing equipment, the personal protective equipment (PPE), and the reagents and consumables, that are likely to be present can be made with confidence. Speculation can also be made about the level of experience and knowledge required to manufacture and disperse the agent, which in turn intimates prior career experience and educational background of the perpetrator and suggests access, opportunity, and motive. The medical history of the perpetrator should also be considered, given the potential for infection during manufacture and dispersal. The perpetrator may have been vaccinated or treated for infection, or may have developed symptoms associated with the improper handling of reagents used in the preparatory process.

Conclusion

In theory, acts of bioterrorism have the potential to be extremely decimating. Many of the biological agents such as *B. anthracis* and ricin can be acquired from the environment and prepared using crude equipment and reagents. Further, the cost involved in the small-scale manufacture of crude preparations is low and crude systems such as spray bottles or needles can be used to deliver the agent. In reality, the likelihood of a successful large-scale biological attack is low. History shows that successful attacks are generally targeted at one or a few individuals, and that attempts to deliver biological agents to large numbers of individuals have been unsuccessful [2–4, 66]. This is mostly due to the lack of knowledge, funds, and resources of terrorists and terrorist organizations, which has prevented the development of effective bioweapons.

Crude preparations may be relatively easy and cheap to prepare, but are largely ineffective unless specifically administered to a victim through close contact. Highly refined, weaponized biological agents are much more effective for large-scale attacks, but are very difficult and very costly to prepare, even

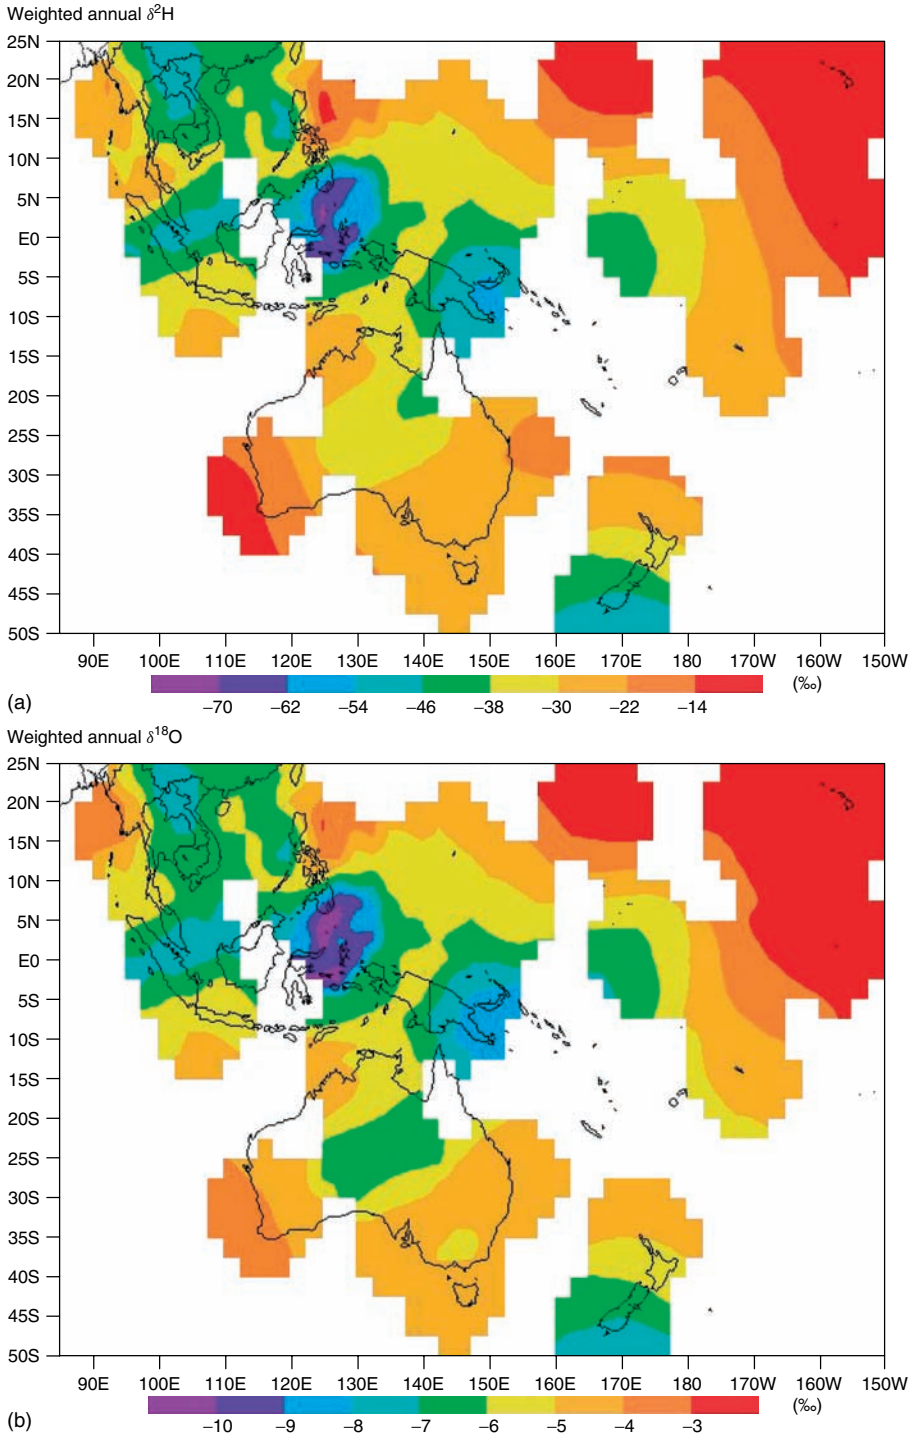

Figure 7 Weighted annual precipitation maps for (a) δ^2H isotope ratios and (b) δ^8O isotope ratios across the South Pacific region [64]

in small-scale volumes. The equipment, technology, knowledge, and financial capital required to prepare weaponized biological agents is not within the reach of most terrorists or terrorist groups.

The 2001 anthrax letter attacks in the United States are a good example of the ineffectiveness of a widespread attack using a crude mode of dissemination. The letters contained sufficient anthrax to kill thousands of people and they leaked as they passed through the postal system, subsequently resulting in the widespread contamination of the US postal system and the postal systems of most other countries across the globe. Yet the result was 22 cases of anthrax and five deaths [67].

When compared to the enormous loss of life caused by naturally occurring diseases, such as Human immunodeficiency virus acquired immune deficiency syndrome (HIV AIDS), malaria, and tuberculosis, the reality is that the threat from bioterrorism and biocrime is low. However, the consequence of even a small-scale attack on society is high.

Biological Stains

Introduction

Over the years, many techniques have been utilized to determine the type of biological material present at a scene or on clothing and the tissue source of that biological material. Profiling a stain using DNA methods has been established as the gold standard in associating a stain to an individual and has been accepted in courts throughout the world. However, it remains critically important to establish the biological source of the DNA profile. Generally, this means identifying semen or saliva in sexual assault cases and blood in assaults and homicides.

Blood

Blood is unique in its appearance in the form of a dried stain and has a distinct reddish-brown color, which quickly becomes recognizable by the experienced analyst. Tools such as an "alternate light source" can be utilized to assist the examiner in detecting trace amounts of blood, especially on dark clothing. Bloodstains absorb ultraviolet light and appear as dark stains on a dark background. However, most bloodstains can be located using a bright white light source, even on dark clothing.

After locating potential bloodstains, "presumptive color tests" are utilized, which turn their color in the presence of the molecule, "heme" [1]. Many chemicals suffice in this regard, the most popular being phenolphthalein, leukomalachite green, *o*-toluidine, and tetramethylbenzidine [2–5]. All these chemicals are colorless in a reduced ionic state. However, in an oxidized state, these colorless reagents turn color rapidly, turning pink, green, or blue green. This color conversion occurs in the presence of an oxidant, e.g., hydrogen peroxide, rapidly in the presence of a catalyst, such as heme (Figure 1). Heme consists of pyrole rings surrounding an atom of iron, and in the presence of protein molecules, comprises the molecule hemoglobin that, of course, is found in red blood cells.

The presumptive color test is an easy test to conduct. A dry, sterile, cotton-tipped swab is rubbed against the suspected stain. A single drop of the testing reagent is added to the swab, followed by a single drop of hydrogen peroxide. An immediate color change indicates that the stain may be blood. The reagents are added in this order for a reason. A color change only after the addition of the testing reagent indicates the presence of strong oxidants and the results can be inconclusive.

A swab moistened with distilled water can be used to collect a small amount of the stain for testing; however, this may rehydrate the stain increasing the chances of bacterial degradation.

A positive presumptive color test indicates that the stain may be blood. The tests are sensitive, reacting with bloodstains that cannot even be seen with the naked eye. However, they may react with other materials such as rust, copper, and vegetable peroxidases. Oxidation of the test reagents will occur over time, so the tests must be read within seconds.

Some laboratories conduct confirmatory tests on extracts from the stains to determine whether the stains are, in fact, blood. "Takayama" and "Teichman" are two such confirmatory tests [6–8]. Small cuttings from the suspected bloodstains are placed on a microscope slide, covered with a coverslip, and the reagent of choice is added to the edge of the coverslip. Capillary action draws the reagent under the coverslip allowing it to react with the stain. Unique rhombic-shaped crystals formed in the presence of the reagents confirm that the stain is blood. However, these reagents react with animal blood as well.

At this point in the analysis, some laboratories will conduct DNA testing (*see* **DNA**) on the bloodstains. The primers used in DNA profiling only react with human and upper primate DNA, and so obtaining a DNA profile indicates that the bloodstain is most likely of human origin. However, with the advent of monoclonal antibody technology, rather simple yet elegantly designed membranes exist that can quickly confirm the presence of human blood. The technology of immunochromatographic membranes that incorporate the use of monoclonal antibodies specific to human hemoglobin or glycophorin A has aided the field of forensic science [9, 10]. Approximately 100 µl of stain extract are added to a well in the cassette. The sample is absorbed onto a pad which contains mobile monoclonal antibodies. This antigen–antibody complex migrates down the membrane where it comes into contact with an immobilized monoclonal antibody. If the extract contains human blood, a visible line will appear indicating that the sample is human blood (Figure 2).

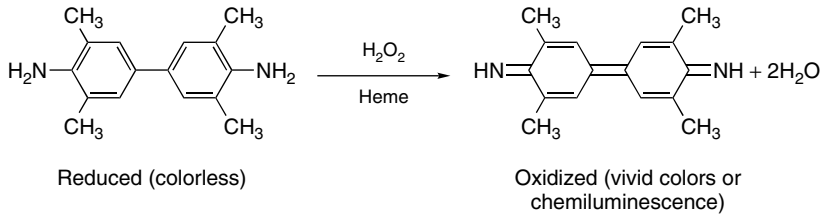

Figure 1 The catalytic conversion mechanism of presumptive color reagents for the presumptive detection of blood

A caveat exists here. Certain membranes are known to react with upper primate and ferret blood. Hence, this matter must be taken into consideration when conducting these tests and preparing reports.

Finally, after thorough analysis of the stain has been completed, a portion of the stain is cut out and is extracted (*see* **Extraction**) for DNA analysis. At the conclusion of the DNA testing, the forensic scientist may conclude that the bloodstain could have originated from a certain individual (based on accompanying statistics (*see* **Case Assessment and Interpretation**)), or exclude someone as a donor of that bloodstain.

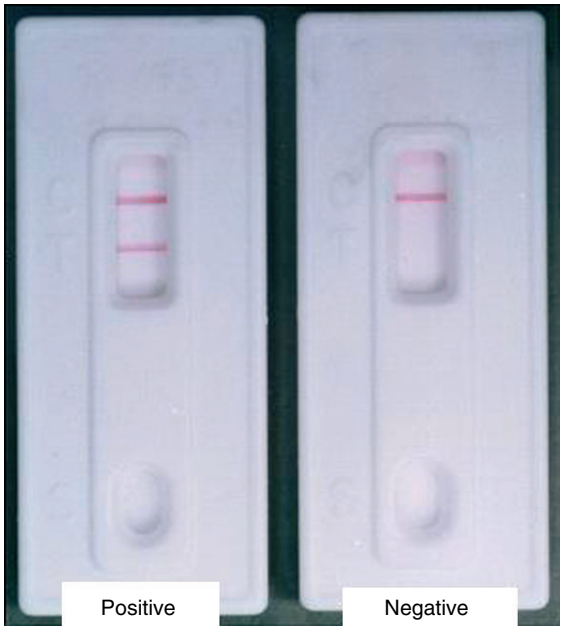

Figure 2 Immunochromatographic membrane testing of blood using monoclonal antibodies specific to human hemoglobin

Semen

Semen is the fluid that is discharged from the penis during ejaculation. It consists of a fluid portion called *seminal fluid*, a complex fluid that contains many proteins and chemicals required for the survival of the "spermatozoon". The spermatozoon is the reproductive cell of the male and consists of a head, neck, and tail region. A good analogy that helps to explain the constituents of semen is a swimming pool. The swimming pool with all of the bathers inside the pool would be analogous to semen. Remove the bathers, or in our analogy, the spermatozoa, and you are left with the pool water, or seminal fluid, with all of the chemicals.

The approach to the analysis of semen mimics that of bloodstain analysis in that articles of clothing and bedding are examined with an alternate light source. Contrary to bloodstains, semen stains "fluoresce" when exposed to ultraviolet light. The source of this fluorescence has been debated but is thought to be due to nonproteinaceous compounds found in semen. Whatever the source, dried semen stains frequently fluoresce intensely under ultraviolet light aiding in their detection.

After suspected semen stains are located, they are tested with a presumptive color test that detects the presence of "acid phosphatase" [11]. Acid phosphatase (*see* **Acid Phosphatase**) is an enzyme (*see* **Enzymes**) found in large amounts in semen and is responsible for the hydrolysis of phosphates resulting in energy for the sperm. Acid phosphatase can be found in much smaller quantities in other biological fluids including vaginal secretions and saliva, hence, the presumptive nature of this test.

A number of chemicals have been used over the years for the detection of acid phosphatase. Basically, all of them involve the hydrolysis of a substrate such as α-naphthyl phosphate by acid phosphatase. This reaction results in the formation of free naphthyl,

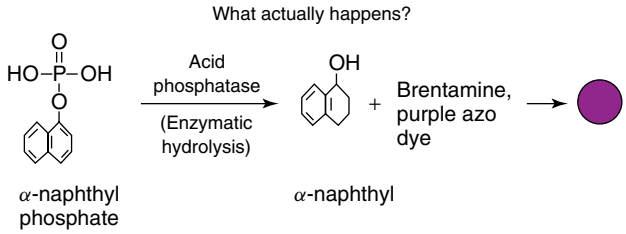

Figure 3 The enzymatic breakdown of α-naphthyl phosphate by acid phosphatase is the basis for the presumptive color test for seminal fluid

which reacts with an azo dye, such as *o*-dianisidine, resulting in a very dark pink color, generally within minutes (Figure 3). The test is very sensitive and reacts with as little as two units of acid phosphatase, known to exist in vaginal secretions. The stronger and faster the test result, the more likely the stain is from semen.

The time tested method for conclusive determination of semen is a microscopic examination and the observation of spermatozoa. The morphology of the spermatozoon is unique from other cells in the body. Using contrast stains such as hematoxylin and eosin or, the more popular nuclear fast red and picroindigocarmine, commonly referred to as *Christmas Tree stain*, the structure of the spermatozoon takes shape [12]. A flattened oval shaped head has its nucleus compacted into the lower half of the head which stains intensely with nuclear stains (Figure 4). An acrosomal cap on the top half of the head prevents staining and appears clear. A short midpiece is attached to the base of the head followed by a single, long flagellum, or tail, which moves the sperm cell. Some laboratories require that a tail, or a portion of a tail is found on the cell to confirm the presence of spermatozoa, but other laboratories allow the identification of a single head lacking a tail. It is known that the longer the time interval between assault and collection of samples, the less likely sperm with tails will be found. The number of spermatozoa decreases and often become misshapen (Figure 5). Typically, sperm can be found in 72-h postcoital swabs and occasionally up to 96 h, the longest surviving constituent of semen in the vagina (Figure 6).

There may be situations in which semen is found lacking spermatozoa (aspermic). This may be due to vasectomy, disease, drug use, and frequency of ejaculation. In such cases, semen can

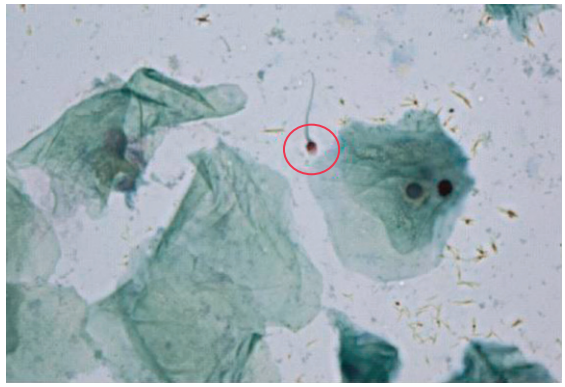

Figure 4 A single sperm cell with its tail among vaginal cells stained with the Christmas Tree reagents

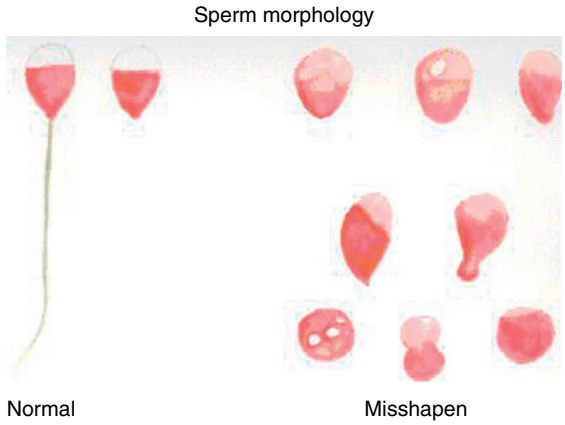

Figure 5 Morphological changes of sperm cells as they degrade

be confirmed using immunochromatographic membranes that utilize monoclonal antibodies specific for either prostate-specific antigen (PSA) [13–15] or

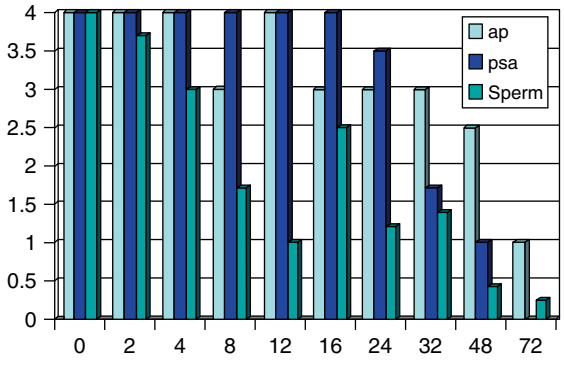

Figure 6 The relative levels of acid phosphatase, PSA, and sperm at various times postcoitus from vaginal samples. Hours postcoitus (x-axis) and relative levels (y-axis). (See Laux, D.L. Forensic detection of semen IV: the persistence of acid phosphatase, P30, and sperm postcoitus, *Midwestern Association of Forensic Scientists Meeting*, Columbus, Ohio, October 24, 2003)

"semenogelin". These proteins are highly specific to seminal fluid. PSA was initially believed to be found only in the prostate of males, but recent studies have shown that it can be found in female urine and breast milk [16, 17]. The amounts of PSA in these fluids is incredibly low compared to that of seminal fluid and proper extraction of the stain or swab can distinguish semen from these fluids [18]. Semenogelin seems to be only expressed by testicular tissue and so may become a more definitive source of seminal fluid [19].

It is known that DNA profiling can be accomplished on aspermic semen samples. There are other sources of nucleated cells in semen besides spermatozoa including epithelial cells lining the vas deferens, Sertoli cells, and white blood cells.

Saliva

Saliva stains are frequently found in sexual assault cases. Once again, preliminary examination is accomplished with an alternate light source. Saliva stains will fluoresce under ultraviolet light, albeit, not as bright as semen stains. The use of varying wavelengths and colored goggles increase the likelihood of finding saliva stains.

After locating possible saliva stains, the stains can either be mapped or cut out and directly analyzed. Mapping has the benefit of observing the location and distribution of saliva stains and allows for photographic documentation. Mapping can be simply accomplished by overlaying stains with moistened starch papers, pressing them against the stains, and developing them with an iodine solution [20]. Iodine reacts with starch to produce a dark purple color. Areas that do not turn purple and remain white indicate the presence of the enzyme "amylase" (Figure 7). Amylase is found in high amounts in saliva and starts the digestion of starches and carbohydrates. Amylase can be found in other biological fluids such as semen, feces, and in bacteria. However, the levels of amylase in saliva are 1000 times the levels found in other body fluids [21, 22]. In addition, amylase levels drop in dried stains as they sit at room temperature and thus, make it more probable that positive amylase results are due to the presence of saliva.

At this time, no agreed confirmation test for the presence of saliva exists. Immunochromatographic

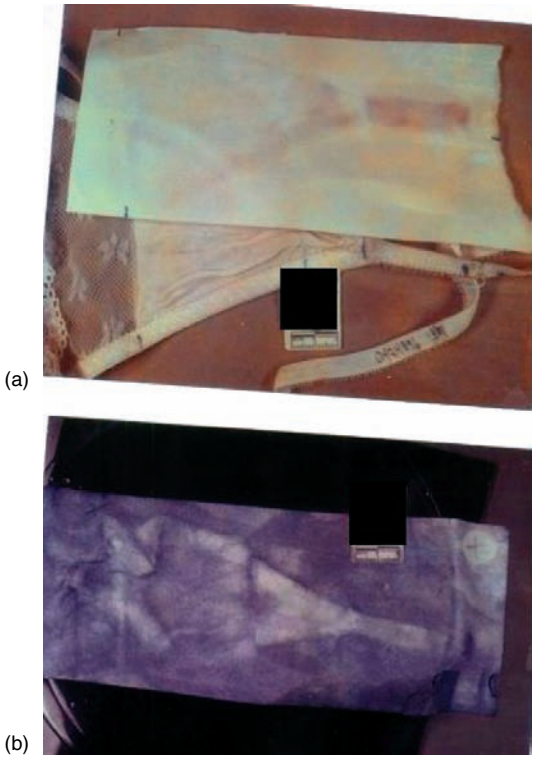

Figure 7 Mapping of underwear for acid phosphatase (a) and amylase (b). Purple-(dark) stained areas (a) demonstrate acid phosphatase distribution. (b) White (light) areas demonstrate the distribution of amylase

membranes are available that utilize monoclonal antibodies to amylase, however, these have been found to react with human feces, dog feces, and upper primate saliva [23].

DNA profiling results on saliva stains are mixed. It really depends on the number of nucleated cells that are found. Saliva is a liquid and stains are located by the reaction of amylase. A large amount of saliva may be present, but if the number of nucleated cells is small, a DNA profile may not be obtained.

Urine

Urine stains typically have a unique smell due to the presence of uric acid and urea. Occasionally, it may be necessary to determine the presence of urine and attempt DNA profiling on the stains. Assault cases have occurred in which the victims had been urinated upon. In addition, corrections officers have had liquids thrown upon them and determination of the source of the liquid becomes important.

No confirmatory test exists for the presence of urine. All of the tests rely on the determination of various components of urine such as uric acid, urea, and creatinine. "Creatinine" is a component of urine and exists at a relatively high concentration ($311-1790\,\mathrm{mg\,l^{-1}}$) [24]. The classic test for creatinine is called the *Jaffe test* [25]. A portion of the stained area along with a portion of the substrate lacking the stain (a "control" area) is cut from the garment or bedding. A drop of sodium hydroxide (NaOH) is added to the stain followed by a drop of concentrated picric acid. The formation of an intense orange color is a positive indication of creatinine (Figure 8). A clear demarcation between the control area and the orange color makes the determination easier. The test can be run on sterile cotton-tipped swabbings of the stained areas as well.

DNA results from urine stains have been obtained; however, the likelihood of obtaining results using genomic DNA is not high.

Feces

Fecal stains, such as urine stains, have an odorous component that can be used in the analysis. The unique smell is due to the chemicals skatole and indole, which are by products of bilirubin catabolism (part of the breakdown mechanism of hemoglobin).

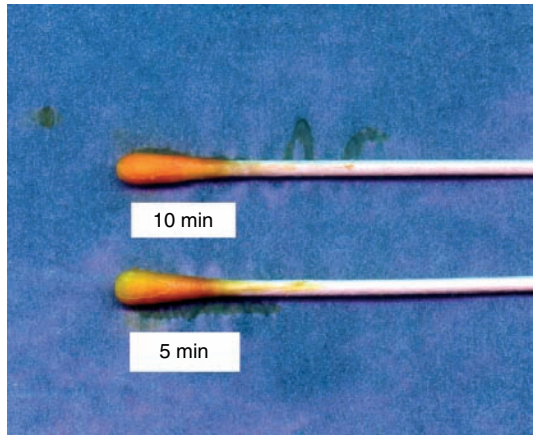

Figure 8 Creatinine color change at 5 and 10 min

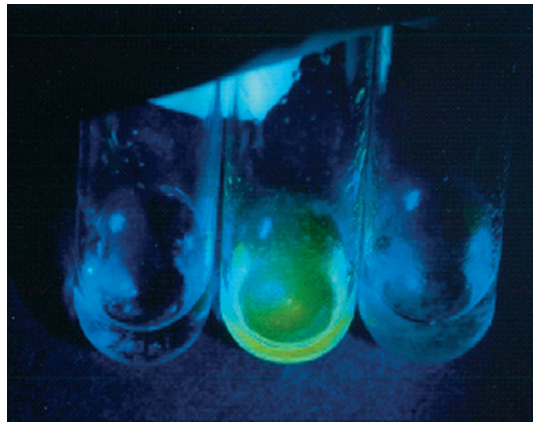

Figure 9 Urobilinogen test for the presumptive detection of fecal material. Tubes (from left) blank, positive fecal sample, and control

Fecal stains generally have a brown appearance and can be located visually. They can be confused with aged bloodstains and may contain traces of blood, so a positive reaction with a blood-testing reagent may occur.

Methods of analysis of fecal stains have centered on chemical and microscopic analyses. Microscopic analysis of an extract from the stain may reveal the presence of plant and animal materials, which would support the conclusion of feces. A simple chemical test can be performed on an extract of the stain dissolved in distilled water. Added to this extract are a few drops of ethanol followed by a

few drops of concentrated zinc chloride in ethanol. Under ultraviolet light, an intense apple green color results indicating the presence of "urobilinogen" [26], a breakdown product of bilirubin and a component of feces (Figure 9).

DALE L. LAUX

Biological Swabs

Purpose

Swabs are used for removing biological samples from people and objects for subsequent analysis. Their most frequent applications are as follows:

- to take reference DNA samples from victims or suspects;
- to remove wet or damp biological fluids from the skin and orifices of victims of sexual assault or corpses; and
- to remove dry biological fluids from nonabsorbent surfaces such as skin, water-proof clothing, footwear, furniture, and flooring.

Reference DNA Samples

A buccal swab or scrape is frequently used for collecting DNA samples as it is a noninvasive method that does not require a medical examiner. Sampling involves repeated firm rubbing of the swab on the inside of the cheek to remove some of the epithelial cells. Some organizations opt to have the damp saliva transferred to FTA paper, which is commercially available, contains chemicals that enhance DNA stability. It allows for easy storage of DNA samples at room temperature and suits automated analysis as samples can be removed with a punch [1]. The absorption and release properties of the swab fabric are critical for the transfer process and organizations using FTA paper favor swabs with sponge-type material.

Removal of Biological Fluids

The forensic medical examiner uses dry swabs to remove wet or damp samples of semen, saliva, blood, or any other foreign tissues from orifices, genitalia, skin, and hair of complainants of sexual assault, suspects, or deceased persons.

Dry stains can be removed from skin surfaces at scenes or items examined within the laboratory by wetting the swab with sterile water and rubbing the stained area or the location where biological fluids are suspected to be present. The wet and dry swabbing technique [2] is more successful than wet alone. It is thought that this is due to the fact that the dry cells rehydrate and plump up after the wet swabbing and come away on the dry swab. This technique is less successful on absorbent surfaces such as clothing and soft furnishing.

Small pointed swabs are superior for swabbing small visible stains, especially blood, as the stain concentrates in a small area rather than excessive dilution across a larger swab head. Some laboratories recommend using this type of swab for removing foreign cells from under fingernails rather than cocktail sticks.

Dry or wet swabbing of clothing is used by some organizations to remove epithelial cells to determine the DNA of the wearer, rather than extracting pieces of the fabric. Other laboratories have replaced this technique with mini-taping (see below).

Preservation of Biological Material on Swabs

Damp swabs are an inhospitable environment for DNA and prone to bacterial and fungal growth. Hence, swabs need to be either air-dried or frozen after sampling. Concerns about the possibility of contamination while air-drying have increased with improved DNA sensitivity. Many laboratories freeze the swabs, even though this leads to long-term storage problems. Some organizations use cardboard or paper containers or modified swab containers with a removable plug, both of which allow drying after packaging. Air-drying instruments with internal racks to hold the swabs are popular in the United States.

Swab Types

The most commonly used swab consists of a shaft and handle (approximately 16 cm in length) with a piece of absorbent material at one end. Plastic shafts are preferable to wooden ones as the latter can absorb liquid during the DNA extraction process.

Although many different types of material are used in the swab heads, there is little published data on their relative efficiency for recovery and release of biological fluids. Windram *et al.* [3] report superior yields of DNA from foam popules relative to nylon, polyester, and cotton. Overall, recovery of biological material from swabs is remarkably poor. Unpublished work suggests that less than 25% of spermatozoa are

recovered from swabs. Gartside *et al.* [4] estimated an extraction efficiency of 1% or less for prostate-specific antigen from cotton swabs. Most research, to improve recovery of DNA from swabs, focuses on the optimization of extraction methods [5–7].

Although swabs produced for medical use are sterile, they are not necessarily DNA free. There are rare reports of contamination by manufacturing staff [8]. Treatment with ethylene oxide gas has been shown to be superior to UV or other radiation in removing DNA contaminants from swabs [9]. The poisonous property of the gas means that the sterilization process is limited to approved companies.

Use of Mini-Tapes to Remove Biological Samples

Swabbing of surfaces has been replaced in some laboratories by mini-taping. This method uses small pieces of adhesive tape to remove cells from clothing, weapon handles, and other items [10]. The increased recovery of foreign DNA from clothing is significant. Caution in the interpretation of results is required, due to the possibility of detecting DNA, following innocent secondary transfer.

Biometric Devices

Introduction

First records of allowing human fingerprints as evidence in a court of law date back to late nineteenth century, when the Home Office of the United Kingdom accepted every individual's fingerprints to be unique [1]. Owing to the apparent potential of this in forensics, research in the field advanced, and methods

of comparing fingerprint marks became increasingly efficient. Nevertheless, the manual methods involved were still quite laborious and monotonous. So when the demand for the comparisons kept increasing, an effort was made to improve the efficiency of the methods by automating the systems. Advances in computer technology, sensor technology, and pattern recognition led to automated fingerprint identification systems (AFISs) in the past few decades [1, 2]. In the mean time, other disciplines such as image processing, computer vision, machine learning, and signal processing advanced as well, leading to other ways of comparing records of a variety of human traits considered to be useful in authenticating people. Examples of this are facial geometry, hand geometry, voice, vein pattern, and iris recognition. However, it was only in the 1990s that the common ground in the various disciplines was recognized enough to spawn an independent field called *biometrics* [3]. The International Biometrics Group (IBG) uses the following technical definition of biometrics [4]:

> The automated measurement of behavioral or physiological characteristics of a human being to determine or authenticate their identity.

This actually means that in biometrics, computers are used to check to what extent a particular human behavior or physical characteristic matches with similar records in a database. This enables machines to check if a person is who he says he is (verification), or if he can be matched with anyone from a database (identification). The matching reliability strongly depends on the technology and the methods involved. A comprehensive background on many aspects of biometrics can be found in literature [1–3].

Currently, the potential uses for biometrics are not limited to forensics alone, but include prevention of identity fraud, logical access control to information systems, such as computers or networks, and physical access control to facilities such as buildings or across borders. Terrorist attacks have had a distinct influence on investments in and the development of the biometrics market, which has been growing rapidly. The US Visit Program, currently in effect, requires travelers passing the US border control to have their two index fingers scanned and a digital photograph taken, to be compared to those stored in their "biometric passport" for authentication [5]. Such biometric passports, containing a chip with biometric data, are in the process of being installed in more countries around the world.

As the use of biometric systems becomes more widespread, the implications of it for the forensic practice should be investigated. It is of interest in the field of forensics to know about the reliability of the performance of various biometric systems. As such systems often involve computers, usage logs are common. What would the forensic expert say if biometric system log files are being used as an alibi, or to incriminate potential trespassers of the system? Or, how safe is an access control system that uses biometrics really? How difficult is it for unauthorized persons to hack their way into the system? Can criminal suspects hide their sensitive data from the forensic expert's eye by protecting it with biometrics?

This article discusses some of the technologies involved in biometric devices. In addition, we briefly deal with what is involved in evaluating a biometric system's reliability and then focus on a particular aspect of circumventing biometric devices using fake copies of biometric samples.

Human Characteristics Suitable for Biometric Systems

Table 1 lists biometric characteristics that have received attention in the research and development industry because of their potential for automatic identification and verification of persons [1, 6]. Not all of the biometric features from this table have yet yielded commercial applications, gained a foothold in the market, or indeed show promise of doing so in the near future.

There is a wide range of biometric products in the market. For this article, we have focused on the physical characteristics that are currently most commonly used as biometric identifiers in biometric devices, as well as some that show promise. Notably, facial geometry (2D and 3D) shows great promise, although this is not in the scope of this document. The workings of a biometric system and the technologies used in biometric devices that involve the selected biometrics are explained in the following section.

Biometric System Components

The major functional components of a simplified biometrics-based authentication system are (see Figure 1) [7] as follows:

Table 1 List of biometric characteristics having received attention because of their potential for automatic recognition of persons

Physical characteristic		
Biodynamic signature	Finger surface (3D)	Odor
Bioelectric field	Finger vein pattern	Palm print
Bite marks	Finger wrinkles	Pores
Bone sound transmission	Fingerprint	Reflection of acoustic waves in the head
Cardiac pulse	Hand geometry	Retinal pattern
Corneal surface topography	Hand pressure profile	Skin impedance
Dental geometry	Hand thermogram	Skin pattern
DNA	Hand vein pattern	Skin spectrum
Ear	Iris	Smile
Facial geometry (2D/3D)	Knuckle creases	Voice print
Facial thermogram	Lips	
Finger geometry	Nail	
Behavioral characteristic		
Dynamic grip recognition	Handwriting	Tapping
Eye movement tracking	Keystroke dynamics	
Gait	Mouse dynamics

3. Create template: conversion of the intermediate data into a user template for storage in a database.
4. Compare: comparison with the information in a stored reference template.

A biometric system has two principal modes: enrollment and verification/identification. Enrollment is the process in which new users are enrolled into the system database. The verification or identification mode involves the comparison of a user with one or more records in the database. The capture part (component 1) of both modes takes place using a biometric device. This device captures the relevant

human characteristic using some kind of sensor, for instance, a light-sensitive chip in a camera or an air-pressure-sensitive chip in a microphone. The data that is ultimately used in the comparison (using component 4) is always an abstraction of the actual biometric. It is an interpretation of sensor output, from which features are extracted (using component 2) that are believed to capture the essentials with which to discern between individuals. Using carefully designed algorithms, a captured fingerprint could, for instance, be abstracted to just the minutiae locations and types. For storing the data in a database in enrollment mode, the abstracted data is combined with general user information into a user template (component 3). This template is stored in the database. The comparison algorithm provides details on whether or not a match has occurred after computing a matching score and checking whether it passes a predefined matching threshold.

Depending on system requirements, the specifics of the system may deviate from this generic case. For instance, a database may hold just the essential abstracted data, or some intermediate form from which the abstraction can still be derived later. The latter can be useful when different methods and algorithms are available for extracting features. For instance, storing an image of a fingerprint instead of the minutiae information as extracted by a particular algorithm, allows different algorithms to be used on database records without having to recapture all the fingerprint data, thus increasing interoperability between different systems that use that same biometric sample as input. In addition, the physical location of the hardware performing the functions may vary, depending on the biometric system setup. A biometric device may be a standalone device, with integrated extraction, database, and comparison functions. The device could also be no more than a capture station, relaying all computations and storage to linked computers and software.

Biometric Device Technologies

Biometric devices come in a great variety. Next, we discuss the technology involved in a number of fingerprint scanner types, a simple iris scanner, a hand geometry scanner, and a hand vein pattern scanner.

Fingerprint Recognition

Fingerprint recognition using biometric devices involves taking fingerprint images from fingertips. Patterns of fingerprint ridges and valleys are detected and stored in a simplified data template that can be used for comparison with other fingerprint templates for verification or identification. The images are acquired with some kind of sensor. A variety of fingerprint sensor technologies are used in commercial fingerprint scanners [1, 6].

Optical Sensors.

- *Frustrated total internal reflection* (*FTIR*): This technology is based on the behavior of light at boundaries from one material to another. The finger is placed on the top side of a glass prism (see Figure 2) [1]. Light entering the prism from a light-emitting diode (LED) on one side of the prism is partially reflected at the contact surface and then captured via a lens with a light-sensitive chip (for instance, charge coupled device (CCD) or complementary metal oxide semiconductor (CMOS) image sensors) on the other side of the prism. Image contrast is caused by the fact that light is randomly scattered or absorbed at the points where skin ridges and the prism make contact, and totally reflected at the valleys, where no contact is made.
- *Surface-enhanced irregular reflection* (*SEIR*): This technology shares some characteristics with

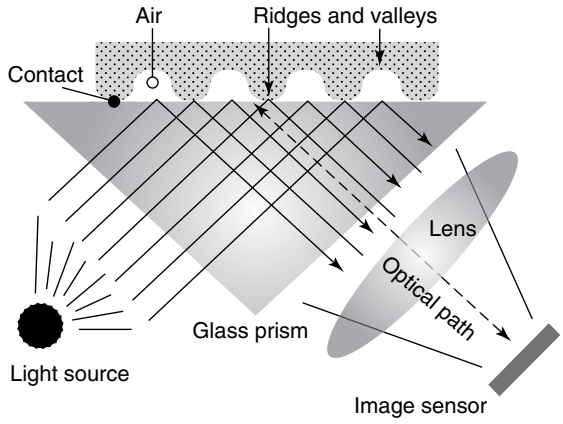

Figure 2 FTIR-based fingerprint sensor [Reproduced from Ref. 1. © Springer-Verlag, 2003.]

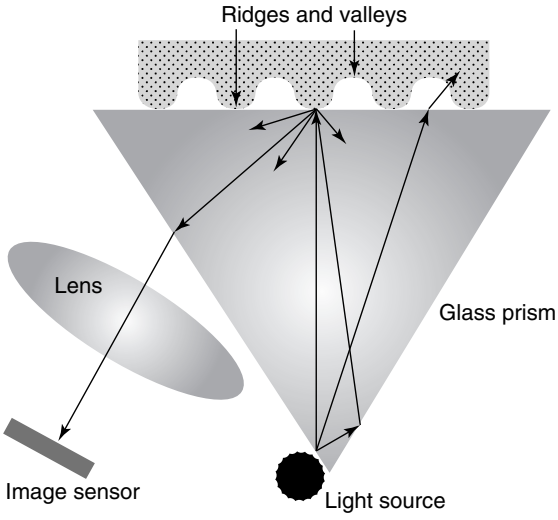

Figure 3 SEIR-based fingerprint sensor

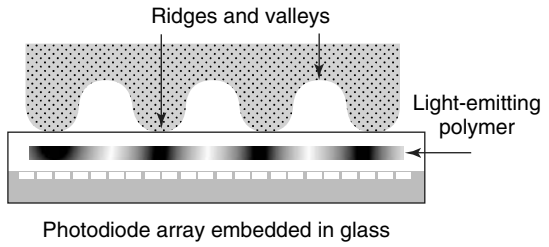

Figure 4 Electro-optical fingerprint sensor [Reproduced from Ref. 1. © Springer-Verlag, 2003.]

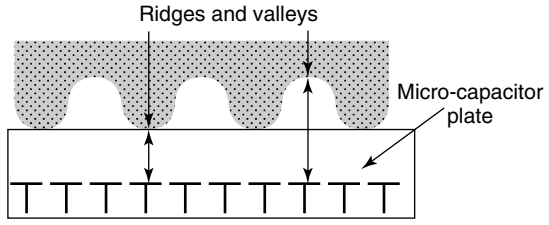

Figure 5 Capacitive fingerprint sensor [Reproduced from Ref. 1. © Springer-Verlag, 2003.]

FTIR technology. The contrast between ridges and valleys is also brought about by the different behavior of light after hitting the ridges and valleys. In this case, however, the light hits the contact surface perpendicularly (see Figure 3), scattering at the ridges but completely passing at the valleys; hence, no scattering occurs. The scattered light is collected by the image sensor and thus produces bright spots for ridges and dark spots at valleys. The sensor manufacturers claim that this technology gives higher contrast images than FTIR technology [8].

- *Electro-optical*: These sensors use a layer of light-emitting polymer, of which the light emission varies on the basis of the potential applied on one side (see Figure 4) [1]. When placing a finger on the polymer surface, ridges touch the polymer and valleys do not, causing the potential to vary across the surface. Thus, a luminous representation of the fingerprint is generated. A second layer, consisting of a photodiode array or a CMOS, converts the light pattern into a digital image.
- *Direct sensing/touchless*: In this case, a high-quality camera is used to focus on the fingertip and directly read the fingerprint. Usually some kind of mechanical support is present to facilitate presenting the finger at a set distance.

Solid-State Sensors.

- *Capacitive*: A capacitive sensor is a two-dimensional array of microcapacitor plates embedded in a chip. The finger skin acts as a second microcapacitor plate (see Figure 5) [1]. Small electrical charges are created between the array and the finger, of which the magnitude depends on the distance between the surfaces. As such, the resulting capacitance pattern represents the ridge and valley pattern of the fingerprint.
- *Electric field:* This type of sensor generates a small radiofrequency field, which is modulated by the highly conductive subsurface of the skin (live skin cell layer). A matrix of antennas receives the modulated analog small-amplitude signal, which is then further processed and digitized to obtain an image representing the contours of the live skin layer (see Figure 6) [9].
- *Piezoelectric*: These sensors make use of the piezoelectric effect. The sensor surface is made of a nonconducting dielectric material that generates small amounts of current when pressed. The amount of current depends on the pressure applied. When pressing a fingertip on the sensor,

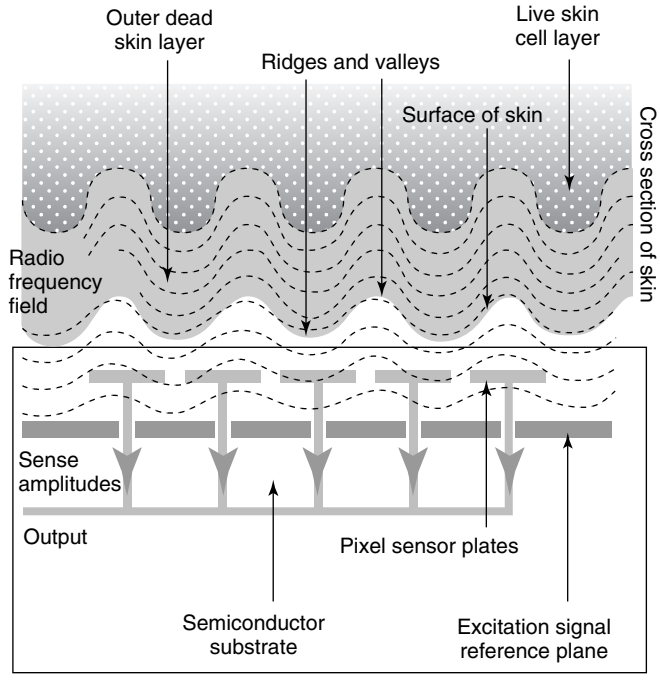

Figure 6 Electric-field fingerprint sensor [Reproduced with permission from Authentec Inc.]

the ridges will apply a higher pressure than the valleys as they are closer to the sensor surface. Typically, the sensor material uses some kind of threshold to determine whether or not a sensor element is "pressed", thus only enabling acquisition of binary images [1].

- *Thermal (sweep sensor)*: These sensors are made of pyroelectric material that generates current based on temperature differentials. Sweeping a finger across an electrically heated sensor allows measurement of heat flow to the skin, which is higher at direct contact with the sensor, thus allowing distinction between finger ridges and valleys [1, 6].

Other Sensor Types.

- *Ultrasonic*: This type of sensing is based on sending acoustic signals toward a fingertip and capturing the echo signal. As each change of impedance gives a partial echo, this technology can be used to image the subsurface of the skin [1] (see Figure 7).

Iris Recognition

Iris recognition technology uses a near-infrared light source and optical camera to capture an image of the iris [10]. Using pattern recognition algorithms, the image is converted to a template (also known as *IrisCode* [11]), which allows comparison with other enrolled templates (see Figure 8).

Hand Geometry Recognition

Hand geometry recognition is currently used mainly for physical access control applications. Typically, devices using this feature map the size and shape of a person's hand, compute a template from it, and verify this with a previously enrolled template.

A source of light illuminates two perpendicular mirrors and the reflected light is captured by the device. When a hand is inserted at the proper location (using guidance pegs), it partially blocks the light reflecting from the mirrors, thus creating a silhouette image on the sensor of both the top view and the side view of the hand (see Figure 9) [12].

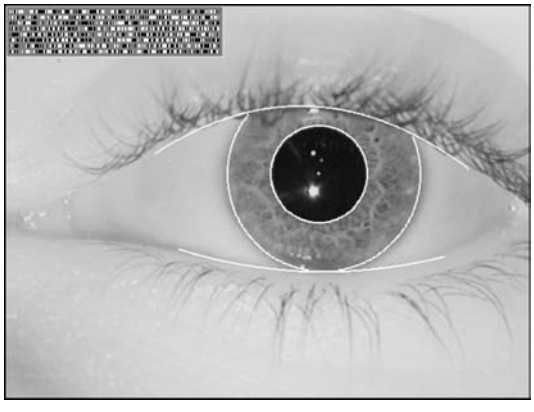

Figure 8 Iris pattern and IrisCode, J.G. Daugman, 2004 [Reproduced from Ref. 11. © IEEE, 2004.]

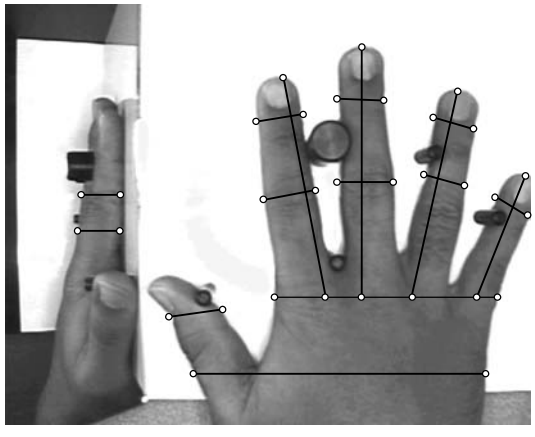

Figure 9 Hand side views used for hand geometry recognition [Reproduced from Ref. 12. © Michigan State University.]

Hand Vein Pattern Recognition

This technology is based on comparison of vascular pattern images of the back or palm of a hand. The devices use a near-infrared light source to shine on the hand and a near-infrared optical sensor system to capture the reflected light. Since near-infrared absorption and scattering properties of tissue and blood differ [13, 14], an image of the vein pattern is effectively captured. Image-processing algorithms are used to facilitate template creation and comparison (see Figure 10) [15].

Manufacturers claim that no nonbiometric patterns can be enrolled, as extensive checking is done of whether or not an actual, living hand is presented, for instance, by sensing the temperature pattern [16] or an active flow of hemoglobin through the person's veins [15]. In general, such checking of "aliveness" is referred to as *liveness detection*.

Reliability of Biometric Systems

There are a number of factors influencing the reliability of a biometric system. A proper evaluation of a biometric system should include the following tests [7]:

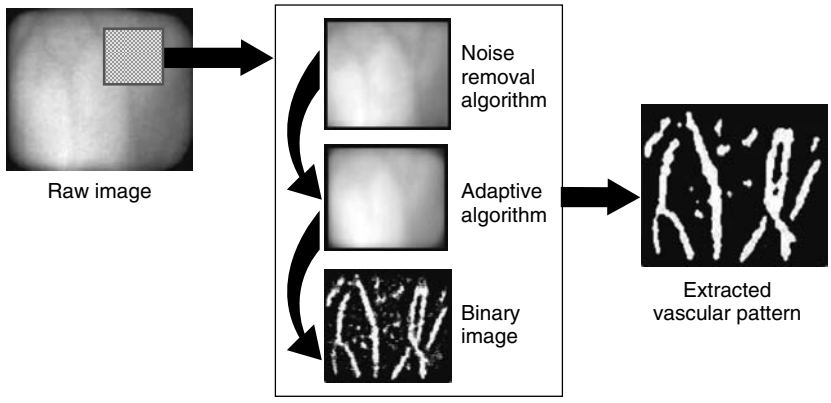

Figure 10 Hand vascular pattern extraction process flow

- *Environmental testing*: Biometric systems are affected by their physical environment. For instance, a device for recording facial images or iris patterns relies on ambient lighting conditions. Other influences include ambient sound levels, temperature, ambient electromagnetic noise, atmospheric humidity, dust, voltage supply variations, shock, and vibrations. The effects of such environmental influences should be investigated.
- *Statistical performance testing*: The performance of a biometric system is often described using particular error rates that can be evaluated by performing real-life automated biometric comparisons for which the ground truth is known. The larger the number of comparisons, the more accurate the calculated rates will be. Frequently reported rates include the following:
  - *False accept rate* (*FAR*): The frequency at which the system concludes that a claimed user identity is true, while in reality it is not.
  - *False reject rate* (*FRR*): The frequency at which the system concludes that a claimed user identity is not true, while in reality it is.
- *Vulnerability testing*: A biometric system has several aspects that introduce potential vulnerabilities. Data streams may, for instance, be intercepted and modified or a fingerprint sensor may be deceived by an artificial finger. Such vulnerabilities should be analyzed.

Environmental and statistical performance testing is beyond the scope of this article. Independent statistical performance evaluation reports are available on many specific biometric devices and comparison algorithms, for instance, through the IBG or the National Institute of Standards and Technology (NIST). The following paragraph deals with the locations in biometric systems that are potentially vulnerable to attack.

Biometric System Vulnerabilities

Biometric System Threat Locations

The Common Criteria Biometric Evaluation Methodology Working Group (CCBEMWG) [7] has put together an extensive list of potential threats to a general biometric system. An example of such a threat is that an authorized user's biometric, such as a fingerprint, could be copied, unknowingly, willingly, or unwillingly, and made into a fake fingerprint and presented to the biometric device sensor by an impostor. Or, a virus could be programmed to intercept or manipulate digital data being sent from any one component to another. Databases could be hacked and templates could be inserted or deleted. System administrators may make errors in setting up matching thresholds, or even be hostile and manipulate user records and privileges on purpose. Hardware components may be bypassed, deactivated, or otherwise tampered with. Many of the threats can be partly or completely eliminated by proper system design. Nevertheless, all threat locations should ideally be analyzed. This article deals mainly with the threat of fake biometric samples.

Biometric Device Spoofing

Most biometric devices can be fooled, also known as *spoofing*, using relatively simple means. This makes that these devices still require human supervision when used in high security applications to ensure that this weakness is not exploited. Furthermore, it diminishes the forensic reliability of user traces in unsupervised biometric access control systems, as they could originate from fake biometric samples. The following paragraphs show the methods that have been tested.

Fingerprint Spoofing

The following types of fake fingerprints were tested:

1. gelatin fingerprint from silicone mold;
2. super-soft plastic fingerprint from silicone mold;
3. wood glue fingerprint from digital image of fingerprint printed on sheet;
4. rubber fingerprint stamp from digital image of fingerprint.

The first two methods require cooperation of an authorized user, as an actual finger is needed to make an impression in silicone. The last two methods require a digital image of a fingerprint. For the spoofs made here, a rolled ink fingerprint was used as source, which was then digitized using a flatbed scanner. Alternatively, one could use conventional forensic methods to get a digital photograph of a residual fingerprint that an authorized user left on some object. This can potentially be used to steal a person's fingerprint and enter a biometric system without cooperation of the authorized user. The making of the molds and the artificial fingerprints is described in the following section.

Making the Silicone Mold. We used a two-component low-viscosity silicone paste for making a mold (see Figure 11). This material captures the details of a fingerprint well, and can be used multiple times for making an artificial finger without getting damaged. The procedure entails mixing the two components in the right proportions quickly but thoroughly, and then pressing the finger into the mixture the same way one would press a fingerprint sensor. After holding still for a few minutes until the paste has dried and hardened, careful removal of the finger leaves a good quality mold.

Making a Usable Digital Image of a Fingerprint. The third and fourth spoofing methods require the digital image of the fingerprint to be binary. Digital photographs of a fingerprint residue made visible by standard forensic methods and scans of a rolled fingerprint are usually in color or grayscale format; hence, some image processing must be done. For the

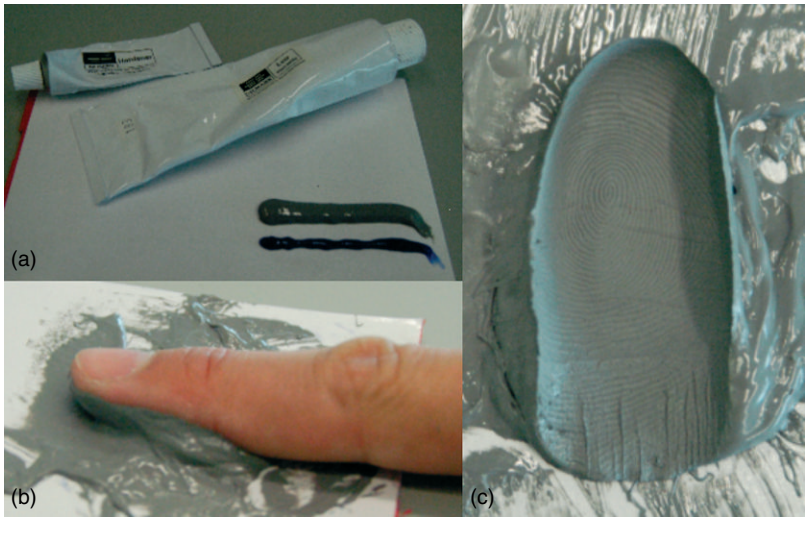

Figure 11 Making a silicone mold: (a) paste and hardener; (b) pressing finger in the mixture; and (c) the resulting mold

scanned image of the rolled fingerprint, we used an image-editing package to change the brightness and contrast with −60 and +100, respectively, effectively binarizing the image (see Figure 12). Depending on whether the image is to be used as input for a mold or a stamp, it may have to be inverted and/or mirrored.

Making the Gelatin Fingerprint. Making the so-called gummy fingers has been done extensively before [17–19]. The method involves dissolving "kitchen-quality" gelatin in near-boiling hot water and pouring it into a mold, such as the previously described silicone mold. When cooled down, the result is a flexible, transparent, yellowish cast of the finger. The main reason for using gelatin solution is that its electrical conductivity and moisture level resemble that of a human finger [17]. Sensor technologies based on such finger properties are therefore usually also responsive to this material.

A solution of approximately 55% water and 45% gelatin was used. Dissolving such relatively high amounts of gelatin in water without getting bubbles requires some practice. Gentle stirring and repeatedly cooling down and heating up the solution (while keeping below boiling point) may be necessary to allow bubbles to escape the mixture.

This spoof produced an acceptable result with all the tested scanners. It gave the best overall image quality of all the spoofs, based on visual inspection. Gelatin is cheap and available in almost every supermarket. However, durability is not very good. When kept in the open, it quickly dries and shrinks. When kept in a plastic bag it lasts longer but will become moldy. Keeping it in a refrigerator extends its lifetime. Also, it takes some practice to prepare the mixture properly. In our tests, user cooperation was needed for the mold. Note that there are other methods that can use the digital image of a fingerprint as source [19], thus only requiring a latent fingerprint.

Making the Super-Soft Plastic Fingerprint. Super-soft plastic (see Figure 13) is a nontoxic polymer that comes as a whitish opaque liquid. After heating, it turns solid when cooled down to room temperature. The result is a soft, flexible, transparent, and colorless plastic. It is typically used for creating fish lures, and may be found in some fishing shops.

A small amount of super-soft plastic is heated in a microwave just until the liquid turns completely colorless and transparent. One must keep a constant eye on the substance while heating, as it can easily overheat and consequently burn, turning yellowish and lumpy, diminishing its usability. The heated

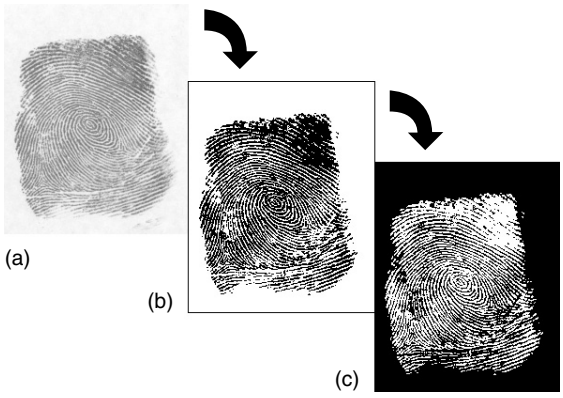

Figure 12 Processing a rolled ink fingerprint: (a) scanning; (b) binarizing; and (c) inverting

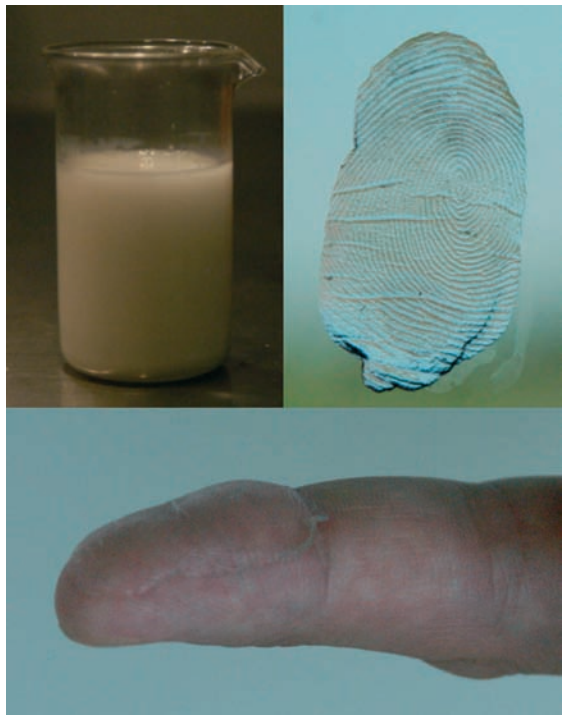

Figure 13 Super-soft plastic spoof

plastic is then poured into the silicon mold and left for some time to cool down and turn solid. For making a thin spoof, just pour in a small quantity and tilt the mold a bit to spread the liquid out over the mold surface.

This spoof was shown to be able to deceive the optical FTIR and SEIR scanners, as well as the ultrasound scanner. It can be used relatively inconspicuously when a thin specimen is stuck on a fingertip. However, because of the transparency of the material, the optical scanners sometimes show a faint impression of the underlying structure, which gets more obvious with a thinner spoof. Furthermore, it has good durability and it is very easy and cheap to produce. One does need a real finger to be able to make a proper mold.

Making the Wood Glue Fingerprint. This technique is based on the fact that when printing with a laser printer, the toner forms a relief that is deep enough to be useful for making a fingerprint mold. Water-proof wood glue is an appropriate material for the fake fingerprint, as it can be smeared out in a thin layer, dries up transparently, and returns to its dried-up shape well after bending or stretching.

This spoof can be made as follows [20] (see Figure 14):

1. Print the binarized, inverted image of the fingerprint on a plastic sheet using a laser printer.
2. Smear out a thin layer of ordinary wood glue across the image.
3. Let it dry until the glue becomes transparent.
4. Carefully peel off the layer of glue.
5. Cut the glue sheet to a size fitting your fingertip and stick it on. If it does not stick well enough by itself, use theatrical glue.

This spoof was able to deceive the FTIR and SEIR optical scanners, as well as the ultrasound scanner. The basic materials are cheap and readily available and it is quite easy to prepare this spoof. It is also the thinnest, most inconspicuous of the spoofs.

Making the Rubber Fingerprint Stamp. Professional stamp-making machines used by stamp factories need only a digital, binary image as input for making a stamp. A laser with a fixed intensity burns away the appropriate parts by passing the surface of a rubber sheet to leave a relief of the input image, up to a precision of 1000 dots per inch (DPI) (see Figure 15). The burn depth is determined by the movement speed of the laser. This speed is constant for a single stamp; thus, there can be no variation in the depth up to which the rubber is burnt away. A 25-W Trotec laser engraving machine was used to make our stamps. One can use natural as well as synthetic vulcanized rubber, the latter being more resistant to chemicals.

For a stamp to be used directly on a sensor, a binary image of a fingerprint will do. If a mold stamp

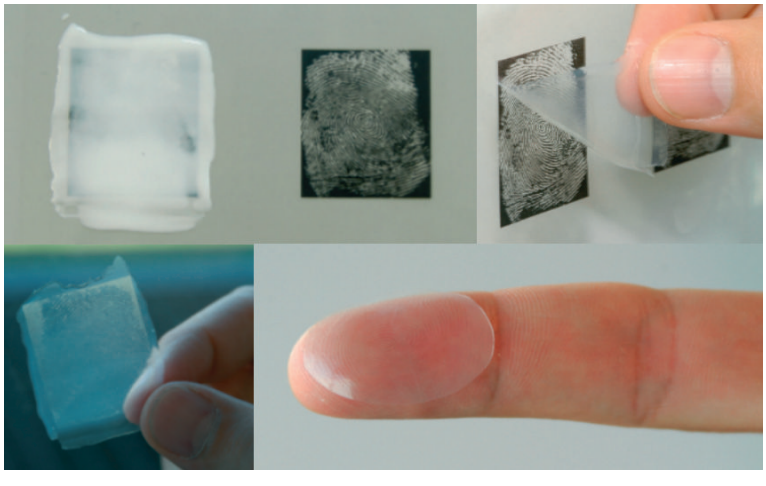

Figure 14 Making the wood glue fingerprint spoof [Reproduced with permission from Ref. 20. © Chaos Computer Club, 2004.]

Figure 15 A set of fingerprint stamp spoofs made of natural vulcanized rubber

is to be made, the image must also be inverted and mirrored. We found, however, that the method is not particularly fit for making molds, as only the surface of the protruding edges of the stamp is as smooth as the original material was, but the burnt-out parts are somewhat irregular.

The spoof was able to deceive all scanners except the ones that use electrical properties of the skin. One can, however, easily discern the spoof by visual inspection of the digital images. Durability is very good. They can be used over and over again. The fingerprint image that is needed can be made with some knowledge of basic image-processing software. Many stamp makers allow online ordering of stamps, where stamp images can be uploaded, making access to the technology quite easy. In addition, making stamps is quite cheap.

Spoof Capture Examples. Figure 16 shows examples of the images acquired when presenting each of the spoof types to an SEIR fingerprint scanner. Figure 17 shows images from eight different fingerprint scanners for the most successful artificial fingerprint: the gelatin spoof. The gelatin spoof passed verification with all software that we tested.

Iris Spoofing

For this test, a low-end desktop iris scanner was used with biometric software, which enables logging on to a computer using iris verification. A live iris was enrolled into the database and fake irises were presented to the camera. Our tests confirm previous successful tests [20] in which a basic iris scanner was fooled using a paper photocopy of an iris. We, however, used much lower resolution images than were thus far considered necessary. Note that high-end iris scanner such as those used at airports have several antispoofing measures incorporated, preventing the use of paper irises.

Paper Iris Method. All that is needed is a black-and-white low-resolution image of the authorized user's iris printed on paper (see Figure 18). As the scanner does check for the presence of a retina reflection, the pupil must be cut out to allow the user to look through the hole when presenting the paper iris. When taking a photograph of the iris, care must be taken not to "pollute" the iris region with reflections. One can photograph through a tube to get a good result, and when the photo is taken from the front, any flash reflection will be inside the pupil region.

In the tests, irises from both a 6 megapixel portrait photograph and a 6 megapixel close-up of the eye were used, which after rescaling to actual size resulted in a 240 and 500 pixels per inch (PPI)

Figure 16 Comparison of images from an optical SEIR scanner using a live finger and fake fingerprints

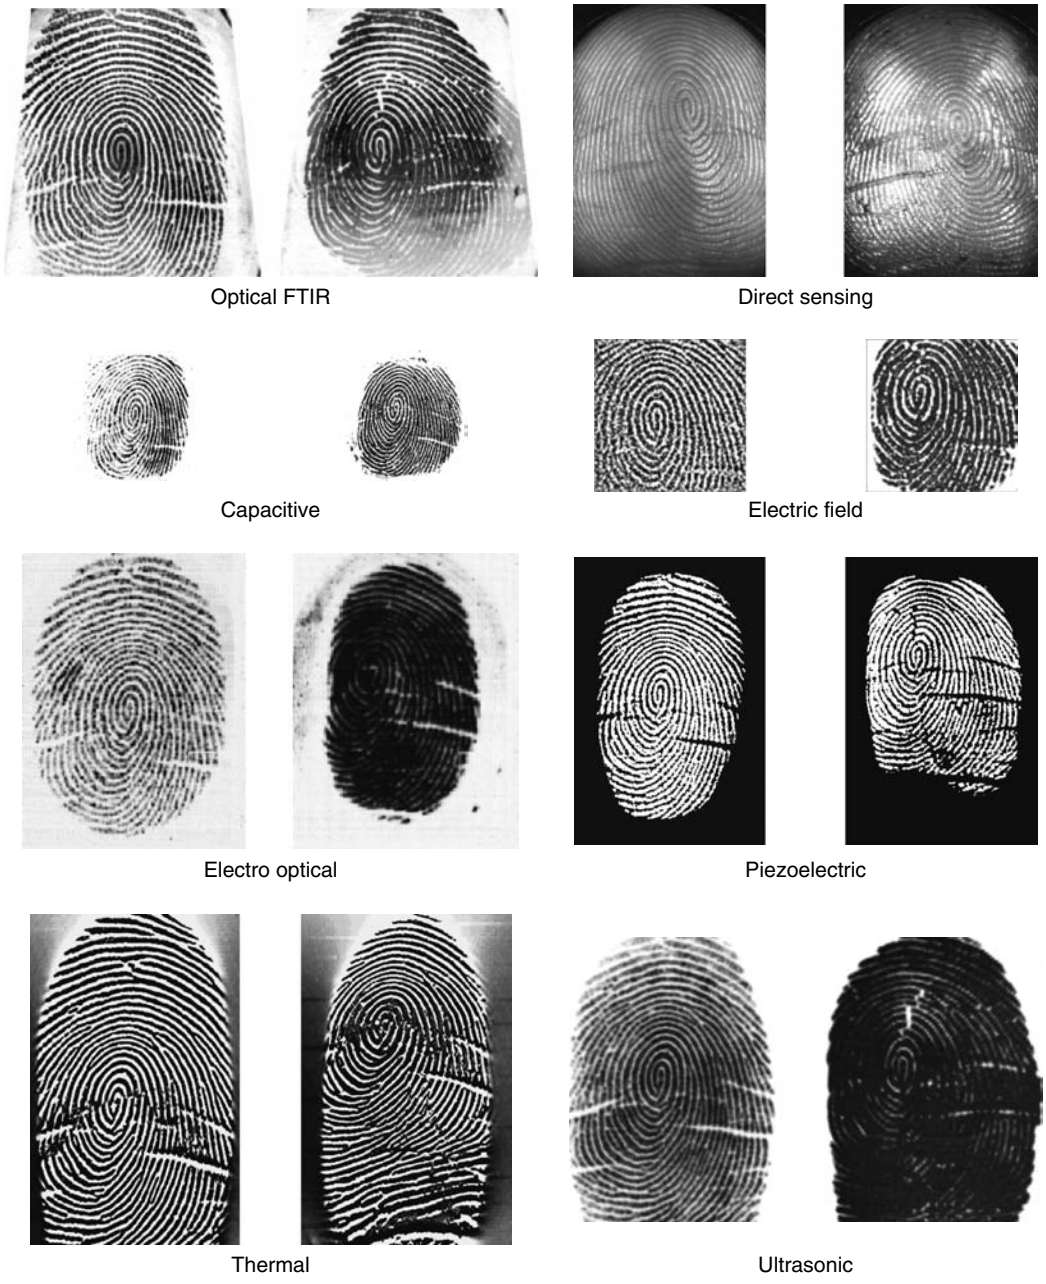

Figure 17 Images acquired using eight different fingerprint scanner technologies. The left of each pair shows a natural finger, the right shows a gelatin spoof

image, respectively. The images where printed using 600 DPI laser printer. After some practice, it was quite easy to pass the system using the fake irises, especially with the 500 PPI version. So far, we have only been able to spoof the device using copies of light eyes.

To test the usability of old photographs, a similar test was also done using an analog photograph of

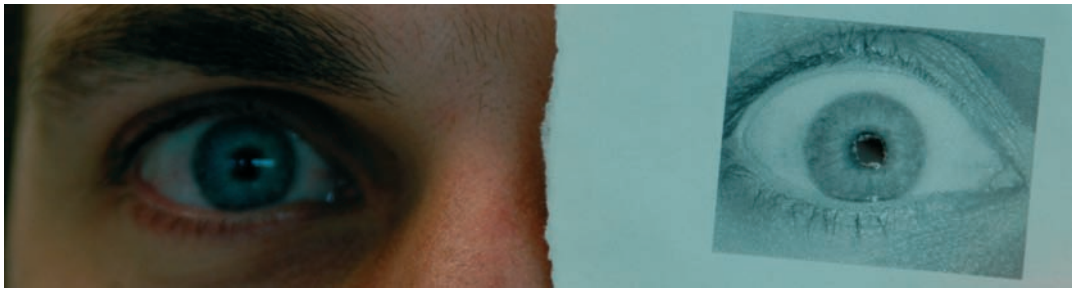

Figure 18 Original live iris and the paper spoof

the authorized user from his childhood (from over 20 years ago). The photo was scanned to digital format and slightly brightened to make the details stand out more. The paper spoof created with this image was also accepted for verification.

Hand Geometry Spoofing

Our tests have shown that a basic hand geometry recognition device can, in principle, be deceived using something other than an actual hand, when security level is set somewhat below the factory setting. Furthermore, an unauthorized user with approximately the same hand size as the authorized user scores reasonably well, confirming the well-known fact that hand geometry uniqueness can be an issue [21].

Paper Hand Method. The image extraction method used in hand geometry recognition suggests that it need not be presented with an actual 3D hand for getting a valid result, as only the side views are captured. Furthermore, judging from a hand geometry recognition patent [22] (see Figure 19), the influence of the side view is not expected to be so big. The figure shows that the side view of the hand accounts for a relatively small part of the information captured by hand geometry recognition devices.

Tests show that a top view silhouette of a hand cut out in paper can indeed be enough to pass the verification check of the device, albeit at a lowered security level. Thus, this is not a representation of practical use of the device.

The paper hand can be made as follows (see Figure 20):

1. Measure the sizes and relative positions of the guidance pegs.
2. Precisely draw the pegs in the proper configuration using drawing software and print it on a transparent sheet (alternatively, print it on paper, and then copy it on sheet).
3. Make a photocopy of the authorized user's hand with a photocopier. Use the sheet with the peg configuration to properly position the hand and fingers on the copier.

Figure 19 Typical image captured by a hand geometry recognition device

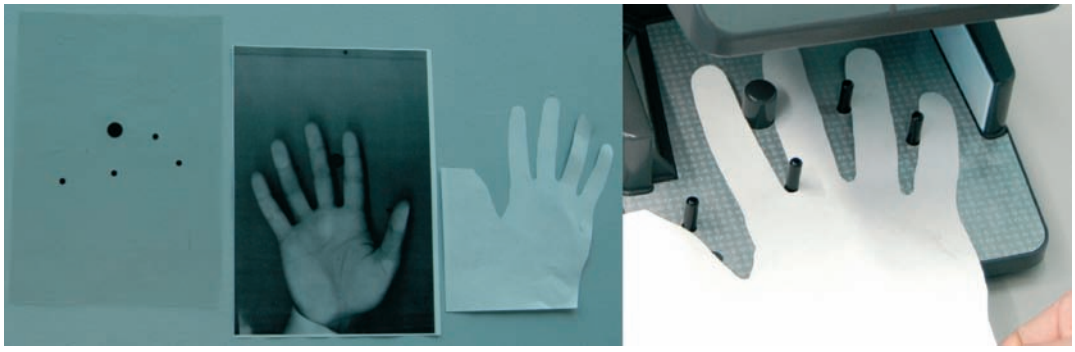

Figure 20 Hand geometry verification device spoofing at lowered security settings

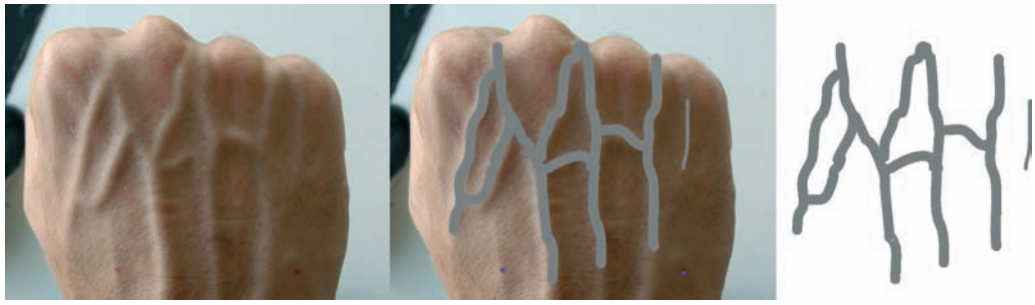

Figure 21 Obtaining a vascular pattern using a digital camera: (a) image of the back of a hand shot in daylight using a common digital photo camera; (b) visible veins manually traced using image-processing software; and (c) the drawn layer ready for printing

4. Cut out the paper hand.

It is expected that the quality of the spoof can still be improved by cutting a more accurate representation of the hand top view. In addition, adding the side view silhouette to the paper hand is expected to improve matching scores. Currently, however, an actual authorized hand gives better scores than the paper hand spoof.

Hand Vascular Pattern Spoofing

For hand vascular pattern spoofing, deceiving the biometric pattern capture and recognition part does not suffice. The liveness detection also has to be passed. With the device we tested, we were not successful in spoofing both at the same time. However, the liveness detection can be turned off by the system administrator. We found that with liveness detection turned totally off, a paper printout of the vascular pattern of an authorized user can be enough to pass the verification. Also, with liveness detection turned totally off, a paper printout of a person's vascular pattern can be enrolled. Then, when turning the liveness detection back on, the actual person can log into the system using his own hand. Hence, we can conclude that the biometric pattern recognition part can be spoofed. The method for making the partial spoof is elaborated below.

Vascular Pattern Printout Method (Partial Spoof). Basically, one must create a gray-and-white copy of the pattern of the veins on the back of the hand. Some people have clearly visible veins that lie close to the surface of the skin, in which case a normal digital photograph of the top view of the hand in enrollment attitude will do as a starting point (see Figure 21a). In that case, the following procedure can be followed:

1. Draw reference dots on the back of the hand at known distances from each other. These can be used later to scale the photograph to the right size.
2. Take a photograph of the top view of the back of the hand (Figure 21a). The hand should have the same attitude as it would have when enrolling.
3. Use image-processing software that can work with layers to manually trace the vein pattern (Figure 21b).
4. Print just the drawn layer in the actual size (scale the picture using reference dots). Color contrast of lines and background should not be too great. Gray value 128 on a white background works fine (Figure 21c).

If the veins are not sufficiently discernable in visible light, a camera with "nightshot" function can be used. Such cameras use a near-infrared lamp to illuminate the target and a sensor array that is sensitive to near-infrared light to capture the reflecting rays. The quality of the nightshot function varies with camera type. In this experiment, a Sony DCR-TRV9E digital video camera recorder was used with good results. The spoof can be made as follows (see Figure 22):

1. Cover the camera-mounted near-infrared lamp with some sheets of tissue. This blocks a portion of the light, which is necessary to prevent spots of overexposure that make postprocessing more difficult.
2. In a dark room, take a shot of the top view of the back of the hand using the nightshot function of the camera. The hand should have the same attitude as it would have when enrolling. One can include a measuring stick at the same height as the back of the hand to the shot to facilitate scaling later on.
3. Use either the previously discussed tracing method or a sequence of image-processing filters to obtain a two-color representation of the vascular pattern. An example of a filter sequence that was used in this test is as follows:
   (a) Apply a Gaussian blur on the image. Use a blur radius large enough to make the details fade. We used a radius of 25 pixels for a 720 × 576 pixel image.
   (b) Subtract the blurred image from the original. This reduces the more global differences in intensity that may be present due to uneven lighting conditions.
   (c) Binarize the image using a gray value threshold that leaves the veins well visible.
   (d) Apply a Gaussian blur on the image. Use a blur radius large enough to make pixels that make out the veins connect, but small enough to keep the vein lines standing out. We used a radius of 3 pixels for a 720 × 576 pixel image.
   (e) Binarize the image again using a gray value threshold that leaves the veins well visible.
   (f) Lower the contrast by changing black to gray (for example, gray value 128).
4. Scale the image, and thus it represents the actual size and print the resulting image.

The paper pattern can be stuck on someone's hand or anything else, such as a bottle. When presenting the spoof to the vascular pattern scanner, care must be taken to match the pattern position with the position

Figure 22 Processing a vascular pattern from a nightshot camera to a usable spoof: (a) nightshot camera image; (b) half-way processed; and (c) fully processed

of original live hand, as the devices can be very sensitive to shifting of the pattern.

Conclusion

It is evident that the current state of the art of biometric devices leaves much to be desired. A major deficit in the security that the devices offer is the absence of effective "liveness" detection. At this time, the devices tested require human supervision to be sure that no fake biometric is used to pass the system. This, however, negates some of the benefits these technologies potentially offer, such as high-throughput automated access control and remote authentication. On a positive note, biometric device technologies are constantly evolving; thus, current weaknesses may well be overcome in the near future.

The independent testing of biometric devices is still nontrivial as manufacturers tend to oversell the capabilities of their products. The latter can give a false sense of security, adversely affecting actual security if not recognized in time. It is an issue that we encounter in many forms of technology today; if it can be cracked, it will be cracked. Accepting this would need a different attitude of manufacturers, in which more of what is going on inside the device and the accompanying software is made public. It would allow potential users of biometric systems to better judge the fitness of such systems for their particular purposes.

From a forensic point of view, care should be taken when drawing conclusions from information extracted from access control systems that use biometric devices. The possibility that the system was compromised, falsely linking persons to events consequently, should be examined or at least noted in the forensic examination report.

Blood Grouping

Introduction

Before Sir Alec Jeffrey's pioneering discovery of the power of DNA fingerprinting in 1984 [1] and its first use in a criminal case in 1986, human identification, relationship testing and population studies were done through assessment of protein variation seen in blood groups and various proteins found within body fluids.

Enzymes and other proteins exist in different isoforms and are observed as *phenotypes* (*see also* **Phenotype**) through the use of techniques such as electrophoresis. Different phenotypes may result from different genotypes, the genetic instructions that result in the different protein forms, or *alleles*, that are translated, but can also be produced through the influence of environmental factors, various subunit interactions or different posttranslational modifications.

Polymorphism (*see also* **Polymorphism: Genetic**) exists when more than one phenotype exists and is very common. It results from evolutionary forces relating to genetic selection, adaptation, and biodiversity. Polymorphisms are heritable factors and only change if a mutation occurs between parent and offspring. Unlike DNA short tandem repeat polymorphism, the current technique used for human identification, mutant events in gene products between parent and child are rare because a genetic mutation is likely to result in a dysfunctional or nonfunctional product associated with disease implications or with potentially lethal effects.

To be considered a polymorphism, the least common form should be seen in at least 1% of the population to distinguish this from products of random mutation events [2].

Protein polymorphisms are the result of changes in amino acid composition, which can affect both structure and function. Traditionally, these have been investigated using electrophoretic techniques. The charge exhibited by a protein depends on the relative content of basic and acidic amino acid residues and its environmental pH. At a low pH, basic amino acids gain protons (H^+) and become positively charged, and move toward the cathode in an electrophoresis tank. At a high pH, this is reversed: the acidic amino acids lose protons, acquire negative charges, and travel toward the anode.

The point at which net charge is zero is the *isoelectric point*, and is, therefore, the point at which electrophoretic mobility is zero. *Isoelectric focusing* (*IEF*) [3], like simple electrophoresis, is a technique for separating different molecules according to their electrical charge, but provides greater resolution by taking advantage of the fact that the electric charge of a protein varies according to the pH of its environment. For example, standard electrophoresis identifies only three variants of the polymorphic phosphoglucomutase (PGM) protein system, whereas IEF distinguishes 10 variants. A pH gradient can be produced in a medium with the use of *ampholytes,* molecules that have both basic and acidic groups. A variety of *polyampholytes* with different isoelectric points are introduced to a starch, agarose, or polyacrylamide gel, and an electric current applied, producing an immobilized medium, graded according to its pH. Proteins to be analyzed are then introduced into the process and are separated according to their isoelectric point. Use of this technique produces gel bands that are much sharper than other gels.

While *protein polymorphisms* are those nonmembrane bound proteins found in blood or body fluids, or intracellularly, *blood group polymorphisms* are restricted to blood cell surface *antigens*, although the ABO blood group is an exception to this, as the A, B, and H antigens of this system are found in various body secretions in some individuals (*secretors*). Blood groups are inherited characters of the red cell surface (antigens) that are detected by specific *alloantibodies* and the defining interactions are observed when an antigen–antibody reaction takes place in a group of red cells and they *agglutinate*.

Typing of samples by immunogenic testing or electrophoresis is not only very time consuming but also requires significant expertise, so that the processes are properly executed and the correct interpretation made. Problems can occur if rare variants are not recognized because of their unusual presentation, or if gel resolution is poor. All of these factors can result in typing errors. Although this form of typing can be speeded up with the use of microtiter plates, for example, this is not sufficient with the speed of throughput required in the expansion of forensic identification. In electrophoresis, although several samples can be introduced on to a single gel, in IEF only one system can be typed per gel because of the different pH gradients required, and in other systems specialized development techniques are often required to detect the particular proteins concerned. It is for these reasons that these systems have gradually been phased out in favor of DNA analysis.

DNA (*see also* **DNA**) is the genetic code that provides the instructions for proteins to be produced, according to the particular sequence of nucleotides along a DNA strand. In its natural state, DNA is a double-stranded molecule with two antiparallel polynucleotide strands, assembled into chromosomes. The particular nuclear DNA inherited by an individual is contributed to equally by both parents and results in individuals having two alleles for every protein sequence. Individuals who inherit the same allele (gene sequence at a particular locus), from both parents are said to be *homozygous* for that allele, whereas individuals who inherit different alleles are *heterozygous* at this locus.

Nucleotides are the basic building block of the DNA molecule and consist of a base, a deoxyribose sugar, and a phosphate group. Nucleotides differ only according to the base they carry. There are four different bases: the purines, A (adenine) and G (guanine), and the pyrimidines, C (cytosine) and T (thymine); the double strand of the DNA is stabilized with hydrogen bonds between complementary bases, A pairs with T, and G with C.

In a sequence of nucleotides, a group of three nucleotides (*a codon*) codes for a particular amino acid, which, on translation, determines the primary structure of a molecule. Proteins are the products of genes, or combination of genes, that are present within *exons* on DNA strands, being separated from each other with noncoding portions (*introns*). The sequence details are first converted into messenger ribonucleic acid (mRNA) and intron sequences removed to leave the exons in series. Proteins are synthesized through translation of the amino acid sequences which determine primary, secondary and tertiary structure of the protein. Protein polymorphisms can result from genetic changes and, in principle, classical markers can be predicted through examination of the genetic material.

Most protein polymorphisms are the results of single amino acid substitutions, often through missense mutations (*single nucleotide polymorphism* or *SNP*), in which one nucleotide is altered in a codon, leading to a different amino acid being produced. For such changes to be detectable using electrophoresis, this change has to alter the charge or isoelectric point of

the protein. Some mutations do not result in changes in amino acids as some codons code for the same nucleotide.

Polymorphisms can also be the results of insertions or deletions that produce *frame shifts*. These also disturb the codon sequences and hence lead to changes in amino acid sequences. Sometimes, recombination events may be unbalanced and can produce subtle protein changes that are not detected through examination of the genetic structure.

While DNA profiling has, understandably, replaced the use of classical markers in forensic identification, the ability to examine many of these polymorphisms with modern genetic methods means that these systems can be revisited and have already been utilized in "cold" case reviews. Molecular analysis further offers the opportunity to predict classical polymorphisms in small and degraded samples, and the technique is not restricted to a particular cellular source.

Blood Group Polymorphisms

While any variation detected in blood could be considered to be a blood group, the term is normally restricted to red blood cell surface antigens. These antigens are detected by *alloantibodies* (which are naturally occurring), or as a result of *alloimmunization* with red cells (through blood transfusion or from a fetus during pregnancy).

The entity of a blood group was first described by Landsteiner [4] in 1900 when he reported how the plasma of some individuals agglutinated the red cells of others. Not all antibodies lead to direct agglutination and it was only after 1945, when Coombs and others [5] developed the antiglobulin test, that many new antigens that describe a large number of different blood groups have been discovered. Only a few of these have traditionally been used by the forensic scientist.

Blood group antigen determinants are the result of two main types: proteins or carbohydrates. They have a number of fundamental differences: while most blood group antigens are synthesized in the red cell, some antigens result from adsorption on to the cell from plasma, and while most antigens are only detected on red cells, others are found throughout in secretions.

ABO Blood Group System

Pioneering research in the first quarter of the twentieth century led to a basic understanding of this blood group system in which it was shown that only three alleles at one locus could describe the four different blood groups, A, B, AB, and O (although many subtypes have since been defined).

The A and B red cell antigens are modifications of the H antigen. The H antigen is defined by a specific chain of carbohydrates produced by the O gene and individuals with this antigen form blood group O. Inheritance of the A gene or B gene, which codes for different glycosyl transferases (acetylgalactosaminyl-tranferase and galactosyl-transferase, respectively), enables the movement of particular terminal immunodominant sugars to the H antigen, leading to blood groups A and B, respectively [6]. In comparison with the other blood groups the H gene (fucosyltransferase1 FUT1) has a nucleotide deletion, which results in a truncated protein that has no active transferase. Some rare individuals lack the H gene (*Bombay blood* group) and therefore have no H antigen on their red cells, neither do they produce A or B antigens, even if they have the appropriate glycosyl transferase [7]. Table 1 defines the main characteristics of the ABO blood group system.

The H antigen is also present in body secretions of about 80% of Europeans (*secretor*) [8, 9], determined by the FUT2 gene [10]. Secretors of H substance also secrete A or B if they are of the appropriate group. Nonsecretors do not secrete H, A, or B. The ability to secrete H substance is also related to the phenotypes observed within another blood group system, Lewis [11].

ABO blood group typing of liquid blood may be undertaken by mixing red cells of an individual with appropriate antisera (*forward group*), or by mixing the plasma from an individual with

Table 1 Characteristics of the ABO blood group system

Blood group (phenotype)	Genotype	Red cell antigen	Serum antibody
A	AA or AO	A	Anti-B
B	BB or BO	B	Anti-A
AB	AB	A and B	None
O	OO	Absent	Anti-A,B

Table 2 ABO forward and reverse grouping
Forward grouping uses red cells from a person and antisera

Cells from blood group	Anti-A	Anti-B	Anti-AB
A	+	−	+
B	−	+	+
AB	+	+	+
O	−	−	−

Reverse grouping uses serum from a person and indicator red cells

Serum from blood group	A cells	B cells	AB cells	O cells
A	−	+	+	−
B	+	−	+	−
AB	−	−	−	−
O	+	+	+	−

appropriate red cells (*reverse group*). For example, cells from a blood group A individual are agglutinated by serum from a group B person, and a group O person, as both of them have anti-A in their serum. Serum from a blood group A individual has anti-B in his plasma and therefore, agglutinates the red cells of someone with blood group B, or AB. Table 2 illustrates the reactions.

In forensic analysis, blood stains may often be found dry on a substrate. In this case, an *absorption-elution* technique is used [12]. In this technique, portions of the bloodstained material are exposed to the different antisera. In the presence of the corresponding antigen and antibody, a complex forms within the stained material, which is then washed to remove any unbound antibody. Raising the temperature of the liquid in which the stained material is placed to about 50 °C–60 °C, dissociates antigen and antibody. If a complex had been formed in the initial part of the test, then antibody is now eluted into the surrounding fluid and addition of the appropriate red cells result in agglutination, visible in the fluid.

For example, if the dried blood comes from a group A individual, then mixing the stain with anti-A forms an antigen-antibody complex. After removal of excess antisera, the bound anti-A can be eluted and agglutinate A cells, but not B cells. In contrast, mixing the stain with anti-B does not result in an antigen–antibody complex, and any antisera present is washed away. Because no antibody has been bound, there is nothing to be eluted and no agglutination occurs, whatever the red cells added. Although the technique is very sensitive, antisera that work with fresh stains may not be sufficiently strong to detect antigens in older stains and adjustments may be made in the antiserum dilution used. Factors affecting the elution of antibodies from bloodstains are discussed in a publication by Lincoln and Dodd [13].

Determination of the ABO blood group can also be made through the typing of body fluids amongst individuals who are *secretors* of ABH substance. *Lewis* antigens are also tissue antigens, carbohydrates, which are adsorbed onto red cells. They require a FUT for the expression of the Le antigen, coded for by the FUT3 gene [14]. There are two alleles, Le^a and Le^b, expressed by individuals who have the Le gene. In 1948, it was noted by Grubb [15] that most people with the Le^a antigen, having Le (a+) red cells detected by anti-Le^a, did not secrete ABH substance (*nonsecretors*). A general rule has developed: Le (a + b−) cells come from nonsecretors; Le (a − b+) come from secretors, and Le (a − b−) cells come from either.

Grubb later proposed a theory that explained the different observations [16]. It was stated that the presence of Le^a was controlled by a single locus, Le (LE or FUT3 gene), while Le^b appeared to be an interaction between Lewis and the secretor gene, present on the same chromosome. People with the Lewis (Le) and secretor (Se) genes have both Le^a and Le^b in their secretions, but have Le (a − b+)

Table 3 Interaction between Lewis and secretor genes and resultant phenotypes

Genotype		Red cell	Body fluid		
Lewis	Secretor	Lewis phenotype	Secretor of H	Secretor of Le^a	Secretor of Le^b
LeLe or Lele	SeSe or Sese	Le (a − b+)	Yes	Yes	Yes
	Se^wSe^w or Se^wse	Le (a + b+)	Weak	Yes	Yes
	sese	Le (a + b−)	No	Yes	No
Lele	Any	Le (a − b−)	Yes or no	No	No

red cells. Individuals who have the Lewis (Le) gene, but are homozygous for se, the nonsecretor allele, have only Le^a in their saliva and Le (a + b−) red cells. Some secretor genes are weak (Se^w) allowing the expression of Le^a and Le^b, with Le (a + b+) red cells. Table 3 summarizes these variant phenotypes in a person whose blood group is O (expressing the H antigen only).

Although these substances can be found in a wide range of body fluids, forensic analysis is normally concerned with saliva or semen. Their detection requires an indirect technique because there are no cells to agglutinate. The detection of Le^a and Le^b is detected using an *absorption-elution* technique, as described earlier. This method can also be used to detect ABH in secretions but, because of the very high levels of these substances in secretors, greater care must be taken, and the methodology requires the use of a set of dilutions [17] and both *absorption-inhibition* and absorption-elution techniques.

The absorption-inhibition technique is less sensitive than the elution method, but is suitable for detection of ABH, particularly, because its concentration is relatively high and its implementation in a variety of fluids with different concentrations of soluble antigens is improved with use of several dilutions [18]. Antiserum is added to the fluid and antigen–antibody complexes are allowed to form. If antigen is present, then most of the antibody is bound. Subsequent addition of red cells containing the relevant antigen leads to agglutination if there is plenty of free antibody (and no antigen), or agglutination is absent, or weak, if antigen were originally present in the fluid. It must be remembered, however, that in dealing with forensic material that might be susceptible to bacterial contamination, spurious results may occur. *Escherichia coli*, a common contaminating bacterium, for example, produces B-like, and sometimes A-like substances that can lead to discrepant typing [19, 20].

For ABO grouping, antisera are needed against A, B, and H antigens. Anti-A and anti-B are available from the serum of people of blood groups B and A, respectively. Anti-H can be found as a lectin (seed extract) prepared from *Ulex europaeus*, which contains a phytohemagglutinin specific for the H antigen [21]. Table 4 illustrates the type of results that are obtained using these techniques in saliva.

Pre-DNA forensic cases often have serological typing undertaken and confirmation of these in material from cold cases can require a return to older techniques. This is not a problem for blood group polymorphisms because antisera and indicator cells remain readily available because of their use in blood

Table 4 Grouping of saliva using absorption-inhibition and absorption-elution methods

Group	Method	Anti-A then A cells	Anti-B then B cells	Anti-H then O cells
A secretor	Inhibition	−	+	−
	Elution	+	−	−
B secretor	Inhibition	+	−	−
	Elution	−	+	−
O secretor	Inhibition	+	+	−
	Elution	−	−	+
B nonsecretor	Inhibition	+	+	+
	Elution	−	−	−

transfusion laboratories. Nevertheless, it may be useful to use genetic methods that are more sensitive: detection of SNPs found at the ABO blood group locus has been found to provide reliable typing as low as 200 pg [22].

Cloning of the ABO gene in 1990 [23] has led to the development of various molecular techniques to predict ABO blood group phenotype. The coding region of the gene has seven exons over 18 kb with exons 6 and 7 containing most of the coding sequence. SNPs in exon 7 distinguish between groups A and B, whereas O is defined through SNPs in exon 6 and 7 [24]. While many different alleles have been described, reflecting mutations in the gene, most of these are not important in determining phenotype and SNP analysis can provide a cost-effective, sensitive, and rapid methodology for typing of many classical markers. cDNA, produced from isolated RNA, has shown that A and B cDNA differ by seven nucleotides that lead to four amino acid differences between the *A*- and *B*-transferases that produce the A and B antigens [25]. The O sequence is identical to in its first part, except that there is a single base deletion, which results in a frame shift and produces a premature "stop" signal, leading to a truncated protein produced with no transferase activity [26].

ABO frequencies differ across the world. Individuals originating from western and central Europe have high frequencies of both group O and A. In America, and in parts of African and Australia, group O is the most common. Indeed, in South America, some populations are mainly group O, suggesting that they were group O before the European invasion [9]. While the frequency of A is high in most of Europe, especially in the northwest, it is rare in virtually all of the other indigenous populations. Group B is most prevalent in central Asia with a clinal decline, east to west, across Europe [27]. Table 5 gives estimated frequencies of ABO phenotypes across three different population groups.

Table 5 ABO blood group frequency estimates across three populations (Caucasian, black, and South Asian) resident in the United Kingdom [28]

Blood Group	Caucasian	Black	South Asian
A	0.410	0.228	0.238
B	0.111	0.225	0.287
AB	0.027	0.043	0.087
O	0.452	0.505	0.388

MNS Blood Group System

The MNS blood group system was first fully described by Sanger and Race in the middle of the twentieth century [29]. M and N were first described by Landsteiner and Levine in 1927 [30], but were later found to be associated in some way with S [31]. About 86% of individuals who possessed the S antigen, also had the M antigen [32]; later, when the *s* allele was identified, family studies showed that the MN and Ss blood group systems were, indeed, closely linked (unlikely to be separated by recombination events) and so are usefully considered together as a complex blood group system [33]. Both MN and Ss are polymorphic in all populations and provide valuable additional discrimination in human identification of blood. In a Caucasian population, about 28% have MM, 22% have NN, and 50% have both: MN. Similarly, about 11% have SS, 45% ss, and 44% Ss.

Unlike in the ABO blood group system, antibodies to M and, especially, to N are not very common and, originally, typing was done in the cold using antibodies produced in rabbits [34]. The seeds of the *Vicea graminea* plant were also shown to have potent anti-N activity [35]. Anti-M and anti-N are cold-reacting and agglutinate at room temperature, like ABO. In contrast anti-*S* and anti-s are immune antibodies, active at 37 °, and so these antibodies can be identified within serum of exposed individuals. Anti-s is, however, very rare [36], and the presence of the s antigen is usually inferred from the absence of the S antigen in people of non-African origin.

S, with or without s, is associated with the U antigen, discovered by Wiener [37] in the mid-1950s, and individuals who express neither S nor *s* also tend to have absent or very low levels of U. Wiener proposed that a pair of alleles control the expression of U. Individuals without the U antigen are defined as"*u*", meaning an absence of U. Its association with Ss led to the definition of the S^u antigen for the silent gene at the *Ss* locus that also produces no antigen (S-s-U-, or S-s-u). Although U− red cells are almost always S-s-, about 50% of S-s- cells are U+, although the strength of the U antigen in these is variable, and it is generally considered as a variant allele of U. The presence of this variant U is almost exclusively

confined to people of African origin [38]. Individuals with S^u have a deficient or truncated glycophorin B GPB molecule [39]. The prevalence of u amongst blacks, albeit low, means that MNSs typing amongst this population should include the use of anti-*s*.

More recent methods have allowed the manufacture of *monoclonal* antibodies. Monoclonal antibodies are typically made by fusing myeloma cells (cancer cells that can be maintained *in vitro*) with the spleen cells (containing antibody-secreting cells but which die *in vitro*) from a mouse that has been immunized with the desired antigen, and the antibody reagent is produced by clones (*murine hybridomas*) [40].

The lipid membrane of red cells contains many proteins and glycoproteins [41]. Some are heavily glycosylated (are *glycophorins*) and two carry the MN and Ss determinants – GPA and GPB, respectively.

The M and N antigens differ according to the amino acid sequence of GPA, three nucleotide substitutions producing two amino acid changes. M individuals have serine at position 1 and glycine at position 5; in contrast N individuals have leucine and glutamic acid, respectively, in these positions [42]. The determination of the S and s antigens depends on a single amino acid substitution (Met-Thr) at position 29 [43]. Both of these SNP variants can be used in molecular assays to predict MNSs blood type from any nucleated material.

M and N are much less variable between populations across Europe, Africa, and East Asia, being around the 50% level [44]. High levels of M (over 90%) are found in Native Americans and low levels (down to 2%) are found in the Pacifics [27, 45]. S is less common in the Far East than in Europe and both *S* and *s* are almost always found in Caucasians, although about 1% of Africans lack both (S-s- or S^u) [27]. Table 6 shows the estimated frequency of the different linked MNSs blood groups across three population groups.

Table 6 MNSs blood group frequency estimates across three populations (Caucasian, black, and South Asian) resident in the United Kingdom [28]

Phenotype	Caucasian	Black	South Asian
MS	0.058	0.003	0.051

MNS^u		0.006	

Rhesus Blood Group System

The Rhesus blood group system is the most complex of the blood group systems consisting of 46 different antigens.

In 1940, Landsteiner and Wiener injected the blood of a Macacus rhesus monkey into guinea pigs and rabbits [46]. The antiserum obtained not only agglutinated rhesus monkey red cells but also approximately 85% of a panel of New Yorkers. A lack of association with any of the other known blood groups made Landsteiner and Wiener realize that they had detected a new blood group antigen. They named the antibody as anti-Rh and individuals whose blood was agglutinated by this reagent as Rh positive, in contrast with the nonreactors, which they termed Rh negative. Family studies showed that Rh positive was inherited as a dominant factor [47].

Prior to Landsteiner and Wiener's work, Levine and Stetson had published a case study about a woman who had delivered a stillborn baby [48]. Shortly after the birth, she received a blood transfusion from her husband and had a hemolytic reaction. It was proposed that she had become immunized by being exposed to a "foreign" fetal antigen inherited from the father, and the antibodies that were produced agglutinating the husband's red cells on their transfusion. This report was the catalyst for a series of papers in which Wiener and others showed that the antibody was the same anti-Rh factor that Landsteiner and Wiener had described and that it was owing to the immunization of an Rh-negative mother by red cells from an Rh-positive fetus, *in utero*. They also showed that antibody in the mother could cross the placenta and result in the condition of *erythroblastosis foetalis*, now known as *hemolytic disease of the newborn*, that can lead to severe anemia or death of the fetus (*hydrops fetalis*) [49]. Soon, this antibody was described in several cases of transfusion reaction in which ABO compatible blood had been given [50].

In fact, the anti-Rh that was produced in animals was soon shown to be different from that produced within humans, but by this time, the term Rh had become established in the literature [51].

Some antisera did not seem to react in the same way as others, and it was soon realized that there may be more than one Rh antigen. On both sides of the Atlantic, researchers were coming to very similar conclusions as to how these new antigens were related. Other antisera with different Rh specificities were reported: Wiener had three antisera that defined six alleles [52], and Race had four antisera that defined seven alleles [53]. Apart from anti-Rh, antibodies with different specificities were called *anti-Rh_1*, *anti-Rh_2* and *St*. This led to two different theories to describe and name the various Rh blood group antigens: that developed by *Fisher* and *Race* is perhaps the easier to understand [54], but can be fully related to the nomenclature proposed by *Wiener* [55].

Wiener's theory proposed multiple alleles at a single locus. He suggested that each gene encoded for an "agglutinogen" (antigen), which he called R^1, R^2, R^o, R^z, r, r', r'', and r^y, composed of several blood factors, Rh^o, rh', rh'', hr' and hr''.

Fisher's hypothesis was based on the observation that two of Race's four antibodies were antithetical [54]; everyone either reacted with one person or the other, but not both. He called these anti-C and anti-c, recognizing the C and c antigens. The other two antibodies did not share this pairing characteristic and were later shown to be anti-D and anti-E. The *Fisher–Race* hypothesis proposed three closely linked loci, C or c, D or d, and E or e, inherited as a *haplotype*. Apart from anti-d, all the other antibodies against each of these proposed antigens have been described. Although d is used in the nomenclature, it is now considered to be a silent allele. Anti-D was the same as the original anti-Rh, and thus it is just the presence or absence of the D antigen that defines whether someone is defined as Rh positive, or Rh negative.

While D, in the Fisher–Race nomenclature, has been shown to be the same as Wiener's blood factor Rh^o, rh' and rh'' are the same as C and c, and hr' and hr'' translate into E and e. Table 7 shows how these two nomenclatures are interchangeable and identify the eight haplotypes of Fisher–Race, or the eight Rh–Hr agglutinogens of Wiener. Agglutinogens named with an R indicate the presence of the D antigen; those named r do not have the D antigen.

In 1986, Tippett [56], on the basis of her observations of rare complexes with aberrant expression of the Rh antigens, proposed two genes, closely linked, one coding for D and the other coding for the CcEe antigens. This model has since been shown to be close to the truth.

Most Rh antibodies used for testing are immune, are IgG, and react with antigen optimally at 37 °C [9]. Preparation of antisera for typing requires very careful assessment to ensure that the antisera are of sufficient strength and specificity [57]. Some antibodies are "complete" and require only incubation with the antigen in saline to produce agglutination, whereas other "incomplete" antibodies require other treatment. Complete antibodies are normally IgM, and incomplete are IgG. IgM is a pentamer, and this makes it more able to bind to several antigen receptors on different red cells, facilitating agglutination. IgG, in

Table 7 Components of the Rh blood group system according to nomenclatures proposed by Fisher–Race and Wiener

Fisher–Race nomenclature	Wiener nomenclature			
Haplotype	Rh–Hr agglutinogen	Blood factors		
CDe	R^1	rh'	Rh^o	hr''
cDE	R^2	rh''	Rh^o	hr'
cDe	R^o	rh''	Rh^o	hr''
CDE	R^z	rh'	Rh^o	hr'
Cde	r'	rh'		hr''
cdE	r''	rh''		hr'
CdE	r^y	rh'		hr'
cde	r	rh''		hr''

contrast, is dimeric, and other methods can be used to detect the antigen–antibody complex.

Suspension of the red cells within a protein environment sometimes facilitates agglutination of these antibodies [57]. Use of *bovine albumin* at a 20%–30% concentration has been found to be the most effective, while avoiding problems of pseudoagglutination associated with other proteins. Treating red cells with a *proteolytic enzyme*, such as papain, trypsin, ficin, or bromelin, can reveal more antigen sites and reduce the negative charge on red cells, enabling cells to get closer to each other, making it easier for the small incomplete antibodies to bind [57]. *Blocking tests* can be used to detect incomplete antibodies, but cannot do so in a mixture of complete and incomplete antibodies unless the former are removed first. Incubation of Rh D positive red cells with excess incomplete anti-D in saline fills all of the antigen-binding sites, without agglutination – the cells are said to be "blocked" as no more antibodies can be bound. Subsequent attempts to produce agglutination with saline-acting anti-D fail. This latter technique is only really of use in the detection of antibody, rather than typing of the antigen [57]. The most commonly used method when using incomplete antibody is the *antihuman globulin* (*AHG*) or *Coombs test* [5]. Like the blocking tests, this can be used in a "direct" manner to detect the presence of antibody already on red cells, but its use in typing of antigen involves the indirect form of the test. This involves mixing of antiserum and test cells. If the antigen is present on the red cell, then the antibody binds. Rigorous washing of red cells removes any excess antibody and then the presence of antibody on the cells can be detected by addition of antihuman globulin, resulting in agglutination. A negative reaction clearly indicates absence of antigen.

Typing can sometimes produce inconclusive results. Stratton [58] described the D^u variant allele, which was positive with IgG anti-D antisera detected through the AHG test, but not with the use of IgM anti-D. D^u was not an antigen, but related to the number of D antigen sites available on a red cell. D^u is now called *weak D* [59].

Anti-D antisera are mostly IgG, but many also contain an IgM components [9] – they are *polyclonal.* The development of monoclonal antisera to replace polyclonal reagents has not been as simple as for the MNS system as the mouse hybridoma approach failed. Instead, human, or mixed human–mouse hybridomas are used. Typically, Epstein–Barr virus (EBV)-transformed lymphoblastoid cells [60], or CD40 activated lymphocytes [61], are fused with myeloma cells to produce a hybridoma.

Because of the large number of haplogroups, Rh blood typing is more useful than most other markers. Stains can be typed using the absorption-elution technique [17]. The method is not as simple as that used for ABO and MNS typing because the number of antigenic sites is not as high and more material must be used. It is also not possible to elute directly into a cell suspension because incubation at high temperature to disturb the antigen–antibody complex also destroys the ability for red cells to agglutinate. Generally, incomplete antibodies are used for detection, because they are of a higher titer and apparently more heat stable, along with enzyme-treated indicator cells.

Because large amounts of the stain must be used, and an essential component of the tests is the ability to wash out any unbound antibody, the composition of the stained fabric becomes important. Rh typing of denim is not normally successful, probably because of the "size" treatment of the material to facilitate the dye coloring. Detection of weak D forms are difficult, as is typing of stains that are old, and therefore, high avidity antisera and confirmatory controls must be employed [17].

Molecular analysis has shown that the Rh antigens are encoded by two closely linked genes on chromosome 1 (RHD and RHCE), producing the RhD and RhCcEe proteins, which are hydrophobic nonglycosylated proteins that appear to loop in and out of the red cell membrane 12 times [62]. The two polypeptides differ by about 35 amino acids but the gross gene structure is very similar. They each have 10 exons and have about 94% homology [63]. The greatest difference between the two genes is seen in intron 4. The two genes are orientated tail to tail, with their 3′ ends facing each other. On either side of the RHD gene are two homologous regions known as *Rhesus boxes* [64]. Deletion of RHD, the most common reason for the Rh-negative phenotype, occurs between two regions within each of the Rhesus boxes. This also explains why a *d* antigen, allelic to D, has never been found.

A variety of molecular techniques can now be used to predict Rh phenotype in a variety of nucleated material. Some methods exploit the presence or absence of RHD to detect Rh D phenotype, looking for particular sequences on RHD, but not RHCE [65];

another method uses sequence specific primers to identify different sized products from exon 7 [66], and a third method uses a single pair of primers across exon 4 of both genes producing 600 bp from RHD and 1200 bp from RHCE, with the Rh D negative phenotype being predicted by the absence of a band after electrophoresis of the polymerase chain reaction (PCR) products [67].

Errors may occur using these methods if variants are present and tests of more than one region of RHD are recommended [68]. Most Rh D negative Caucasian people in the United Kingdom are cde/cde and don't possess introns 4 and 10, but other Rh D negative haplotypes produce discordant results due to frameshifts and stop codons. Rh D negativity in about 65% of black Africans is due to an inactive RHD gene (RHD_{ψ}), either inherited as a homozygote, or as a heterozygote with the RHD deletion gene. RHD_{ψ} is due to a duplication of a region of intron 3 and exon 4, which causes a frameshift and potentially introduces a stop codon, but there is also a mutation in exon 6 that also produces a stop, ensuring that, despite the presence of the RHD gene, no RhD protein is produced. A multiplex approach has been described that detects exon 7 and intron 4 from RHD, RHD_{ψ}, and the C and c alleles of RHCE [69].

RHD_{ψ} is much lower in frequency in black African-Americans, but two other common variants seen in Rh D negative black Africans are seen more commonly amongst the black American population. This difference is likely to be due to owing to *founder effects* related to the particular African populations involved in the slave trade.

The Rh C/c polymorphism is associated with six SNPs in RHCE that produce four different amino acids [70]. Of particular importance is the T307C polymorphism in exon 2 of RHCE, determining C, but exon 2 is identical in RHD and RHCE, and so allele-specific primers for C are only useful in Rh D negative people. C/c genotyping can now be done in two PCR reactions to detect a C-specific region within intron 2 of RHCE and a second to detect the C nucleotide at 307 in exon 2, which defines c [71].

Both C and c are commonly seen in Caucasians (at 68% and 81%, respectively) [72], but C is lower and c higher amongst the African population, in contrast to East Asia, where the frequency of C approaches 100% and c is much lower [27, 45] C^w and C^x were initially thought to be alleles of C/c, but were subsequently found to be alleles of a high incidence antigen, *MAR* [73], owing to two different SNPs in exon 1 of RHCE producing two different amino acids in the RhCe protein [74]. The different proteins produced appear to result in conformational changes that lead to quantitative and qualitative abnormalities of $C.C^w$ is seen in about 2.6% of European populations, whereas C^x is much rarer, being seen in about only 0.12% of this population [9]. Both variants are, however, much more common in Finland [73] where their frequency is around 9% and 2%, respectively, and it is therefore not surprising that it was in this population that anti-MAR was first recognized.

Rh E/e is another pair of antithetical antigens and is associated with the C676G SNP in exon 5 of RHCE, producing a protein change in one of the extracellular loops of the polypeptide RhCcEe protein [70]. As in C, G676 on RHCE, determining e, has the same sequence on RHD, yet the latter does not express the e antigen; this suggests that the expression of the e antigen is a conformational difference. This also means that the e antigen cannot be defined in everyone by simply using the G676 marker, but detection can be combined with an RHCE specific nucleotide in exon 5 (A787) [75]. The E antigen can be defined by detecting the C676 SNP in exon 5 [76]. There is very little variation in E and e frequencies across populations [27], e being seen in 98% of the population with E present in around 30% [72].

These population frequency differences amongst the separate antigen pairs reflect the different haplotype frequencies between populations [27]. Rh-negative haplotypes are rare in South-East Asian populations and in indigenous Americans, whereas about 15% of white Europeans are Rh negative. CdE (r^y) is very rare in all populations, whereas cDe (R^o) is the commonest haplotype in Sub-Saharan Africa, being found in about 60%, in comparison with a frequency of less than 5% in other populations.

Inheritance of the Rh blood group is Mendelian, with each parent passing a haplotype to the child. The Rh blood groups therefore provide a powerful system in *parentage testing*, but they can be complex to interpret, and prediction of actual haplotypes that have been inherited is difficult from the phenotype [77]. The eight established haplotypes can be paired into 36 different genotypes, but using the five standard antisera only 18 phenotypes can be distinguished, and, because many phenotypes represent more than one genotype, only eight of these represent

a single genotype and the CcDEe phenotype could be explained by six different genotypes. For example, an individual with the phenotype cde, can only have the genotype cde/cde, and someone with the phenotype cdEe must be of genotype cde/cdE. This is clearly not the case for someone with a phenotype such as cDEe, which could be the result of cDE/cde or cDE/cDe, or cDe/cdE genotypes. In addition to doubts about the true genotype, prediction of the most likely genotype will depend on the population of origin, and it must be remembered that in the case of disputed paternity the tested man may not originate from the same population as the true father. The phenotype example cDEe is most likely to be cDE/cde, if both parents are of Caucasian origin. In an African origin population, cDE/cDe would be the most likely genotype. When using these markers for paternity tests, it is important to predict all possible genotypes of the child in order not to exclude a man whose likely genotype does not match with the likely genotype of the child.

Despite there being a large number of possible genotypes, many haplotype combinations are very rare. Table 8 gives the frequencies of observed phenotypes in three different population groups.

Protein Polymorphisms

Many enzymes (*see also* **Enzymes**) and other blood proteins exist in different polymorphic forms. *Isoenzymes* are enzymatically active proteins that catalyze the same reaction within a species, but have different physical or chemical properties. One such difference can lead to a variation in mobility when exposed to an electric field and this can be examined through *electrophoresis*.

A large number of polymorphic proteins and enzymes, found in many body tissues but normally analyzed within red cells or serum, have been utilized in forensic analysis and in the investigation of paternity [17]. Many of those analyzed for forensic purposes are red cell enzymes: these include adenosine deaminase (ADA), adenylate kinase (AK), carbonic anhydrase (CA), erythrocyte acid phosphatase (EAP), esterase D (EsD), glucose-6-phosphate dehydrogenase (GPD), glutamate-pyruvate transaminase (GPT) glyoxylase I (GLO), peptidase A (Pep A), 6-phosphogluconate dehydrogenase (PGD), and PGM. Others, found within red cells, or within serum, can also be useful in forensic analysis, but have more often been utilized as polymorphic markers (in conjunction with the markers already mentioned) in the investigation of paternity. This required the use of a large number of independent genetic systems to obtain sufficient power to answer questions of parentage prior to DNA testing. These systems include the following: α^1-anti-trypsin (PI), α^2-HS glycoprotein (α^2-HSG), group specific component (Gc), GM blood group factor (GM), haptoglobin (Hp), hemoglobin (Hb), KM blood group factor (KM), plasminogen (PLG), and transferrin (Tf) [28]. Many of these systems are discussed below.

Red cell enzymes lose their activity in stains more readily than red cell antigens and are, on the whole,

Table 8 Rh blood group frequency estimates across three populations (Caucasian, black, and South Asian) resident in the United Kingdom [28]

Phenotype Fisher–Race	Phenotype Wiener	Caucasian	Black	South Asian

inactive after a few weeks. Analysis of these systems is through electrophoresis on some form of support medium. Those most commonly used in forensic analysis are:

Starch gels, traditionally made from potato starch, can be used on glass plates to form a thin opaque gel with a pore size approaching that of the protein molecules under investigation. It therefore acts as a molecular sieve. Detection of enzymes is through an assay that links function to a staining reaction and therefore may require that the enzymes are still functional after separation.

Acrylamide gels produce tough, flexible, clear gels in which the pore size can be adjusted by altering the percentage of acrylamide, polymerized through *cross-linking* with chemical reagents, or exposure to UV light, for example, creating density gradients. *Native gel electrophoresis* (*Native PAGE*) separates proteins according to their charge to mass ratio, which means that different proteins with the same molecular weight will migrate differently, as each protein has an isoelectric point and molecular weight according to is primary structure. *Sodium dodecyl sulphate polyacrylamide gel electrophoresis* (*SDS-PAGE*) denatures secondary protein structures and applies a negative charge proportional to its mass. This means that the charge to mass ratio is similar for all proteins, which migrate proportional to the size of the protein.

Adenosine Deaminase (ADA)

ADA deaminates adenosine to produce inosine. It is found in most tissues, particularly red cells, lymphocytes, and macrophages, but is not normally detected in semen or vaginal secretions. There are two main alleles produced at a single locus: ADA^1 and ADA^2 that lead to three phenotypes: ADA 1, ADA 2, and ADA 2–1 [78]. Rare variant alleles have also been described, and numbered 3, 4, and 5.

ADA in blood stains is analyzed through electrophoresis of lysates in thin layer starch gels at 4 °C [17]. The enzymes alleles are distributed in different zones, with the 1 variant moving further toward the anode. The enzyme variants are detected through an enzymic action: adenosine and subsequent detection chemicals (nucleoside phosphorylase, xanthine oxidase, Dimethylthiazol 2 yl diphenyltetrazolium bromide (MTT) tetrazolium and phenazine methosulphate (PMS)) are added to a 2% buffered agar solution, which is poured over the gel anodal to the origin. When set, the whole is covered and incubated at 37 °C for the enzymic reaction to take place.

Adenosine in the agar is converted to inosine by the ADA in lysate. Inosine is subsequently converted to hypoxanthine by nucleoside phosphorylase, added to the agar reagent. Hypoxanthine is then oxidized by xanthine oxidase and, in the presence of PMS, MTT tetrazolium, which has a yellow color, is reduced to MTT formazan, which is an insoluble blue compound. The bands therefore appear blue on a yellow background.

Typically, there are two or three bands, one band being common to all. ADA 2-1 has three bands. In ADA 1 the cathodal band is absent and in ADA 2 the cathodal band is more prominent than the central band and there may be some weak activity in the anodal band area. Variants with type 1 show bands that are more cathodal (types 3 and 4) or more anodal (type 5) than the normally observed bands. These variants are very rare.

Problems can arise due to oxidation of lysates although this can be reversed through treatment with β-mercaptoethanol [17]. Oxidation results in the faster anodal bands becoming stronger and the slower bands weaker, leading to mistyping in these situations. In material that is very old, or is, perhaps, infected with bacteria, a single slow moving band is seen. Phenotype frequencies of the ADA variants are shown in table 9.

ADA phenotypes can be predicted through analysis of a G/A SNP that results in an amino acid change from aspartic acid (Asp) to asparagine (Asn) [79].

Adenylate Kinase (AK)

AK catalyzes the transfer of a high energy phosphate group from one molecule of adenosine diphosphate (ADP) to another to produce one molecule of

Table 9 ADA frequency estimates across three populations (Caucasian, black, and South Asian) resident in the United Kingdom [28]

adenosine triphosphate (ATP) and one molecule of adenosine monophosphate (AMP) with magnesium ions acting as a cofactor. It is found in most tissues, but is difficult to detect using electophoretic techniques in semen and vaginal secretions. There are two main alleles: AK^1 and AK^2 that result in three phenotypes: AK 1, AK 2–1 and AK 2, although the latter is very rare [80]. Variants have also been described.

Detection is through electrophoresis in a thin layer starch gel [17]. Typically, a cotton thread, soaked in a red cell lysate, is introduced into the gel and electrophoresed in the cold. After electrophoresis, enzyme detection reagents (ADP, glucose, magnesium chloride, hexokinase, G6PD, Nicontinamide adenine dinucleotide phosphate (NADP), MTT tetrazolium, and PMS) are introduced in an agar overlay with incubation in the dark at 37 °C.

AK in the gel converts ADP in the detection reagent to produce ATP and AMP. ATP acts on glucose to produce glucose-6-phosphate (G6P). Glucose-6-phosphate dehyrogenase (G6PD) then oxidizes G6P to produce 6-phosphogluconate and NADP is converted to Reduced nicontinamide adenine dinucleotide phosphate (NADPH). Reoxidation to NADP occurs along with reduction of MTT tetrazolium to the insoluble blue MTT formazan, with PMS acting as a cofactor. Like ADA, the enzyme bands of AK activity appear blue on a yellow background.

AK 2–1 appears as two strong bands and a weaker cathodal band. In AK 1 homozygotes, the most anodal band is absent; in AK 2 the most anodal band is the strongest, with a weak central band. A very weak cathodal band may be seen. Standard analysis is done at pH 5.0, but rare variants are better separated using pH 7.0. Problems can occur if the red cells are not properly lysed as this can produce weak shadow bands leading to interpretation difficulties.

The AK1 (red cell) gene is found on chromosome 9 and has seven exons [81]. The AK locus has been shown to be closely linked to the ABO locus [82] and this must be borne in mind if these markers are to be used together in analysis of parentage. Table 10 shows the frequencies of the various phenotypes across three populations.

Erythrocyte Acid Phosphatase (EAP or ACP1)

The *EAP* enzyme is now more frequently known as soluble *acid phosphatase 1* (*ACP1*) and is distinct from the ACP2 gene (*see also* **Acid Phosphatase**). Although called 'red cell', there are reports of the enzyme being found in other tissues, which are also known to demonstrate a variety of other acid phosphatases. EAP acts as an acid phosphatase and as a protein tyrosine phosphatase. It hydrolyzes orthophosphoric monoesters to alcohol and orthophosphate, and protein tyrosine phosphate to protein tyrosine and orthophosphate. There are three common variants, EAP^A, EAP^B, and EAP^C, which give rise to six phenotypes: A, B, C, BA, CA, and CB [83]. Rare types R and D have also been described using starch gel electrophoresis [84]. SDS-PAGE shows that each allele encodes two electrophoretically different isozymes, 'f (fast)' and 's (slow)', which are produced in allele-specific ratios (2 : 1 for Af and As; 4 : 1 for Bf and Bs; 1 : 4 for Cf and Cs) [85].

Traditionally, EAP is analyzed in a thick (2 mm) gel, necessary to detect weaker bands [17]. Lysates of blood mixed with dithiothreitol (DTT) (a reducing agent to prevent oxidation complications of additional bands associated with storage) on filter paper or within stained fibers are electrophoresed with a cooling plate. Postelectrophoretic analysis involves placing filter paper, soaked with the reaction mixture, on the gel, followed by incubation within a closed box to prevent evaporation.

Detection involves EAP catalyzing the removal of a phosphate group from 4-methyl umbelliferyl phosphate to form methyl umbelliferone, which fluoresces under UV light. A complex pattern of bands is produced with movement from the origin toward the anode. The A band is strong and the most anodal and is associated with a second band, more cathodal, the latter being weaker in heterozygotes. B and C bands are seen as two bands in the same positions, flanking the weak cathodal A band. In B, however, the more anodal band is the stronger, and in C, it is the more cathodal band that is the strongest. The rare R variants are found beyond the anodal A band, whereas the D variant travels in a cathodal direction and is

Table 11 SNP typing of the ACP1 locus

Phenotype	SNP observed at the 15-3F locus	SNP observed at the 12-3S locus
A	C	T
B	C	C
C	T	C
BA	C	T/C (heterozygous at this locus)
CB	T/C (heterozygous at this locus)	C
CA	T/C (heterozygous at this locus)	T/C (heterozygous at this locus)

found on the other side of the origin. R is more often observed in people of African origin. C is rare in all populations and homozygous have not been observed in a large population series.

Distinction of C and CB can sometimes be problematic as differentiation depends on a weak B position band in the former, which is stronger in the latter. Similarly BA has strong bands in the B and A positions, with a weak band in the C position, in comparison with CA, which has strong bands in all three positions, but particularly in the C and A positions. Molecular analysis has shown that the coding portions of the B and C alleles are identical and it is the different ratios of the f and s isozymes that explain the identical electrophoretic mobility but different intensity of the bands. The A allele has a single amino acid substitution at residue 105.

The ACP1 gene is located on chromosome 2 and consists of seven exons. Alternative splicing of exons 3 and 4 account for the different f and s isozymes, which probably serve different functions within the cell [86]. The sequences of these isozymes are identical, apart from a 108 bp sequence within the reading frame.

The presence of SNPs at two locations (ACP1-15-3F and ACP1-12-3S) allow molecular phenotype prediction [71, 87]. The two SNPs are both C/T – (Asp)GA*C* to (Asp)GA*T*, and (Ser)AG*C* to (Ser)AG*T* predict the f and s isozymes. Table 11 shows how these SNPs can be interpreted:

Table 12 shows how these phenotypes vary in frequency across different populations.

CB	0.057	0.006	0.008
CA	0.032	0.003	0.002
RB	0.001	0.045	
RA		0.012	

Esterase D (ESD)

A variety of different esterases exist. In particular, the ESD enzyme has been found to be identical to S-formylglutathione hydrolase (FGH) and hydrolyzes thiol esters of glutathione. There are two common variants: ESD^1 and ESD^2, producing three phenotypes: 1, 2 and 2-1 [88], although a large number of rare variants have been described [89].

Electrophoresis of lysates in DTT is achieved through placing stained cloth inserts in thin layer starch gels as relatively large amounts of material need to be applied [17]. Detection reactants are soaked in filter paper, which is placed on the gel, postelectrophoresis, followed by a short incubation at 37 °C. The gel is viewed under UV light to detect fluorescent bands.

Like EAP, ESD can catalyze the removal of a phosphate group from 4-methyl umbelliferyl phosphate to form the fluorescent methyl umbelliferone. Five bands are defined, numbered 1 to 5, from cathode to anode. Weak fluorescent bands are also seen, one cathodal of position 1 and the other coincident with position 5. These weak bands are related to other esterase enzymes. ESD 2–1 shows three bands, strong in position 2 and weak in position 1 and 3. ESD 1 has two bands, strong in position 1 and weak in position 2; ESD 2 also has two bands, strong in position 3 and weak in position 4.

While ESD 2 is more readily identified because of its very different mobility, distinguishing between

Table 13 ESD frequency estimates across three populations (Caucasian, black, and South Asian) resident in the United Kingdom [28]

ESD	Caucasian	Black	South Asian
1	0.773	0.848	0.539
2–1	0.177	0.139	0.360
2	0.011	0.009	0.079
5–1	0.032	0.003	0.016
5–2	0.006		0.006
5	0.001		
1-var	0.001		

ESD 1 and ESD 2–1 can be problematic as this depends on the relative strengths of the bands. This is particularly the case in stains, which often produce weak and diffuse results in which the faint bands are difficult to see. Additional bands also result after frozen storage, or in dried stains, but addition of more DTT can remove these and help reduce background fluorescence.

ESD is located on chromosome 13 and the variants are due to a polymorphism at a single locus. SNP typing can be used to differentiate the two variants: (Gly)C*G*A to (Glu)C*A*A, the former defining ESD 1, and the latter, ESD 2 [89]. Table 13 shows the frequency of the phenotypic variants in three populations.

Glyoxalase I (GLO-I)

GLO-I catalyzes the conversion of methyl glyoxal to S-lactolyl glutathione lactate using glutathione as a cofactor; glyoxylase II (GLO-II) subsequently converts this to lactic acid and glutathione. GLO-I is associated with cell division and has been found in a variety of tissues, including semen. Two main types exist: GLO^1 and GLO^2, leading to three phenotypes: 1, 2 and 2–1 [90].

Lysates in mercaptoethanol solution (which acts as an antioxidant) are electrophoresed in a cooled thin layer starch gel [17]. Although mercaptoethanol and DTT (used in other assays) are similar, they produce different GLO-I mobilities. Postelectrophoretic treatment involves placing filter paper soaked in detection reagents (methyl glyoxal, glutathione, iodine) on the gel and incubating at 37 °C, followed by removal of the filter paper and pouring of an indubiose agarose solution containing iodine over the gel.

GLO-I catalyzes the reaction that converts methyl glyoxal and glutathione to S-lactolyl glutathione. In the absence of free glutathione, the iodine reacts with starch giving a blue-black color. The remainder of the gel surface still has reduced glutathione on it, which has a reactive SH group that reacts with the iodine, leaving insufficient free iodine to react with the starch gel.

GLO-I type 2–1 has three bands, the central one being weaker. Type 1 shows just the more cathodal band, and type 2 the more anodal band. Problems can arise if the iodine is not properly dissolved to avoid blue coloration in the agar overlay. If stains are old, the cathodal band of the type 2–1 is weak and the anodal band stronger, which might, falsely, suggest the presence of a variant.

GLO-I is located on chromosome 6 and shows six exons [91]. It shows strong linkage with the Human leucocyte antigen (HLA) locus, so the results cannot be combined in the statistical assessment of paternity [92]. GLO-1 phenotypes can be predicted through use of an SNP at a single locus that leads to an amino acid substitution: (Ala)G*C*G to (Glu)G*A*G, the former defining type 1, and the latter, type 2 [93]. Table 14 shows the allele frequencies across three population groups.

Phosphoglucomutase (PGM)

PGM 1 catalyzes the reaction that transforms glucose-1-phosphate into glucose-6-phosphate. It is found in all human tissues. Three unlinked loci determine the production of PGM [94]; here we are concerned with only the first, which has four common variants: 1+, 1−, 2+, and 2−, producing 10 different common phenotypes. Rare variants 3+, 3−, 7+, 7− are seen in some oriental population groups.

Starch gel electrophoresis detected the types PGM_1-1 and PGM_1-2 [95], but isoelectric focusing in acrylamide gels enables these isozymes to be split

Table 14 GLO-I frequency estimates across three populations (Caucasian, black, and South Asian) resident in the United Kingdom [28]

2 + 1+	T/C	T
2 − 1−	T/C	C

into + and − forms, originally referred to as A and B forms [96]. Ampholines are used to produce a pH range between 5.0 and 8.0 within a UV-polymerized gel. Lysates in filter paper inserts are electrophoresed, and development of the postelectrophoretic gel is through an agar overlay with reaction chemicals (glucose-1 phosphate, glucose 6 phosphate dehydrogenase, PMS, MTT tetrazolium, and NADP) [97].

PGM catalyzes the reaction from glucose-1 phosphate to glucose-6 phosphate, which is then transformed to 6-phosphogluconate through the action of glucose-6-phosphate dehydrogenase [17]. At the same time NADP is reduced to NADPH. Using PMS as a transfer reagent, MTT tetrozolium is reduced to the insoluble blue MTT formazon and NADPH reoxidized to NADP. PGM activity bands are seen as blue bands on a yellow background.

The different allelic forms separate in the order 1−, 1+, 2−, 2+ from pH 7.0 through to pH 5.0 and phenotypes are readily identified from the band positions.

PGM_1 is found in chromosome 1 and the variants 1 and 2, and + and −, are due to reciprocal intragenic recombination between two SNP sites in exons 4 and 8, associated with amino acid substitutions: (Arg)*C*GT to (Cys)*T*GT and (Tyr)*T*AT to (His)*C*AT [98]. SNPs PGM_1 723 and PGM_1 1320 can be used to predict phenotype from genetic material.

Table 15 shows how SNP variants can be interpreted, and table 16 shows the phenotype frequencies across three population groups.

Table 16 PGM frequency estimates across three populations (Caucasian, black, and South Asian) resident in the United Kingdom [28]

PGM	Caucasian	Black	South Asian

Group Specific Component (Gc)

Gc was first described by Hirschfeld [99] in 1959 using an immunoelectrophoretic technique to investigate the α_2 globulin of human serum. He recognized three different precipitation patterns that, family studies showed, were under genetic control. Immunoelectrophoretic patterns are characteristic precipitant bands that form in arcs in an agar gel [100]. Homozygote phenotypes Gc-1, Gc-2, and the heterozygote were described. Gc-1 was subsequently divided into "fast" and "slow" types [101], Gc-1F and Gc-1S, respectively, through use of the isoelectrofocusing technique, and a number of other variants were reported [102].

Gc was soon discovered to be identical to the vitamin D binding alpha globulin (VDAG) [103]. The high frequency of Gc-2 was associated with low levels of sunlight with the 2 gene being expressed in about 30% of the white population, in comparison with only about 7% of the black African population [104]. On the other hand, about 80% of the black African population has the Gc1F gene, in comparison with about 15–20% of other populations.

Thin layer acrylamide and *bis*-acrylamide gels are prepared using pH ampholines in the range 3.5–5.0 and 4.0–6.0 in a 5 : 1 ratio [105]. Addition of tetramethylethylenediamine (TEMED) and ammonium persulphate polymerizes the gel. Serum-soaked filter paper was placed close to the cathode and electrophoresed. Coomassie brilliant blue was used to stain the proteins and the rest of the gel destained.

The staining pattern produces between 1 and 4 bands. Gc-2 provides the maximum number of cathodal bands. Gc-1 provides a pair of more anodal bands, the Gc-1F being more anodal than the Gc-1S bands. Individuals with phenotypes involving both Gc-2 and Gc-1 produce three bands, and those with Gc-1F1S have four. A large number of variants have also been described. The technique has been used to successfully type blood stains in a collaborative study.

Gc is a single polypeptide; originally, two alleles were described Gc-1 and Gc-2, with Gc1F and Gc1S thought to be posttranslational [101]. Subsequent analysis has shown the gene to be present on chromosome 4, consisting of 13 exons, but the totality is not translated [106]. Exon 11 is responsible for the differences between the types with SNPs producing amino acid changes at positions 416 and 420 [102]. Table 17 summarizes these, and table 18 shows the phenotype estimated frequencies in three population groups.

Table 17 SNP typing of the Gc locus

Phenotype	SNP observed at the 416 locus	SNP observed at the 420 locus
1F	(Asp) GA*T*	(Thr) A*C*G
1S	(Glu) GA*G*	(Thr) A*C*G
2	(Asp) GA*T*	(Lys) A*A*g

Table 18 Gc frequency estimates across three populations (Caucasian, black, and South Asian) resident in the United Kingdom [28]

Haptoglobin (Hp)

Hp is a tetrachain glycoprotein, much like hemoglobin, and is only found in man. It is secreted in the liver as an α^2 globulin in serum and binds with hemoglobin after hemolysis. It is believed that this action reduces the loss of iron through urinary excretion during red cell breakdown, preventing kidney damage [107] There are two genes, Hp^1 and Hp^2, resulting in three phenotypes: Hp1, Hp2, and Hp2–1 [108]. In addition, there are a number of rare types, including Hp2–1M and Hp0 [109].

Two slightly different methods of detection are used, depending on whether serum or a blood stain is being used [17]. Serum is mixed with hemoglobin A (adult Caucasian red cells) to form a haptoglobin–hemoglobin complex, and soaked into a filter paper wick to be loaded onto a thick layer starch gel for electrophoresis. Alternatively, the bloodstain is eluted into buffer and used to load the gel. The gel is cut vertically so that the wick can be inserted into the full depth. After electrophoresis, the gel is sliced, horizontally, along its length. The open gel is stained with phenolphthalein, which is a colorless solution in alkaline, but in the presence of an oxidizing agent, such as the perioxidase of hemoglobin, a deep pink color develops. Reading should take place immediately because the color fades after a few minutes. Other stains, such as leucomalachite green of amido black can also be used.

The Hp1 band forms a single, thick band, close to the free hemoglobin band on its cathodic side. Free hemoglobin moves fastest from the origin. Hp2 and Hp2–1 show a cluster of bands that are further toward the cathode. The Hp1 component of Hp2–1 is in the same position as Hp1, but is much weaker, and this band is absent in Hp2. Hp2–1 has an additional band, closest to the cathode, which stains heavier than any of the Hp2 bands. Hp2–1M looks like the Hp2–1, but the cathodic cluster of bands is missing.

The haptoglobin gene is found on chromosome 16 and its variants seem to be associated with a duplication event, seen in Hp2, but not in Hp1, encompassing exons 3 and 4 [109]. Hp2–1M, is due to reduced Hp2 and an SNP is found in position 61 of the promoter region. Hp0 is an absence of haptoglobin (*ahaptoglobinemia*) and is believed to

Table 19 Interpretation of bands produced using primer pair amplification of the Hp gene

Primer pair	Purpose	Band present	Band absent
A	HpA and HpB – identifies Hp^1 by product size	Hp1, Hp2–1	Hp2
B	HpA and HpARev – identifies Hp^2 due to HpARev overlapping the duplication of Hp^1 in the Hp^2 gene	Hp2, Hp2–1	Hp1
C	HpA2 and HpB2 – identifies Hp^1 by product size	Hp1, Hp2–1	Hp2
D	HpC and HpD – identifies Hp^2 due to the section of Hp^2 amplified in the PCR product overlapping the duplication of Hp^1 in the Hp^2 gene	Hp2, Hp2–1	Hp1

Table 20 Hp frequency estimates across three populations (Caucasian, black, and South Asian) resident in the United Kingdom [28]

Hp	Caucasian	Black	South Asian
1	0.153	0.330	0.029
2–1	0.478	0.379	0.287
2	0.363	0.148	0.684
2–1M	0.001	0.076	–
0	0.005	0.067	

be due to SNPs at 61 and 101 within the promoter region [110].

Distinction of the main allelic types by molecular methods must target the duplication [111]. Seven primers defining forward and reverse sequences are used in four pairs for interrogation and confirmation of phenotype, and a set of SNPs are used to determine the common variant SNPs in the promoter region. Primers A and B target Hp^1, and primers C and D target Hp^2; confirmatory primers are also used. Table 19 shows how the results of the PCR using the primers are interpreted, and table 20 gives the phenotype frequency of the Hp markers across three populations.

Summary

This large collection of polymorphic antigens, enzymes, and other proteins have provided useful human identification markers over many years. The analysis of these markers generally, however, requires significant expertise, in comparison with DNA technology, and much of the equipment used and reagents of suitable quality are not so readily available.

As products of genes, classical markers are not subject to the same intergenerational mutations that can hamper investigations of parentage when DNA markers are used. In contrast, their use in criminal investigations is more limited, not only because of their poor availability in some tissues of interest, especially saliva and semen or, in the case of enzyme activity assays, they may be too old to be analyzed, but also because they are not a informative as DNA markers. While the use of DNA short tandem repeat analysis has overtaken classical markers in both forensic and parentage analyses, the greater understanding of the molecular basis of many of these classical markers means that it is now possible to predict most of the classical marker phenotypes in nucleated materials of any age and size, and this has already proven useful in analysis of old cases.

DENISE S. COURT

Bloodstain Pattern Interpretation

Introduction

"All criminal investigation is concerned either with *people* or with *things*. Only people commit crimes, but invariably do so through the medium of things. It is these things that together constitute the broad field of physical evidence" [1]. Bloodstain patterns at crime scenes are often highly significant in allowing an accurate reconstruction of what prior events must have occurred to have produced them.

Dr Kirk, a true pioneer in scientific crime detection, was the inspiration for an early research in the geometric interpretation of bloodstain patterns. The report, *Flight Characteristics and Stain Patterns of Human Blood* [2], was the result of a Department of Justice funded research project on the topic. It also was the first publication on this subject in the western hemisphere. As a result of that report interest in, and acceptance of, bloodstain patterns, as evidence grew very rapidly.

During the last three decades, bloodstain evidence has become accepted as an important tool by the forensic community for the investigation of crimes wherein blood has been shed. Perhaps even more importantly, bloodstain evidence may be

used to exculpate an innocent suspect or defendant. Identification or elimination of an individual by DNA has become a routine event that is reported in the media almost on a daily basis. Eyewitness identification and other personal accounts of what they believed happened can be, and frequently are, inaccurate. The scientific reliability of physical evidence, in this case bloodstain pattern interpretation, is more accurate in reconstruction of prior events than evidence based upon the memory of an eye witness. However, bloodstain patterns, like other physical evidence, must first be detected, preserved, examined, interpreted, and properly presented in court to utilize its evidentiary value.

A Brief History of Bloodstain Pattern Interpretation

In 1971, this author was only able to locate 15 references on the subject of bloodstain pattern interpretation. However, considerably more research had been conducted in this discipline than was originally believed. In fact, well over 400 references on this subject have been found that were published before 1970; most are in forensic, academic, and medical libraries throughout the world.

In October 1971, this author wrote "Although it would seem that prior investigations of physical evidence would have resulted in a wealth of knowledge regarding the significance of bloodstains, such is not the case." This statement appears in the introduction of *Flight Characteristics and Stain Patterns of Human Blood*. Today, some 38 years later, it is clear that this statement was incorrect.

For those who would like to read a detailed book on the early literature in this discipline they could review *Segments of History, The Literature of Bloodstain Pattern Interpretation, Segment 00: Literature Through the 1800's* [3]. This reference includes reports of a murder case that occurred before 100 AD, another in London in 1514, the murder of his wife by a minister in Upstate New York in 1859, and several others prior to 1900.

The outstanding research of Dr Eduard Piotrowski [4] in 1895 was undoubtedly one of the most comprehensive works of the nineteenth century. He was involved in a beating death and conducted many experiments using rabbits, which he documented in great detail. His book included 22 color plates, which illustrated his experiments.

Unfortunately, it is not possible to include a synopsis of the classic works of Gross [5], Orsos [6], and Balthazard [7] in this article. Suffice it to say that many early forensic scientists recognized the potential value of bloodstain patterns but, for whatever reason, this subject was essentially never practiced in the United States until Dr Paul Leland Kirk became involved with the Dr Samuel Sheppard case in 1955. His affidavit [8] on bloodstains in that case appears to be the first in-depth use of evidence of this type in the reconstruction of a homicide.

Serious students seeking additional information on this subject will find some 450 references on bloodstain patterns in the first issue of *Quinnipiac Health Law* [9].

Characteristics of Liquid Blood

In order to understand why blood behaves as it does, one must have a basic understanding of two important properties of human blood; its surface tension and its viscosity. These properties of blood are sufficiently similar to those of water that it is unnecessary for the reader to formulate an entirely new concept to deal with blood as a liquid. Basically, it is within the common experience that everyone has had with water insofar as how it pours, splashes, and spatters. However, water is colorless and, therefore, it makes the casual observations of these phenomena more difficult than with blood. Bloodstains will always have a greater contrast over a light-colored background surface than water does.

Perhaps the most important physical property of blood that should be understood by the forensic investigator is its surface tension. To a large degree, this property explains why blood behaves as it does. Like all liquids, blood is held together by cohesive forces between its molecules called *Van der Waals force*. On the surface of a glass of water, or a lake, this intermolecular attraction produces a skin-like surface that is resistant to penetration or separation. Technically, this phenomenon is known as the *surface tension of the liquid*. It is this skin-like property of water that allows water bugs to walk across a pond. Likewise, if a razor blade or a small needle is carefully lowered onto the surface of water, neither will sink even though steel is 7.8 times denser than water. They are not "floating" in accordance with Archimedes' Principle, but rather they are supported by water's surface tension.

Surface tension across the surface of a liquid decreases its surface area. When small volumes of a liquid become detached from the main body of the liquid, such as from a medicine dropper, they assume a spherical geometry because such configuration minimizes surface area. The so-called teardrop shape, so often seen in the artist's rendition of falling raindrops, simply has not, does not, nor ever can exist in nature. Blood drops, like all other liquids, have a spheroid or ball shape, and not the "teardrop" shape. In his amazing book, *Flash*, Dr Harold Edgerton shows high-speed photography to show how drops are formed as their shape in free fall [10]. Figure 1 shows four such photographs.

The study of bloodstains is primarily concerned with what happens to blood once it has left the body. When blood spatters, drips, or is gushing from an artery, it must follow the laws of physics, specifically that of ballistics, which is the study of projectiles in motion. Therefore, interpretation of the significance of bloodstain evidence should be conducted by a physical scientist rather than a pathologist whose expertise is generally limited to the behavior of blood within the body. However, they should recognize the more common bloodstain patterns that can be present within the body of a deceased person.

Basic Pattern Principles

The study of bloodstain patterns must be directed toward the understanding of several basic pattern

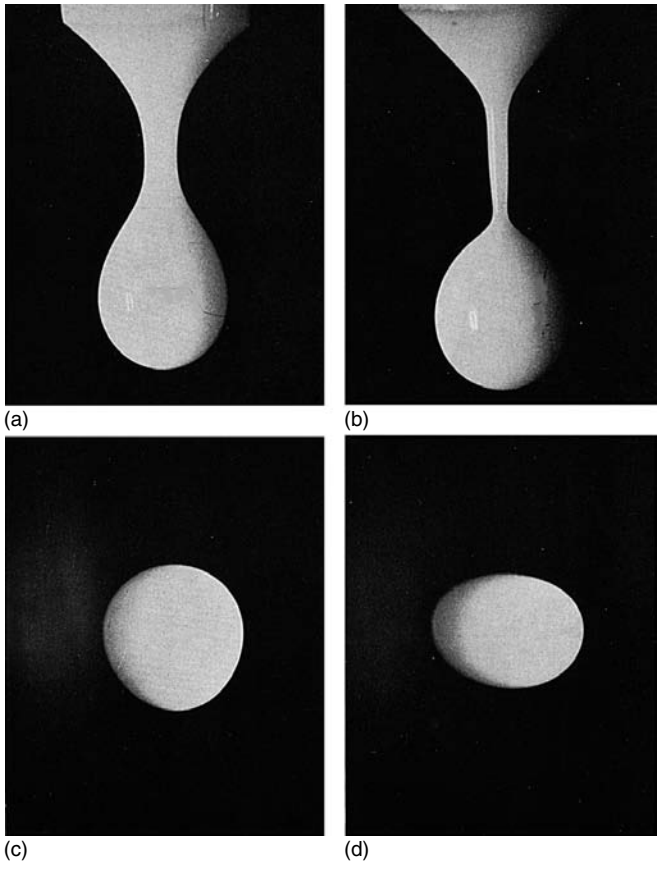

Figure 1 The formation of a drop of milk recorded by stroboscopic photography. (a) Weight of the forming drop begins narrowing the connecting source. (b) Surface tension still holds the drop before the drop falls free. (c) In free fall the drop immediately forms a spheroid or ball. (d) Because of its fluid nature and relatively large volume, the drop will oscillate in free fall

types and how they can be produced. These are discussed in detail later but, by way of an introduction to the significance of bloodstain patterns, the more significant considerations are listed below in a general order of decreasing significance:

1. The shape of the individual bloodstains, which may allow their origin to be determined in three dimensions. Under certain circumstances, this category can also include some transfer patterns.
2. The size of the individual bloodstains, which suggests the kind of energy that was available for their production if they were the result of an impact.
3. The distribution and concentration of a bloodstain pattern may suggest the distance between the origin of blood and the surface upon which it was deposited. This can be important in differentiating among impact spatter, expirated blood, and arterial patterns.

Blood Patterns within the Human Body

A frequent observation of a bloodstain pattern within the human body is the recognition of blanched or void patterns, which appear as the result of external pressure on compressed areas of the body, such as the back, arms, or legs. Such pressure prevents the uniform development of livor mortis in those areas and often can outline a common geometric shape that may be easily identifiable. When such patterns are observed, they should be immediately photographed since such images may fade quite rapidly depending upon how long it has been since the livor mortis developed.

Surface Texture Influence on the Degree of Bloodspatter

The degree of spatter that results when a drop of blood falls onto a surface is far more dependent upon the nature of the surface than it is on the distance the drop has fallen before it impacted the surface. Generally speaking, the harder and less porous the surface, the less spatter will occur. This is due to the fact that, even though the drop undergoes considerable geometric distortion upon impact because it spreads out and then contracts, the shape of the drop remains intact because of blood's high surface tension. Protrusions and rough texture of irregular and porous surfaces can rupture surface tension and result in increased spatter.

When free falling, the surface tension of a drop of blood is not unlike a rubber balloon filled with water. It can be "teased about" over a smooth surface to great degrees of geometric distortion, but the same balloon will likely rupture and discharge its contents if abraded in contact over a coarse surface such as sandpaper.

There are also distinctions that can be drawn between hard and soft porous surfaces. Raw wood and asbestos board are certainly porous, but they are also hard in contrast to newspapers or paper towels. Consequently, there will be fewer spatters on the raw wood and asbestos board. Likewise, irregularity of the target surface is an important factor that should not be overlooked. The two sides of a sheet of singularly corrugated cardboard may be of the same composition, but they usually differ markedly in texture.

Estimations of the distance of a drop of blood that has fallen from the extent of satellite spatter around the central bloodstain, or from "spines" that may also be produced, will usually not be accurate at all if surface texture of the target is not considered. Spines are the pointed streaks of blood that radiate away from the center of a bloodstain. As an example, the bloodstain shown in Figure 2, was produced by a drop of blood that fell over 80 ft before it struck a hard, smooth, glossy cardboard surface but no spatter whatever resulted. While it might seem that blood ought to spatter upon impact after falling so far, it does not. Surface tension of blood, and the fact that it reaches a terminal velocity when air resistance and gravitational attraction become balanced, prevents a drop from spattering *regardless of the height it falls before striking a smooth, hard surface*. In contrast, the bloodstain shown in Figure 3 was produced when a drop of blood fell only 18 in. before striking a desk blotter.

From Figures 2 and 3, it is obvious that correct interpretation of spattering in bloodstain patterns requires consideration of the surface texture of the target upon which it impacted.

Bloodstain Characteristics: Shape of Stain

The shape of bloodstains produced when individual drops of blood strike a surface, whether simultaneously or sequentially, will be either round or

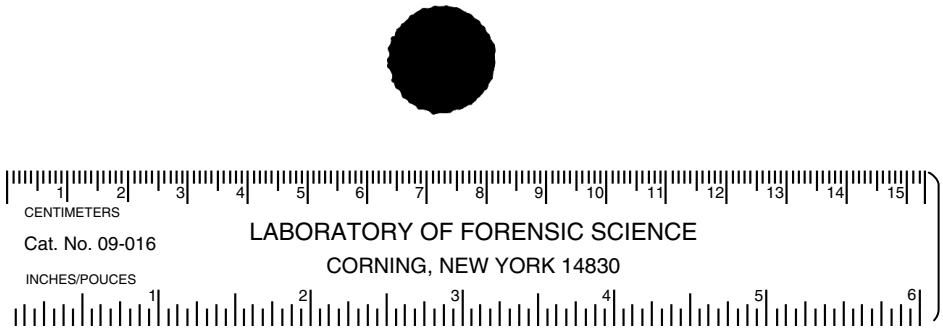

Figure 2 The bloodstain produced when a typical 0.05-ml drop of human blood fell 80 ft before striking a hard, smooth, glossy cardboard surface

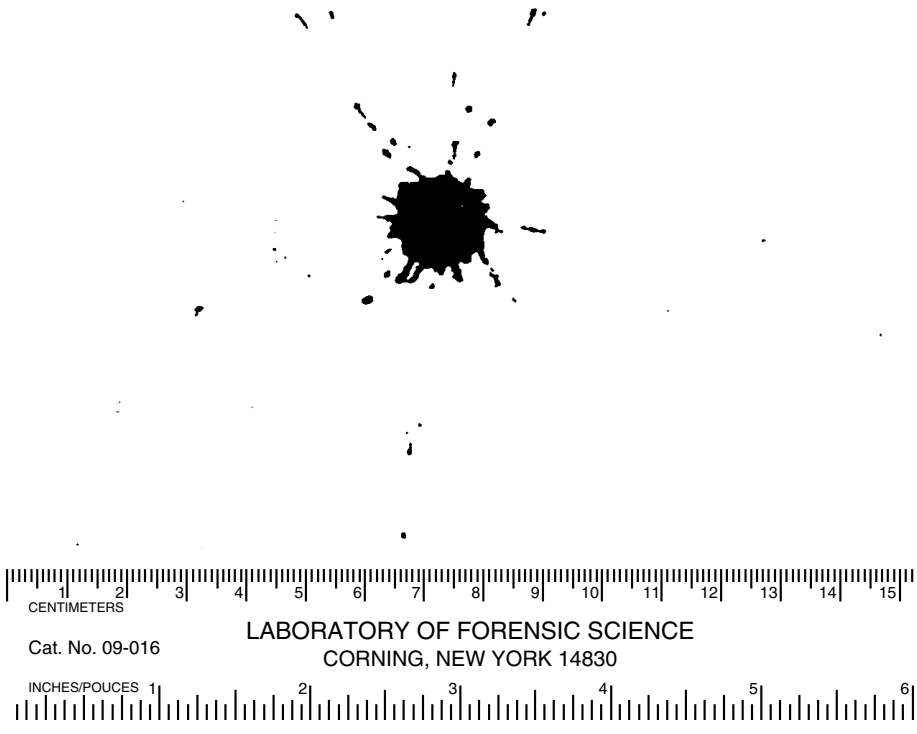

Figure 3 The bloodstain produced when a typical 0.05-ml drop of human blood fell 18 in. before it struck a soft desk blotter. Note that extensive spatter resulted when the blotter's fibers ruptured its surface tension

elliptical. The horizontal direction these blood drops were traveling prior to impact may often be determined from the shape of the resulting bloodstains. Establishing such directionality is possible even when there are no edge scallops, spines, or satellite spatters. Measurements are not necessary to determine the direction of flight of a drop of blood immediately prior to an angular impact onto a flat surface when one end of the ellipse displays a point, which looks like the artist's incorrect rendition of a tear drop. This point indicates its forward direction of travel prior to impact. The bloodstains shown in Figure 4 resulted from droplets that were traveling from left to right prior to their striking a flat horizontal surface.

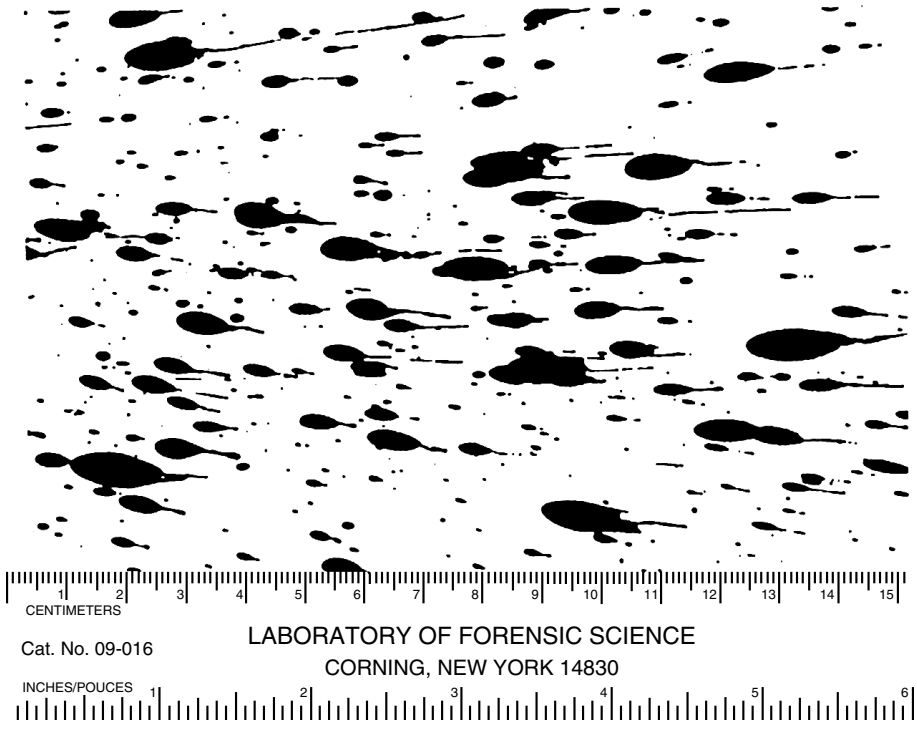

Figure 4 This pattern resulted from many droplets of blood that were traveling from left to right prior to their striking a flat level surface

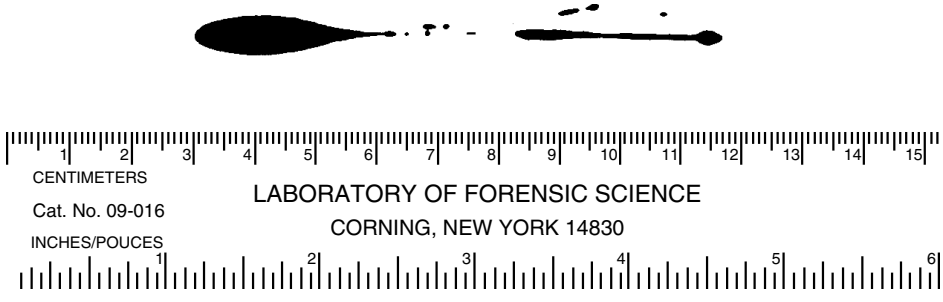

Figure 5 The parent bloodstain is shown on the left and the smaller wave cast-off is on the right. The blood drop that produced this pattern was traveling from the left to right before it struck a horizontal smooth cardboard target at an angle of approximately 16°

A smaller droplet may sometimes be thrown from a larger parent drop upon impact to produce a "wave cast-off". An example of this is shown in Figure 5 where the parent drop is on the left and the wave cast-off is on the right. The obvious direction of travel of the blood drop prior to its impact on the surface was from left to right.

The two-dimensional origin of a bloodstain pattern may be established by drawing straight lines through the long axis of the bloodstains. These lines represent the direction of each blood drop's trajectory prior to its striking the surface. The intersection of these lines represents the origin of bloodspatter in a two-dimensional configuration as shown in Figure 6. The

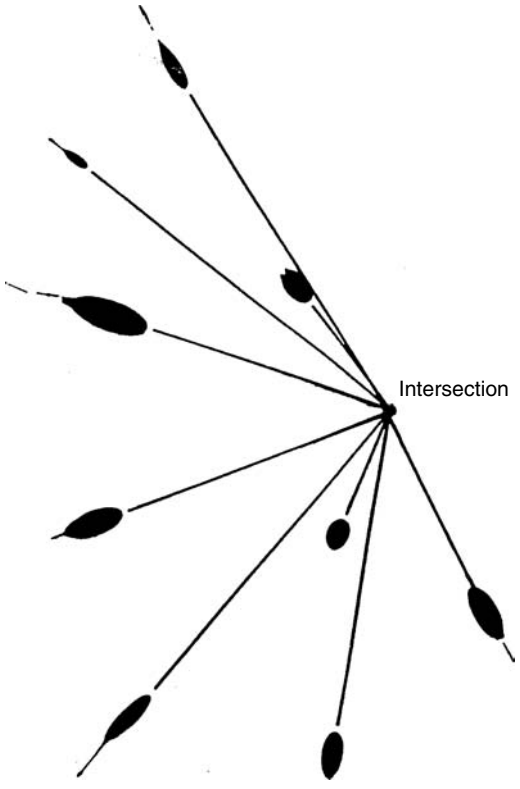

Figure 6 The origin of bloodspatter on a surface can be determined by establishing a convergence of lines drawn through the long dimension of several bloodstains. This shows a two-dimensional origin

actual origin of blood spatter would have been at some point above this intersection.

Tracing bloodstain directionalities on flat surfaces to find their general area of convergence does not provide sufficient information to determine the height of the origin of bloodspatter above that surface. To achieve this, the impact angle of several individual bloodstains must be calculated and projected back above their convergence on the surface, thereby constructing a three-dimensional model.

Estimation of the height above or away from a surface may usually be established by calculation of the impact angle of each bloodstain and projecting their trajectories back to an axis that is placed 90°, or normal, to the intersection of the previously established two-dimensional origin. This is discussed in greater detail in the next section.

Impact Angle Considerations

Blood that falls onto a flat surface that is not horizontal will produce an elliptical rather than a round bloodstain. Its degree of distortion from a circle is inversely proportional to the impact angle. That is, as the impact angle decreases from 90° to 10°, the bloodstain's shape becomes progressively elongated. Figure 7 shows nine bloodstains that resulted when single drops of blood struck a smooth surface at impact angles of 10, 20, 30, 40, 50, 60, 70, 80, and 90°, respectively.

There is a mathematical relationship between the shape of the bloodstain and the angle the blood drop that produced it struck the surface. Therefore, the impact angles may be determined quite accurately using the bloodstain's width-to-length ratio. This ratio has a trigonometric relationship to the angle of impact. The calculation is elementary and uses standard trigonometric tables. Simply divide the width of an elliptical bloodstain by its length. The result will always be one or less and is the sine of the impact angle. The formula to use for this calculation is:

$$\text{arc sine of } \frac{\text{width of bloodstain}}{\text{length of bloodstain}} = \text{impact angle}$$

Accuracy in the determination of impact angle depends on the care that is taken in the measurement of the length and width of each bloodstain. However, since the fluid nature of blood does not produce a perfect ellipse when it impacts a surface at an angle other than 90°, the pointed end of the bloodstain must be "rounded off" so it is symmetrical with its opposite end as may be seen in Figure 8. The more acute the angle of impact, the more pointed the forward end of the ellipse will be. It points in the direction of its travel prior to impact.

When evaluating bloodstains of <5 mm on their long dimension measurements should be made with some type of 20× pocket microscope which has a built-in reticule. Regardless of their size, only bloodstains that are well defined should be measured.

By determining the angles of impact for several bloodstains in conjunction with their distances from the origin (on a two-dimensional plane), it is possible to estimate that the distance of the origin of spatter was from the stained surface. This origin would be either the height above a floor or the distance from a wall or ceiling. A three-dimensional model may be

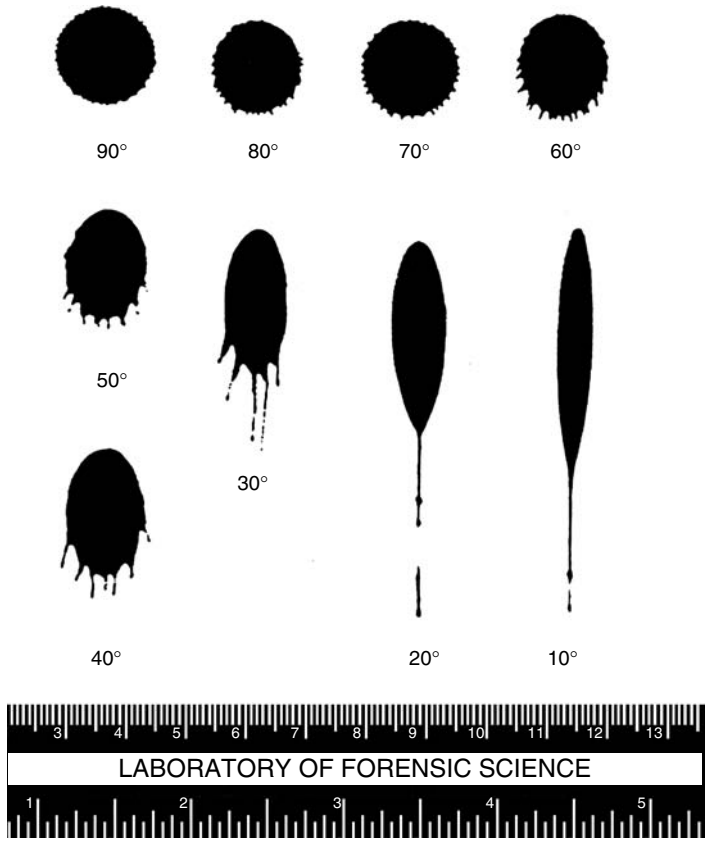

Figure 7 Patterns produced when typical drops of blood that fell 42 in. onto hard, smooth, cardboard at the indicated impact angles

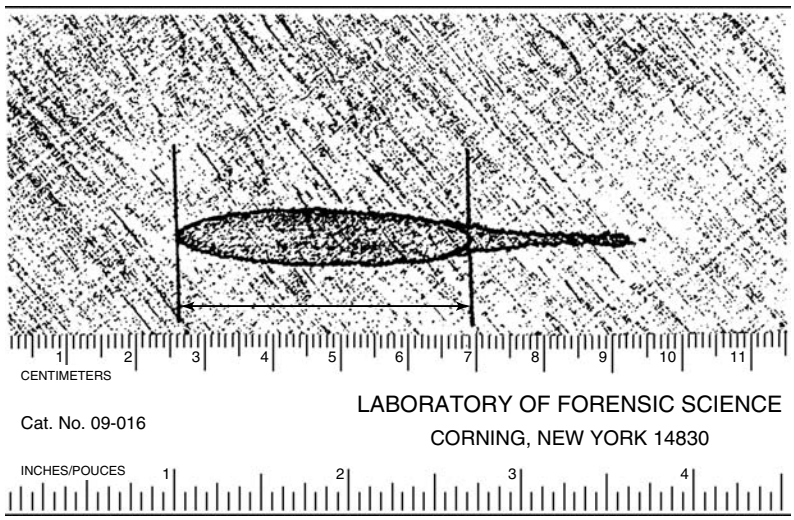

Figure 8 A curved line is traced over the bloodstain to identify the length of the ellipse at its pointed end

constructed at the scene from bloodstains using string, tape, and a protractor; or it may be done back at the laboratory from measurements taken at the scene. Both the location and geometry of several bloodstains are necessary to prepare an accurate model or graph to identify the origin.

It must be emphasized that when measurements and angles are used to establish the origin or origins in space, not only will the actual origin be somewhere below the point or points of convergence but it must also be remembered that the investigator is actually determining a space and not a point of origin. Since the practical application of establishing this space, which is more accurately identified as a volume, it is only establishing whether the victim was standing, sitting, or kneeling, on or just above the floor, in a chair or on a bed; pinpoint accuracy is not necessary nor can it ever be obtained. Wounds are never a pinpoint size.

Computer programs have been developed that can calculate the exact origin of spatter from bloodstains on the walls, floor, or ceiling of crime scenes. While this is a practical application of computer technology, such precise measurements will seldom be necessary. If the origin of bloodspatter can be established within the volume of a grapefruit, or even a basketball, and that origin is either at a standing height of 5–6 ft above the floor, at a level consistent with sitting on the piece of furniture in question, or lying on the floor, a satisfactory reconstruction will be achieved in all but the most unusual circumstances.

Bloodstain Characteristics: Size of Stain

Most information on this subject frequently neglected two essential considerations in their estimation of the distance a drop of blood had fallen before it struck a surface. These are the volume of the drop of blood and the nature of the target surface.

There is a very wide range of "wettability" of surfaces. Soft porous surfaces, such as a piece of cloth, will often have a large bloodstain that results from liquid blood soaking into the fabric. Conversely, blood that falls onto glass, or some other nonporous surface, and does not "wet" the surface, will result in smaller bloodstains as it contracts before it dries because of its internal cohesive forces. The result is that a smaller bloodstain will be produced than would have been the case had the same drop of blood fallen the same distance onto a tile floor, a wooden surface or a tight pile carpet. The cohesive property of blood may be easily and dramatically demonstrated by simply letting drops of blood fall onto a smooth, hard surface such as the top of a coffee can. Rub a very thin layer of oil or grease onto one half of the can top and leave the other half clean. Allow a drop of blood to fall 3 ft or so to one surface at a time. The drop that strikes the "greased surface" will immediately begin contracting until it is approximately one-half its original diameter. The drop that strikes the clean side will not contract at all because it "wets" the surface. This is an excellent way to demonstrate the terms "*wettability*" and "*surface tension*" to a lay jury: a "jury friendly" exercise, which helps them understand why many bloodstain patterns are produced as they are.

The resulting edge characteristics of a bloodstain are far more dependent upon the texture of the target surface upon which the drop lands than they are upon the distance it fell before impact. Therefore, conclusions as to the significance of "spines" or spatters as a function of distance fallen cannot be reliable unless texture of the target surface is considered. Bloodstains on glass will not spatter regardless of the distance they fell before impact, but bloodstains on wood or paper spatter to various degrees because they have wide variations in their surface texture.

Provided the volume of a drop of blood was known to be that of the 0.05-ml drop, which is typical, it is possible to estimate the distance it fell prior to impact. However, in almost 50 years of study this author has yet to find a practical application for such information.

Blood Spattered from Low-Velocity Impact (Dripped and Splashed Blood)

Blood dripping into blood produces a characteristic stain pattern. Liquid-to-liquid impact of this type results in many very small droplets being spattered upward and out away from the center of the blood pool that is being formed. This action is somewhat like a water fountain wherein small droplets are projected up and away from its center and they return to the surface from whence they came at obtuse angles. A typical drip pattern is shown in Figure 9.

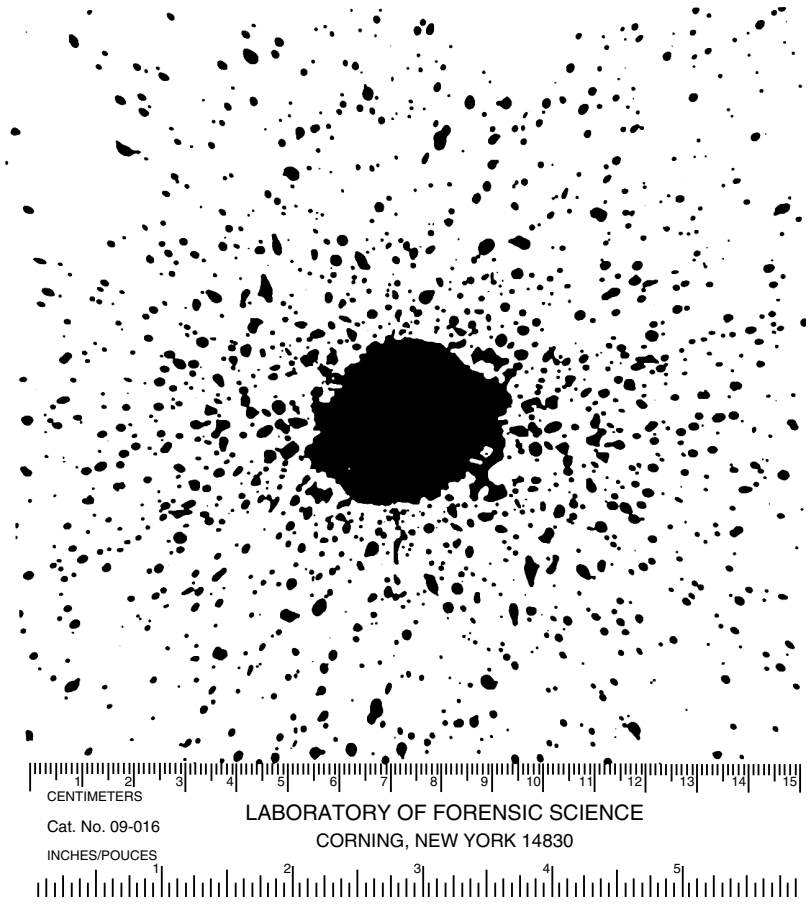

Figure 9 A typical drip pattern produced as blood fell into blood. Several drops of blood were released to form this low-velocity impact pattern

Blood acted upon by a low-energy, low-velocity force, such as when someone steps into a small pool of blood on a floor, will be splashed away from the point of impact. The drops that are produced will strike the surrounding area at very acute angles that are more streaks than ellipses. The resulting bloodstain pattern will usually have these long streaks radiating out away from the original source of blood as shown in Figure 10. Blood cannot have an upward trajectory from impact by the underside surface of a flat object such as a shoe. As a result the splashed blood can only skim along the surface before the individual droplets streak to a halt. Splashed bloodstain patterns are most often formed when larger volumes of blood are available for impact of this type.

Blood Spattered from Medium-Velocity Impact

During a beating, a stabbing, or other violent act it is common for blood to be shed. As blood accumulates on the surface of the victim's clothing or bare skin, if additional blows are made to the same area blood will usually be spattered. The force of the blows, with or without a knife blade, will usually have sufficient energy to overcome blood's surface tension releasing hundreds of very small droplets. The resulting spatter pattern is described as medium-velocity impact spatter. It is important to understand that the velocity of the weapon is usually higher than the velocity of blood, which leaves the main blood source, usually the victim's body. The preponderance

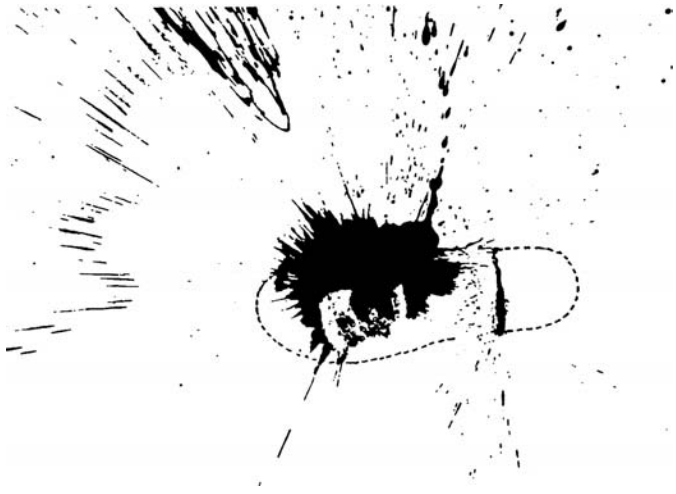

Figure 10 Low velocity, surface splashing caused by stepping into a pool of blood

of bloodstains resulting from medium-velocity impact spatter have diameters of 1 mm or larger as shown in Figure 11. It must be noted that while the diameter of most bloodstains produced by these mechanisms is well over this dimension, some are also much smaller.

Homicides due to beating are usually quite characteristic because of the large amount of blood that spatters. It is usually more than from a stabbing, cutting, or shooting. Exceptions, of course, do exist. If a broad axe were used as an instrument for delivering multiple blows or if a baseball bat repeatedly struck a victim's head in the same location the amount of bloodspatter would be considerable. In fact, multiple blows being struck to the head will create more bloodspatter than from any other common mechanism except gunshot wounds.

Those who administer beatings will often become spattered with blood. The absence of bloodspatter on the accused's clothing does not, however, prove nonparticipation as many defense lawyers would like to believe. To the contrary, it is possible to beat someone and not receive any backspatter whatsoever.

Many earlier researchers conducted beating experiments and reported that they found that blood was not always backspattered on garments worn by the perpetrator even though considerable blood was spattered elsewhere [4–6, 11–14]. Some of them pointed out that assailants could also have worn outer protective garments or had simply changed their clothes after they beat their victim. In many cases, it has also been reported that the perpetrator was nude when committing the crime and afterward simply showered and got dressed so they had no blood on their body or clothing.

Scientists should concern themselves with what they "see" rather than speculate as to why they do not see something they think they should. Nevertheless, when blood spots in the medium-velocity impact range are discovered on a garment, they are usually somewhat below the resolution of the average juror's eyesight. Some simple means of providing a "road map" identifying the location of these small spots of blood should be considered so a jury can understand not only their location but also their size and distribution. One convenient method is simply to place small white three ring binder reinforcers around each of the bloodstains and then to photograph the garment. Reinforcers should never be glued onto the garment but just placed around the bloodstain long enough to photograph the garment. An example of this technique is illustrated in Figures 12 and 13. In this case, a farm laborer beat his employer's wife to death with a hammer and a wrench. His work shirt, shown in Figure 12, was spattered with over 250 small bloodstains. Note the blood spots over his shirt pocket flap. Figure 13, shows the same shirt with the flap over his shirt pocket raised up. The presence of bloodspatter beneath the flap is evidence that the flap portion of his shirt was moving up and down at the time it was spattered with blood, a movement completely consistent with raising his arm up and down as in a beating.

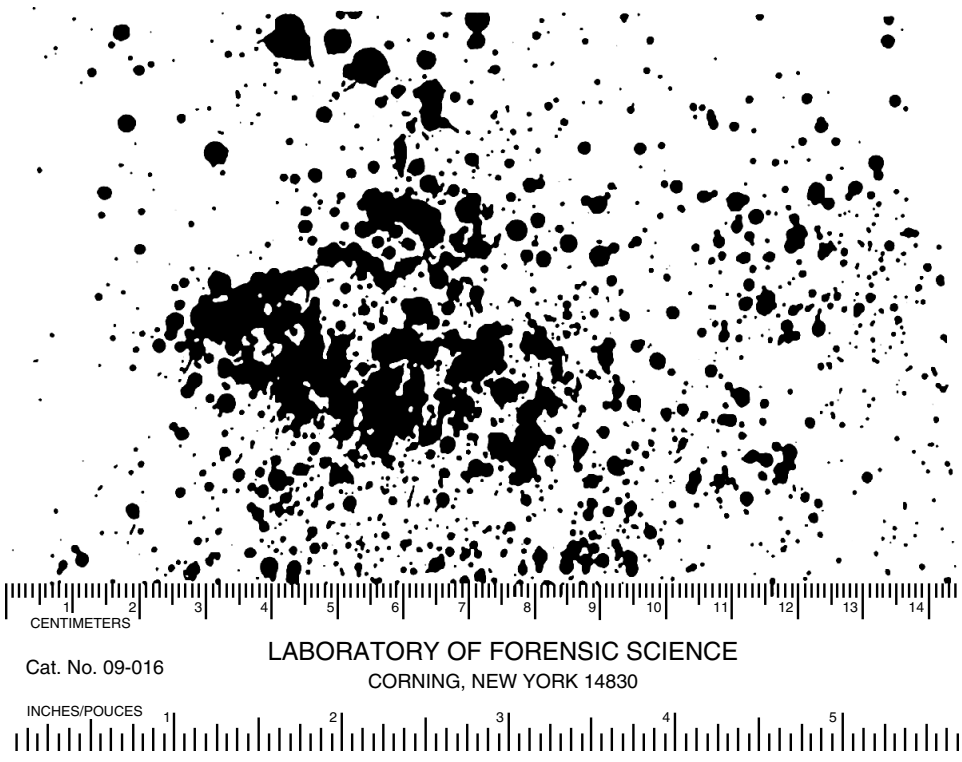

Figure 11 Typical medium-velocity impact spatter. Although the majority of these stains are over 1 mm in diameter, many are also much smaller

Another, perhaps more popular method of photographing the location of small bloodstains is to cut small, sharp triangles from masking tape and simply press them onto the garment so that their most acute angle points to the individual bloodstains. The blue jeans in Figure 14 show an example of this procedure. The triangular pieces of masking tape could be numbered for specific identification of each bloodstain, if desired. Surprisingly, masking tape adheres quite tenaciously. Garments that were marked in this manner had the tape still sticking to them several years after a trial even though they had undergone considerable handling.

Impact velocity associated with beatings and stabbings has been measured about 25 ft s^{-1}. Therefore, medium-velocity impact spatter is considered to be spatter that results from an impact to a blood source in this range. Extreme situations, of course, must always be considered. For example, a golf club may be swung at a velocity of over 75 ft s^{-1}. Fortunately, beatings with a golf club are rare but when such an uncommon event is encountered, it must be given proper consideration when interpreting bloodstain patterns that result. The highest beating velocities cannot approach the velocity of the slowest projectiles fired from handguns, rifles, or shotguns. For this reason, differentiation between bloodstain patterns that result from these two mechanisms is easily recognized by investigators who are familiar with evidence of this type.

Although very small bloodstains can only be produced when some form of energy is available, there are times when the mechanism that caused bloodspatter cannot be determined. Caution is required before forming a firm conclusion as to the only manner by which a pattern could be produced. It is usually better to use the words "consistent with" than it is to be more definite. This advice can be applied to many different bloodstain pattern types and is not restricted only to those that result from a medium-velocity impact.

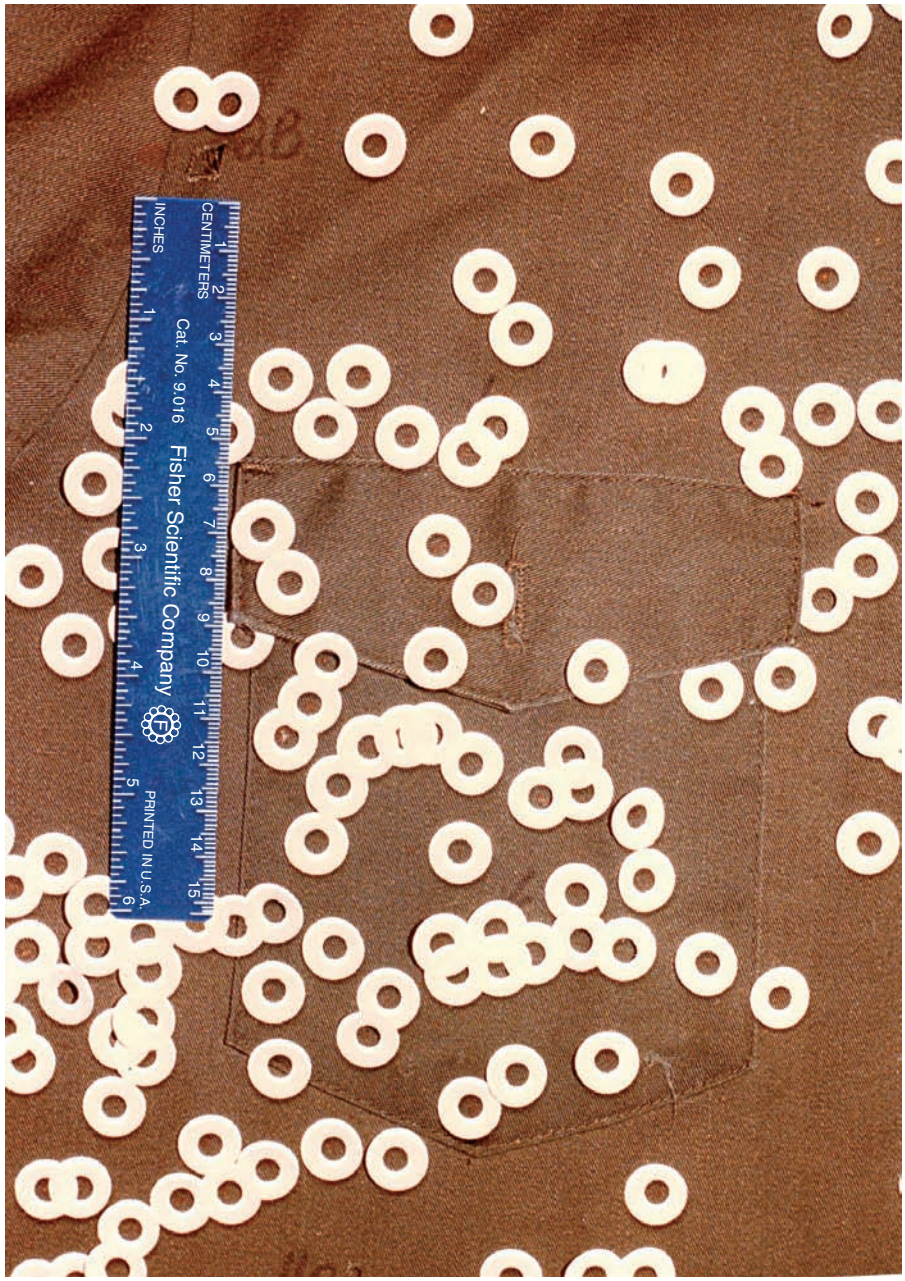

Figure 12 Three ring binder reinforcers used to identify the locations of each small bloodstain on the shirt front. Bloodspatter was present on both the outside and the inside of this pocket's flap

An important rule is that in most beatings there is little, if any, bloodspatter resulting from the first blow. The first blow in a beating does not usually strike blood. If it is severe enough, this blow only creates an open wound that will bleed. After blood comes to the surface of an injury any subsequent blows delivered to the same location will cause blood to spatter.

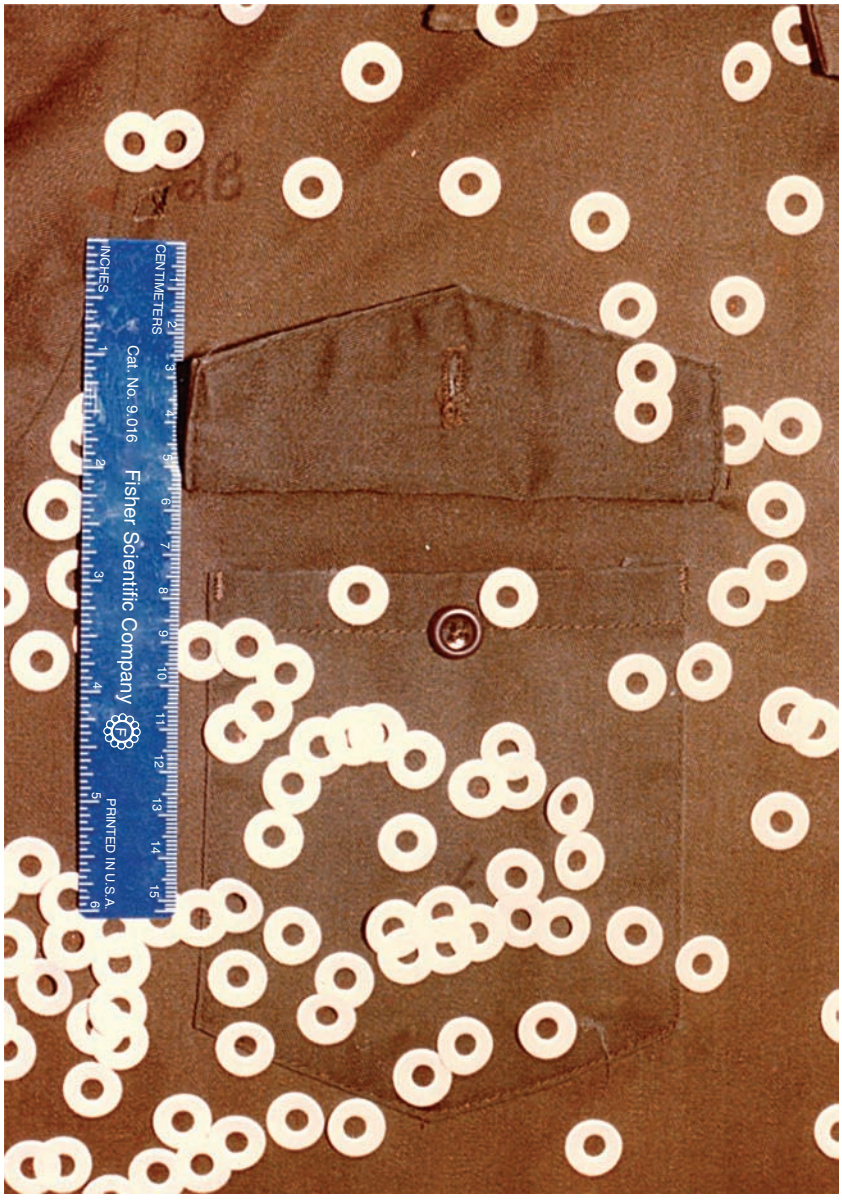

Figure 13 The same shirt that was shown in Figure 12 but the pocket flap has been raised to show that blood had also spattered under the flap and onto the front of the pocket beneath it. Therefore, this flap had to be up as well as down to allow blood to spatter onto both these locations. If the person wearing this shirt were raising and lowering their arm as they were beating someone, such a motion could produce this pattern

Blood Spattered from High-Velocity Impact

When considerable energy is applied to a liquid such as blood, the result is a proportionally greater dissociation of the liquid resulting in extremely small droplets. Stated quite simply, the more energy that is available, the more blood will spatter as its surface tension is ruptured by hydrostatic force. High energy allows much greater subdivision of liquids

Figure 14 Triangles of masking tape placed on the blue jeans to show the locations of small blood spots. Each piece of tape can be numbered so that a correlation between the results of chemical tests and the stains tested can be easily established

upon impact than can be accomplished during a beating. Thus, the higher the energy source, the smaller the blood drops. In almost all criminal cases wherein high-velocity impact spatter is produced, it is the result of one or more gunshots. It must be remembered, however, that almost any type of explosive force is capable of producing this type of pattern when a source of blood is available. The explosion of a hand grenade, high-speed machinery, or an aircraft propeller can also produce high-velocity impact spatter. Such cases are unusual but should caution the reader to remember that the term "*high-velocity impact spatter*" means just that and is not necessarily the result of gunshot.

In the usual case of a shooting where the projectile strikes exposed skin, the energy at impact is hydrostatically transmitted throughout much of the adjoining tissue. This results in the spattering of blood in a very fine, almost mist-like, spray. These atomized droplets of blood have a very high surface area and, therefore, cannot be projected very far in a horizontal direction. Usually, these very small droplets will be found within 3 or 4 ft of the impact point.

In addition to very small, mist-like droplets, several larger droplets will be produced as well. A typical

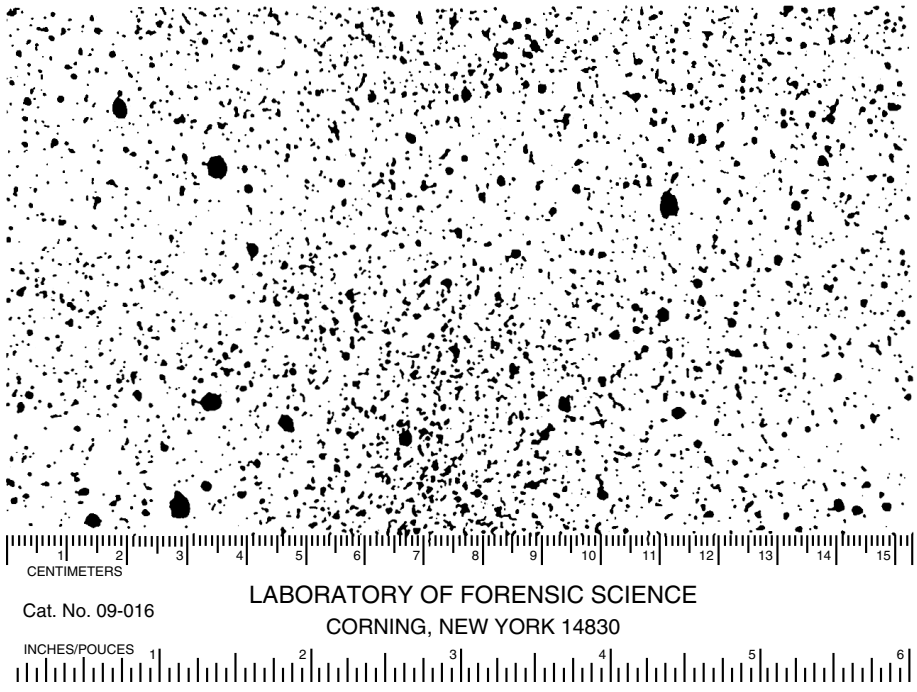

Figure 15 A high-velocity impact pattern resulting from a gunshot. Note that the diameter of the majority of blood spots is <1 mm but some much larger are also produced

spray pattern, characterized as high-velocity impact spatter, may be seen in Figure 15. Note that while the vast majority of these blood spots are well <1 mm in diameter, many larger ones are also produced. Interpretation of the bloodstain patterns of this type at a crime scene may be difficult when the body is not present. The investigator may believe that he is looking at medium-velocity impact spatter when he is actually looking at the larger droplet stains, which were projected beyond the limits of the characteristic mist that resulted from a gunshot impact. This is an unusual situation but it has been known to occur and will likely occur again.

The scene of a typical shooting showing extensive bloodspatter from high-velocity impact is shown in Figures 16 and 17. The weapon used in this case was a 30–30 rifle. It is evident in Figure 17 that void areas on the wall resulted when bloodspatter was intercepted by the brass tubing frame of the head of the bed. Such well-defined vertical lines demonstrate that the spatter came from a single impact and not what would likely have resulted had multiple blows been administered during a beating. The very small mist-like bloodstains that were on the wall cannot be resolved in this figure.

When very fine bloodstains are observed in a shooting incident, they should always be considered as most likely having originated from the impact of a bullet. In more than one case, the characteristic mist-like spray of blood was present inside the shirt cuff of a suspected suicide victim. Such evidence requires the open cuff area to be facing the victim's wound indicating a posture consistent with their holding a gun to their head.

It is important to examine a high-velocity impact spatter very closely to be able to resolve the very small blood spots that identify this type of pattern. However, it is frequently obvious that a gunshot wound has occurred from viewing scene photographs that were taken at a normal distance to show an overall area. The crime scene photograph shown in Figure 18, for example, is too distant to resolve the fine spray that can only be seen by getting very close to the ceiling. Nevertheless, when blood is projected upward onto the ceiling, such as shown in this figure, it is almost always the result of a gunshot that had

Figure 16 High-velocity impact spatter at the scene of a shooting. The victim was lying in bed with her head just to the right of the pillow when she was shot in the mouth with a 30–30 rifle

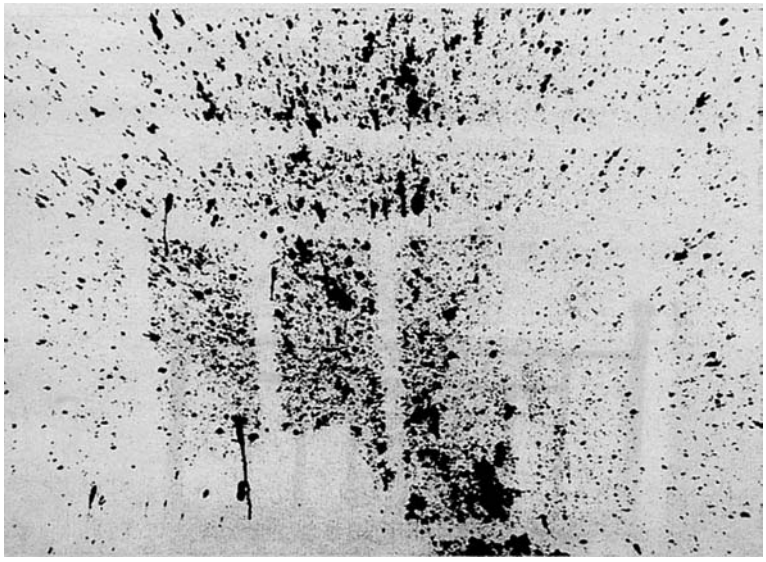

Figure 17 Close-up of the bloodstain pattern on the wall behind the bed shown in Figure 16. Void areas clearly define the outline of the brass headboard and the pillow. Such clear lines of demarcation establish the position of the victim when she was shot in her head

an upward trajectory. Such trajectory is most often associated with a suicide, as was the case shown in Figure 18.

When a high concentration of high-velocity impact spatter is found on a floor, furniture, or other surfaces, it will usually be directly below the point of impact that produced it. Clothing and shoes that are stained with high-velocity impact spatter must have been very close to the victim at the time of the shooting.

Figure 18 A high-velocity impact blood pattern on the ceiling of a bedroom. Although the very fine individual blood spots cannot be resolved in this photograph it is easily recognized from its overall appearance

It must be remembered that when blood is spattered as the result of a high-velocity impact, the fine mist produced does not travel very far in a horizontal direction. Air resistance acts against the projected droplets slowing them down so their distance traveled is inversely proportional to their cross sections. Thus, even the extensive spatter shown in Figure 19 did not result in any very fine, mist-like droplets reaching the walls or doors as they could only travel 5 ft or less. An examination of the walls and door in this figure suggests that considerable energy was available to have produced such extensive spatter.

It seems appropriate to discuss an apparent difference of opinion between two schools of thought regarding terminology of impact spatter. This author prefers the term *velocity*, rather than *energy* to describe the nature of an impact that results in bloodspatter. Thus, the terms *low-velocity impact spatter, medium-velocity impact spatter, and high-velocity impact spatter* are preferred over *low-energy impact spatter, medium-energy impact spatter, and high-energy impact spatter*. While these two physical terms are closely related, the justification for using *velocity* rather than energy may be demonstrated by a comparison of the difference in bloodspatter resulting from two events of equal *energy*. In the first example consider a bullet impacting a sponge that has been saturated with blood. The result is a very fine spray of blood, high-velocity *impact* spatter, which is easily recognized. In the second example, an elephant steps into a large pool of blood causing very large splashes of blood to appear around the elephant's foot. The "elephant splashes" could never be mistaken as being produced by gunshot and yet the same *energy* was available in both instances. Thus, the more appropriate descriptive term *velocity* is the better choice. Possibly, the term *flux*, which could be used to describe the *rate of flow of energy,* ought to be considered.

Bloodstain Patterns Resulting from Projected Blood

When large volumes of blood are projected onto a surface, a somewhat unique bloodstain pattern can result. The impact surface may be a wall, a floor or any other surface. Only under unusual circumstances could it be a ceiling. The most common situation in which this occurs is when an artery, usually a major artery has been severed or otherwise breached from gunshot or some form of blunt force injury. Systolic arterial pressure may cause blood to spurt or gush from the wound in large volume pulses. If blood is projected in this manner and strikes a surface that is relatively close to the injured victim, the resulting bloodstain pattern will fall into one of three basic classifications each of which may be easily recognized.

Figure 19 Extensive bloodspatter resulting from a shotgun discharge to the victim's face. When he was shot, the victim was lying face up on the floor. This photograph is an excellent example of how larger blood drops, produced from high-velocity impact, can travel great distances but mist-like smaller droplets cannot

Type I Arterial is characterized by large bloodstains, which have very elongated spines. The elongated spines indicate that an energy greater than that resulting from normal gravitational attraction was present.

An example of a Type I Arterial projected bloodstain pattern is shown in Figure 20. A young girl was stabbed in the neck and her left carotid artery was severed. She fell to her knees as she crawled away from her assailant and left a trail of large arterial splashes on a driveway. The trail of her blood extended over 60 ft from where she was stabbed to where she was found.

Type II Arterial is characterized by bloodstains which are, somewhat smaller than Type I. They have well-defined borders with few, if any, spines. Bloodstains of this type often have sufficient volume that blood run down a wall or other vertical surface. They usually result from a wound that somewhat restricts the clean projection of blood away from the victim's body or that is a few feet from the target upon which they land. An example of this is shown in Figure 21.

Type III Arterial is a difficult arterial pattern to recognize because it consists of small drops rather than the large splashed blood volumes, which identifies Types I and II Arterial. Smaller drops of blood are produced because the artery, which is breached or severed, is covered with overlaying tissue, which can restrict blood from exiting in the large discrete pulses typical of Types I and II Arterial. Nevertheless, one characteristic of Type III Arterial identifies it with certainty when it is present, the appearance of a series of individual heartbeats, which reflect the systolic mode of the heart. Such patterns look somewhat like one that could be produced by raising and lowering a garden hose nozzle, which was set to a coarse spray while slowly moving it to one side or the other. Figure 22 shows an excellent example of Type III Arterial that resulted from a self-inflicted gunshot would to the right temporal area.

Another example of Type III Arterial where blood spurted from beneath crushed tissue over an anterior temporal artery may be seen in Figure 23. These patterns resulted from spurts of blood onto a bathroom wall. Individual heartbeats are identified as the peak of each spurt in this figure.

Cast-Off Bloodstain Patterns

During a beating, blood usually does not accumulate on the surface of the victim's wound after the first blow. After blood covers that area, however, a "second" blow to the same area will produce spatter and often adheres to the beating instrument. As a

Figure 20 A Type I Arterial pattern produced by blood, which was projected from a carotid artery that had been severed by a stabbing. Well-defined pulses are evident

Figure 21 A Type II Arterial pattern that was produced when blood gushed from a wound to a wall at a greater distance than in Figure 20. Therefore, the large spurts separated into smaller drops. Two distinct pulses are evident

Figure 22 A Type III Arterial that was produced when blood from the victim's severed right temporal artery was projected on the carpet several feet from its origin. As her head turned slowly to her right side, blood created a zigzag pattern on the floor. This pattern is like a hospital strip chart recording of a cardiogram

Figure 23 A Type III Arterial spray pattern that was produced when the victim of a beating stood in front of his bathroom sink. Blood was sprayed from his crushed temporal artery to a wall indicating that he stood in that location for several seconds. Very small droplets were produced because of his skin overlying his wound

bloody hammer is raised and swung back by an assailant, the path of the hammer head is more up and back than it is in a curved motion. A study of the beating mechanism, using high-speed strobe photography confirmed this rather right angle course. As a result, when the direction of the hammer head is shifted from an upward, raising motion, to a backward, swinging arc, the angular momentum of the blood adhering to the swinging hammer is usually sufficient to overcome the surface tension of blood

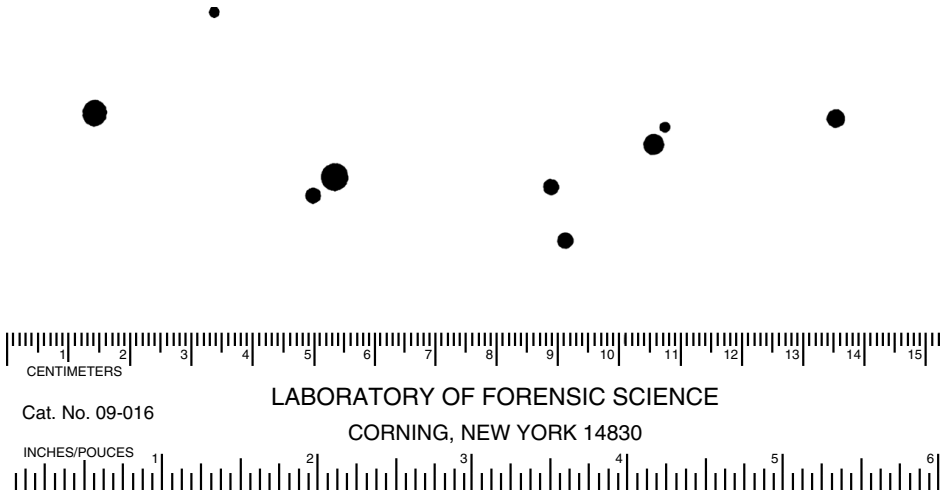

Figure 24 A cast-off bloodstain pattern on a ceiling directly over the point of impact. These spots are round because they struck the ceiling about 90°

allowing small drops to be released. These small drops usually strike the ceiling about 90° directly over the victim. A few bloodstains that were on a ceiling directly over the head of a person who was beaten on a bed are shown in Figure 24. The direction the instrument was being swung when this pattern was made cannot be determined from blood spots that are as nearly circular as those that are shown in this figure.

As the instrument continues to be swung backward, its movement accelerates and additional blood droplets will be cast off from its surface. If any of this blood reaches the ceiling, it will strike at ever increasing acute angles and the bloodstains will become more elongated. Figure 25 shows the continuation of the cast-off arc pattern shown in Figure 24, but at a distance some 22 in. further to the right. Directionality of these bloodstains is clearly from left to right. Observing a cast-off pattern such as this on a ceiling identifies the location where a beating had occurred. Although only the two ends of this pattern have been used as an illustration, the entire overhead pattern is in a "single file" straight line configuration.

Frequently, multiple cast-off patterns are present when a victim is struck repeatedly in the same general area so blood can accumulate on the weapon being used. If the victim was not mobile the minimum number of blows may be estimated by counting the individual cast-off blood trails. One blow should be added to the total because the first blow struck will not usually allow blood to adhere to the beating instrument in a sufficient volume to produce a cast-off pattern on the backswing. If the victim was mobile while being beaten, ceiling cast-off patterns can appear at more than one location and do not radiate out from a single origin. Likewise, if more than one person administers a beating, or if a single assailant moves about, more complex patterns can be produced.

When sufficient blood adheres to a beating instrument while it is being raised up, cast-off patterns can also be produced on the downward or beating swing. If such pattern is produced, it will most likely consist of two or more parallel lines whose individual blood drops will show a downward directionality. The reason for the "single file" bloodstain pattern on the upswing and the "double (or triple) file" bloodstain pattern on the downswing is simply that more blood is released, or flung from the instrument nearer the end of a swing when it is at its greatest velocity. The upward swing casts blood off while the instrument is accelerating, while the downward swing has already reached its maximum velocity. This applies to walls only as these patterns reverse for cast-off bloodstains on ceilings. When there is a considerable blood volume on an instrument, it may create a confusing "double file pattern" where there are bloodstains that appear to be traveling in two different directions. This only occurs when the victim is near a wall and the person doing the beating is facing that wall. Some

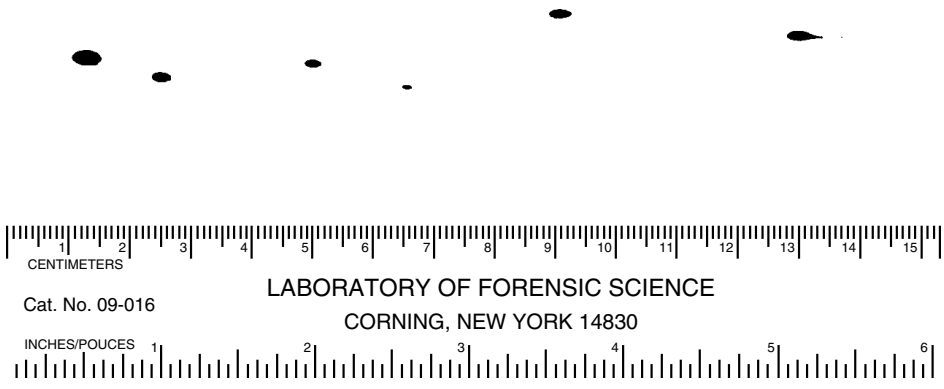

Figure 25 A continuation of the right side of the pattern shown in Figure 24. The sharp pointed ends on the right of these bloodstains show their direction of travel, left to right

large drops of blood are released as the instrument is raised and they do not travel upward very far before falling and they strike the wall in a downward direction. Many smaller drops are then released as the instrument continues to be swung upward and even though they are actually part of the same cast-off "single file" pattern, they were traveling in the opposite direction when they struck the wall.

Horizontal cast-off patterns are common when blows are delivered by horizontal rather than vertical movement. As a result of gravity, the end of such patterns will be seen to be falling off or downward toward the floor.

Expirated Bloodstain Patterns

If blood accumulates in the air passages of an injured person, it is frequently blown out through the mouth, the nose or a combination of both. Blood projected by such mechanism is called "*expirated*" *blood*, not "aspirated" blood. Aspiration is the sucking in action of a chest wound, not a blowing out. Blood that is projected blood by expiration produces bloodstains that appear very much like those which result from a medium or high-velocity impact. In contrast, however, droplets that are blown out of the nose or mouth can only be found in locations where such an origin is possible.

Blood spots on the fingers and hand shown in Figure 26 appear small enough to have been produced as a result of a medium-velocity impact. The actual origin of this blood, however, was the victim's mouth, as shown in Figure 27. If there is a question as to whether or not blood could have been expirated, rather than from impact, photographs should be taken of the victim's face and their oral and nasal cavities should be swabbed if it is not obvious that they contain blood.

Recognition of expirated bloodstain patterns is not difficult. Common sense dictates that if the victim had no blood in the nasal or oral orifices it would have been impossible for blood to have been expirated from either. When air bubbles are present in bloodstains this is evidence of expirated blood. However, it should be remembered that penetrating wounds to the chest can also produce bubbles in blood. In such cases, there may not be obvious blood accumulated in the mouth or nasal passage.

Expirated blood may also be blown out of wounds as well as from the nose or mouth. In a case in Pittsburgh, a man stabbed himself in the chest with a large buck knife that remained stuck in the wound. Several very small bloodstains were evident on the knife directly over his wound as a result of blood that was expirated up onto it.

Transfer Bloodstain Patterns

Human blood is frequently a medium of transfer, which allows geometric shapes of various kinds to be reproduced as a mirror image onto a surface. Bloody fingerprints, footprints, and footwear prints have been received in evidence countless times so an extension of this basic transfer mechanism to include fabrics, hammer heads, knives, clubs, tire irons and the like, is nothing unusual. A transfer pattern frequently

Figure 26 Bloodspatter on the victim's hand suggests that it was the result of medium-velocity impact; however, the actual origin of this expirated bloodstain pattern was the victim's mouth

Figure 27 Actual source of the bloodstains shown in Figure 26. Blood was expirated from the mouth and/or nose onto the victim's hand

encountered in homicide investigations is the hair swipe pattern. Two basic patterns of this type are quite distinct in appearance and both are easily identified. The first is produced when hair that is wet with blood makes a lateral swiping of a surface and leaves characteristic fine lines and a feather-edged reproduction of several individual hairs. A typical hair swipe pattern is shown in Figure 28.

When hair that is wet with blood comes into contact with a surface without lateral movement, the result is compression transfer rather than a swipe pattern. A young girl was killed when her assailant

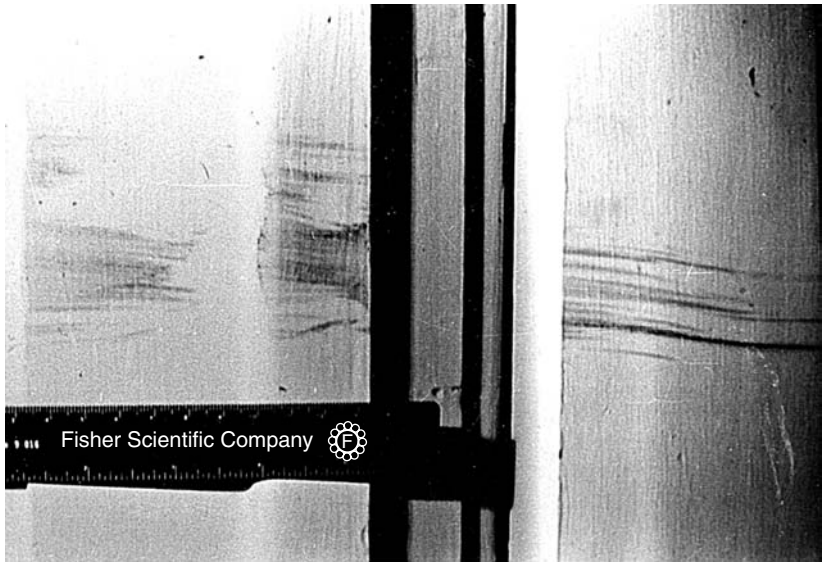

Figure 28 A typical hair swipe pattern that was caused when bloody hair latterly brushed across a door and doorway

Figure 29 A typical compression transfer pattern produced when blood soaked hair pressed against a surface without lateral motion. Fine line transfers show the impressions of individual hairs

stamped on her head after raping her. Considerable blood had soaked into her hair and when her head came into contact with a wall and baseboard a compression transfer was produced. That pattern is shown in Figure 29. A study of this figure discloses several points of contact where characteristic fine, single hair replicas have been left on the baseboard and the wall above it.

In most instances where a compression transfer pattern is produced, blood is deposited from a bloody object in a mirror image of the original. However, when a coarse fabric, such as corduroy or knit

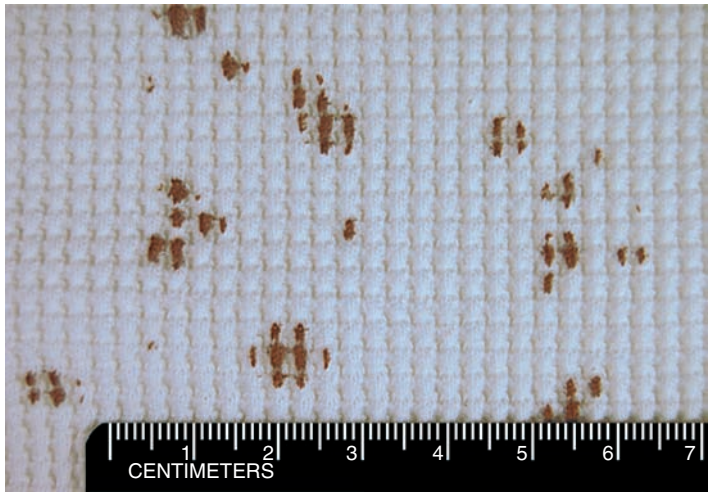

Figure 30 A typical bloodstain pattern resulting from compression transfer. Only the top of several strands of fibers are bloodstained

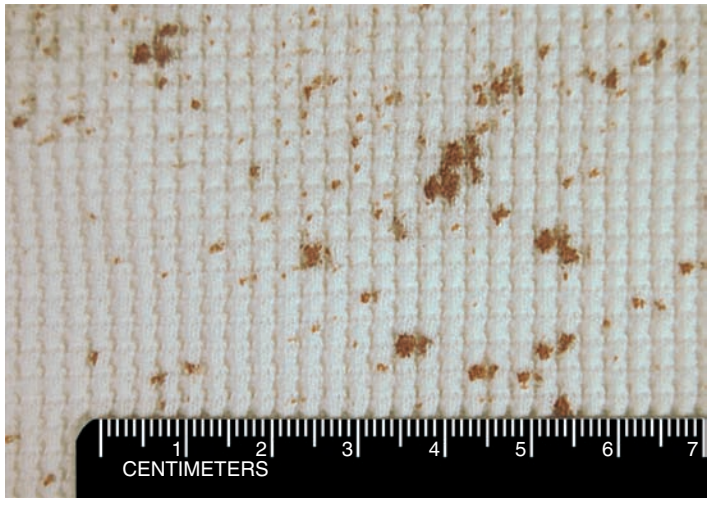

Figure 31 Appearance of small bloodstains that resulted from blood that was projected onto a sweater. Note their random distribution between and on the "ribs"

sweater, is involved, only the top of the fabric will become stained. The presence of blood on the "ribs" or upper weave portion of a fabric will establish the staining as a transfer mechanism because had the blood been projected onto the fabric it would be equally deposited between the "ribs" as well as on top of them.

A bloodstain compression transfer pattern may be seen in Figure 30, which resulted when a person who was wearing a sweater bent down over a fresh bloodstain pattern. Blood was transferred only to the top of the weave pattern. Projected blood droplets on fabric are not restricted to the top of a weave as they penetrate down into the lower portion or "valleys" as well.

Figure 31 shows bloodstains that were projected to the back of the same sweater shown in Figure 30. Because of their random distribution, many of these stains landed between, as well as on the top of, the

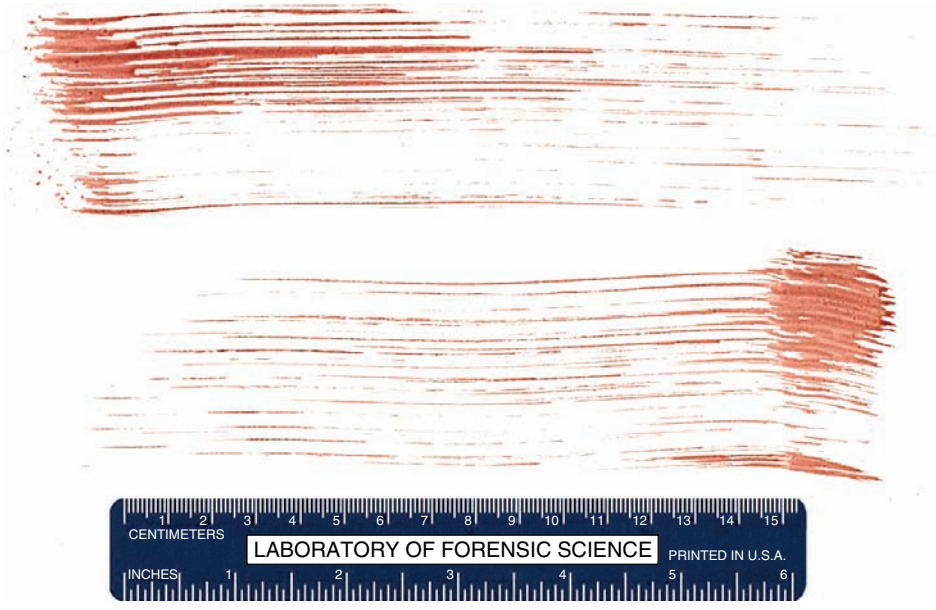

Figure 32 Two similar lateral swipe transfer patterns. Both were produced from a left-to-right lateral motion

weave pattern. This is a relatively simple observation that can be made with only a hand magnifying glass.

Some authors have written that it is possible to determine the direction of travel of the object that created a swipe transfer pattern. This may often be true with hair swipes; however, it is not possible to make this determination with 100% accuracy when a bloody fabric leaves the bloodstain. Figure 32 shows two swipe bloodstain patterns both of which were made by a left-to-right lateral motion although the lower one appears to be just the opposite. Obviously, caution must be exercised in forming a firm opinion when exceptions to general rules are known to exist.

Recovering and Documenting Bloodstain Pattern Evidence

Photographic Documentation

It is essential that good photographs be taken of all bloodstains at the scene of a crime. Close-up photographs should be taken of all bloodstain patterns. These should be taken normal (90°) to surface upon which the bloodstains are found. A ruler or some other scale of reference should be included in each photograph. It is always important to document which bloodstains are being photographed. One convenient way to achieve this is to use a felt marker to circle and number all bloodstains and/or any bloodstain patterns which are of interest. Overall photographs should be taken to show the geometric relationship of bloodstains to the general crime scene area as well as to each other. When photographing bloodstains at 90° it is important not to have a flash on the camera. The satin-like sheen of dried blood will cause serious flash back and the bloodstains may not show up.

The exact location of bloodstains, which will be used for calculating angles of impact, must be recorded in some systematic manner. The distance of a bloodstain from the floor or ceiling and from the nearest wall should be entered on a form that provides a blank space for the width of a blood stain, its length, and its width-to-length ratio followed by space for the impact angle after it has been calculated.

Distant or overall photographs do not usually require a reference scale because furniture and/or other objects are usually present, which allow the viewer a good size relationship. If the origin of bloodspatter is to be photographed, elastic string that has contrast with the background should be selected.

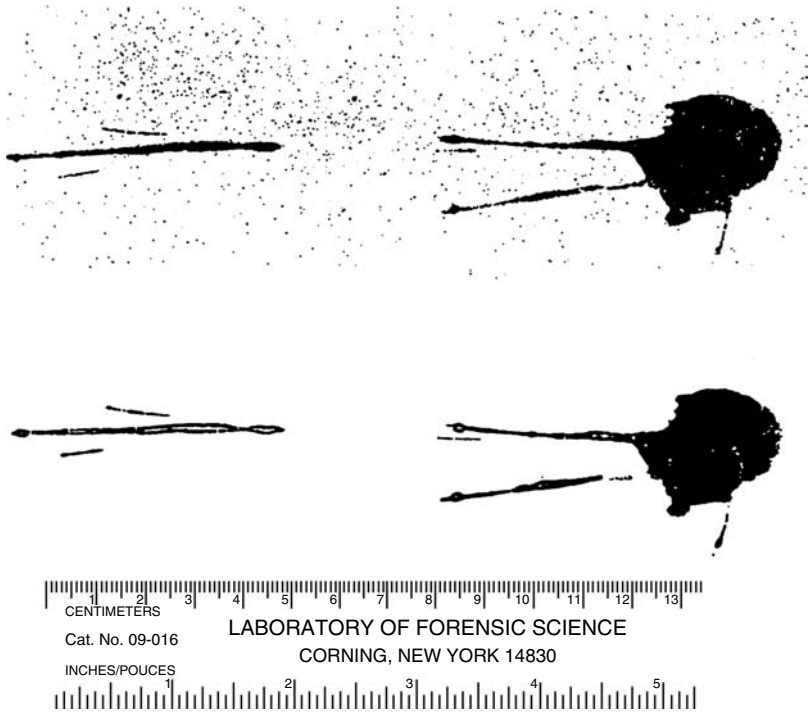

Figure 33 Bloodstains that were lifted from a kitchen floor tile. The top stain shows how the blood appeared before it was lifted. The bottom stain is the lift that was removed from the floor with clear tape

Lifting Bloodstain Pattern Evidence

In addition to the photographic recording of bloodstain patterns, another simple, and perhaps even better technique, should be considered; remove the bloodstain itself. This recovery method at a crime scene is apparently not often employed by investigators. The method is no more difficult than lifting a processed fingerprint and, in fact, employs the same material, transparent fingerprint tape.

After photographs have been taken if bloodstains are on a flat, hard, smooth surface, such as major kitchen appliances, an attempt should be made to lift some of the bloodstains to preserve them as evidence. One and one-half inch wide transparent fingerprint tape, which also can serve as a scale of reference, can be used. The procedure is very straightforward; one simply presses the transparent tape over the bloodstain applying considerable pressure to the stain area with a ballpoint pen or fingernail. The tape is then carefully peeled from the surface. The bloodstain is frequently almost completely removed. The lift should be placed on white plastic so, if for any reason, it can be lifted again in a laboratory to expose the blood. This is to suggest that this is not a method of choice for recovering blood samples for serology.

Although hard, smooth surfaces are ideal for lifting bloodstains at a crime scene, many unlikely surfaces often yield excellent results. Nothing is lost if the attempt to lift a bloodstain is unsuccessful so there is really no reason not to make the effort. Figure 33 shows how efficiently a bloodstain was removed from a kitchen floor tile. Blood shown in the top of this figure is how it appeared on the floor. Blood shown at the bottom of this figure is what was lifted using fingerprint lifting tape.

Blood that remained on the floor tile consisted of very fine lines that would fill the narrow voids in the streaks of the lift. Recovery was well over 99% effective. Many other more porous surfaces such as wallpaper often permit removal of the bloodstain; however, part of the wallpaper is frequently removed as well. In such cases, the size and shape of the bloodstain are still preserved so nothing is really lost.

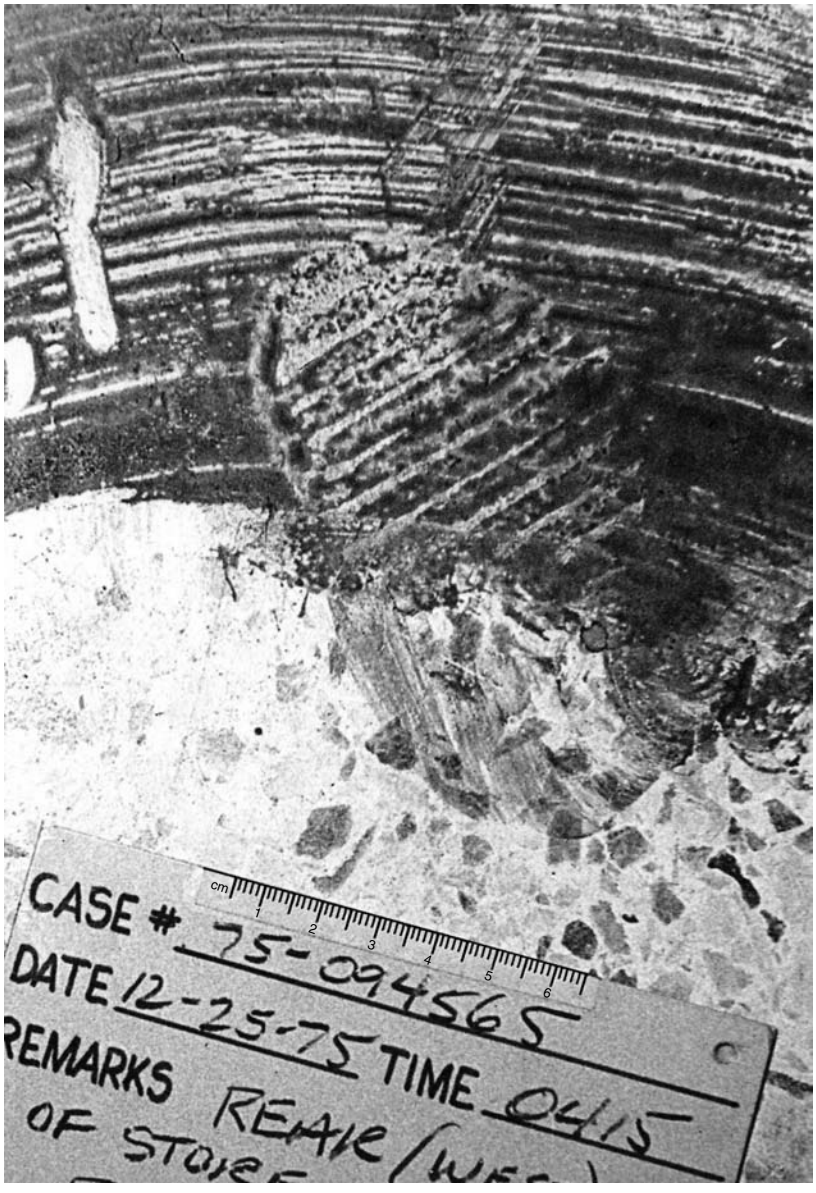

Figure 34 Large, thick smear of blood on the floor of a furniture store

Research When Necessary

From time to time, bloodstain patterns in a case will have some aspect that could be difficult for a jury to understand. When that happens, it may be advisable to conduct and document certain experiments. This was the situation in a Florida case where the elimination/identification was in dispute. There was a large smear of blood on the floor of a furniture store where four people had been murdered. Within the smear there was a void that looked very much like it could have been caused by the heel of a shoe. Its overall appearance and size matched the suspect's shoe; however, when the shoe and the photograph were sent to a federal laboratory for evaluation, the examiner reported that the pattern could not have been made by

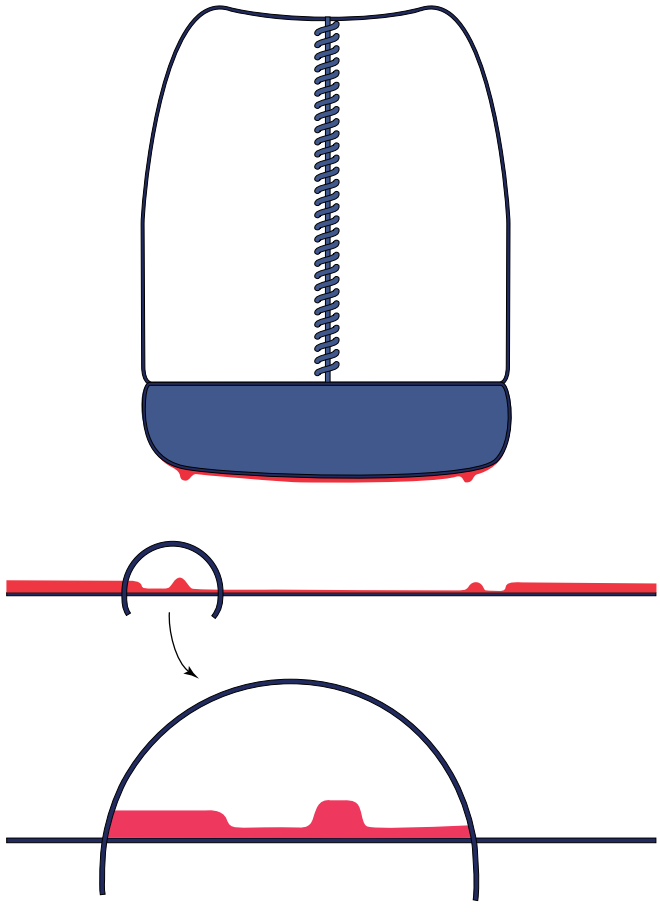

Figure 35 Blood on the heel after being lifted off the blood smear on the floor. The broken web of blood is on both the shoe heel and the floor

the suspect's shoe. The basis for concluding that the bloodstain and the shoe did not match was the presence of a ridge of blood, which was just inside the outer edge of the heel. The arrow points to this ridge in the large blood smear shown in Figure 34. The suspect's shoe was very smooth in the corresponding area and had no such ridge.

The prosecution had a problem. If this was not the defendant's heel print, then another person must have been at the scene of the murders. Actually, it should be obvious to any scientist why there was a "false ridge" in the bloodstain; it is called *capillary action* and is the result of the surface tension of blood. When the suspect stepped into the thick smear of blood almost all of the blood was forced to the sides of the shoe. Then, as the shoe was raised up, blood around its edges was drawn back under the shoe by capillary action.

As the shoe was raised up still further a "web" of blood formed and broke leaving the false ridge just within the outline of the heel and on the heel itself. A diagram of this phenomenon is shown in Figure 35.

To demonstrate to the jury how easily a false ridge of this type could be produced, a smear of blood was made on a tiled floor. The defendant's shoe was pressed down into the blood and raised back up. This was done several times using the evidence shoe and on every occasion a clear false ridge was produced. The result of four experiments may be seen in Figure 36. This experiment had been conducted at least 300 times at the Bloodstain

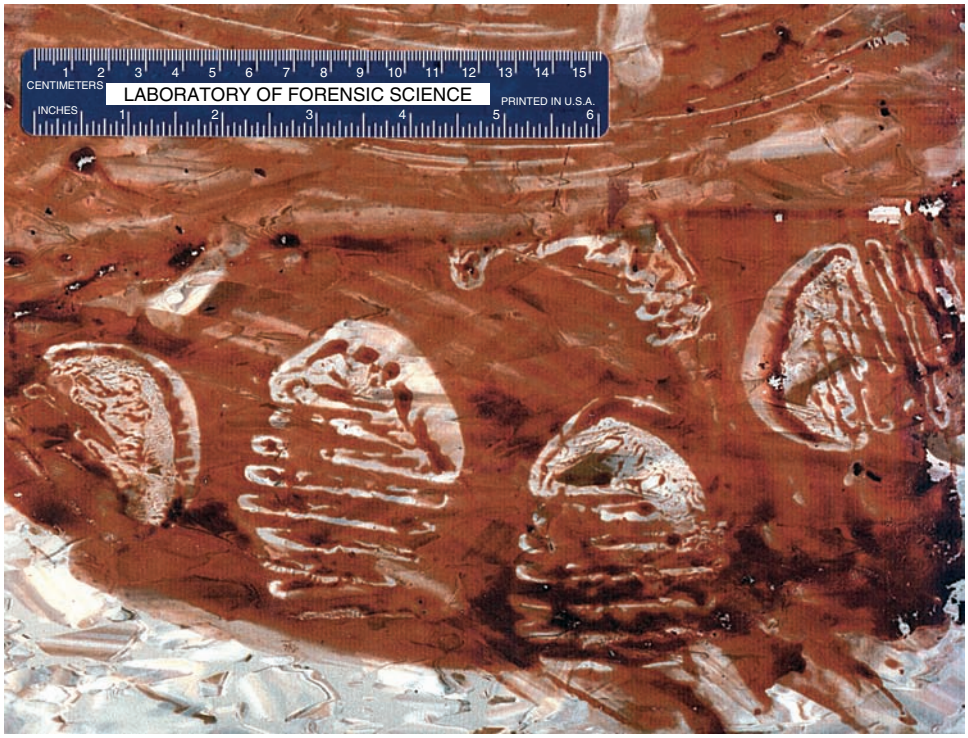

Figure 36 Blood ridges produced using a shoe that is absolutely smooth in the area of concern

Evidence Institute, using a shoe of the same type that was worn smooth in the same area and to the same degree as the evidence shoe. The results are always the same.

A young girl in Oregon claimed that bloodstains on the ceiling of an upstairs bedroom resulted from an injured older lady shaking her hair, which was wet with her own blood. The ceiling patterns were obvious cast-off patterns, which are characterized by their in-line and arc-like geometry. A series of experiments using live subjects, whose hair was saturated with human blood (this was before acquired immune deficiency syndrome (AIDS)), were conducted to determine how bloodstain patterns produced by blood cast off from hair would actually look. Several younger and more athletic girls with a wide variation in their hair lengths were the models. None of them could throw even one small drop of blood from their hair to strike a ceiling of the same height above a bed as in the actual case. It was proven that blood was cast off from a fire poker and not the victim's long hair.

Reconstruction of Events Using Models as Victims or Perpetrators

People were used as models for over 30 years to aid in a better understanding of what is and is not anatomically possible [15]. I have data on some 250 individuals in my computer who are listed by gender, height, weight, hair length, hair color, color of eyes, and age to pose in a reconstruction so they can be photographed and better show a jury what the evidence suggests rather than a word description.

Case Example #1

A young girl was found as shown in Figure 37. She had many bloodstains on her body and clothing and it was obvious that she had been put in the location and posture in which she was found after her blood had run on her legs. How it ran down both sides of her right leg was resolved by using a model.

In Figure 38, a technician is transcribing bloodstains that are shown in Figure 39 to a model's leg

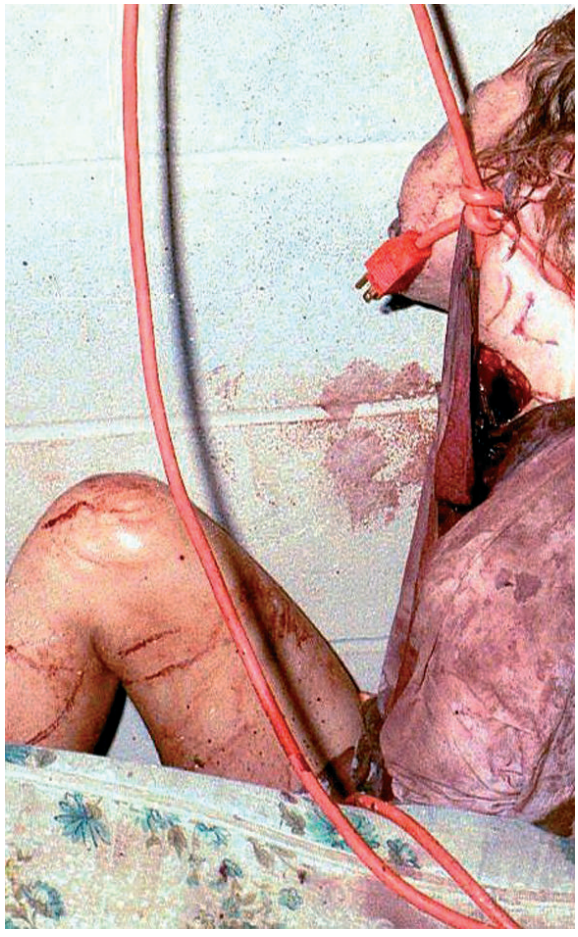

Figure 37 Victim as discovered and photographed at the crime scene

using a red felt marker. After this had been done, the model assumed a position similar to the position the victim was in when she was found as shown in Figure 37. Several photographs of the model were taken to show how her leg had to have been in a normal sitting posture when blood ran down her leg. Blood does not run sideways nor can it flow upward under normal circumstances.

The victim had a slit on her wrist, which was more consistent with a defense wound rather than one that had been self-inflicted. This cut was the only logical source of the blood, which had run down both the inside and the outside of her right thigh. Figure 39 shows how easily that cut could have caused the bloodstains on her leg if her arm was resting on her knee.

Case Example #2

In the OJ Simpson case, many bloodstains of various sizes and shapes were present on Nicole Brown Simpson's back but none of these were ever collected for analysis. Figure 40 shows the size and shape of many of these bloodstains. The bloodstain over her left shoulder was the size of an adult fingernail, yet it was left only to be washed away at the morgue.

The question as to the origin of these bloodstains was solved by having a model of the same physical build assume the posture in which Nicole Brown Simpson was found and photographed. Using seven photographs of Nicole's back taken at the scene the location, size, and shape were transcribed to a model's back using a red felt marker as shown in Figure 41.

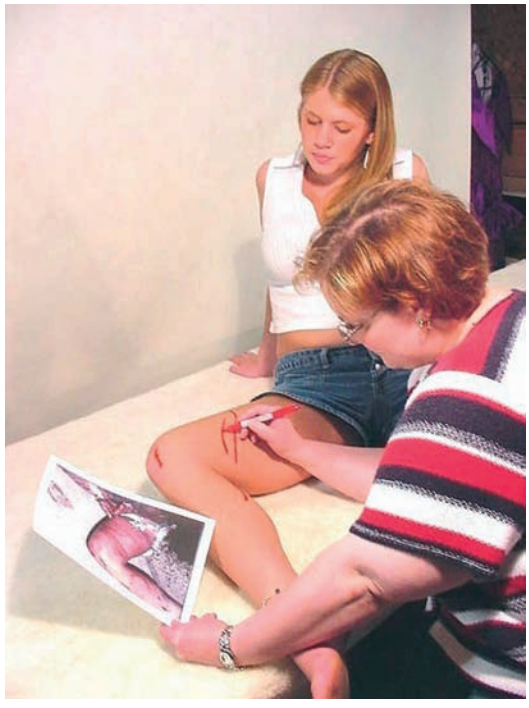

Figure 38 Drawing "bloodstains" on a model's leg with a red felt marker in the same size, shape, and location as it appears on the victim's leg in the crime scene photograph

Figure 39 "Bloodstains" on the model's leg in relationship to a cut on her wrist

Figure 40 Bloodstains on the back of Nicole Brown Simpson which were never collected

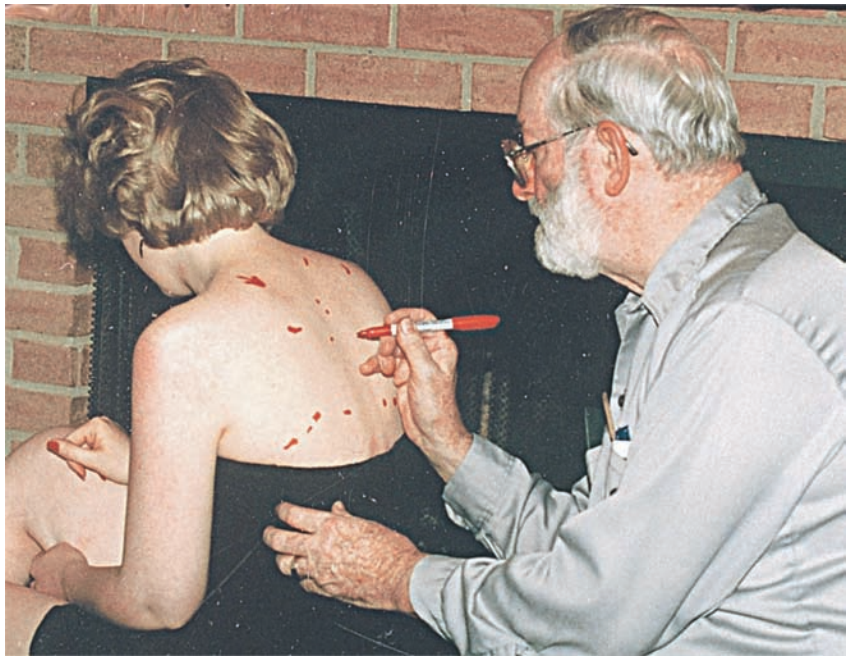

Figure 41 Drawing a bloodstain on the model's back with red felt markers in the same location, size, and shape as those of the back of Nicole Brown Simpson. Seven separate photographs were used for maximum accuracy

Figure 42 (a) Bloodstains on Nicole Brown Simpson's back at the crime scene. (b) "Blood" drawn on the back of a model with a red felt marker duplicating the same pattern of spattered blood shown in Figure 42(a)

Figure 43 Notice the concentration of blood that was spattered from the victim's head wounds to the snow over her right shoulder. The dark spots over her left shoulder are small stones and not bloodstains

Figure 44 This figure shows the only location where the perpetrator could have been standing relative to the victim to have had blood spattered over her right shoulder as seen in Figure 43

After all of the larger bloodstains were drawn on the model's back, she assumed the position of the victim. A comparison between the victim's position and that of the model may be seen in Figure 42 (a), (b). Using the "bloodstains" on the model's back, it was possible to estimate the location from whence the blood spattered. As it turned out there was no need for this information; however, it was available had it been wanted.

When comparing Figure 42(a) to Figure 42(b) it must be noted that they were taken from slightly different perspectives. Therefore, the bloodstains on the top of Nicole Brown Simpson's shoulder, which are very evident in Figure 40, do not show up well at all in Figure 42(a).

Case Example #3

In an Ontario case, the relative position of the man who beat a woman to death was important as a witness had given this information to the police. This was a relatively simple task as may be seen from the location of the bloodspatter pattern in the snow. The victim's wounds were all to her right temporal area. From the pattern of blood shown in Figure 43, it does not appear to have but a single origin. This is in agreement with the witness' statement that the victim was already incapacitated when the final beating took place.

The instrument used for this beating was an automobile jack. It had a long oval slot cut out of the metal and an impression of its outline was clearly evident on the victim's skin around her head wounds. Therefore, there were only two places the person administrating the beating could have been standing at the time. He was either standing beside her right side or over her left shoulder. For blood to have spattered in the location where it was found there was only one possible choice. He stood as shown in Figure 44, over her right shoulder. This provided corroborative evidence as that is what the eyewitness had reported.

Summary

When bloodstain pattern evidence is properly studied and evaluated, it should result in a more accurate reconstruction of events than otherwise would have been achieved. In conjunction with other evidence, bloodstain pattern interpretation can often be of great assistance to juries. Frequently, bloodstain patterns will be helpful in confirming conclusions that have been established from other evidence, such as a projectile's trajectory and *vice versa*.

Physical evidence is evidence that can be measured and analyzed. It is usually evidence of substance, but not always. When blood ages, it goes from

red to maroon to almost black, so, can the color of a bloodstain be useful in estimating its age? Yes and no. The most important factor is where the bloodstain is located and how it is viewed and/or photographed. If the bloodstain is on the floor or some opaque surface, its age can be estimated within a reasonable range of days. However, if it is on a curtain or a lamp shade and there is light behind it so the view is by transmitted rather than reflected illumination, it can appear dark red when, if on the floor, it would appear black. Thus, the age of the bloodstain is erroneously estimated as being much more recent that it actually is. Estimating the age of a bloodstain from its color in a photograph is especially difficult. There must be at least one other colored object in the photograph for comparison to be sure that the color rendition of that object is accurate. Still, a range must be assigned to estimate the age of the bloodstain.

Several years ago, the following was written:

> You can lead a jury to the truth, but you can't make them believe it. Physical evidence can not be intimidated. It does not forget. It doesn't get excited at the moment something is happening - like people do. It sits there and waits to be detected, preserved, evaluated, and explained. That is what physical evidence is all about. In the course of a trial, defense and prosecuting attorneys may lie, witnesses may lie, the defendant certainly may lie. Even the judge may lie. Only the evidence never lies [16].

Much of this glossary has been taken from nomenclature that was compiled by the Terminology Committee of the International Association of Bloodstain Pattern Analysts (IABPA). A suggested list of bloodstain terminology was proposed to that organization in 1996 during their annual meeting held in Albuquerque, New Mexico, with the following important qualification: "The committee's goal was to comprise a list of basic terms that are used and taught by the majority of bloodstain analyst [sic] in the field. It is offered only as a guideline, and is not designed to be all encompassing." It continued, "It is strongly recommended by this committee that Bloodstain Pattern Analysts be able to individually define terms as it [sic] pertains to their own use."

Terminology used and defined in this article is not limited to the terms on the IABPA listing. Of the 37 terms on the IABPA list 36 have been included in the above glossary. The term *impact site* is not included because it has the same meaning as does the lay term. Variations exist in many textbooks and other sources.

The terminology presented here represents significant agreement and consensus of opinion of many practitioners who have had extensive experience in this discipline. Interestingly, the great majority of what could be considered "bloodstain pattern" terms are the same ones coined in 1969 to have a working vocabulary during the law enforcement assistance administration (LEAA) original research into this discipline. At that time no one could have realized how important they would eventually become. Not all were good choices.

Blunt Force Trauma

Injuries to the Integument

Abrasions

Abrasions are superficial injuries to the skin characterized by traumatic removal, detachment, or destruction of the epidermis, mostly caused by friction. In so-called *tangential* or *brush abrasions* [1], a lateral rubbing action scrapes off the superficial layers of the skin (e.g., if the body slides across a rough surface; Figure 1) and leaves a denuded corium, which is initially covered with serosanguineous fluid. In fresh grazes, the direction of impact can often be determined by abraded epidermal shreds, which remain attached to the end of the scrape. Later, the tissue fluid dries out and forms a brownish scab. If the lesion does not reach the dermis, it heals within several days without scarring. Infliction just before or after death results in a leathery ("parchment-like") appearance with yellowish-brown discoloration.

Another type of abrasion is caused by a vertical impact to the skin (the so-called *pressure* or *crushing abrasion*). In such cases, the injuring object may be reflected by the shape of the skin injury, so that the patterned abrasion can be regarded as an imprint of the causative object (Figure 2; [2–6]). Photogrammetry may be used to obtain a three-dimensional image of an abrasion and to compare the data with an object that may have caused the injury [7].

When investigating dead bodies, it should be borne in mind that abrasions are easily overlooked as long as the epidermis-free areas have not changed their initially pink color due to drying [4]. The location of an abrasion always indicates the site of contact or impact. If the skin was affected before death, the resulting injury often consists of both an abrasion and an underlying bruise.

Fingernail scratches constitute a special group [1] and are particularly often found in sexual offenses and attacks to the neck; they can be seen both on the victims and the offenders, if the victims have defended themselves. Depending on the intensity of the abrading traumatization, the appearance of such lesions may range from superficial reddening of the skin via shallow excoriations to deep, bleeding skin lesions extending down to the corium. Terminal epidermal tags indicating the direction, from which the abrasion was caused, are easily lost and thus relatively seldom seen in surviving trauma victims. Typical features of fingernail scratches are parallel abrasions (if two or more fingernails were raked across the skin simultaneously) of roughly equal width along their course, whereas, e.g., handcuffs leave linear, much thinner, train tracklike marks on the wrists [4].

Under special circumstances, the form and location of abrasions may be indicative of a special

Figure 1 Back of a passenger who was flung out of the car in a traffic accident and suffered extensive excoriations with black particles from the asphalt surface rubbed into the skin on being dragged along the road

Figure 2 Excoriation on the left side of the neck from the safety belt (31-year-old car driver who ran away after having caused a traffic accident)

trauma; e.g., crescent-shaped fingernail marks and/or scratches in manual strangulation, linear excoriations with subsequent parchment-like drying in cases of hanging and ligature strangulation, seat belt marks in vehicle occupants after head-on collisions, human bite marks (typically, showing two semicircular bows with their concavities facing each other). In contact shots, the muzzle imprint is a patterned pressure abrasion reflecting the contours of the barrel end and other constructional parts situated near the muzzle (**Gunshot Wounds**).

Contusions

Contusions or bruises are extravasations of blood within the soft tissues originating from ruptured vessels as a result of blunt trauma (mostly caused by squeezing, but sometimes also by suction). In this context, only the contusions that are visible externally are considered. Textbooks usually differentiate between intradermal and subcutaneous bruises. In the former category, the hemorrhage is located directly under the epidermis, i.e., in the corium. This kind of superficial hematoma is usually sharply defined and red, whereas the more common bruises of the deeper subcutaneous layer have blurred edges and, at least initially, a bluish-purple color. Blood localized in the subcutis appears blue on the surface due to scattering processes in the dermis, as the blue wavelengths of the light are scattered (and thus reflected) to a greater extent than the red wavelengths [8].

Figure 3 Thoracic wall of a 37-year-old car driver with a patterned abrasion/contusion mark caused by the starlike Mercedes logo of the steering wheel

Figure 4 Intra- and subcutaneous hematoma in an infant who died from physical child abuse. The pattern of the intradermal bruises reflects the texture of the fabric covering the region of impact

Intradermal bruises may reflect the surface configuration of the impacting object (Figure 3). The skin squeezed into grooves will show intradermal bleeding, whereas the areas exposed to the elevated parts remain pale. Especially in falls from a height, in physical child abuse, or in traffic accidents, the texture of the clothing may produce a pattern of intradermal bruises corresponding to the weaving structure (Figure 4). Patterned extravasations of this type are also seen in tire tread marks, if an individual is run over by a wheel, and in bruises from vertical stamping with ribbed soles [1].

Subcutaneous bruises are usually nonpatterned. Nevertheless, there may be bruising of special significance. If the body is struck by a stick, a broomhandle, a pool cue, a rod, or another elongated instrument, every blow leaves a double "tramline" bruise consisting of two parallel, linear hematomas with an undamaged zone in between [1, 4, 6]. Human bites produce bruises forming two opposing arches (from the upper and lower jaw) with a pale center in between; often the hematomas are combined with abrasions and/or lacerations, which may sometimes reflect individual teeth characteristics (**Odontology**; [1, 2]).

Victims of blunt force violence often sustain contusions from self-defense, typically located on the ulnar aspects of the forearms and the back of the hands [9]. The upper arms may show groups of roundish bruises from fingertip pressure in cases of vigorous gripping [1]. A periorbital hematoma ("black eye") is induced by either direct indirectly (e.g., punch or kick; Figure 5) or indirectly (due to seepage of blood from a fractured orbital roof, a fractured nasal bone or from a neighboring scalp injury of the forehead; Figure 6).

In darkly pigmented individuals, contusions are sometimes invisible to the naked eye. In such cases, the use of infrared light sources can be helpful for diagnosing subcutaneous blood extravasations

Figure 5 Periorbital hematomas and excoriations in the victim of a robbery attacked with fist blows to the face. Photograph taken three days after the incident

[2]. Diaphanoscopy (also called *transillumination*) is another means to determine the presence of bruises, which otherwise would remain undetected [10].

In general, bruises are regarded as a *sign of vitality* indicating that the contusion was inflicted prior to death. During life, the blood from the ruptured vessels is forced into the soft tissue by active extravasation. Nevertheless, to a limited extent postmortem formation of contusions is possible due to passive ooze of blood. In the surviving victims, a deep bruise may not become apparent on the skin until several hours or even days later because of the slow percolation of free blood from the original site to superficial tissue layers.

In a living person, the contusion undergoes a temporal series of color changes usually proceeding from the periphery toward the center. Initially, most subcutaneous bruises appear purple-blue. As the hematoma resolves during the healing process, the hemoglobin released from the red blood cells is

Figure 6 (a) Surgically treated laceration above the left eyebrow and periorbital hematoma in a 28-year-old man who was found dead six days after sustaining the injury. The man had left the hospital against the physician's advice. (b) Purulent meningitis caused by pneumococci arising from the nasal sinuses due to a fronto-basal fracture of the skull with concomitant laceration of the dura mater. (c) Close-up view of the anterior cranial fossa with fronto-basal fracture line (arrow)

chemically degraded into other pigments such as hemosiderin, biliverdin, and bilirubin. The color changes – usually in the course of several days – to green and yellow before it finally disappears. However, the rate of change is quite variable and depends on numerous additional factors, above all the extent of the bruise.

The size of an intradermal or subcutaneous hematoma is not always indicative of the intensity of the force applied to the affected area. Elderly people or patients suffering from bleeding diathesis may get bruises from slight knocks or for other minor reasons. On the other hand, absence of an externally visible injury does not necessarily mean that there was no relevant trauma. Subcutaneous bruises of the surviving victims are often followed by gravity shifting of the hemorrhage leading to a secondary downward movement of the hematoma.

A special type of blunt injury to the soft tissues is frequently seen in pedestrians who were struck or run over by motor vehicles. Both the skin and the subcutaneous layer may be avulsed from the underlying fascia or bones by shearing forces so that a blood-filled pocket is formed, typically in combination with crush damage to the adjoining fatty tissue [6].

Lacerations

Lacerations are tears of the skin or of internal organs (see below). They may be caused by blows from blunt objects (such as a hammer, a whipped pistol [11], a rod, a toe-cap of heavy footwear, or a fist); other lacerations are produced by impact from vehicles or by a fall to the ground. Lacerations occur most commonly in body regions where the integument directly overlies a firm bony base acting as support (scalp, face, back of the hand, shins, and elbows). When the force acts on the skin, the subcutaneous tissue is squeezed between the injuring object and the bony platform so that the integument is compressed and crushed until it tears and splits sideways (Figures 7 and 8).

In contrast to incisions (**Wounds: Sharp Injury**), lacerations are characterized by abraded, bruised, and crushed wound margins. The edges of the tears are typically irregular and ragged with bridging tissue strands (vessels, nerves, and fibers) running from side to side. The wound slits may be linear (especially in blows with a narrow, edged instrument), Y-shaped, or starlike. Semicircular or crescent-shaped tears of the scalp are produced by blows with an edged instrument having a round contour such as the flat end of some hammers. If the impacting object hits the skin at an oblique angle, one of the edges will be ripped away resulting in unilateral undermining (undercutting and avulsion), which indicates the direction of the force. Sometimes foreign material from the causative instrument/surface is deposited in the depth of the wound slit. The abrasion surrounding the tear may correspond to the shape and dimensions of the impacting blunt-surfaced instrument or – in case of a fall to the ground – the area of contact (Figures 7 and 8).

Figure 7 Shaved occipital region of a 55-year-old man who fell down stairs with a blood-alcohol concentration of 320 mg per 100 ml. Slitlike laceration of the scalp surrounded by a reddish-brown excoriation

Figure 8 Parietal region of a 48-year-old man, whose scalp was shaved before autopsy, showing a stellate laceration with an eccentric abrasion (suicide by jumping from a height)

Head Injuries

The head is a common target in assaults with blunt objects; other frequent causes of head injuries are traffic accidents, falls from a height, and falls from a standing position. The area of impact usually reveals injuries of the scalp or the facial skin, but it has to be emphasized that severe and even lethal traumatization is not necessarily associated with scalp bruising, marked swelling, excoriation, and/or laceration. There may be no externally visible signs, especially in skin areas covered with cushioning hair and in cases of a fall onto a flat surface. An impact site on the vertex may suggest that the head sustained a blow, whereas in falls from standing positions the scalp injuries are expected at the level of the brim of the hat. According to autopsy studies, there are many exceptions to this "rule": only the "top of the head" lacerations (in the dorsofrontal and parietal regions) are quite uncommon in falls from a standing position [12].

Skull Fractures

These may involve the cranial vault, the base of the skull, and the facial skeleton. Though the presence of a skull fracture indicates severe traumatization, the fracture itself rarely threatens the victim's life. There are several types of skull fractures to be distinguished [1, 3–6].

Single or multiple *linear fractures* are caused either by a blow with an object having a broad, flat surface area, or by a fall on the head so that the skull is deformed (flattening/indenting at the point of impact and outward bending/bulging in the periphery). The fracture lines originate where the bone is bent outward and therefore is exposed to traction forces exceeding the limits of the bone's elasticity; from these extruded parts of the skull, the fractures extend not only toward the area of impact but also in the opposite direction. For this reason, either of the ends is often in congruity with the impact injury of the scalp (local hematoma with/without concomitant abrasion and/or laceration, Figure 9a). Several fracture lines may radiate outward from a central point of impact where the skull is often depressed and/or shattered to pieces forming a *spider's web* or mosaic pattern consisting of radiating and circular fractures. The sequence of skull injuries may be determined according to Puppe's rule: a later fracture does not cross a preexisting fracture line, but terminates when reaching an earlier one.

Before fusion of the cranial sutures (i.e., in children and young adults), a fracture may travel along the seam resulting in diastasis (*diastatic fractures)*. If a gaping fracture runs from one side of the cranial base to the other (mostly after lateral impact or side-to-side compression), this transverse type is called a *hinge fracture* (Figure 10) because of the independent movement of the front and rear halves of the skull base.

Longitudinal fractures of the base of the skull frequently occur due to a fall on the occiput; in such instances, the linear fractures typically run through the posterior fossa either ending near the foramen

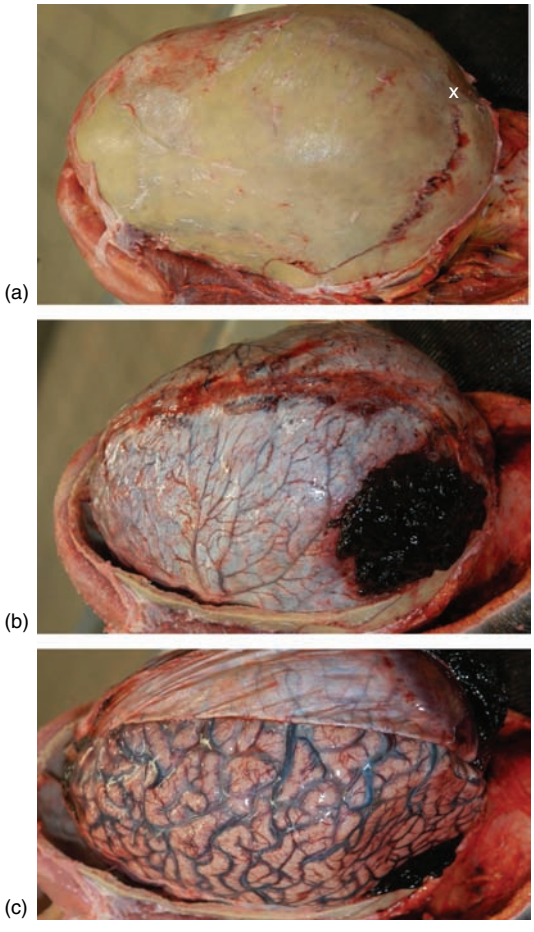

Figure 9 (a) Left half of the cranial vault with linear fracture of the skull. The dorsal end is in congruity with the area of impact (x). After a fall on the occiput, a 51-year-old man suffered from a headache, but did not seek medical treatment. He was found dead three days later. (b) Extradural (epidural) hemorrhage in the parieto-occipital area. The hematoma is located between the inner surface of the skull and the detached dura. (c) Concave impression of the brain surface after removal of the space-occupying epidural hematoma. The dura mater was reflected upward during autopsy

Figure 10 Transverse (side-to-side) "hinge fracture" dividing the skull into a front and a rear half

magnum or extending to the floor of the middle and anterior fossa. On the other hand, longitudinal fractures of the base can also be produced by impaction of the frontal region.

Depending on its course and location, a *base fracture* may be followed by several *clinical signs*: bleeding from the ear (in fractures of the temporal bone with concomitant hematotympanum and rupture of the eardrum); bleeding from the nose and mouth (in fractures involving paranasal sinuses, which provide a communication with the nasopharynx); periorbital hematoma (from fractures of the orbital roofs); leakage of cerebrospinal fluid coming out of the nose or the ear (if the *dura mater* is injured along the fracture); bacterial infection of the meninges (by spread from the nasal cavity, the paranasal sinuses and the middle ear, especially when the fracture is accompanied by a tear of the *dura mater*; cf. Figure 6).

Some special types of skull fractures can only be mentioned briefly. A *ring fracture* is located in the posterior fossa and encircles the foramen magnum. It mostly occurs in a fall from a height onto the victim's feet or buttocks, so that the cervical spine is driven into the skull. Another mechanism takes effect in high-speed head-on collisions: the frontal impact

abruptly decelerates the vehicle and the trunk of belt-restrained passengers, whereas the head continues to move in the previous direction due to inertia resulting in hyperextension/hyperflexion of the craniocervical junction. Ring fractures of the skull base are also seen in motorcyclists [13].

Bone impressions and *depressed fractures* are always localized at the point of impact where the head is struck with an object having a relatively small surface area such as a hammer, a protruding corner of a piece of furniture or another edged implement (Figure 11). The outline of a clean-cut defect in the outer table may reproduce the shape and size of an edged instrument, for instance, in cases of pistol-whipping. If only limited force is applied, the depressed fracture can be restricted either to the outer or, less often, to the inner table of the skull (the latter with inward displacement of the bone fragments). A depressed fracture from a blow striking the skull cap at an angle may be concentrically terraced.

The diaphanoscopic postmortem examination of blunt impact injuries to the head sometimes reveals nondiaphanous regions derived from intraossary hematomas. Their location coincides with the corresponding injuries of the scalp such as contusions and lacerations so that conclusions can be drawn as to the area of impact, even if, owing to postmortem changes, the scalp is no longer assessable [14].

Hole fractures from bullets perforating a flat bone of the skull are mostly roundish and clean cut at the site of entrance, but beveled out in a craterlike manner at the exit site (**Gunshot Wounds**).

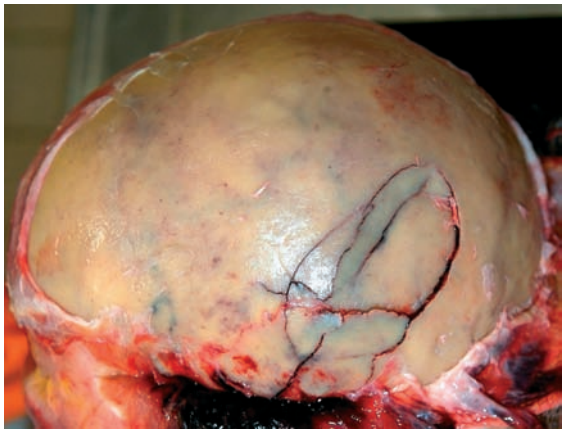

Figure 11 Depressed fracture of the left parieto-temporal region sustained in a fall down a staircase hitting the edge of a step

Blunt force applied to the occiput, mostly as a consequence of a fall on the back of the head, frequently causes independent fractures of the anterior cranial fossa such as cracks of the thin orbital roofs (*secondary fractures)* at the site of the contrecoup [3].

A fracture of the base of the skull involving an air sinus (e.g., in the sphenoid bone) provides a communication between the cranial cavity and the nasopharynx permitting the passage of blood into the airways. If the victim has lost consciousness, aspiration of blood into the lungs will be the consequence, possibly followed by fatal asphyxiation. The same complication can be seen after blunt traumatization of the visceral cranium.

Intracranial Hemorrhages

A space-occupying bleeding under/over/between the brain membranes is followed by local displacement of the brain and raised intracranial pressure with concomitant flattening of the cerebral hemispheres. Intracranial hematomas as well as traumatic brain swelling, which often accompanies head injuries, may result in transtentorial (uncal) herniation (in cases of supratentorial mass lesion) and/or herniation of the cerebellar tonsils which are forced into the foramen magnum leading to compression of the brainstem with secondary damage and failure of the medullary respiratory centers.

From the clinical and forensic point of view, the possible occurrence of a so-called *lucid* or *latent* interval has to be mentioned. After initial unconsciousness (due to cerebral concussion), there may be a symptomless period of several hours or even days before the victim becomes comatose again because of the increased hemorrhage leading to elevated intracranial pressure.

Epidural (extradural) hemorrhages are located between the skull and the underlying *dura mater*, which is stripped from the bone by bleeding from a torn vessel (Figure 9b, c). Epidural hematomas have a typical disk- or lens-shaped appearance, which can be demonstrated by means of pre- or postmortem computed tomography (CT) scans (**Radiology**; Figure 12; [15–17]). The most common site is the temporal and the adjacent parietal region where the branches of the middle meningeal artery are easily lacerated in the course of a transecting fracture

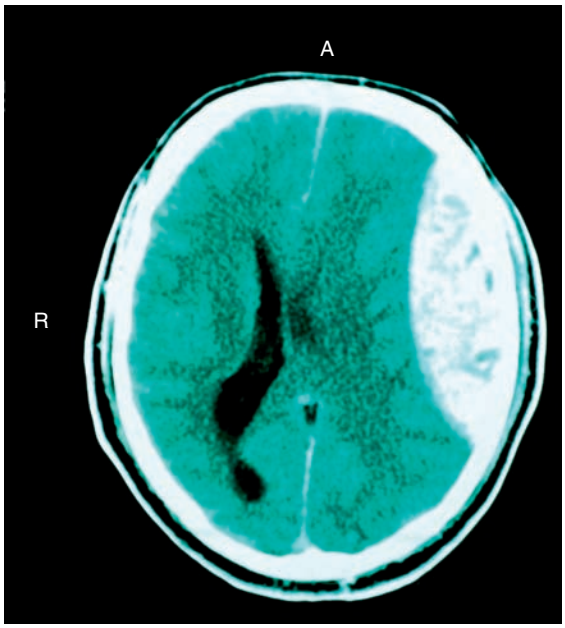

Figure 12 Computed tomography (CT) scan of a 39-year-old man showing a large left-sided extradural hematoma with concomitant shift of the midline to the right and brain swelling. The victim was hit by a fist blow to the face and fell on the back of the head. The extradural hematoma was associated with frontal contusions. The patient underwent neurosurgical craniotomy with removal of the space-occupying blood accumulation and survived with only slight neurological deficits

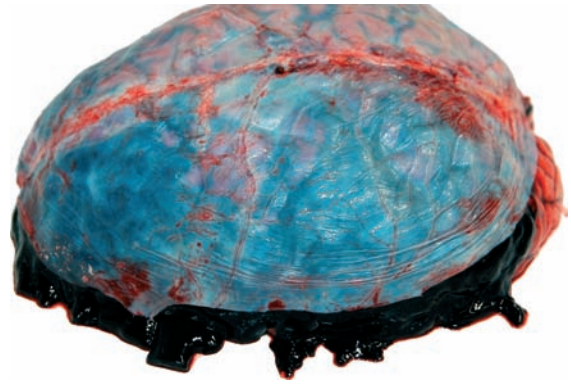
line. Since the well-adherent dura mater has to be avulsed from the bone, epidural hematomas originate more often from arterial bleeding than from venous bleeding (e.g., due to a torn dural sinus). In the great majority, an extradural hemorrhage is associated with a cranial fracture.

An antimortem traumatic extradural hematoma must not be confused with a postmortem epidural thermal hematoma [18]. The latter one is seen in severely burnt bodies with an (at least partially) charred skull. It is caused by a heat-induced shift of bloody fluid from the diploe and the venous sinuses. The thermal hematoma has a crumbly or fatty appearance and a brick-red or brown color (**Injury: Burns, Scalds, and Chemical**).

Subdural hematomas are intracranial bleedings located beneath the dura mater and above the arachnoid (Figure 13). Most often the hemorrhage arises



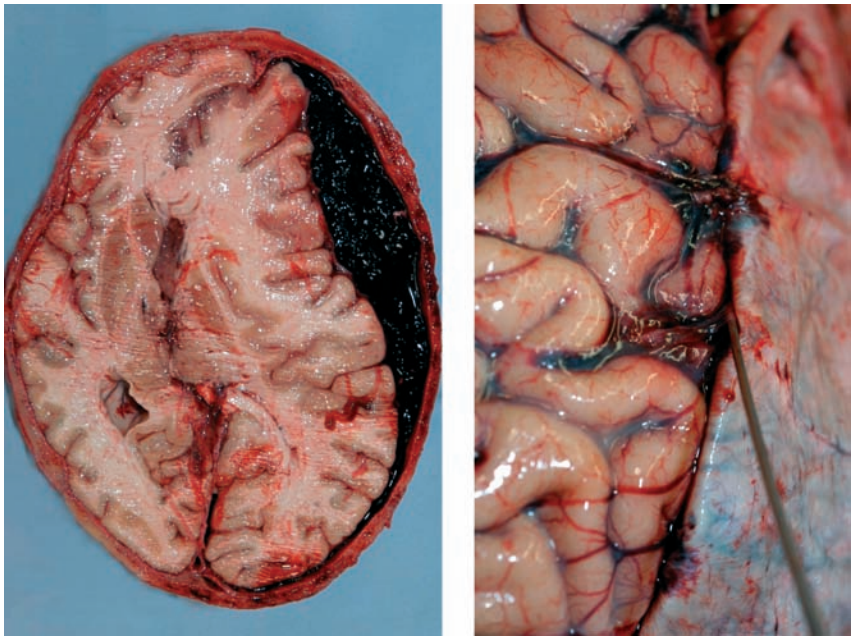


Figure 13 Aspect of the left cerebral hemisphere still covered with the dura which is discolored by an underlying hematoma arising from torn bridging veins

from the tearing of overstretched bridging veins that traverse the subdural space between the surface of the cerebral hemispheres and the superior sagittal sinus (Figure 14). Other possible sources of subdural bleeding are injuries to venous sinuses or to the cerebral parenchyma (such as cerebral contusions with concomitant laceration of the arachnoid). The subdural hemorrhage usually covers one cerebral hemisphere in a caplike manner from the parasagittal area via the lateral surface down to the basal fossas; on a horizontal section, it appears as a sickle-shaped accumulation of blood.

In contrast to epidural hematomas, subdural hemorrhages are often not associated with skull fractures; additional damage to the brain tissue may also be absent. A high percentage of subdural bleedings are caused by acceleration or deceleration of the head, for instance, not only in falls when the head impacts a hard surface but also in traffic accidents and physical child abuse (battered child and shaken baby syndrome, **Battered Child Syndrome**; **Shaken Baby Syndrome**). Apart from acute and subacute subdural hemorrhages, there are prolonged cases of hematoma formation and organization, mainly in elderly people and sometimes without a history of previous traumatization. Such chronic subdural hematomas typically consist of brown and gelatinous blood accumulations adherent to the meninges and sometimes covered with a tough membrane [1].

Traumatic subarachnoid bleeding may result from damage to the cortex such as brain contusion (e.g., contrecoup lesions), from penetrating injuries to

(a) (b)

Figure 14 (a) Acute subdural hemorrhage. The unilateral space-occupying hematoma has markedly shifted the midline of the brain to the opposite side. (b) Close-up view of torn bridging veins (source of the subdural bleeding). Probe inserted into a ruptured vessel

the brain and as a consequence of vessel tears within the subarachnoid space. An extensive hemorrhage in the basal cisterns and around the brainstem may arise from a laceration of an artery belonging to the circle of Willis or from another great vessel (such as a torn basilar and vertebral artery).

In sudden deaths without any preceding trauma, subarachnoid hemorrhage is most often due to a spontaneous rupture of a so-called berry aneurysm, which is typically located at bifurcations and branches of cerebral arteries belonging to the "circle of Willis" [1]. The blood extravasation usually fills the basal cisterns and then spreads laterally over the cerebral hemispheres. Sometimes the question arises whether a preexisting aneurysm was mechanically ruptured by a blunt head injury.

Cerebral Injuries

"Concussion of the brain" is a clinical diagnosis which means a disorder of cerebral function following immediately upon a (blunt) head injury. It is usually characterized by a transient loss of consciousness (initial coma) with subsequent amnesia from the actual moment of trauma; it is often combined with retrograde amnesia and vegetative signs such as nausea and vomiting. In mere concussions, the unconsciousness lasts only for a relatively short time (less than 1 h) and the brain tissue does not show any evidence of structural damage. Nevertheless even a simple cerebral concussion may be followed by the victim's death, if the head trauma is joined by interfering mechanisms (for instance, drowning or aspiration of gastric contents during unconsciousness).

Cerebral contusions are traumatic lesions of the brain frequently seen in the cortex and sometimes extending into the underlying white matter [19, 20]. Fresh contusion hemorrhages are mostly located on the crests of the gyri and composed of grouped streak-like or punctate blood extravasations. The cortical lesions are often covered with subarachnoid bleeding. In contrast to cerebral contusions, the term "laceration" means a major destruction of the anatomical context (for instance, mechanical separation of the tissue due to bone fragments or penetrating bullets).

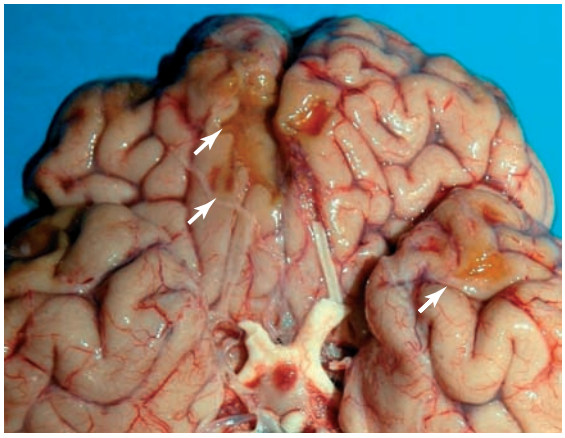

Figure 15 Undersurface of the brain in a 46-year-old alcohol addict who died from hypothermia. Autopsy accidentally revealed survived contusion hemorrhages with a yellowish-brown appearance and softening of the tissue (right frontal lobe and left temporal lobe, arrows)

In case of survival, the contusion hemorrhages are reabsorbed and assume a yellowish-brown appearance with softening and finally liquefaction of the affected areas (Figure 15).

Due to the injuring mechanism, most cerebral contusions occur in brain regions that are directly opposite to the point of impact. This contrecoup type of contusion is classically caused by a fall on the occiput, when the moving head is suddenly decelerated with the consequence that the inlying brain is damaged due to inertia. In falls on the back of the head, the contrecoup areas of the brain (poles and undersurfaces of the frontal and temporal lobes) are subjected to an ultrashort negative pressure ("cavitation") resulting in vessel ruptures and cortical hemorrhages (Figures 16 and 17). On the other hand, the so-called coup contusions arise at the area of impact due to the local deformation and compression of the brain. Even severe coup and contrecoup injuries are not necessarily associated with skull fractures. In victims with both the coup and contrecoup lesions, the degree of contrecoup damage is usually more pronounced. Fracture contusions are localized in topographical correspondence to fracture lines and/or depressed fractures.

Severe head traumas are often followed by posttraumatic epilepsy, especially in victims with penetrating head injuries, depressed skull fractures, dural tears, intracranial hematomas, and structural brain damage. Early posttraumatic seizures occur within the first week, whereas late posttraumatic epilepsy develops at any point thereafter [16, 20].

Figure 16 Contrecoup contusions on the undersurface of the frontal lobes and the right temporal pole with minor subarachnoid hemorrhage

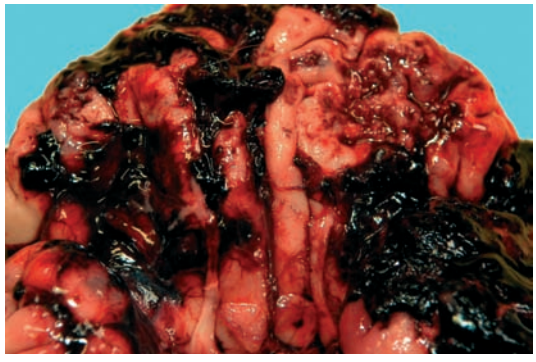

Figure 17 Contrecoup contusions on the undersurface of the frontal lobes (fall on the back of the head, survival time one day)

Diffuse axonal injury (DAI) and the accompanying tissue tear hemorrhages are considered a consequence of shear and tensile strains from sudden acceleration/deceleration or rotational movements of the head. Overstretching of the nerve fibers in the white matter leads to axonal injury varying from temporary dysfunction to anatomical transection, the latter being followed by microscopically visible club-shaped retraction balls on the axons. The sites of predilection include the corpus callosum, the parasagittal white matter, the superior peduncles, and the rostral brainstem. In the course of the repair process, microglial cells proliferate in the areas of axon damage. In victims of substantial head injuries, especially after traffic accidents, diffuse axonal injuries may be responsible for prolonged coma and a fatal outcome even in the absence of an intracranial mass lesion. Macroscopically, DAI is characterized by small focal hemorrhages and salient cerebral swelling [19, 20].

Cerebral edema is a frequent finding in significant head injuries. The formation of edema is due to an increase in the fluid content of the brain, predominantly in the white matter. Posttraumatic edema may be generalized (diffuse) or related to focal tissue damage (e.g., adjacent to an area of cerebral contusion or laceration). At autopsy, the weight of the brain is increased; the gyri are pale and flattened with shallow sulci in between. From the pathogenetic point of view, edema is attributed to a heightened vascular permeability which in turn may be worsened by additional hypoxia.

As with space-occupying bleedings such as subdural or epidural hematomas, brain swelling is a common cause of raised intracranial pressure. The enlarged volume of the edematous brain leads to a displacement of cerebral tissue downward through the midbrain opening resulting in grooving of the unci and/or hippocampal herniation. Expansion of the subtentorial brain leads to herniation of the cerebellar tonsils which are forced into the foramen magnum. Herniation with concomitant compression of the brainstem may be followed by secondary hemorrhages (localized in the midbrain and pons) and finally by lethal dysfunction of vital centers.

Injuries of the Chest

Nonpenetrating blunt force may damage the thoracic wall and/or the chest organs [1, 4, 5]. *Rib fractures* are caused either by direct or by indirect violence. In the first case, a localized force is applied and the underlying ribs are broken in the contact area (for instance, along the seat belt in head-on collisions); the other (indirect) type of rib fracture occurs away from the impact, mainly due to compression of the chest.

Rib fractures are frequently associated with *complications* that may be dangerous or even life threatening.

- If a victim sustains numerous fractures, the rib cage loses its rigidity so that the injured section of the chest wall will not participate in the expansion of the thorax during inspiration with the result of paradoxical respiration (*flail chest)* and concomitant hypoxia.
- Sharp, pointed ends of the rib fragments may penetrate the pleura and lacerate the lung and/or the intercostal blood vessels with consecutive bleeding into the chest cavity (*hemothorax).*
- A leak in the visceral pleura or a penetrating injury of the thoracic wall permits air to enter the pleural cavity (*pneumothorax)* so that the lung collapses, if it is not fixed to the chest wall by preexisting pleural adhesions. A valvelike leakage in the pleura leads to a so-called tension-pneumothorax caused by an increasing pressure of trapped air in the pleural cavity and followed by a complete collapse of the affected lung and a shift of the mediastinum to the opposite side.
- The presence of air bubbles in the subcutis (Figure 18) or in the mediastinum (*subcutaneous/mediastinal emphysema*) may derive from injuries of the trachea, the bronchi, the thoracic wall or the lungs by air entering the adjacent soft tissues.

Blunt force injuries to the *lung* are mainly encountered as contusions or lacerations. A contusion is typically caused by a substantial impact on the chest with consecutive inward bending of the thoracic cage. In young victims, contusions are not necessarily accompanied by fractures of the ribs or of the sternum because of the high pliability of the juvenile thoracic cage. From the morphological point of view, a contused lung shows bruising either as a subpleural suffusion (Figure 19) or as an intrapulmonary hemorrhage. Lacerations of the lung can result when a severe compressive or crushing force is applied to the chest so that the pulmonary tissue bursts or tears.

Figure 18 Subcutaneous emphysema of the face in a traffic accident victim (massive blunt thoracic trauma, severance of a large bronchus)

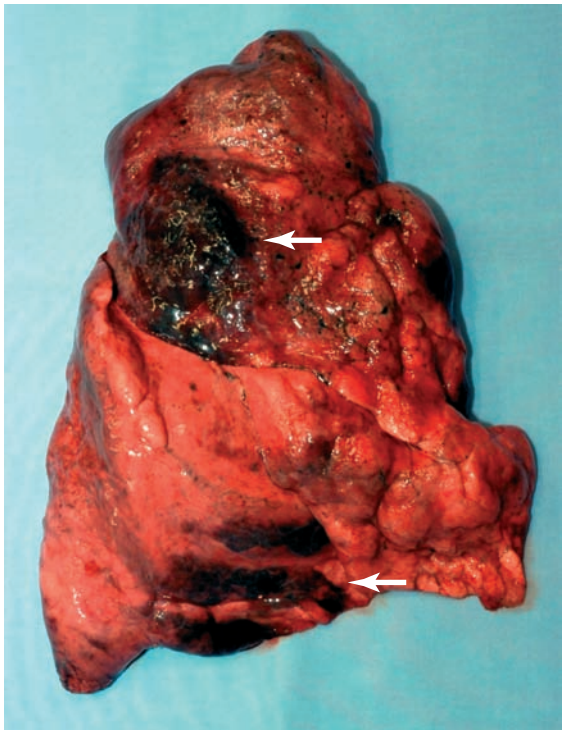

Figure 19 Right lung of a 44-year-old car driver who sustained a blunt trauma to the thorax with contusions of the pulmonary tissue (arrows)

Another possible mechanism is inward displacement of a fractured rib which impales the lung.

Blunt traumatization of the *heart* manifests itself as concussion, contusion, or myocardial rupture. In most cases, the force is directly applied to the anterior chest, which compresses or crushes the heart between the sternum and the vertebral column. Bruises of the cardiac wall may be localized in the subepicardial fatty tissue (sometimes in combination with posttraumatic coronary occlusion) or within the myocardium, which then appears dark red from interstitial hemorrhage. Lacerations of the heart are most often seen in the relatively thin right ventricle (Figure 20) or in the atria; they are less common in the left ventricle, the papillary muscles, the cardiac valves, the interatrial, and interventricular septum.

The risk of cardiac rupture is especially high during diastole, when the heart chambers are filled with blood and therefore easily burst on being exposed to a sudden compressive force. Such injuries usually have a fatal outcome either from massive blood loss and hemorrhagic shock (if the pericardial sac is torn and the blood pours into the pleural cavity) or from cardiac tamponade (blood accumulation in the pericardial sac resulting in insufficient filling of the

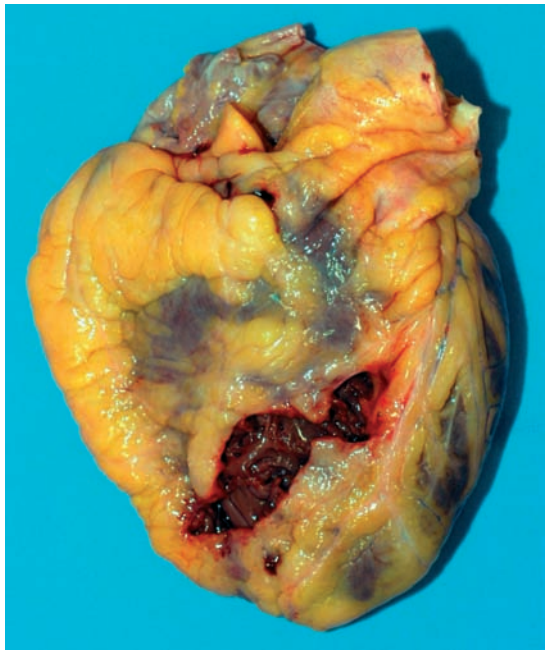

Figure 20 Anterior aspect of the heart of a 37-year-old motorcyclist who died after a head-on collision with a car. Traumatic laceration of the right ventricular wall

cardiac chambers and impaired forward circulation). In very rare cases, the traumatic heart rupture may be delayed, if the blunt chest trauma first led only to a tear of the inner myocardial layers, which later perforates into the pericardial sac [21].

Traumatic aortic ruptures typically occur in vehicular accidents and in falls from a height. The most important mechanism is sudden deceleration, possibly in combination with compression and/or shearing. Traction forces tear the aorta transversely at two sites of predisposition: in the descending part of its arcus (near the attachment of the ligamentum arteriosum; Figure 21) or immediately above the cusps of the aortic valve. Other locations (for instance, in association with a dislocated vertebral fracture) are rather rare. The laceration of the aorta may occur either as a complete or partial transection. In the latter case, the outer layers of the vascular wall are not damaged; the intimal tears are often multiple, semicircular, and parallel (so-called ladder-rung tears). If the trauma is survived at least for a short time, a parietal thrombosis or a posttraumatic aneurysm may follow as secondary complications.

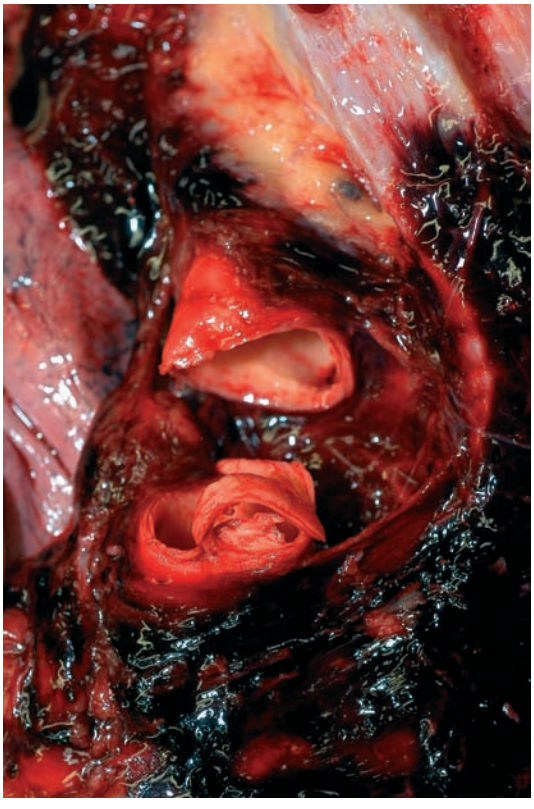

Figure 21 Traumatic severance of the aorta in the distal part of the arch (deceleration injury) surrounded by perivasal hematoma of the mediastinum

Abdominal Injuries

Blunt force injuries of the abdomen are frequently seen in traffic and work accidents, in child and spouse abuse, in other criminal assaults (with kicking, stamping, and punching), and also in suicidal falls from heights. The abdominal organs most vulnerable to blunt trauma are the solid liver and spleen on the one side and the mesentery on the other. Concomitant external signs of blunt traumatization such as contusions or abrasions are by no means obligatory.

Substantial injuries to the liver, the spleen and the mesentery always have to be regarded as life threatening and potentially fatal, especially in cases without rapid surgical treatment. The main reason is internal bleeding into the peritoneal cavity from lacerations. Ruptures of the liver and spleen can be classified as either transcapsular or subcapsular laceration. In the first case, both capsule and parenchyma are injured (Figures 22 and 23) so that the blood instantaneously pours into the peritoneal cavity. The second type of laceration is characterized by the initial formation of a subcapsular hematoma which expands continuously and may cause a delayed rupture when the covering capsule tears due to overstretching (mostly several hours or even days after the trauma).

Figure 22 Ruptures of the right hepatic lobe

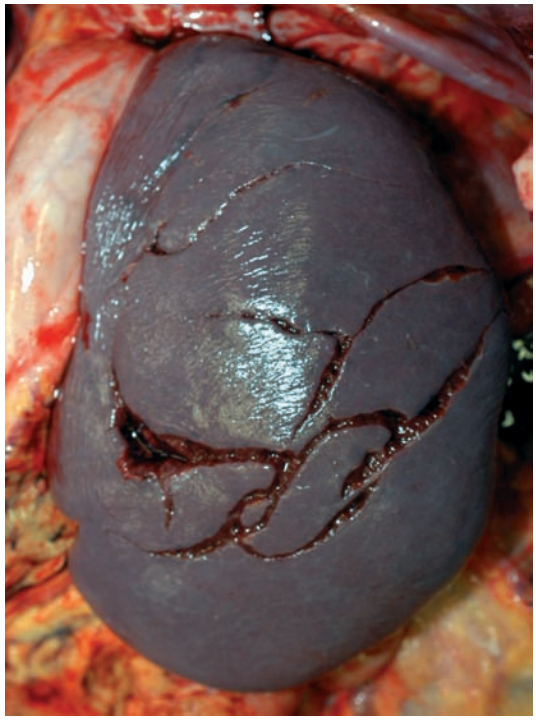

Figure 23 Laceration of the spleen

The stomach and the intestine are less susceptible to blunt traumatization than the parenchymatous abdominal organs. The hollow viscera are more likely to rupture, if they are filled with food or fluid. Another reason why the intestine or stomach might be prone to damage is squeezing of the organs between the indented abdominal wall and the lumbar vertebrae. Fatal outcomes from contusions or lacerations of the gastrointestinal tract are usually due to diffuse peritonitis.

Renal injuries are a relatively rare source of severe bleeding since the kidneys are deeply located behind the peritoneum. Nevertheless, they can be ruptured by a heavy impact to the loin (for instance, in traffic accidents or assaults).

Although the empty urinary bladder is placed within the pelvis, when filled it moves upward and is therefore exposed to blunt traumatization of the lower abdomen. Consequently, rupture of the empty bladder is expected to be extraperitoneal and accompanied by pelvic fractures, whereas a bladder distended with urine may rupture into the peritoneal cavity.

Blunt traumatization of a pregnant uterus is a possible cause of fetal death, mostly due to separation or rupture of the placenta.

Injuries to the Extremities

Apart from injuries to the skin and the subcutaneous layer (see above), other anatomical structures such as the muscles, the bones, and the joints may be involved in blunt force trauma. Extensive crushing of the soft tissues, the formation of blood-filled cavities, comminuted fractures, and severance of large vessels are frequent findings in victims of automobile-pedestrian accidents. Internal bleeding (from closed injuries) and external bleeding (from traumatic amputation, severe avulsive wounds and compound fractures) are important factors contributing to hemorrhagic shock. Another sequel to blunt trauma is pulmonary and systemic fat embolism (caused by globules of fat, usually subsequent to fractures or damage of fatty tissues). In cases of prolonged survival, intercurrent infection, sepsis-associated multiorgan failure and pulmonary thromboembolism (originating from posttraumatic venous thrombosis) are dangerous and often fatal complications of an originally nonlethal injury (e.g., fracture of the femur neck).

Bomb Scene Management

Introduction

An explosion is the rapid production of gas from liquid or solid usually accompanied by the production of heat, light and sound. The reaction is very efficient and the end products usually bear no resemblance to the ingredients. Sometimes traces of unreacted explosive and associated bomb components can be recovered from the scene. Explosions can occur without criminal involvement for example in industrial accidents where gaseous fuels or organic dusts like flour form explosive mixtures with air and explode with devastating effects. Typically, boiling liquid and expanding vapor explosions (BLEVEs) represent a significant hazard to firemen extinguishing large gas tank fires. Explosives are used by criminals for a wide range of purposes, including intimidation. Bombs remain the favored tool of terrorists because of their ability to create chaotic scenes that are visually dramatic and newsworthy.

The role of all first responders is primarily to save life, then to preserve the scene. The focus then moves to the creation of order from chaos. The objective of an investigation is to identify the cause, clarify the facts, determine whether a criminal act has been committed, and if so identify perpetrators and bring the matter before the Court with the ultimate purpose of protecting society.

The investigators' questions will include the five "W's" (What, Where, When, Why, Who) and How, plus permutations thereof, for example; *What* was the target? *What* was the intended target? *What* was the bomb made from? And so on. If inductive reasoning suggests criminal involvement, deductive reasoning may be used to narrow the field of suspects. In most crimes there are usually a lot of people who may have a motive; however, fewer have both motive and opportunity, and very few have the motive, opportunity, and the means to commit the crime. Physical evidence, sometimes in the form of invisible traces that can be linked with both the scene and suspect can provide strong evidence of the suspect having the "means" to commit the crime (See Figure 1).

The forensic forward commander contributes to the investigation by coordinating the activities of those involved in the recording, collection, preservation, and evaluation of the potential evidence.

Figure 1 The suspect's triangle

The investigators may use physical evidence to identify a suspect; however, it should be appreciated that much of the power of science lies in exclusion. The role of the scientist changes from establishing facts to challenging the proposition that implicates the suspect. The jurors need to consider the robustness of the challenge when determining their findings.

Crime Scene Movements

A successful bombing on a civilian target results in pandemonium. Inevitably a bomb scene will have a number of professional groups transitioning through it and each has the potential to diminish or destroy evidence. Controlling this traffic at the earliest practical opportunity will help mitigate loss of valuable evidence (See Figure 2).

The forensic forward commander usually arrives at the scene some hours after the explosion. A great deal of change is likely to occur in that period; however, little can be done about this. The period between notification and arrival does provide a valuable window to mentally prepare oneself, collate information, scope the magnitude of the task, and consider possible resource implications such as how to sustain a lengthy or multifaceted investigation. It is important to record decisions and their rationale.

There are a number of actions that should be initiated in the immediate aftermath to protect the crime scene and to capture potential evidence that would otherwise be ephemeral. A good example of this was the actions of police in meeting victims of the first Bali bombings at the Australian airports. First hand accounts and the examination of their clothing yielded evidence, including the confirmed identification of trinitrotoluene (TNT) from those who were in Paddy's Bar at the time.

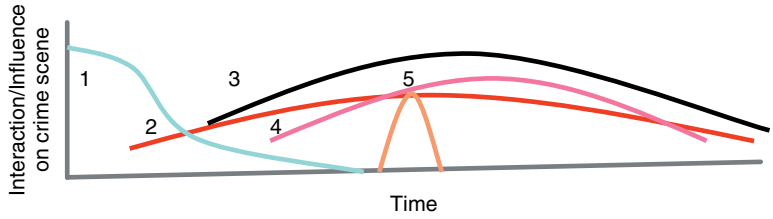

Figure 2 Depicting movements through the crime scene. 1, the nonambulatory victims and the general public; 2, first responders–emergency services–fire brigade–bomb technicians; 3, investigators, forensic forward commander, specialists, and scene recorders; 4. disaster victim identification – body recovery; 5. coroner and other administrators of governance

The main purpose for taking control of the scene is to protect evidence until it can be captured in a thorough examination. It is important to reduce the risk of contamination and ensure that the integrity of all the evidence is maintained from crime scene to courtroom.

There are a number of activities that can help reduce the loss of potential evidence.

- Only those persons with legitimate need should have access to the scene. Strategies may need to be implemented to discourage others. An entry log that records time and date, identity, intended purpose, and their potential availability as a witness should be created.
- The wearing of protective clothing such as overalls/Tyvek suits in the primary scene sends a strong message that the scene's integrity is of utmost importance to the forensic practitioners.
- Actions such as defining the locations for the inner and outer perimeters, and arranging for them to be marked with barrier tape and guarded will help control traffic.
- Under calm weather conditions explosive residues will not travel more than about 60 m from the epicenter, unless carried by primary fragmentation [1]. Buildings and landscape will define the shape of the cordoned areas, but as a general rule, the inner perimeter should be one and a half times (1.5×) the distance from the epicenter of the outermost piece of primary fragmentation. The outer perimeter is a convenience to keep the public and media out of the working area.
- Some of the main ingredients in improvised explosives are soluble in water. Therefore it may be important to initiate actions to protect against moisture damage, e.g., erecting tents over areas of high interest, and covering areas with plastic sheeting.
- All potential evidence should be collected as soon as possible, packaged in appropriate pristine containers at the scene, sealed, labeled, and kept cool. They should be conveyed to the laboratory at the earliest practical opportunity.
- An effective team has defined roles for its members. The size and complexity of a Bomb Scene Examination team may vary according to jurisdiction, the size of the incident, and the available resources. Typical team roles include a leader, a bomb technician, a photographer/recorder, search members, and an exhibits officer. A common observation of effective teams is that their members "think evidence and not just exhibits". In other words, experience and good judgement are particularly desirable attributes especially under challenging circumstances such as threatening inclement weather.

Coordination of the Various Forensic Disciplines

The forensic forward commander reports to the police forward commander and is responsible for

- coordinating the activities of all the various forensic specialists, including the disaster victim identification (DVI) teams; and
- working with local authorities in charge of utilities such as transport, health, electricity, gas, business councils, and the like.

Although DVI is important in its own right, it is also useful in the immediate investigation. The location of victims and the nature of their injuries can provide important information about the bombing. Similarly, victims and deceased persons often become repositories of primary fragmentation. Explosive residues were identified from the clothing of witnesses to the first Bali bombings, and shrapnel recovered from the wounds of a living victim at the second Bali bombing confirmed the presence of TNT by two independent techniques gas chromatograph with thermal energy analyser and negative chemical ionisation gas chromatograph with mass spectral analyser (GC-TEA and NCIGC-MS) (See Figure 3).

It is very important for the forensic forward commander to include the specialists such as pathologists in comprehensive briefings, as their ability to recognize potential evidence will be enhanced if they are aware of its relevance in the crime scene.

The pathologist plays a vital role in bomb scene investigations, not only in recovering evidence, identifying victims, determining the nature of injuries and cause of death, but also in identifying the perpetrator in suicide bombings. There is a natural tendency in major bombing cases to focus on whole bodies first in order to make rapid progress. This is a potential mistake because if suicide is involved, the perpetrator will be in small parts and usually mixed with the bodies of other victims. Decomposition and exposure

Figure 3 Metal objects recovered from wounds of living victim. (Note TNT was confirmed by GC-TEA and NCIGCMS)

to extraneous body fluids will make DNA analysis more difficult. If suicide is suspected, the investigator's priority is to have the small parts examined first so that a DNA profile can be collected and compared with the suspect's direct relatives.

Contamination Minimization Strategies

There are no chemical solutions that chemically degrade explosives. It has been stated by the Bureau of Alcohol, Tobacco and Firearms (ATF) that clothing, footwear, and tools cannot be effectively decontaminated following exposure to *bulk* explosives [2]. While it may not be possible to totally eliminate the potential for contamination, in most cases where the degree of exposure is relatively low the risk can be reduced to acceptably low levels by wearing protective clothing, washing, and dispersal.

Tools and footwear should be scrubbed with soap and water and rinsed with alcohol. Swabs should then be taken for testing. Ion mobility spectrometry is a useful technology for the presumptive screening of most organic explosives and nitrate, however quantifying inorganic traces and the peroxides is more problematic.

The bomb scene and mortuary are referred to as *primary scenes*, and any scene associated with a suspect is referred to as a *secondary scene*. It is critically important for primary and secondary scenes to be processed independently from each other to ensure trace matter has not been inadvertently transferred between the two.

Good primary scene hygiene involves

- defining epicenter (hot zone), inner perimeter (warm zone), and outer perimeter (cool zone);
- defining an access route that is unlikely to have been used by the perpetrator;
- locating the crime scene evidence collection post at the edge of the inner perimeter. In some cases it may also be beneficial to locate analytical support (mobile laboratory) here as well;
- wearing of clean protective clothing and the use of stepping plates;
- deploying a practiced team with defined roles such as
  - the team leader coordinating activities,
  - the searcher ("dirty" man crawling through the debris),
  - the collector ("clean" man taking notes and packaging samples in as hygienic manner as possible), and
  - the scene photographer and recorder.

Good secondary scene hygiene includes

- deploying a team and equipment that has not been in the primary scene, or which have been showered, scrubbed and rested;
- planning the entry to record, search and sequentially collect potential evidence in a manner that protects and minimizes the loss, and (in tropical climates) allows those in the scene to reduce their personal protection as quickly as practical;
- wearing clean pretested protective or disposable clothing, double gloves, and boot covers. This includes using clean and preswabbed sample collection equipment;
- using collection methods and packaging techniques that protect and preserve potential evidence.

If the main laboratories examination area for secondary scene samples is limited, and if the sizes of the items are large, such as vehicles, it may be worth considering choosing another location and setting up an improvised laboratory and examination area.

Searching for Evidence and Explosive Residues

The objective of the examination is to establish the facts, identify the cause, and if criminality is involved, identify the perpetrators. It is important to record the scene from the outset, and detail the recovery of potential evidence during the systematic search.

An unexploded bomb has the highest potential to yield evidence of the perpetrators identity, skill, and physical evidence of association. If the incident involves more than one bombing, the scene with least damage probably has a higher propensity to yield evidence than the scene where the bomb damage is greater. There is a natural tendency to be drawn to the site of greatest damage, and this can be a mistake.

The force of the explosion decreases exponentially with distance, so items in close proximity to the main charge will exhibit greater fragmentation than items further away. Sometimes components of the bomb are ejected or only partially consumed. Metal objects such as ends of detonators, leg wires, crimps, and plastic casings may survive smaller explosions. The recovery of nails, ball bearings, bolts, or other metal fragments from around the epicenter should arouse suspicion that "shrapnel" was part of the bomb.

The way the bomb was manufactured and set will affect the dispersal of postblast components and residues. It is always important to record where things are found and employing a planned search strategy such as a grid or a zone search can reveal useful insights, for example finding fragments of shattered fabric on opposing sides of the epicenter is evidence of it being part of the bomb. Similarly, the metal fragments found around the crater and in victims is evidence of shrapnel. This would suggest a higher degree of malice by the bomb maker (See Figures 4–7).

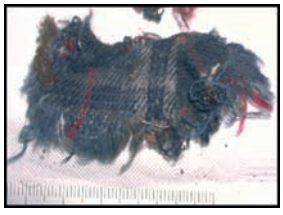

Figure 4 Tartan fabric

Figure 5 Fabric pieces

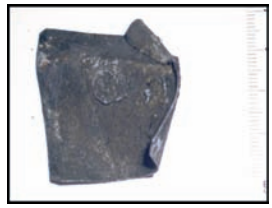

Figure 6 Metal fragment

It is important to collect "control" samples. There are two types, (i) equipment – to demonstrate tools and containers were not contaminated with relevant substances prior to use; and (ii) environmental – to quantify background levels of ions and traces of interest. Environmental controls should be collected from a site as near as practical to, but not associated with, the incident under investigation. The examiners should search for areas that were protected, such as soil from under the bitumen road adjacent to the crater was found to be most appropriate at the first Bali bombings 2002.

Explosives that are organic in nature such as TNT are more soluble in organic solvents than water. They tend to preferentially persist in moist or wet environments compared to water-soluble materials. Improvised explosives are often made by containing mixtures of strong oxidizers such as nitrate and chlorate salts with a fuel which may also be either organic (diesel, flour, or sugar) or inorganic (sulfur or aluminum dust). Inorganic materials such as the strong oxidizing salts are particularly soluble in water and prone to being washed away by a burst water main or the fire fighters' hoses. While the solvent and swabbing techniques used by forensic scientists vary, most would agree that small swatches soaked with isopropanol, such as MediPrep wipes commonly used in medicine, are convenient and effective.

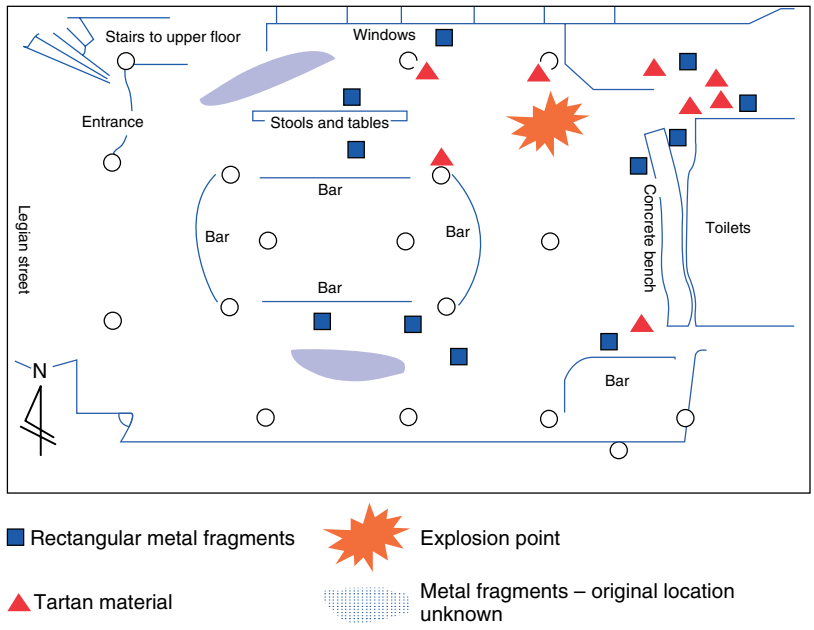

Figure 7 Sketch showing distribution of fabric and shrapnel around epicenter in Paddy's Bar – first Bali bombings 2002

There is no documented evidence of natural sources of chlorate in the environment. Intuition would suggest it is highly reactive and liable to attenuate and degrade in moist fuel rich environments. Logan [3] concluded that high humidity combined with city grime and soot was likely to cause the rapid disappearance of residues following the first Bali bombings in 2002. A review of the scientific literature adds further support in that, although effluent-chlorate anions have been found to be relatively stable in sea water they are nonpersistent in other environments due to natural biological processes.[a] Nitrates however, can and do persist in the environment and especially in soils, and especially those to which fertilizers have been applied. In these circumstances, before it can be argued that elevated levels were found in the vicinity of the bombing one must conduct environmental surveys to determine background.

Kelleher [1] observed that there is evidence to support the suggestion that explosives residue is derived from a thin outer layer of the charge and that the proportion of residue will decrease as both the charge size and the velocity of detonation increase. He also found that simple mathematical models indicate that residue not associated with fragments is concentrated within a limiting radius of approximately 60 m regardless of the charge size (excluding wind effects), however the distribution of explosives fragments and residue does not follow a simple inverse square distribution. High concentrations of residue are encountered near the blast seat and on primary fragmentation, but also in areas further from the blast seat than would be expected if the distribution followed a simple inverse square law.

Therefore, it may be necessary in a large bombing case to screen very large numbers of samples in order to find one that is rich in residues. In such cases, deploying scientists with portable instruments/mobile laboratory capability can be particularly useful and cost effective.

Mobile and Improvised Laboratories

Recent technological advances have seen the emergence of small instruments for use in the field. They are small, portable, "smart" (microprocessor control), easier to operate, more sensitive, and less expensive per sample to run. This means that scientists can offer better service from the incident scene and in recent years we have seen the development of mobile laboratories for field appreciation. A mobile laboratory provides a safe clean work area where

extraneous variables can be controlled. The high cost of transporting a mobile laboratory platform by air to an incident overseas becomes unattractive when an improvised laboratory that is almost as effective can be set up in a motel room near the incident. The most important thing about a mobile or improvised laboratory is that they enable work to be performed to a standard as the work performed in the main accredited laboratory. Practices and procedures, especially for cleaning and preparing examination areas for samples should be the same.

The technologies commonly used in these laboratories include microscopy, ion chromatography, infrared spectroscopy fourier transform infra-red spectroscopy (FTIR), ion mobility spectrometry, and a range of microchemical spot tests.

There are many advantages for deploying a mobile laboratory to the scene of a major incident. The mobile laboratory should be located between the inner perimeter and outer perimeter. Interfacing with the warm zone will facilitate the rapid screening of large numbers of samples, but without incurring the problems associated with decontaminating all the surfaces in the various instruments. Portable instruments should not be taken into the actual scene because decontamination becomes problematic.

The mobile laboratory preliminary findings are welcomed by investigators because of their timeliness and potential value to progress the investigation rapidly. It is important however, for investigators to understand what a *presumptive* test result means, and to appreciate the importance of treating this information in a tentative manner, similar to intelligence.

One of the main advantages of deploying scientists and portable instruments is to reduce the amount of irrelevant work that can so often clog up the main laboratory. A smaller number of samples can be subjected to far greater scrutiny and in depth analyses. Field samples that yield positive presumptive test results can be sorted and sent to different laboratories for independent testing. A higher degree of confidence can be placed in a conclusion by different scientists working in different laboratories and using different methods and procedures.

Circumstances will dictate the best site to operate the mobile laboratory as there can be advantages in setting it close to the work area, and advantages in being further away. When it is adjacent to the work area it will enable the rapid examination of a large number of samples, however, contamination is likely to become more of an issue. When it is positioned at a more distant location such as in a motel room or adjacent to the forward command post, it may be easier to access, communicate, and sustain, and contamination issues may be minimized; however, the throughput is likely to diminish.

In all cases, good science requires the laboratory furnishings and instruments to be cleaned, swabbed, and tested prior to use. Another good practice is to relocate the mobile laboratory when the investigation moves into the secondary phase (examining samples associated with suspects and secondary scenes).

Report Writing

The forensic sciences evolved under the influence of legal process. It is important for practitioners to understand the client they service and to appreciate the nuances between adversarial and inquisitorial law, especially if invited to offer a "second opinion" by investigators from another country.

The degree of confidence that can be placed in an instrumental result has been subject to deliberations by international experts from both the Technical Working Group for Fire and Explosive (TWGFEX) and the Forensic International Network of Explosive Examiners (FINEX). A guideline was published by experts sitting in the Laboratory Explosion Group of TWGFEX, and although it refers to *intact* explosives, there appears to be general agreement in the international scientific community that it is applicable for trace work. If applied, it means that scientists from around the world will be in agreement as to the degree of confidence that can be placed in the identification of an explosive based on instrumental analyses. Similarly, investigators must appreciate the limits and caveats associated with the scientist's report as some observations may be based on presumptive test as opposed to confirmatory tests derived from testing in the laboratory.

Bomb-Pulse Dating

Introduction

Traditionally, radiocarbon dating has been considered as an archaeological tool rather than a forensic one (*see* **Radiocarbon Dating**). Radiocarbon or carbon-14 (^{14}C) is produced naturally in the atmosphere by cosmic ray interactions with nitrogen. Single carbon atoms in the atmosphere are chemically reactive and are quickly oxidized to carbon dioxide CO_2. The atmospheric concentration of natural ^{14}C with respect to all carbon has remained relatively stable at about 1.2 parts per trillion over the past several thousand years. With a radioactive half-life of 5730 years, the radioactive decay of ^{14}C is minimal within the time period of interest in medical forensic cases and applicable for samples over 300 years of age. Willard Libby was awarded the Nobel Prize in Chemistry in 1960 for the development of radiocarbon dating [1].

Atmospheric testing of nuclear weapons during the 1950s and early 1960s doubled the concentration of $^{14}C/C$ in the atmosphere (Figure 1) [2]. From the peak in 1963, the level of $^{14}CO_2$ has decreased with a mean life of about 16 years, not due to radioactive decay, but due to mixing with large marine and terrestrial carbon reservoirs. The ^{14}C has not actually disappeared, it has simply moved out of the atmosphere. The temporal variations of artificially high levels of atmospheric radiocarbon have been captured in organic material worldwide and thus offer an opportunity to determine a date of synthesis for biomolecules. Since radiocarbon is incorporated into all living things, this pulse is an isotopic chronometer of the past half-century.

The atmospheric $^{14}CO_2$ curve depicted in Figure 1 is a northern hemisphere annual growing season average. It is constructed using several different data sets that used tree rings, recent plant growth, and direct atmospheric sampling to provide carbon samples [5–8]. Since there were relatively few geographic sources of bomb-pulse ^{14}C, the upswing and the peak values of the curve do vary with location around the globe [7, 8]. However, since CO_2 is a gas, the pulse of $^{14}CO_2$ mixed in the atmosphere with all other CO_2 to produce a relatively homogeneous distribution of atmospheric $^{14}CO_2$ by the late 1960s [9].

The isotopic content of new plant growth reflects the atmospheric radiocarbon concentration. New leaves are produced in a matter of weeks while larger fruits and vegetables form over the period of a month or two. Herbivores lag the atmosphere slightly because their primary carbon source is on the order of months old. Omnivores and carnivores lag the atmosphere further because their carbon sources are another step removed.

Within organisms, tissues turn over at different rates so ^{14}C levels vary between tissues. The date of formation of a tissue or specific biomolecule can be estimated from the bomb-curve by considering these lags in incorporation and relating the ^{14}C concentration with the date. Using an annual average of the carbon intake over a growing season can account for much food chain lag and produce a usable curve (Figure 1). Caution must be exercised when dating an elevated sample since the pulse is double valued. Placing a sample on the ascending or descending side of the pulse can often be accomplished if other information is available.

Measurement of Radiocarbon Samples

Today most ^{14}C dating analyses are conducted using accelerator mass spectrometry (AMS), although there are still labs that use decay counting. AMS is much faster and generally more precise than decay counting since it measures differences in carbon atom mass and is not constrained to wait for atomic decay. AMS can also use smaller samples than decay counting, an important issue when analyzing evidence.

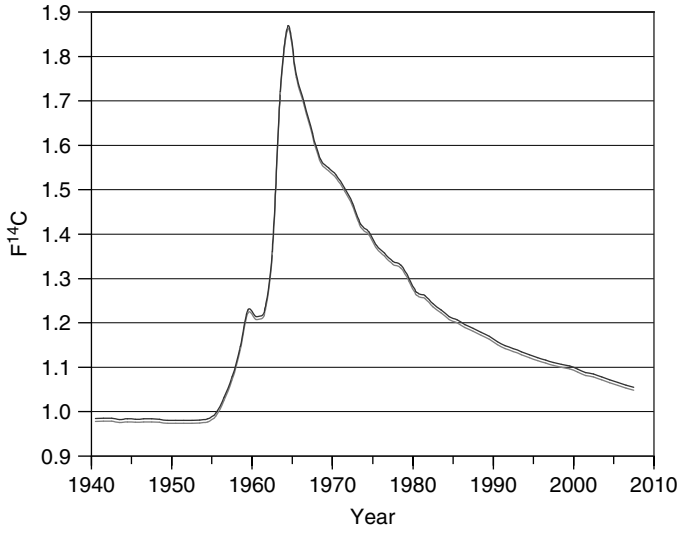

Figure 1 Northern hemisphere growing season average of atmospheric ^{14}C concentration in CO_2 from 1940–2007. The vertical axis uses the $F^{14}C$ nomenclature defined by Reimer, *et al.* (2006) specifically for bomb-pulse applications [3]. Other nomenclatures for expressing ^{14}C concentration can be found in the literature [4]

Sample preparation and measurement details vary among AMS facilities, depending on the type of sample to be analyzed and the design of spectrometer. Routine radiocarbon analyses using AMS are performed on samples containing about 1 mg carbon. Samples as small as 50 μg carbon can be analyzed at some laboratories, but measurement uncertainties are larger. Nearly all AMS facilities that perform high precision dating follow these general procedures to minimize contamination from outside sources of carbon and reduce measurement backgrounds. Samples are dried completely and then combusted with excess oxygen to produce CO_2. The CO_2 is purified to remove water vapor, nitrogen, oxides of nitrogen, and oxides of sulfur. It is then reduced to graphite or elemental carbon on metal catalyst, often cobalt or iron powder.

Primary standards, secondary standards, and backgrounds are similarly processed to produce graphite, which is the form of carbon analyzed by the majority of AMS systems [10]. Graphite is the preferred form of carbon because it can be made easily at high purity and produce intense negative ion currents. It is important to have consistent sample source material (e.g., all carbon graphite) because different molecules ionize with different efficiencies. A handful of gas accepting ion sources that take direct feed of CO_2 exist, but they are not typically used for high precision dating.

The precision of bomb-pulse dating depends on the ability to measure the ^{14}C concentration in a sample and the slope of the curve. It is relatively easy to achieve 0.5–0.8% precision when analyzing recent full-sized samples. As the slope of the pulse flattens, the uncertainty in ^{14}C analysis translates into a larger chronological uncertainty. When the slope was steep, the uncertainty was typically ±1 year. Since 2000, that same measurement precision yields a chronological uncertainty of ±2–4 years.

Soft Human Tissues Amenable to Dating

Most soft tissues exhibit relatively rapid carbon turnover. In a forensic context, the ^{14}C concentration in soft tissues can be used to determine an approximate date of an event, such as death of an unidentified body. Shortly after the start of the bomb-pulse [11], Broecker *et al.* [12] noted that bomb-curve radiocarbon concentrations in human tissues lag the atmosphere, relating to dietary issues and tissue turnover [13, 14]. They documented a lag time of about 1.1 years for blood and 1.8 years for lung tissue [12]. Libby *et al.* further noted that ^{14}C concentrations in human brain tissue can lag atmospheric levels by

only a few months [15]. Nydal *et al.* found good agreement in radiocarbon levels between samples of human blood and hair [16].

Most soft tissues decay quickly in the environment and are unsuitable for dating. Hair is a notable exception [17]. Hair tends to resist rapid decay and is often found with skeletal remains. Hair also records exposure to toxins and drugs and has been used to determine causes of death. Although individual strands of hair have little mass, the carbon content of hair is high and milligram-sized samples are relatively easy to attain. Although not widely used to determine date of death, bomb-pulse dating of hair has been used in several cases [18, 19].

Bone and Cartilage

Bone is among the preferred samples for traditional radiocarbon dating. Bone's ability to resist rapid decay while containing a relatively high concentration of carbon makes it a desirable material for traditional dating [20]. Traditional bone dating uses a collagen extraction to avoid potential complications with mineral exchange of carbonates in the environment. Collagen is a protein and is not affected by environmental carbonate exchange like the mineral component of bone.

Attempts to use bone and cartilage for bomb-pulse dating have not been very successful. Bone and cartilage do not lock carbon in an inert structure like hair. Bone and cartilage are alive and exhibit low but variable turnover, depending on activity and type of bone [21–29]. Furthermore, bone and collagen turnover varies with age. Older individuals tend to lose more bone than they replace during the bone recycling process. In general, bomb-pulse dating of bone can be used to determine if someone was alive during the period of the pulse, but cannot determine a date of birth or death. Cartilage has the same limitations as bone. In 1964, an autopsy study of the cartilage collagen of 70-year-old adults showed little increase of artificial radiocarbon despite living throughout the entire rise of the bomb-pulse from 1955 to 1964 [15].

Teeth

Although dental enamel is the hardest substance in the body, teeth are not routinely used in traditional radiocarbon dating due to fear of carbonate mineral exchange during centuries of burial. After being produced, there is no turnover of enamel, and the ^{14}C concentration reflects the level in the atmosphere at the time of enamel formation. Since teeth are formed at distinct, well-documented ages during childhood [29, 30], the ^{14}C concentration in dental enamel can be used to determine an approximate date of birth [31, 32]. The absence of bomb-pulse carbon from enamel places date of birth in the 1940s or earlier. The technique reports accurate determination of teeth of known age with precision ± 1.5 years, a significant improvement over previous techniques.

Processing of enamel samples is different than soft tissues because the carbon resides in a mineral matrix. Enamel samples must be dissolved in acid and the liberated CO_2 must be trapped for isotopic analysis.

The live part of the tooth, principally dentin, is like bone, with high collagen content and slow turnover and recycling of the carbon. It provides little information from ^{14}C other than whether an individual was alive during the pulse [27].

Efforts to develop a laboratory test for assessing age at death from teeth has focused on measurements of racemization of aspartic acid [33–38]. Aspartic acid slowly changes its structure over time at body temperature, but slows dramatically at cooler temperatures. Racemization analysis works best in cold climates in which ambient temperature is well below body temperature. The technique does not work for bodies that have been burned at high temperature. By measuring the ratio of one orientation (D-aspartic acid) to the other (L-aspartic acid) an approximate age can be determined. Reported precision varies widely among labs over the past 30 years [33–38]. Recent studies report precision of ± 1.5 years, similar to bomb-pulse dating. A single tooth can be split and analyzed for both aspartic acid and ^{14}C to get estimates of date of birth and age at death.

Documents

Radiocarbon dating is routinely used to date archaeological and art objects to the correct era. The purpose of the date is to detect forgeries. In theory, the same approach can be used to date documents originated during the bomb-pulse. Unfortunately, the carbon in paper is not from a specific year due to the relatively long lifetime of trees. The absence of bomb-pulse

carbon in paper does not necessarily indicate a document is more than 50 years old. The presence of bomb-pulse carbon does, however, place the document after the onset of the pulse.

Seeds, Pollen, and Agriculture

Seeds and pollen are used in traditional radiocarbon dating to place archaeological sites in a historical context. Since both are produced during a relatively short window of time in a single growing season, they are considered good archaeological dating samples. Because seeds and pollen are produced during limited times, they are potentially useful for placing forensic evidence in a historical context. The bomb-pulse has been used to date agricultural products in a couple of applications [39]. Vintages of recent wines can be confirmed. Interdicted contraband, such as illegal drugs, can be dated with the pulse to determine year of production. Products such as ivory from endangered species can also be dated, but customs services have not routinely used the technique.

BRUCE A. BUCHHOLZ

Botany

Botany is a branch of biology. The study of botany involves the scientific investigation of organisms classified as plants. What classifies as a "plant" is not as simple as it may appear. The naming and classification of organisms, *taxonomy*, is broadly a part of *systematics*. The main goal of systematics is to trace evolutionary history or *phylogeny*.

Classically, taxonomy involves some form of hierarchical system of classification that groups similar organisms. Unfortunately, an examination of a variety of botany books is likely to be confusing even to a general scientist, far less a "lay" reader, as there are numerous ways of grouping organisms and these have changed with time. Most systems since the late 1960s attempt to classify evolutionary branches in groups called *clades*. However, clades do not always align with taxonomic classification.

Plant Kingdom

In a classic introductory botany book that was being used in the 1960s, *Intermediate Botany* by Brimble [1], the Plant Kingdom was classified into five divisions as shown in Table1.

In 1969, Whittaker proposed a classification of five kingdoms in which fungi were separated from the Kingdom Plantae (see [2]). More recent research, including emerging DNA evidence, and based on the concept of "clades", would suggest a three-domain system in which Plantae and Fungi are included in a higher level of Eukarya.

Table 1 Classification of plant kingdom

Divisions	Examples
Thallophyta	Algae, Fungi, and Lichens
Bryophyta	Mosses and Liverworts
Pteridophyta	Ferns, Horsetails, and Clubmosses
Gymnosperms	Conifers, Cycads, Gnetophytes, and Ginkgo
Angiosperms	Monocotyledons and Dicotyledons

According to Brimble [1]

The principle goal in forensic botany is to accurately identify and assign a name. This in turn will lead to information about the plant bearing that name [3].

The lowest distinct group or population is a *species*. This is defined as the population whose members have the potential to breed with one another to produce fertile, viable offspring. The species is the lowest level of distinct *taxon*. The next level is called a *genus* (plural genera). Owing to the eighteenth-century Swedish botanist, Karl Linnaeus, who proposed the "binomial" system of nomenclature, all species are named by their genus and species name; for example, ryegrass is *Lolium perenne*.

To give some idea of the complexity facing the forensic botanist, there are in the order of 12 000 mosses, 12 000 ferns but over 250 000 flowering plants or angiosperms! To complicate matters further, there can also be significant variation within a species!

The study of plants within each major group is a specialization in its own right. Within each group, there are also many subspecializations. Along with this complexity, there are two other factors. Firstly, the knowledge base of specialists is often further narrowed by their area of application. For example, a botanist who works on cereal grains is unlikely to know much about "ferns". The second major problem facing the forensic botanist is that they will be dealing with small and incomplete examples, often a few fragments or seeds. Plant classification classically relies on having access to complete, flowering specimens.

Role of Forensic Botany

Although is has been suggested in several papers that forensic botany is a relatively recent endeavor, this is not the case. Indeed, before the significant developments of the 1960s in analytical instrumentation, the emergence of broader forensic biology, and, most recently, the emergence of DNA technology, forensic botany formed a significant part of forensic science. This was because much could be achieved with the use of microscopic techniques. There was also less emphasis on identification of suspects simply because, with the exception of fingerprints, it was not possible.

Paradoxically, the emergence of DNA, and its more recent application to forensic botany, has led to a *renewed* interest in forensic botany (see [4]).

As botany has such a wide coverage, it cannot be expected that even a botanist specializing in forensic applications can be an expert in all areas. Broadly, it can be expected that the forensic botanist will have expertise in the following areas:

- assessing the potential for forensic botany to contribute given case specifics;
- advising on appropriate sampling and scene examination;
- preliminary examination of material of possible botanical origin;
- more detailed examination depending on the specific expertise of examiner;
- advice on appropriate external experts; and
- working with nonforensic experts to ensure forensic standards and requirements are met.

The "bread and butter" for forensic botanists in many parts of the world remains the examination and identification of plant material alleged to be cannabis. However, the potential scope of forensic botany includes examination of the following:

- partially digested food such as stomach contents, vomit, and feces;
- wood and wood fragments;
- pollen and other spores;
- poisonous plants;
- diatoms;
- plant fibers used as textiles or in paper;
- plants, or plant parts, used in illicit drugs, including, but not limited to, cannabis;
- nonspecific plant parts or whole plants which may be present only as fragments or physical traces; and
- soils for organic, botanical traces.

Such examinations may assist in the following:

- locating a crime scene;
- determining the timing of an event;
- reconstructing events;
- drowning diagnosis;
- investigating war crimes;
- providing intelligence in drug investigations;
- establishing evidence of illegal importations; and
- establishing contact between individuals and scenes.

The above is not a complete list of possible areas where forensic botany may be able to assist. The forensic botanist needs to have a broad background aimed at recognizing key indicators that would identify the type of plant material. Although there is a shared body of general botanical knowledge, a local knowledge of the flora and an understanding of the local ecology are the essential components in a competent forensic analysis. Added to this is a knowledge of how plant materials may be altered due to a wide variety of environmental and other impacts. For example, what will a cereal grain, and its components parts, look like after being processed into a food product or after traveling through the human digestive tract?

Because of the limitations placed on identification owing to the incomplete nature of many forensic samples, examinations may only be comparative. Often, however, plants possess very characteristic features that are strongly indicative of identity. It is critical to understand that identity, although the gold standard, is only one aspect of the work of a forensic botanist. Prior to identification, the forensic botanist needs to consider criminalistic aspects such as the following:

- Is the nature of recovered material what would reasonably be expected, given what is known about the alleged case circumstances?
- Is the material recovered "consistent" with the transfer and persistence of botanical materials (little research has been done in this area)?
- Can any missing species or differences where the "known" sample has more species present than the recovered sample be explained?

The answers to these types of questions are rarely simple, in part, due to the dearth of research into criminalistics aspects of forensic botany.

It is beyond the scope of this article to consider *in detail* the broad range of materials that may be present to the forensic botanist. A few examples are presented to illustrate what can, and what cannot, be done. Finally, the current status of the potential contribution that DNA may make to forensic botany is considered.

Plants and Plant Fragments

Besides the more specialized categories of plant material, the forensic botanist may be confronted with an almost endless array of plant fragments, seeds, or even (but rarely) whole plants. This is because plants are to all intents, ubiquitous. Even the barest alleyway will have some plant material, whether it is a weed growing out of a crack in the road, moss or algae on a rock, or dried seeds blown in by the wind. Many seeds are specifically adapted to adhere to the surface of passing animals and this mechanism for dispersal also results in ready adherence to various fabrics. While such materials may be recovered during evidence collection and triage, only in those rare cases where the plant material may be critical, is it likely that it will be examined.

The task of a forensic botanist is to attempt to identify (usually) fragments or specific parts (such as seeds) from plants. This requires a generalist approach to recognize the broad grouping to which the recovered material belongs. If the botanist has some specialist knowledge of this group then it may be possible to identify to a more specific level. Where the scene of the incident is known and appropriate known samples are available, this is extremely useful. First, identification of the actual plants at the scene is invariably made easier and second, it is then possible to compare the "fragment" recovered from the case item with the relevant part of the known plant. In some cases, the reverse may apply where the botanist is able to suggest a type of ecological site based on the plant species present. Although the basics of plant examination are the same worldwide, knowledge of the local flora and habitat is *vital*.

The use of identification keys, with a few exceptions, is not especially useful to the forensic botanist. Demmelmeyer and Adam [5] discuss some specific examples where keys may be of value. More recent interactive keys do not require keying out in a particular order, which increases there potential value for application in a forensic context.

In summary, the forensic botanist needs to be first and foremost a generalist and in many cases will need to consult with a specialist in the type of plant present in the particular case.

From a crime scene perspective, it is most likely that the scene will be an outdoor setting, although indoor settings are encountered. The types of case in which botany are most likely to be encountered will be sexual assault and/or murder cases. In some cases, the body may be in a shallow grave or simply covered with plant debris. A rather specific type of outdoor scene is where a body is located partly or fully submerged in water or near water where drowning is suspected.

If it is not possible to have a forensic botanist attend the scene, the guiding rule should be to collect more, not less. Plant material should be placed in either cardboard boxes or in paper bags and preferably *not* in plastic bags. If the material is damp, it can be placed for a short term in plastic but must be dried as soon as possible. Finally, the possibility of a physical fit between the scene and suspect samples should be considered.

Plants from an outdoor scene will often be associated with soil.

Cannabis and Other Plants Used as Illicit Drugs

By far, the most common plant material examined in forensic laboratories is cannabis, *Cannabis sativa*. The identification of cannabis plant material is straightforward because the combination of microscopic features of cannabis was unique. Excellent descriptions of the microscopic features of cannabis are to be found in older pharmacy books, reflecting the fact that cannabis was commonly used as a medicinal drug (see [6]).

From a crime scene perspective, the forensic investigator is only likely to be involved in more serious cases involving cultivation. These may involve outdoor scenes, the use of glass houses and increasingly indoor settings with nonsoil-based hydroponic cultivation. This type of specialist assessment is not the normal role of the crime scene investigator, unless they have relevant competencies and experience. The competencies will include botanical training to identify male and female cannabis plants, to assess the state of maturity, and form an opinion (where appropriate) on likely yields from a particular crop situation. This is most accurately achieved when the crop is mature and can be weighed. In other situations, it is sometimes possible to broadly estimate a potential yield of an immature crop from an assessment of the site and growing conditions. Without being prescriptive, this assessment could include factors such as the number of plants present, potential of the site to nurture that number of plants, water and nutrient availability, time-of-year climatic factors, comparison with similar crops where the yield is already known, or for an indoor cultivation, lighting, and temperature conditions. Provided it is supported by appropriate data, it is also sometimes possible to predict a range of potential yield for a site.

Papaver somniferum is one of approximately 100 species of poppy and is generally considered to have two subspecies, i.e., subspecies *somniferum* and subspecies *setigerum*. Both subspecies are annual herbaceous plants. The wall of the immature seed capsule produces a milky latex, which contains various opiates, including morphine. When the capsule is scored, the latex is exuded and congeals on the outer wall surface. This is later collected and can be smoked or consumed with tea, or the morphine extracted from the raw opium gum and converted into heroin. The subspecies *somniferum* is legally cultivated in some countries, including Australia, for the supply of morphine to the pharmaceutical industry.

Whole plants in flower or with intact seed capsules are readily identified; however, detached capsules need to be analyzed chemically for the presence of morphine as they lack sufficient features to enable identification to species level.

Other plant species are used as sources of drugs with some plants being common in specific geographic areas.

Pollen Analysis

Pollen grains from the male reproductive cells of angiosperms and gymnosperms have highly resistant outer walls, which can be intact for very long periods of time under the right conditions. The study of pollen, *palynology*, is a specialist field of botany and requires specific training in the preparation of samples and in the identification of pollen grains. It is normal for there to be pollen present from a number of species and this is called a *pollen assemblage*.

Plant species present at a scene may be unique, rare, or quite common but the "assemblage" may be quite specific for a vegetation area, which may indicate a scene. Because it would be very difficult to avoid carrying away pollen adhering to shoes, clothing, tools, or a vehicle, these objects can be potentially linked back to a scene. Specialist knowledge is required about the species in a locality and how pollen from these species may be dispersed to properly interpret a pollen assemblage. For example, pollen from wind pollinated species (anemophilous) is borne by air currents and can travel considerable distances. Pollen from plants that require insect intervention tends to be heavier and displaced pollen will generally be located very close to the parent plant. Hence, interpretation of what is a meaningful difference in comparing two samples is not always simple.

The forensic literature contains a significant number of case reports that illustrate how forensic palynology can contribute to questions of interest to the investigator and, ultimately, in a court situation. Papers from two major international meetings on forensic palynology since 2000 have been published in special editions for the journal, *Forensic Science International*. In the lead editorial to the 2006 volume, Mildenhall *et al.* [7] present persuasive arguments for why forensic palynology is of value and how it can be used.

Wood

The need to examine wood or wood fragments can arise from timber or timber products used as weapons, where wooden doors or window frames are damaged during a break and enter, or from wood shavings that were used in older style safes where the shavings formed the "ballast". The latter was an important part of forensic biology until, at least, the 1970s.

Botanically wood is divided into two broad groups, *softwood* and *hardwood*. These can be distinguished by very obvious differences in the major cell types present. While the anatomy of wood is quite complex, it is well described for all commercial species. There are numerous physical and computer-based keys and programs for the identification of small samples or fragments of wood. Their use requires a detailed knowledge of the tissues and cellular features found in wood. This requires detailed knowledge and is quite a specialized field. The relevant expertise is not commonly found in today's forensic laboratory.

There are keys for the identification of larger wood samples using a hand lens. At present, the identification of a wood sample would often require the use of a scientist in a wood research institute. Scientists experienced in looking at wood or timber are very good at identifying timber by eye or with the aid of a hand lens. However, for forensic purposes identification must be based on a full examination using appropriate identification keys and confirmation through comparison with a verified reference specimen.

Identification usually requires information gained by examining three types of sections: a transverse cross section, tangential, and radial longitudinal sections. As wood ballast consists of very small fragments, often of 1 mm or less, examination involves preparing sections of these using a freezing microtome. Sections are suitably stained and their microscopic features recorded. With very small particles of wood, it may not be possible to obtain all three sections even with the aid of a freezing stage microtome.

In collecting the samples for examination, and/or comparison with a questioned forensic sample, it is important to think about what might be available for transfer and in what form. The collection of appropriate known samples, and later of possible reference samples, can require some specialist advice or involvement. For example, care should be taken to ensure that samples are representative. It is not unknown for a wooden window to have a repaired section comprising a different timber from that used in the original construction. This is especially so in older properties as a wider range of commercial timbers were used historically in building construction than is the case today.

The possibility of physical fits with wood should also be considered. Wood or timber may also be associated with other potential evidence, for example, paint, which may have higher probative value Fiddian [8] gives several examples of physical fit evidence.

As wood is laid down through an annual growth cycle, the annual growth rings in timber can be "read" and give a history of the life of the tree. There are cases reported in the literature in which growth ring patterns have been used to link stolen timber (a

major issue in North America) back to stumps at the location where the trees were harvested [9].

The most famous, or infamous, case in which growth ring analysis played a significant role was in the Lindbergh kidnapping. A home-made ladder, used to gain access to the Lindbergh home, was linked to a piece of wood found in the suspect's home, by matching the wood used to repair a broken rung in the ladder. A full account of this fascinating historical case can be found in [10].

Fiddian [8] also describes the use of growth ring analysis to link a sawn-off rifle or shotgun stocks with recovered weapons.

Food Residues

Food residues may typically present themselves to the forensic botanist in the form of stomach contents, vomit, and feces.

Stomach or gastric contents may be examined as an aid in establishing the time of death. This relies on identifying partly digested residues of foods (plant or animal) to assess when the deceased had last eaten. The analysis of vomit is essentially the same as for stomach contents except that the material to be recovered may be partially or wholly dried by the time it reaches the forensic laboratory. It is not uncommon for people to vomit during a violent assault. Fecal material will contain only the remnants of foodstuffs that are most resistant to the digestive process. Once again, it is quite common for people who are involved in a violent situation to defecate. It is also not unusual for burglars to defecate intentionally as a further "insult to injury".

It is beyond the scope of this article to consider in detail the types of information relied upon by the forensic botanist conducting this type of work. It requires an in-depth knowledge of cell types and their occurrence and appearance in plant foodstuffs. However, much of the useful information can only be found in texts that are invariably old and often out of print. Furthermore, information is generally not available in a systematic way aimed at, or suited for, forensic application. Often the key skill is to recognize the broad type of plant material and then go through a process of using reference works and preparing the known samples for comparison. By necessity, this places a heavy emphasis on an individual's experience and on what the individual has previously seen. Attempts to develop a more systematic analytical approach using manual- and computer-based keys have been made only in those areas where the materials have some commercial or academic interest, for example, with woods, seeds, or powdered vegetable drugs.

An in-depth knowledge of tissue and cell structures and how these are affected by food processing and by digestion are prerequisites for the analysis of food residue samples.

Plant Toxicology

Plants have been used for medicinal purposes, and as poisons, by humans since the ancient days. Many wild plants are poisonous when consumed by humans and exposure to these poisons is a common occurrence in everyday life, causing problems ranging from allergic reactions to gastrointestinal irritation and, at times, death. Fortunately, death by ingestion of toxic plants is relatively rare and occurs more often in young children where plant parts are eaten or chewed because of their attractiveness to the child. However, accidental overdoses of traditional remedies such as herbal medicines have caused deaths in various countries.

Rapid identification of poisonous plants that have been ingested can be paramount in saving a patient's life by providing immediate advice to the treating doctor as to what poisonous compound has been ingested, therefore enabling the administration of the correct antidote. The Royal Botanic Gardens, Kew, in the United Kingdom has developed an illustrated interactive key on CD-ROM to enable doctors to identify plants suspected of causing poisoning [11].

In some countries, certain plants have become popular suicidal agents and the incidence of fatal poisoning has increased. A famous homicide involved ricin, the poison derived from the seed of castor oil plant (*Ricinus communis*), which was most likely administered to the victim via a projectile fired from an umbrella tip. As in this case, where plant toxins have been used in homicides, they usually have been extracted from the parent plant and their identification is carried out by a toxicologist using chemical assays and tests [12]. However, if the "raw" form is used, a botanist may be required to identify the plant parts from a gastric content examination. Fiddian [8] describes several cases in which it was necessary to identify plants or preparations of plants.

In Europe, perhaps less so elsewhere, it is not uncommon for people to mistakenly collect poisonous mushrooms through misidentification and this has resulted in several fatalities.

Diatoms and Other Microalgae

Botanical evidence is not restricted to terrestrial habitats. Aquatic botanical evidence is highlighted in a case study where two young boys were attacked and bound while fishing in a pond, then dragged into the water. They managed to escape and the three suspects were apprehended soon after. The sediment-encrusted shoes of both the victims and the suspects were examined. Numerous species of plankton (or microalgae, i.e., unicellular algae, including various diatoms and chrysophytes) were recovered from the shoes and pond sediment. There were marked similarities in the compositions of plankton species in all the samples, which strongly indicated a common source [13].

Diatoms are the most common microalgae encountered as trace evidence. They occur in many habitats, including marine, freshwater, and terrestrial environments. There are various species that flourish in generally inhospitable environments, such as highly acidic habitats and thermal water bodies, where temperatures prevent the growth of most other life forms. Diatoms have extremely resilient silicous cell walls termed *frustules*, which are composed of two valves. They are classified into two groups based on their symmetry: centric (with radial symmetry) and pennate (with bilateral symmetry). The taxonomy of diatoms is based on frustule morphology, including shape and surface ornamentation [14].

A consequence of the highly resistant nature of frustules, along with the widespread distribution of diatoms in the environment and in manufactured products containing diatomaceous earth, has resulted in their periodic appearance as trace evidence in various situations.

Older types of safes are still widely used, consisting essentially of an inner vault placed inside a metal box, with insulation material (or safe packing) placed between the walls of the two boxes to give the safe fire-resistance. The common types of safe packing include diatomaceous earth and sawdust mixed with vermiculite mica, cement, or gypsum. To gain access to the inner vault, the safe breaker must pass through the packing, releasing it as a trace material. Deposits on the suspect's clothing may be examined by a botanist to ascertain the diversity and relative proportions of foreign diatom species present as well as to identify the wood fragments when present.

Diatoms are also found in other manufactured products, all of which have the potential to be a source of trace evidence. These include abrasive cleaning agents such as car polishes, some paints, and various brands of match heads.

However, the most common use of diatoms in forensics graph is in the diagnosis of drowning. During the process of drowning, plankton in the water are inhaled into the lungs and passed via the lung capillaries into the general arterial circulation. The planktons are thereby dispersed through the body to lodge in tissues such as bone marrow that may only be reached by circulation. This plankton almost invariably includes diatoms, with small pennate species being the most common type found in bone marrow [15].

There is still considerable debate over the interpretation of the presence of diatoms in drowning cases, primarily because it has been reported that diatoms have been recovered from the organs of persons who have not drowned and conversely not detected in persons known to have drowned. However, there would appear to be widespread acceptance that the presence of diatoms *can be* an indicator of drowning, with appropriate understanding of the local and specific case circumstances and appropriate sampling.

DNA Analysis

The use of DNA testing for plants has evolved and matured over the last decade and is well established in a wide range of botanical applications (see [16]). Coyle [4] also describes DNA testing for forensic applications. Although there are a small number of case reports on the use of DNA testing of plants in forensic situations, such testing is still not common. The DNA tests and interpretation of the results will usually be done outside the forensic laboratory. The interpretation of plant DNA is quite different from that of human DNA and needs to be clearly understood.

Thus far, most of the research effort on forensic applications of plant DNA has been with cannabis, to identify cannabis and to compare cannabis seizures. Howard *et al.* [17] have published the first validation

study for the use of short tandem repeat (STR)-based DNA analysis system for cannabis.

Cannabis

Introduction

Cannabis, possibly one of the oldest plants cultivated by man, is thought to have originated on the plains of Central Asia. There is evidence that the Chinese cultivated it over 8000 years ago for fiber and oil. The Chinese recognized its medicinal potential, but it was seldom used as it "disturbed the equilibrium of the brain".

The plant was cultivated in the Indian subcontinent about 2000 BC where it was considered sacred and used in the performance of rituals. The ancient Hindus also hailed cannabis for its medicinal properties.

Its use became widespread in the Middle East, with initially little cultural opposition. Muhammad's teachings forbade the use of alcohol, but not cannabis derivatives. Muslim scholars and clerics debated the use of cannabis for centuries and finally, in the eighteenth century, decided that its use for pleasure was prohibited as it "beclouded" the mind in the same way as alcohol does. Its use for legitimate medicinal purposes was permitted.

Throughout the Middle Ages, cannabis was central to any herbalist's medicine store. However, the Holy Inquisition regarded those using it as sorcerers or witches and forced its use underground.

The word assassin has long been associated with the consumption of the cannabis derivative hashish. The story is based on reports by Marco Polo about a group of highly motivated, skilled, merciless political killers, who may have used cannabis as part of their religion. The use of cannabis, however, does not produce a violent mental state and an assassin under the influence of the drug is likely to be a liability.

The rapid increase in travel in the sixteenth century created an increased demand for hemp cloth and rope. King Henry VIII required all farmers to grow a one-fourth acre of cannabis for every 60 acres cultivated. Farmers were reluctant as the crop gave a poor financial return and impoverished the soil. Russia, the major producer of hemp, provided 90% of Britain's seventeenth century needs [1].

O'Shaughnessy, an Irish surgeon working in India, was impressed with the effectiveness of cannabis derivatives as a muscle relaxant, anticonvulsant, antiemetic, and analgesic. After experimenting on animals and humans, he introduced it to the British medicine in 1830, prescribing it for a wide range of illness. He recognized that the drug did not cure many of the diseases for which it was prescribed but enabled the patient to withstand the suffering. However, the cannabis derivatives were of variable potencies and it was difficult to replicate the desired effects. The advent of specific medicines such as aspirin and barbiturates eventually resulted in cannabis being removed from the British Pharmacopoeia [2].

Source of Cannabis and Cannabinoids

Cannabis (Figure 1) can be recognized at all stages of growth by its distinctive botanical characteristics. It has its own botanical family Cannabaceae and its closest relative is hops (*Humulus lupulus*). The appearance of individual plants is highly dependent on the habitat and the growing conditions. This variability led to the view that there were several different species but it is now widely accepted that only one cannabis species, *Cannabis sativa*, exists.

The cannabis plant is usually unisexual but occasionally both the male and female flowers occur on the same plant. The male plant matures before the female plant and dies off soon after flowering. The female plant is generally denser and leafier than the male plant and survives until the maturation of the fruit. The so-called seed is a very distinctive fruit consisting of a single seed in a pod.

The cannabis plant has a variety of glandular and nonglandular hairs that enable it to be identified microscopically even when finely fragmented. Glandular hairs secrete the resin that contains the psychoactive constituents of the plant and are found on all parts of the plant.

Cannabis contains at least 483 natural compounds of which 6 have been identified in the last decade [3]. While the majority of these are classified as terpenes, hydrocarbons, sugars, flavonoids, and miscellaneous compounds (413 in total), 70 are classified as cannabinoids. The cannabinoids typically contain 21 carbon atoms, although their analogs and transformation products, which may not have 21 carbons, are also included in the 70. The chemical structure of the cannabinoids appeared to be unique to cannabis until the recent discovery of cannabinoid biphenyls in liverwort [4].

Figure 1 Flowering heads of the cannabis plant

The best-known cannabinoid and the one considered responsible for most of the physiological effects experienced by cannabis users is delta-9-tetrahydrocannabinol (THC). This molecule contains two chiral centers and the naturally occurring molecule possesses the trans configuration, illustrated in Figure 2. THC is not only present in plant material but is also formed during the smoking process by decarboxylation of an acid precursor. The amount of THC in confiscated plant frequently exceeds the amount of the precursor [5]. In fresh hemp, the precursor levels may exceed those of THC [6].

THC is found on all parts of the cannabis plant, with the highest concentration being found in the female flowering heads (sinsemilla). The potency of the cannabis plant depends on the source of its seed as well as the growing conditions. Cannabis grown for fiber (hemp) may have negligible THC even on the flowering parts, whereas selected illicit cannabis,

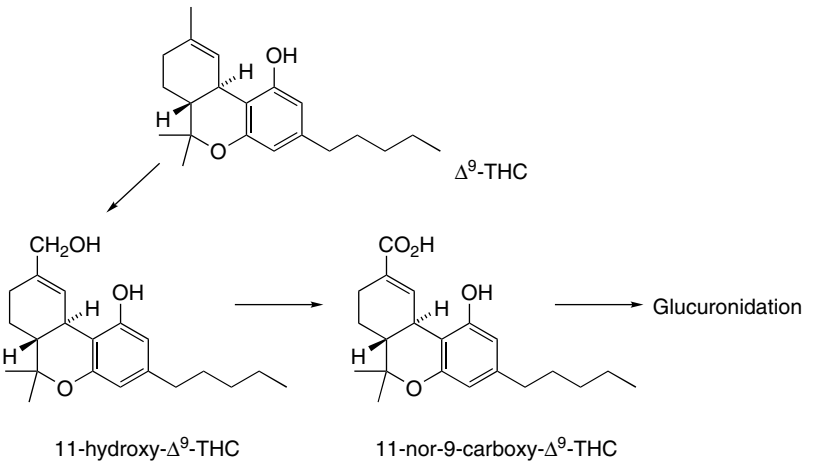

Figure 2 Principal metabolites of THC

grown hydroponically, may produce flowering heads containing more than 40% THC.

Hemp fiber has superior qualities compared to cotton and is currently used in the production of textiles, paper, fiberboard, molded car parts, insulation, and animal bedding. The cultivars grown for hemp production in countries that legislate against cannabis must contain less than 0.3% THC per dry weight of the plant, a level too low to produce psychoactive effects. Cannabis can produce four times as much paper per acre as pine trees, but the plant requires a high level of nutrients. Such requirements may make the plant useful for the removal of excess nitrogen or heavy metal contaminants from soil (bioremediation). Cannabis seeds are oil rich and were used as a human and animal food for thousands of years. The oil produced from the seeds has properties similar to linseed oil and has been used in paints, soaps, and cosmetics. Hemp seed oil does not contain THC and is used in health food and body-care products [7].

Medical use of Cannabis

Interest in the medicinal use of cannabis has recently been rekindled. In particular, cannabis has proved effective for some patients in controlling nausea and vomiting associated with chemotherapy. It has also been found useful as an appetite stimulant for those suffering from AIDS wasting syndrome. The use of cannabis for the treatment of chronic pain has yielded inconsistent results, and while smoking cannabis provides some relief of eye pressure in glaucoma sufferers, the relief is short lived. Studies are continuing on the effectiveness of cannabis for the control of muscle spasms associated with multiple sclerosis and epilepsy [8].

The mode of administration of medicinal cannabis is an issue. Smoking has associated health issues and oral administration produces inconsistent absorption. Aerosol delivery of synthetic cannabinoids offers potential advantages. A number of synthetic cannabinoids have been developed for research purposes. These include nabilone (nausea and vomiting) marketed in several European countries and the United States and rimonabant (obesity) in the United Kingdom [4].

Cannabis Abuse

It would be surprising if consumption of cannabis with its variable ratio of chemical constituents did not produce a wide range of inconsistent physiological effects. Indeed, this very complexity presents a significant scientific challenge in unraveling whether cannabinoids have any future as therapeutic agents. There is a fine line between the desirable medicinal effects and the possibly undesirable physiological effects.

The recreational use of cannabis in the Western world became widespread after World War II and is still increasing. The leaf and flowering parts of the plant are most widely used. However, the use of

cannabis resin (hashish) and cannabis oil (made by extracting the plant with a solvent) is also common.

The determination of recent cannabis usage is important in forensic cases. Drummer [9] has demonstrated that the incidence of THC in a range of Victorian (Australia) coronial case types ranged from 2.2% in natural deaths to 36% in heroin-related deaths. Many studies have found high rates of recent cannabis use by fatally injured drivers (up to 37% in a US study).

Mechanism of Action

It is now accepted that cannabis constituents exert their pharmacological effect by attaching to binding or receptor sites in mammalian tissues. Such sites have now been found in birds and aquatic species [4]. The discovery of these binding sites greatly increased our knowledge of the pharmacology of cannabis. Two types of cannabinoid receptors, CB_1 and CB_2, have been identified [10]. The former are present in the brain, spinal cord, and peripheral tissues, whereas the latter are found in immune and reproductive tissues.

The occurrence of these receptors led to the search for naturally occurring compounds that utilized the receptor sites. Endogenous cannabinoids were soon identified [11], with the neuromodulators, anandamide, and its structural relative, 2-arachidonoyl glycerol being the most significant. THC has some structural similarity to these compounds [2] and mimics their action at the receptors.

Pharmacological Effects of THC

Cannabis combines many of the properties of alcohol, tranquilizers, opiates, and hallucinogens and thus affects many behavioral and physiological functions. It influences mood, induces euphoria, and decreases anxiety. In sociable surroundings, it may increase sociability but anxious users may experience increased anxiety, paranoia, or panic. Cannabis has been linked with psychotic disorders. Acute misuse may produce a temporary psychotic state. Whether cannabis causes schizophrenia or accelerates its development in predisposed persons is still a matter of debate.

Cannabis affects perception with colors appearing brighter, music more vivid, and time and spatial perception distorted. Cannabis also affects an individual's reaction time, memory, and ability to concentrate and to study. It is not surprising therefore that the role of cannabis in traffic crashes has received considerable attention. Early studies did not show that cannabis users had an increased responsibility rate for accidents. More recent studies, however, have demonstrated the opposite [9]. This apparent contradiction appears to be due, at least in part, to the fact that the earlier studies used the long-lived and pharmacologically inactive THCCOOH as an indicator of use. The later studies measured THC, which is more relevant as it is indicative of more recent use. There is therefore increasing support for the position that recent cannabis usage, i.e. within about the last 3–4 hours, is a contributory factor in traffic crashes.

The use of cannabis causes an increase in the heart rate, thus placing people with a preexisting heart condition at risk. In view of the higher concentrations of mutagens in cannabis smoke compared with that in tobacco smoke, it is not surprising that the rates of some cancers, particularly oral cancers, are higher in cannabis smokers. The smoking process produces more than 2000 compounds by pyrolysis [2].

While cannabis abuse is a major concern, it should be noted that, unlike other recreational drugs, no deaths have been attributed solely to a cannabis overdose.

Analysis in Biological Specimens

The analysis of cannabinoids in biological specimens is generally performed as a two-stage process. Low-cost immunoassay screening tests are conducted to determine which specimens may contain cannabinoids. Specimens that give a positive response are subjected to further testing to ensure that the screening result was a true positive and to quantify the cannabinoid concentrations in the sample.

Gas chromatography-mass spectrometry (GC-MS) is the most common confirmatory procedure for quantifying THC in blood and oral fluid and its carboxy metabolite in urine. These methods typically involve a chemical derivatization of the analytes to produce acceptable chromatographic peaks [2]. The limits of detection of $1–2\,\text{ng ml}^{-1}$ of THC in blood that are typically achievable using low-cost instrumentation are sufficient for most applications.

Liquid chromatography tandem mass spectrometry (LC-MS/MS) is increasingly being used for quantifying cannabinoids in biological specimens [12, 13]. This technique has some significant advantages over GC-MS as it eliminates the need for derivatization and can achieve lower limits of detection. LC-MS/MS instrumentation, however, is more expensive than a bench-top GC-MS.

Routes of Administration and Pharmacokinetics

Smoking is by far the most common means of administration of cannabis with THC being detectable in the blood within seconds of commencement of smoking [14]. The bioavailability of the drug is reported to range from 18 to 50% [15], reflecting variability in smoking styles.

Several studies have established that THC is absorbed through passive exposure to cannabis smoke. Concentrations of both THC in oral fluid and metabolites in urine following such exposure are much lower than from active smoking [16].

Oral intake of cannabis, often in the form of cookies, results in much slower absorption, with peak blood THC concentrations being achieved in 1–5 h [17]. The degradation of THC by stomach acids and first-pass metabolism reduces its bioavailability to between 4 and 20%. Peak concentrations of THC in plasma after oral intake are about a third of those achieved after smoking an equivalent amount of THC.

THC is very lipophilic (fat loving) and after absorption is rapidly distributed from the blood to other storage depots in the body. Initially, THC distributes to highly vascular tissues including the brain and then redistributes to fat deposits. This accumulation in fat and the subsequent slow release accounts for the fact that THC has a long terminal half-life of more than 4 days.

Figure 2 shows the major metabolites in man. While the 11-hydroxy-THC (11-OH-THC) has pharmacological activity, the carboxy metabolite (THC-COOH) is inactive.

The typically rapid increase and decline in plasma THC concentrations and corresponding changes in metabolite levels are illustrated in Figure 3 [14]. The rate of decline in THC varies between individuals and is also dependent on smoking technique, frequency of use, and cigarette potency.

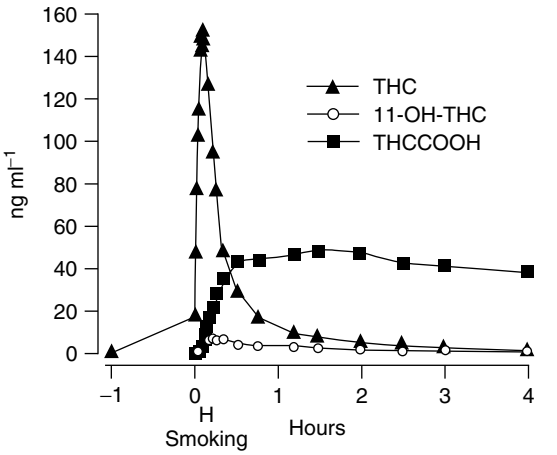

Figure 3 Mean plasma levels of THC and THCCOOH during and after smoking a single 3.55% THC marijuana cigarette [Reproduced from the Journal of Analytical Toxicology by permission of Preston Publications, A Division of Preston Industries, Inc.]

THC is sequestered in the oral cavity during the smoking process, with high concentrations being indicative of recent smoking [18]. Unlike many drugs, there is very little transfer of THC from blood to oral fluid [19].

Most of the drug is eliminated in feces (over 65%) or urine [20]. Minor amounts are excreted in hair, nails, and sweat. The window of detection for cannabis metabolites in urine is dependent on the quantity of drug consumed and the sensitivity of the analytical method employed. Low-to-moderate doses may be detected in urine for up to 12 days, but in heavy users it can be detected for up to 77 days after the last use [9]. Urine concentrations of THCCOOH are useful in determining usage but are of no use in establishing impairment.

Regulatory Aspects and Offenses

The first regulatory control efforts to control the use of cannabis were promulgated in the early twentieth century. The arrival of the drug with Mexican immigrants first brought the drug to prominence in the United States and this rapidly led to moves to control its use. Some observers consider that the "demonization" of the drug by the US authorities at that time has colored attitudes worldwide ever since [7].

Three major international drug control treaties have been developed under the auspices of the United Nations Office for Drug Control and Crime Prevention and ratified by most of the UN members, although many have attached reservations to their treaty signatures. While most countries have thus acknowledged the need for regulations to minimize the harm the use of drug has on society, the means to achieve this end are hotly debated in most democratic societies. Proponents of liberalization policies argue that "... the social and economic costs of cannabis prohibition outweigh any benefits ..." [21]. Prohibitionists argue with similar conviction that rates of cannabis use would be higher if it were legal. Numerous expert inquiries have been set up around the world but few seem to have had a significant impact on the thinking of the government.

Many countries approach cannabis control from the enforcement angle, with users and dealers being liable to prosecution and imprisonment. In the United States, cannabis is listed as a Schedule I substance along with heroin. Courts in a few countries, including Singapore (500 g) and Malaysia (200 g), may impose the death penalty for possession of cannabis.

The Netherlands, by contrast, distinguished itself from other Western countries in 1976 by decriminalizing the possession or sale of small quantities of cannabis. Differences in ethnic, cultural, and socioeconomic factors make it difficult to evaluate which approach is more successful at harm minimization. Certainly the United States has a higher prevalence of cannabis abuse than any of the 32 Western and Central European countries detailed in a 2006 report [22], whereas The Netherlands is ranked in the middle. More important, perhaps, is the fact that The Netherlands has a significantly lower prevalence of opiate, cocaine, and amphetamine abuse than the United States. The Netherlands has a higher prevalence than the United States in only one of the five drug classes documented in the report, namely, ecstasy.

Several countries have introduced legislation to control the use of cannabis by motor vehicle drivers. Studies have demonstrated that the use of cannabis especially in conjunction with alcohol significantly increases the risk of road crashes. The correlation between THC blood concentrations and impairment, however, is not strong. It is only possible to conclude that a person may have been impaired at the time of crash if they have high-blood THC levels indicative of recent use. Several countries (e.g., Germany) have addressed this by specifying blood THC concentrations above which it is illegal to drive.

Oral fluid testing for THC is increasingly being considered as a viable option for roadside testing of drivers, in part, because sample collection is relatively noninvasive. Successful trials in Victoria have led to legislation in other Australian states [23]. Improvements in technology are needed to enable the window of detection to be extended beyond about 2 h and to speed up the test procedure.

Conclusions

The use of Cannabis has had a long and colorful history. The complex chemical mixture in cannabis produces a wide variety of behavioral and physiological effects after smoking or oral ingestion. While some of these effects may produce pleasurable experiences, there are also significant adverse health consequences for some users. Potential medical applications of cannabinoids are emerging but more research is required.

Abuse of the drug has increased rapidly since the end of World War II and this has led to legislation to control its use. Whether harm minimization can be achieved more effectively by cannabis prohibition or decriminalization is still a matter of strong disagreement. The continuing increase in rates of abuse, however, points to the need for better policies.

Oral fluid testing for the use of cannabis looks set to have a significant role in improving road safety.

Capacity Assessment

Introduction

The right to choose is a fundamental societal value, but in certain situations, an individual's ability to make personal choices may be questioned. In such situations, individual autonomy must be weighed against another societal interest – that of protecting the individual. Competency as a legal term, defined by Black's Law Dictionary as "the mental ability to understand problems and make decisions," is closely related to the clinical issue of capacity [1]. Although mental health professionals may make an assessment of capacity, the determination of competency is reserved for the judicial system, and competency requirements may vary from one jurisdiction to another. The common fundamental principles of competency are the focus of this article.

Assessment of competence is based on four elements, specifically with regard to having the requisite mental skills for the acquisition, comprehension, and processing of relevant information in order to make a decision [2]. Essentially, an individual must understand the basic facts of a given situation. Once a factual understanding is attained, the individual must appreciate the implications of the situation and its relation to himself or herself. On that foundation,

the individual must be able to utilize this understanding to rationally assess the risks and benefits of the possible choices. Finally, a competent individual must be able to communicate that choice. For example, a person who articulates a reasoned choice but subsequently changes his or her decision too frequently to allow implementation of a particular choice might be considered incompetent. In order to be considered competent, the choice made by an individual need not be the course of action that most people would prefer. Rather, the question rests on whether the process of choosing was based on the reasoned application of adequate factual understanding.

Capacity may be significantly impacted by preexisting cognitive limitations or an underlying psychiatric disorder. However, the presence of a mental illness alone is insufficient to indicate a lack of capacity. A context-specific functional impairment must also be present. Just as symptoms of mental illness may improve or worsen, capacity similarly may change over time and may require reassessment as circumstances change. Clarifying the type and extent of impairment resulting from mental illness is necessary in determining capacity. There are numerous assessment tools, including the MacArthur Competence Assessment Tools [3] to aid in this task. However, there is no standard tool to evaluate capacity, and evaluations typically include minimum clinical interview and review of available records.

Competency issues arise in both civil and criminal arenas, and in general, the court conducts such evaluations in an effort to safeguard the individual's rights. As the determination of competency for specific issues depends upon skills and abilities specific for each issue, an individual may have competence to decide one issue but not another. As such, a capacity evaluation must address a specific question. In civil settings, such areas include wills, contracts, treatment, and research participation. For criminal settings, competence may be questioned in relation to trial procedures and waiving various rights, including Miranda rights (*see* **Capacity to Waive Miranda Rights**), the right to privilege, to have legal counsel, and to posing an insanity defense. Competency issues may also arise in the sentencing phase and may become particularly contentious in capital cases.

Civil Law

Testamentary Capacity

The determination of testamentary capacity requires that the testator understand the following issues: (i) that he or she is making a will and that the will specifies how his or her estate will be distributed after death, (ii) the extent of his or her bounty, or possessions to be distributed, and (iii) which individuals would be considered the natural heirs. From a legal perspective, competence is presumed until challenged, and the burden of proof rests with the person challenging the will [2, 4, 5].

Testamentary capacity may be questioned, particularly when a preexisting will is significantly altered or if natural heirs are excluded. Legal challenges typically arise after the death of the testator. This creates particular challenges in assessing testamentary capacity, and assessments become retrospective and limited to witness statements, medical records, and other documentation. In some instances, attorneys anticipating potential challenges to a will may have arranged for a contemporaneous evaluation of the testator at the time the will was written. Additionally, some testators may leave a durable record by having the evaluation videotaped. An example of illness contributing to a lack of testamentary capacity is dementia resulting in increased confusion, reduced orientation, or in delusional beliefs that may impact a testator's ability to understand the basic elements of making a will.

The question of undue influence may arise if there are suspicions that the testator was coerced or manipulated into altering a will. The presence of undue influence may void a will even if the testator otherwise has capacity. The presence of the following may suggest undue influence: (i) the relationship between the testator and the beneficiary allowed for the beneficiary to exert control over the will, (ii) "unnatural provisions" in the will, and that (iii) the will did not accurately represent the testator's wishes [5]. A testator may be more susceptible to undue influence as a result of medical o-psychiatric illness such as those described earlier. Should a testator be available for examination, the involvement of another individual besides the testator or his or her attorney may indicate undue influence, particularly if that individual makes the appointment, brings the testator to the appointment, or answers questions for the testator. Additionally, uncertainty on the part of

the testator regarding details of the will may indicate undue influence [6].

In assessing testamentary capacity, an evaluator should also consider the ethical implications. A competent will ensures the appropriate distribution of property and may be of great importance to potential beneficiaries. However, finding a testator incompetent after death negates the last wishes of the deceased with regard to the disposition of their estate [2].

Contractual Capacity

A contract is, by definition, "an agreement between two or more parties creating obligations that are enforceable or otherwise recognizable at law" [1]. Contracts, both implied and written, are essential to society. Competence to contract, as in testamentary competence, is presumed, but unlike writing a will, entering into a contract is a potentially adversarial process. Contractual competence involves three essential elements: (i) the individual understands the various aspects of the transaction, (ii) the relationship of those aspects is appreciated, and (iii) the individual is able to make a rational judgment based on this understanding. If an individual lacks the requisite understanding due to mental illness or defect, a contract may be nullified [7]. In some jurisdictions, if an individual would not have entered a contract "but for" mental illness, the contract is invalid [2].

In determining whether to void a contract, courts consider both the issues of whether incompetence is proven and whether the status quo can be restored. In instances where the status quo cannot be restored, consideration is given to the fairness of the contract, including the possibilities of undue influence or fraud [2].

Capacity to Consent to or Refuse Treatment

In clinical settings, capacity concerns may arise in relation to consent for treatment as well as the converse, to refuse treatment, be that treatment psychiatric or medical/surgical in nature. Justice Benjamin Cardozo described the concept of consent in 1914 when he wrote, "Every human being of adult years and sound mind has a right to determine what shall be done with his own body" [8]. In the present day, patient autonomy remains an important concern [9]. Consent must be informed, voluntary, and competent. (*see* **Treatment, Right to Refuse: Mental Health**; **Treatment, Mandated: Mental Health**).

With informed consent, a competent individual must understand: (i) the nature of the medical condition, (ii) the nature of the proposed treatment, (iii) the risk and benefits of the proposed treatment as well as no treatment, and (iv) possible alternatives to the proposed treatment [2, 10]. However, as in the case of many capacity evaluations, there is no one clinical assessment tool to evaluate the capacity to consent to treatment. As a result, the assessment entails obtaining clinical history in addition to considering cognitive functioning, overall day-to-day functioning, and mental state [11, 12]. A patient's understanding of these basic topics requires a fundamental level of communication from the treatment provider [12]. Prior medical knowledge is not necessary as long as there is an ability to learn, retain, and process information in a rational manner. A key point underlying consent issues is that an individual need not make the "right" or expected decision but a reasoned choice. Even with life-saving treatment, a competent individual must be allowed to refuse treatment if he or she so chooses.

Competent individuals may establish advance directives or a living will outlining their treatment preferences in the event they become incompetent at a later time. Additionally, a proxy may be designated to provide informed consent should the individual become incompetent [13]. In the absence of previously designated decision makers, families may be utilized as substitute decision makes, with preference given to spouses and close relations. Otherwise, the matter becomes a judicial issue, and a court hearing may be requested. In many jurisdictions, a specific "mental health court" addresses treatment issues related to psychiatric illnesses. In this venue, both the patient and the treatment provider have opportunity to present their arguments before a judge.

Medical emergencies, when treatment decisions regarding life-threatening conditions must be made in the moment, constitute an exception to the requirement for consent [10]. For instance, informed consent is not required prior to treating an unconscious patient who requires surgery to stop severe internal bleeding. Similarly, in psychiatric settings, emergency treatment to prevent injury to oneself or to others may be given without patient consent.

Another exception to informed consent is patient waiver. A patient may choose not to be informed; in

this situation, the patient must have the capacity to understand the consequences of not being informed. More rarely used is therapeutic privilege – when a clinician determines that a discussion of risks and benefits of proposed treatment would harm the patient or cause distress to the extent that an informed decision could not be made. A substitute decision-maker would instead be informed and provide consent [10].

An area related to capacity to accept or refuse a specific treatment is that of civil commitment. Inpatient psychiatric treatment often occurs in locked settings where patients cannot simply come and go without agreement from the treatment provider. Civil commitment, therefore, entails a certain curtailment of personal liberty. Further, besides the loss of liberty, courts have noted civil commitment may be associated with social stigma. Patients may agree to inpatient treatment, in which case they are considered voluntary patients. In order to have to capacity to consent to voluntary inpatient psychiatric treatment, an individual must have a mental illness that may benefit from treatment, must understand that treatment occurs in a mental health setting, and must consent free of coercion [2, 10]. In instances where an individual does not agree with inpatient treatment, he or she may be admitted involuntarily but may also challenge the admission in a court hearing. Often, evidence that the individual is a danger to him or herself or to others as a result of their mental illness is required.

Capacity to Consent to Research

Clinical research is essential in increasing our understanding of medical illnesses and in furthering treatment advances. Given the experimental nature of research, informed consent includes understanding of (i) the nature and purpose of research, (ii) the risks and benefits, (iii) alternative treatments to the research protocol, (iv) limits of confidentiality, and (v) compensation [14]. In the area of mental health, the issue of competence to consent to research becomes more complicated, as the very cause of the symptoms targeted in research may also render a participant incompetent [15]. The standards for competency are (i) a factual understanding of relevant issues, (ii) an ability to manipulate that information in a meaningful manner, (iii) an ability to appreciate the nature of the situation, and (iv) the ability to make and articulate a choice regarding participation in research.

Capacity to Waive Privilege

Privilege is an individual's right to protect confidential communications occurring in the context of relationships seen to have societal value, such as attorney–client, doctor–patient, husband–wife, and priest–penitent relationships [16]. However, various exceptions exist, including patient-initiated litigation involving issues of mental health or mental status, court-ordered evaluations, civil commitment, and treatment refusal proceedings, instances in which a patient poses an emergent danger, and situations of child protection or child custody [2]. As privileged information may be damaging, when an individual waives privilege outside these exceptions, capacity to do so becomes important. The individual should be aware of what information may be revealed and what potential impact that information may have on the legal question (*see* **Capacity to Waive Miranda Rights**).

Criminal Law

Capacity to Proceed with Trial

The intricacies of courtroom trial procedures require an ability to understand rules and roles beyond average day-to-day functioning (*see* **Capacity to Stand Trial**). In this adversarial setting, the defendant's ability to interact with their attorney and aid in their own defense is crucial to the fairness of a trial. Just as cognitive impairment or symptoms of mental illness may interfere with competence to make informed treatment decisions, they may also interfere with competence to proceed with trial. For example, mental retardation may prevent a clear, factual understanding of the circumstances of the instant offense or of court procedure. A depressed defendant may be unmotivated to assist in their defense. Schizophrenic defendants with conceptual disorganization may have an impaired ability to understand, reason, and appreciate legal procedures [17].

Historically, competence to stand trial was ensured through duress. In 17th century England, trial could not proceed until a defendant entered a plea. To encourage the defendant to plea, heavy rocks were

placed on the defendant's chest until a plea was given or the defendant was suffocated [2]. After the use of this method was abolished, defendants found incompetent to plead by a jury were merely imprisoned until they could voice a plea. In modern times, a finding of incompetence entails a court mandated psychiatric evaluation of capacity that is used to inform the determination.

In the United States, the standard for competence was established by the 1960 Supreme Court case of *Dusky v. United States* [18]. The defendant, along with two codefendants, was accused of abducting a teenaged girl and transporting her across state lines. The codefendants were accused of rape, and Dusky was accused of attempted rape. Prior to trial, Dusky was detained at a federal medical center for evaluation and found to have a psychotic illness complicated by alcoholism. The evaluator noted that although Dusky understood his charges and basic criminal procedure, he was "unable properly to assist" in his defense due to confusion, suspiciousness, and "an inability to interpret reality from unreality." The trial court, however, maintained that Dusky was oriented and able to assist counsel. After Dusky's conviction, the case was appealed and eventually reversed by the Supreme Court. As articulated by the Court's holding, the proper test for competence is "whether the accused has sufficient present ability to consult with his lawyer with a reasonable degree of rational understanding and whether he has a rational as well as a factual understanding of the proceedings against him."

In the Insanity Defense Reform Act of 1984, the United States federal standard stipulated that incompetence requires that "present mental disease or defect renders the defendant unable to understand the nature and consequences of the proceedings against him or to assist in his defense" [16].

Correct assessment of capacity is essential, as failure to recognize impaired ability may render a court proceeding unfair. Inaccurately finding a defendant incompetent, on the other hand, may unnecessarily delay court proceedings, possibly lengthening the duration of confinement or causing involuntary commitment and treatment [17].

Essentially, a competent defendant understands the nature of the charges as well as court proceedings and is able to assist his or her attorney in his or her own defense. Various assessment tools have been assembled in an effort to delineate the specific skills necessary to fulfill these general requirements [19]. The McGarry Scale articulates 13 different functional abilities: (i) ability to appraise available legal defenses, (ii) level of unmanageable behavior, (iii) quality of relating to attorney, (iv) ability to plan legal strategy, (v) ability to appraise the roles of various participants in the courtroom proceedings, (vi) understanding of court procedure, (vii) appreciation of the charges, (viii) appreciation of the range and nature of possible penalties, (ix) ability to appraise the likely outcomes, (x) capacity to disclose to the attorney available pertinent facts surrounding the defense, (xi) capacity to challenge prosecution witnesses realistically, (xii) capacity to testify relevantly, and (xiii) manifestation of self-serving versus self-defeating motivation [2]. The MacArthur Studies also addressed adjudicative competence, with development of the MacArthur structured assessment of the competencies of criminal defendants (MacSAC-CD). Research utilizing the MacSAC-CD indicated that the presence of psychotic symptoms regardless of diagnosis was associated with a determination of incompetence; a diagnosis of schizophrenia versus other diagnoses was similarly more strongly associated with incompetence [20]. Despite this association, no one diagnosis or symptom necessarily equates the lack of competence to proceed with trial, and just as with other competencies, the lack of competence to proceed with trial does not necessarily indicate a lack of competence in other areas.

Should a defendant be incompetent to proceed with trial, the trial process must be halted, at least temporarily. Incompetent defendants may be committed to long-term psychiatric facilities to restore capacity. However, restoration may not always be possible, particularly if the primary barrier may not be lifted with treatment. Examples may include stable conditions such as mental retardation, progressive illnesses such as dementia, or illnesses with severe, treatment-resistant symptoms. In these situations, a defendant could face commitment for a duration exceeding the possible sentence for a guilty plea. The case of *Jackson v. Indiana* in 1972 involved a mentally retarded and deaf-mute man arrested for two robberies, the value of which totaled nine dollars. He was found incompetent to stand trial and committed for restoration of competency. His attorney appealed on the basis that Jackson was unlikely to become competent given his deficiencies; commitment was tantamount

to a life sentence despite lack of a guilty verdict. The Supreme Court agreed, stating, "due process requires that the nature and duration of commitment bear some reasonable relation to the purpose for which the individual is committed" [21].

Capacity to Waive Legal Counsel

Besides the broader topic of capacity to proceed with trial, more specific capacity issues focus on a defendant's capacity to waive certain rights, such as the right to have legal representation. As discussed earlier, courtroom procedure involves various intricacies with rules and roles not commonly associated with average daily tasks, and many defendants rely on an attorney trained and experienced in legal problems to guide and advise them. Consequently, the decision to waive the right to counsel potentially carries significant consequences, and the ability to make such a decision may become called into question. There are no formal standards in specifically assessing capacity to waive counsel, but this may be assessed as part of an overall capacity to proceed with trial evaluation. Basic considerations are that the defendant understands the role of an attorney and has a rational understanding of the benefits of having an attorney as well as the risks of representing oneself *pro se*.

The US Supreme Court, in the 1993 ruling on *Godinez v. Moran*, held that a defendant's choice to represent himself or herself is contingent on the competence to choose self-representation, not on his or her actual qualifications for self-representation [22]. This position is not undisputed, and an opposing view is that the defendant's functional ability to self-represent is an essential consideration in establishing competence to waive counsel [19.]

Capacity to Waive the Insanity Defense

Despite the perception that the insanity defense is overused and a way to "get off easy," the insanity defense is successful in less than one in two thousand felony cases [2]. In addition, cases arise in which the insanity defense is recommended by defense counsel, but the defendant does not agree. Whether a criminal defendant with a plausible insanity defense has the right to waive it has been a point of contention. Defendants may decline an insanity defense for an assortment of reasons – they may not believe they have a mental illness, may wish to avoid the stigma of being an insanity acquittee, or may be concerned that they may be committed to a psychiatric institution for a longer period than the sentence for being found guilty.

In some jurisdictions, the insanity defense can be imposed against a defendant's wishes, even if the defendant is considered otherwise competent. The rationale is that a defendant's choice, even a competent one, is outweighed by a greater societal interest in the "just determination of the charge against the defendant." An alternative view is that the insanity defense, as a specific legal defense, is encompassed within general evaluations of competency to proceed with trial. According to this interpretation, a competent defendant ought not to have the insanity defense imposed upon them against their will [23].

Capacity for Sentencing

The purpose of sentencing guilty defendants is threefold: (i) to punish the perpetrator, (ii) to act as a deterrent for future offenses, and (iii) to convey a sense of justice. During the sentencing phase, a defendant may introduce evidence that may potentially mitigate the sentence or refute aggravating circumstances that may result in a more severe penalty. For these reasons, capacity remains an important issue. A defendant lacking capacity for sentencing may be unable to make the court aware of important mitigating factors or may even be unable to appreciate the meaning of the sentence itself [24]. In most jurisdictions, competency for sentencing is determined by the same process as competency to stand trial.

Capacity for Execution

Capital punishment is a contentious ethical issue in itself; adding to the conflict are those cases in which the capacity of an inmate to be executed in uncertain. The traditional arguments favoring the death penalty – punishment, justice, and deterrence – come into question when the inmate is incompetent. Historically, in English common law, the execution of an insane person was thought to be "savage and inhuman." Reasons provided spanned the unfairness of trying a defendant unable to make his defense to the lack of example to others [16].

The case of *Ford v. Wainwright* [25] involved the murder conviction of Alvin Bernard Ford in 1974. During trial, there was no question of incompetence,

and he was sentenced to death. Beginning in 1982, he began to demonstrate gradual behavioral changes. Over time, he became increasingly delusional. Two psychiatrists for the defense evaluated Ford, who concluded that he was genuinely psychotic. His attorneys then requested a determination of competency; three state psychiatrists concluded that Ford was able to understand his situation at the time, the nature of the death sentence, and why he had been so sentenced. On appeal to the Supreme Court, the Court ruled that under the Eighth Amendment prohibition of cruel and unusual punishment, execution of an insane prisoner was also prohibited, and therefore Ford had the right to a judicial hearing to determine competency. The Court provided six reasons for ruling that an inmate must be competent prior to execution: (i) an incompetent person might be unable to provide last minute information useful for vindication, (ii) insanity is already a punishment, (iii) an incompetent person cannot make peace with God, (iv) execution of an incompetent person does not deter others, (v) execution of an incompetent person is extreme inhumanity and cruelty, and (vi) retribution cannot be exacted from an incompetent person [25].

The specific criteria for determining capacity to be executed vary by jurisdiction. For *Ford*, the Florida standard stipulated that those to be executed have the capacity to understand the nature of the death penalty and the rationale for its imposition. The Court deemed this standard sufficient and is followed by most states. The alternative standard for competency to be executed is whether the inmate, due to mental disease or defect, is unable to understand the nature of the proceedings, the accusation, the purpose of punishment, and the punishment itself. This standard made additional note that the inmate should be able to convey factual information that may change the verdict or sentence to defense counsel [16].

The Supreme Court, regarding capital punishment and the mentally retarded, has reached separate decisions. In the 1989 case of *Penry v. Lynaugh*, the Court ruled that mental retardation does not equate incompetence to be executed, but may be used as a mitigating factor during sentencing [26]. However, in 2000, the Court in *Atkins v. Virginia* that execution of the mentally retarded constituted cruel and unusual punishment and therefore violated the Eighth Amendment [27] (*see* **Mental Retardation: Death Penalty**; **Death Penalty and Age**).

Significant clinical-ethical concerns arise with relation to determinations by mental health professionals of capacity to be executed, particularly if the evaluator supports a finding of competency, thereby furthering execution. Although the capacity evaluation in itself does not constitute active participation in an execution, some psychiatrists view any involvement in the death penalty to be unethical. Alternatively, such evaluations may spare some inmates from execution. If a prisoner is found incompetent, however, the death penalty is typically not vacated. In such instances, another ethical dilemma arises regarding the question of treating an individual to restore competency for execution. The opinion of the American Medical Association is that in this situation, unless the death sentence is commuted, treatment should only be given for the purposes of relieving extreme suffering [28].

Capacity Consent to Treatment

see Capacity Assessment

Capacity for Guardianship ***see*** Guardianships of Adults

Capacity for Independent Living

Questions about independent living capacity are typically raised by family members, healthcare providers, lawyers, and/or concerned others when an individual is exhibiting or is perceived to exhibit deficits in independent functioning. The issue may become especially urgent when behavior is unsafe, such as when one lacks the cognitive capacity to understand that refusing to eat, bathe, or use a mobility support (e.g., cane) may pose a serious medical risk. It is vital to note that concerns about decisional capacity should not be based on judgments about whether an individual has made "acceptable" choices, but rather on whether one has the cognitive capacity to adequately reason through such choices. Although questions about independent living capacity may be relevant for any adult exhibiting deficits in independent functioning, concerns are more frequent in specific populations, such as individuals with neurological problems, developmental disabilities, psychiatric issues, and substance abuse, and are frequently encountered in adults aged 60 and older with these diagnoses. Since concerns about independent living capacity in older adults will likely increase as this population doubles in the next 25 years [1], this article includes a focus on capacity in older adults, although discussion points are generally broad enough to be tailored to other cases. An invaluable supplement to this information is found in the publication, *Assessment of older adults with diminished capacity: A handbook for lawyers* [2], which provides an excellent overview of practical, ethical, and theoretical considerations regarding decisional capacity, as well as worksheets that can be used when meeting with clients.

Myths about Decisional Capacity

Before defining the concepts of independent living and its assessment, a discussion of some global myths

regarding decisional capacity assessment is helpful [3]. First, decisions about capacity are not "all or nothing" phenomena, and clinical judgments may reflect this by including recommendations for assistance in one area of functioning but not another (e.g., assistance in medication management but not financial management). Such specification of the need for assistance in specific domains, but not in others, is reflected by some states through limited guardianship. Second, a diagnosis in and of itself does not infer decisional capacity. For example, an individual with Alzheimer's disease or schizophrenia may have compromised memory or reality testing, but intact daily functioning and decisional abilities. Conversely, an individual with no cognitive or psychiatric impairment may exhibit impaired decision making. Thus, "it is important that functional performance be defined, measured, and interpreted separately from cognitive performance" [4].

Preserving Autonomy

Several research studies suggest that if older adults lose control of their daily decisions or environment, quality of life can become significantly compromised and mortality rates may increase (see [5] for a review). Clinical observations support these findings, and suggest that some individuals exhibit significant psychological reactions if decisional rights are constrained or revoked. Thus, most clinicians are extremely mindful about the potential impact of decisional capacity evaluations. Most often, there is an attempt to strike a balance between safety and autonomy when making recommendations, with a focus on improving quality of life regardless of decisional ability.

Requirements for Independent Living

Defining Incapacity

The Uniform Guardianship and Protective Proceedings Act (UGPPA) defines an incapacitated individual as one who is unable to receive and evaluate information or make or communicate decisions to such an extent that the individual lacks the ability to meet essential requirements for physical health, safety, or self-care, even with appropriate technological assistance [6]. While incapacity statutes in three states have incorporated the 1997 Act (Colorado, Minnesota, Hawaii), other states have utilized information from the 1982 version of the Act, or from other state-specific sources [7].

What Skills Are Necessary for Independent Living?

Although there is absolute definition of the functional tasks that comprise independent living capacity, two key sources – clinical definitions of independent living capacity and the *Handbook for Judges* [8] – provide helpful guidance.

Clinical definitions of independent living capacity commonly include the constructs of "activities of daily living" (ADLs) and "instrumental activities of daily living" (IADLs). Although triggers for concern about independent living capacity are varied, common scenarios include compromised performance of ADLs or IADLs. While there is no authoritative or complete list of ADLs or IADLs, ADLs often refer to basic self-care skills such as dressing, eating, toileting, transferring, or moving from one sitting position to another, walking and mobility, or bathing [7]. IADLs are more cognitively complex than ADLs and typically include management of finances and medications, medical decision making, transportation use, and management of household functions such as shopping for food and other necessities, preparing meals, doing housework, and doing laundry [4]. Given that IADLs are more cognitively complex than ADLs, IADLs may be compromised before ADLs in individuals with cognitive difficulties. The *Handbook for Judges* also provides a list of general tasks associated with independent living (see Table 1), and provides a supplement including a detailed checklist ([8], p. 33).

Cognitive Functioning

Questions about independent living capacity often relate to concerns about cognitive impairment. Although age-appropriate memory loss occurs throughout the lifespan, starting in the mid-20s [9], if cognitive decline becomes impaired beyond levels seen in normal aging and begins to interfere with daily functioning (e.g., medication management, financial management), a diagnosis of dementia may be considered if the condition leading to cognitive impairment is not reversible or temporary. Although

Table 1 Task associated with independent living[a]

Domain	Description
Care of self	Maintain adequate hygiene, bathing, dressing, toileting, dental Prepare meals and eat for adequate nutrition
	Identify abuse or neglect and protect self from harm
Financial	Protect and spend small amounts of cash Manage and use checks
	Give gifts and donations Make or modify will Buy or sell real property
	Deposit, withdraw, dispose, invest monetary assets
	Establish and use credit
	Pay, settle, prosecute, or contest any claim
	Enter into a contract, commitment, or lease arrangement
	Continue or participate in the operation of a business
	Employ persons to advise or assist him/her
	Resist exploitation, coercion, undue influence
Medical	Give/withhold medical consent
	Admit self to health facility
	Choose and direct caregivers
	Make or change an advance directive
	Manage medications
	Contact help if ill or in medical emergency
Home and community life	Choose/establish abode
	Maintain reasonably safe and clean shelter
	Be left alone without danger
	Drive or use public transportation
	Make and communicate choices about roommates
	Initiate and follow a schedule of daily and leisure activities
	Travel
	Establish and maintain personal relationships with friends, relatives, coworkers
	Determine degree of participation in religious activities
	Use telephone
	Use mail
	Avoid environmental dangers and obtain emergency help
Civil or legal	Retain legal counsel
	Vote
	Make decisions about legal documents

[a] Judicial Determination of Capacity of Older Adults in Guardianship Proceedings: A Handbook for Judges [8]

age is the greatest risk factor for dementia, dementia is not a natural consequence of aging. For example, in North America, only 0.8–1.6% of persons, ages 65–74, are diagnosed with dementia. Although the prevalence of dementia doubles every 5 years after age 74 (impacting 7–8% of persons 75–84 years old and 18–32% of persons over 85; [10]), most older adults are not diagnosed with dementia. Incidentally, the term *dementia* is often used interchangeably with "Alzheimer's disease", especially in the media. To clarify, Alzheimer's disease is the most common of several subtypes of dementia – describing about 50–70% of all cases – and refers to the cellular pathology that is presumably present, though confirmative diagnosis is not possible without autopsy. It is important to note that the increasing older adult population may lead to a projected 70% increase in the prevalence of Alzheimer's disease in the next 25 years [11].

Cognitive functioning may be compromised for brief periods of time because of acute stressors (e.g., delirium, seizures, medication issues, alcohol and drug use, and psychiatric issues, among others), it may be mildly impaired with the possibility of

worsening over time (mild cognitive impairment), and/or it may be permanently impaired owing to other conditions (e.g., irreversible dementia, neurodegenerative disorders, traumatic head injury). Thus, characterization of cognitive impairment as temporary, mild, or permanent and progressive plays a vital role in decisional capacity assessment.

Assessment Domains and Instruments

When decisional capacity is unclear or potentially compromised, a clinical evaluation can be a helpful tool in assessing and documenting capacity, and may assist in identifying the least restrictive alternatives to guardianship. Clinicians including psychologists and physicians often evaluate decisional capacity, and different assessment methods are often utilized. Psychologists are most likely to use psychometric tests to assess cognitive functioning and independent living, though this is not always the case. Typically, the most important criterion in selecting a clinician is his or her level of experience in evaluating decisional capacity [2].

Theoretical and Legal Components

Although there is no gold standard regarding the components of a typical capacity assessment, many clinicians find it helpful to structure the assessment by integrating theoretical principles, legal considerations, and clinical models. Theoretical information from Grisso's conceptual model [12] provides an important guide for the assessment process by integrating legal and clinical considerations into five domains – functional, causal, interactive, judgmental, and dispositional (*see also* **Capacity to Consent to Medical Treatment**).

Although legal requirements for assessment content may be state specific, suggested recommendations are included in the *Uniform Probate Code*/UPC Section 5–306 [13], and the *Handbook for Judges* [2]. Assessment outcomes from the UPC include (i) a description of the nature, type, and extent of the respondent's specific cognitive and functional limitations; (ii) an evaluation of the respondent's mental and physical condition and, if appropriate, educational potential, adaptive behavior, and social skills; (iii) a prognosis for improvement and a recommendation as to the appropriate treatment or habilitation plan; and (iv) the date of any assessment or examination upon which the report is based. The *Handbook for Judges* [8] recommends that a comprehensive evaluation cover "six pillars" of capacity, including the medical condition, cognitive functioning, everyday functioning, values and preferences, risk and level of supervision needed (including social support), and means to enhance capacity at the hearing and later.

Clinical Components

After a clinician has considered theoretical and legal issues, clinical models are often used to guide the actual practice of conducting the assessment. A publication by the Veterans Administration (VA) – *Assessment of Competency and Capacity of the Older Adult: A Practice Guideline for Psychologists* [14] – is particularly helpful in this regard. This model is discussed in the article entitled "Capacity to Consent to Medical Treatment" by Edelstein and Gould, and will be referred to here in the context of assessing independent living capacity. The VA model recommends the following five steps in conducting a capacity assessment.

Clarification of the Referral Question. The more specific the legal question, the better the clinician is able to structure a helpful assessment. For example, a common referral might include the following information: "Mrs X wants to live at home, but her family is concerned that her health has deteriorated due to poor hygiene and medication noncompliance. She refuses any assistance and wants to be left alone. Please assess her cognitive functioning and her capacity for making decisions about where she will live, her ability to manage medications, her self-care, and other common issues that might interfere with her ability to live independently." Since the construct of independent living is so multifaceted (recall the discussion of several ADLs and IADLs), referral questions need to be as specific as possible. On the other hand, referral questions do not need to include an exhaustive list of all problems. Rather, the question should serve as a starting point for a clinician who may uncover additional areas of concern during the evaluation.

Informed Consent. The nature of the evaluation as well as the purpose, risks, and benefits are explained

to the client. The client is asked to paraphrase the information provided, and is asked whether they consent to the evaluation. Consent or lack of consent is documented.

Conduct Evaluation. The typical assessment consists of four components:

Clinical Interview. An interview is conducted with the client to psychiatric history, medical history, social history, mental status, behavior, culture, religion, personality, perception of referral issues, and preferences for support (who would they like to help them, if necessary?). Given the subjectivity inherent in decision making, assessment of values and preferences is integral to this process (see *Handbook for Judges* p. 84 for a list of questions associated with independent living values [8]). The clinician will also note his or her behavioral observations of the client during the interview and testing.

Cognitive Testing. Cognitive tests are administered to assess functioning across multiple areas/"domains" of cognitive skills including executive functioning (reasoning, judgment, insight, mental flexibility), memory, attention, language, and visuospatial abilities, among others (see *Handbook for Judges* pp. 50–52 for details [8]). In essence, the process of cognitive testing is analogous to putting the brain on a "road test". Whereas neuroimaging tools (e.g., computed tomography (CT) scan or magnetic resonance imaging (MRI)) provide a picture of brain structure, cognitive testing is the only tool that can demonstrate how the brain actually *functions* in the outside world. Most cognitive tests are designed to be highly reliable and valid indicators of performance. Incidentally, when independent living capacity is compromised, the cognitive domain that is often most impacted is that of executive functioning [4].

Functional Testing. Whereas cognitive testing provides data about several different cognitive skills, functional tests allow for assessment of skills *specific* to independent living. This process may require the client to demonstrate specific behaviors associated with independent living (e.g., "show me who you would call in an emergency"), and demonstrate reasoning regarding potential situations ("if someone knocked on your door at 3 a.m., what would you do?"). Several psychological tests and interviews have been specially created as functional tests, including tests assessing ADL/IADLs, and instruments designed to assess an individual's need for guardianship (guardianship instruments). Further categorization includes tests and structured interviews designed for clients with dementia or without dementia (see [7], for a complete list of independent living functional assessment instruments).

Informant Interview. An interview with collateral sources including family members and/or healthcare providers about the client's history and behavior is often vital to assessing the validity of other assessment information and resources available to the client.

Integration of Findings. Results from the first three steps are consolidated into a comprehensive clinical report that addresses the referral question. Several sample reports are included in the *Handbook for Lawyers* (Appendix 2, [2]). A report may be entered as evidence.

Follow up. A repeat evaluation is helpful in evaluating the effectiveness of previously recommended interventions and supports and to assess whether there have been any changes in functioning since the previous evaluation. If repeat testing is judged to be helpful by the clinician, the duration of time until retesting is typically specified by the clinician conducting the initial evaluation.

Decision Making about Capacity

As described in the *Handbook for Lawyers* [2], lawyers may make efforts to "enhance capacity" for clients who appear to have minor or momentary difficulties understanding a particular transaction or issue. However, if a client has potentially significant difficulties with capacity and a capacity assessment has been requested, decision making by the clinician requires exceptionally careful integration of assessment information. As previously discussed, decision making about capacity is not an all-or-nothing phenomenon and, even in light of objective test findings, conclusions typically involve a weighing of information that cannot but involve some measure of subjective clinical judgment. Given these considerations, the following questions may be

helpful in guiding clinical decision making after the assessment has been completed:

1. Is there evidence of incapacity in independent living that cannot be explained by values, culture, historic decision making, etc.?
2. If there is evidence of incapacity, what is the presumed cause (e.g., medical, cognitive, or psychiatric condition; lack of reasoning ability in medically and cognitively intact individual)?
3. Is the problem temporary or permanent? Are there variables that impact capacity temporarily (e.g., medications, fatigue, history of substance use, bereavement, sensory problems)?
4. What are the specific functional domains in which incapacity or lack of capacity is demonstrated? What functional domains and skills appear to be intact? (see Table 1; see p. 67 in the *Handbook for Judges* [8])
5. Is there any immediate risk of harm? What level of supervision, if any, is needed?
6. What social supports can the individual be provided with that would allow maximum liberty and independence?
7. What are the least restrictive alternatives to guardianship? (see pp. 62–65 in *Handbook for Judges* for a detailed list of least restrictive alternatives in each functional area, developed by Joan O'Sullivan; [8]). Can the client be provided with "appropriate technological assistance" [6] to enhance capacity?

Conclusion

Given the rapidly growing population of older adults and the increasing awareness of the least restrictive alternatives to guardianship, issues regarding the assessment of capacity for independent living are likely to become more common for lawyers and clinicians. Most lawyers and clinicians share the common goal of maximizing an individual's independent functioning, liberty, and choice. In addition, clinicians are specially trained to make data-based judgments about decisional capacity, and to provide recommendations that balance safety and autonomy and maximize quality of life. An understanding of current theories, instruments, and decisional models, along with the use of medicolegal resources (e.g., the *Handbook for Lawyers* and *Handbook for Judges* [2, 8]), may lead to enhanced decision making.

Capacity to Consent to Medical Treatment

All adults are considered legally competent to consent to treatment unless determined otherwise by a court of law. However, it is not uncommon for the competence of older adults (over 65 years) to be questioned more often than that of younger adults. This trend is unlikely to change, as the older adult population is expected to double by 2020 and more than triple by 2050 [1]. This apparent increase in suspected incompetence is probably due to a variety of factors including aging myths and biases, an increasing prevalence of chronic diseases, and normal age-related changes in selective cognitive abilities. Among the myths about older adults are their characterization as sick and disabled, likely to live in nursing homes, no longer desirous of sexual activities, and often physically tired [2]. Age-related cognitive deficits include slowed information processing, slowed reaction time, and impaired memory [3], although interindividual differences in deficits abound. Most older adults have at least one chronic disease and many have multiple conditions [4]. This latter fact undoubtedly contributes to an increased likelihood of facing medical decisions, as does the increasing prevalence of degenerative diseases (e.g., Alzheimer's disease [5]).

The focus of this article is the assessment of capacity to consent to treatment, with particular attention to the assessment of medical decisional capacity in older adults. Consent is a communication process between a patient and his or her health-care provider, which ultimately leads to the patient's agreement to health services [6]. We use the term *capacity* rather than competency, as many states have moved away from the use of the terms *competence* and *incompetence*. The shift to capacity tends to avoid the categorical conceptualization of competence or incompetence [7], and permits a focus on specific decisional and behavioral strengths and weaknesses. Thus, the scope of decision making of individuals or their surrogates may be limited, as determined by the nature of the medical condition, and the potential consequences of decisions, that is, the risk to benefit ratio.

We begin with a brief history of the doctrine of consent to treatment, followed by discussions of the current state of consent capacity and assessment to determine capacity to make medical decisions.

History of Doctrine of Consent to Treatment

The doctrine of consent to treatment, or informed consent, dates back at least to the writings of early Greek and Byzantine authors [8]. It has its roots in several disciplines, including health, law, social sciences, and philosophy [9]. In his *Laws*, Plato notes that doctors who treated primarily free men, as opposed to slaves, requested information from patients and the patients' friends, and informed patients about their illnesses before seeking consent for treatment. Patients were differentiated on the basis of their autonomy, that is, slaves versus free men. Consent was obtained only from free men, as slaves were not afforded the right to self determination.

The history of consent to treatment in the United States dates back to *Slater v. Baker and Stapleton* [10] in 1767 [11]. In *Slater*, the court stated that "It is reasonable that a patient should be told what is about to be done to him, that he may take courage and put himself in such a situation as to enable him to undergo the operation" [12]. However, informed consent was not extensively discussed in the American medical literature until the late 1950s and early 1960s [9]. The expression "informed consent" was coined in 1957 case law [13]. Martin Salgo, who became paralyzed following treatment, sued his physicians for failing to disclose risks and alternate treatments. Until the late 1950s, "the justification of practices of disclosure and consent seeking were strictly governed by what we shall call a beneficence model rather than an autonomy model of the physician's responsibility for the patient" [9]. The beneficence model emphasizes that behavior of the physician should be in the best interest of the patient, whereas the autonomy model emphasizes the physician's responsibility to respect the autonomy of the patient through information disclosure and the seeking of consent. The Salgo case involved the clashing of these two models.

The doctrine of informed consent "originally developed and flourished under the battery theory of liability" [9]. Battery is intentional touching that is unwanted or legally unpermitted, and which is actionable even if no physical injury results. Individuals have the right to choose whether they are to be touched or treated. The 1914 case of *Schloendorff v. Society of New York Hospitals* [14] nicely illustrates this position. Justice Cardozo argued that "Every human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without his patient's consent commits an assault" [9].

Consent Capacity Today

The prefatory note of the Uniform Health-Care Decisions Act of 1993 [15] states that "... the Act acknowledges the right of a competent individual to decide all aspects of his or her own health care in all circumstances, including the right to decline health care or to direct that health care be discontinued, even if death ensues. An individual's instructions may extend to any and all health-care decisions that might arise and, unless limited by the principal, an agent has authority to make all health-care decisions which the individual could have made. The Act recognizes and validates an individual's authority to define the scope of an instruction or agency as broadly or as narrowly as the individual chooses".

Consent capacity, or health-care decision-making capacity, is defined by state statute. In most states the definition can be found within the advance directives laws [16]. The definitions tend to be similar to that of the Uniform Health-Care Decisions Act of 1993 [16], which defines capacity as "an individual's ability to understand the significant benefits, risks, and alternatives to proposed health care and to make and communicate a health-care decision".

In the 1970s, Meisel, Roth, and Lidz [12] examined relevant scholarly and judicial works on consent to treatment and identified three elements of a valid health-care decision: provision of information (knowledge), competency, and understanding. One precondition (voluntariness) and one consequence (consent or refusal) were also specified. Voluntariness requires that the treatment decision "be free from coercion and from unfair persuasions and inducements" [12]. The authors also argued that there must be social support (e.g., from caregivers) for the individual's right to self determination. The provision of information, the knowledge component, has evolved in recent years. The initial standard came out of the reasonable practitioner clause in *Natanson v. Kline* [17]. Prior to this case, there was no formal requirement of informed consent. Following *Canterbury v. Spence* in 1972 [18], this standard has been replaced in many states by the materiality of information standard, whereby informed consent requires information that an ordinary person would want to know,

thereby shifting the focus from the practitioner to the patient. This information required includes risks, discomforts, side effects of the proposed treatment, alternative treatments (including risks, discomforts, and side effects), and the consequences of not receiving the treatment.

There are four conditions under which nondisclosure or an abbreviated disclosure is permitted. First, if there is an emergency and time does not permit an adequate disclosure, or consent cannot be obtained without jeopardizing the health of the patient. Second, nondisclosure is acceptable if the disclosure of information would disturb the patient to the point the patient is unable to make a rational decision, or if such disclosure poses a serious physical or psychological threat. In this case, the practitioner can withhold the information and invoke "therapeutic privilege". Therapeutic privilege permits the practitioner to be exempt from informed-consent requirements. Third, consent is not required if the patient is incompetent. In this case, a surrogate decision maker would be incorporated into the decision-making process. Fourth, there can be a waiver of medical privilege by the patient. The patient can, for example, say to a physician that he or she trusts the physician to do the right thing and requests that the physician proceed.

Assessment of Medical Decision-Making Capacity

At the present time, there is no gold standard for the assessment of the capacity to consent to or refuse treatment, that is, to make a medical decision. Assessment should address the behavioral, cognitive, and functional abilities of the individual [11, 16]. Assessment has typically involved clinical interviews, reviews of medical records, and often the administration of a mental status examination [19], which can fall short of contemporary recommendations [11, 16, 20]. A recent study of guardianship case files across three states revealed frequent poor documentation of functional abilities when capacity was assessed, and evidence that some older adults are having guardians appointed on the basis of assessment documentation of only a few sentences [21]. The approach to assessment is gradually changing, as functional assessment instruments and interview guides have been developed for the assessment of capacity over the past decade. The instruments constructed for the assessment of functional abilities are intended to be used in conjunction with information obtained through other procedures (e.g., diagnostic interviews, tests of cognitive abilities) [20]. The functional assessment instruments and the associated research were recently reviewed by Moye and colleagues [20] with an eye to clinical implications and research needs. It is important to understand that these are all first-generation instruments, which can undoubtedly be improved through further development of their reliability and validity as well as through the incorporation of additional important features (e.g., values assessment).

Although guidelines and recommendations have occasionally been published to guide the assessment of medical decision-making capacity (e.g., [11, 22]), there remain differences of opinion and confusion regarding how decisional capacity should be operationalized and assessed by clinicians [20, 23]. On a more positive note, recommendations for the interpretation of the documentation of such evaluations have recently been published to guide lawyers [16] and judges [24]. Nevertheless, approaches to assessment remain varied.

Conceptual Model

Grisso [25, 26] has offered an excellent and widely cited conceptual model to guide the assessment process. It enables one to integrate clinical practice standards, law, and clinical research [16]. The most recent version of the model [26] comprises five components that define legal competencies: functional, causal, interactive, judgmental, and dispositional components.

Functional Component. The functional (cognitive and behavioral) component consists of functional abilities that enable one to accomplish specific decisional tasks. These abilities also encompass the knowledge, understanding, and beliefs that are needed in order to complete a task or an action. Grisso [25] argues that functional abilities are central to the determination of a patient's competence. Roth, Meisel, and Lisz [27] identified several tests or elements of competency that comprise the functional abilities. These were later refined by Grisso and Appelbaum [28]. They include the expression of a choice, understanding, appreciation, and reasoning. Demonstration of the ability to express or communicate a choice and maintain it with reasonable stability

over time is the simplest test [28]. The demonstration of the remaining three abilities would be moot if the choice cannot be expressed by the patient.

The demonstration of the ability to understand information relevant to treatment decision making, the second test of functional abilities, requires comprehension of the important information about one's medical condition, treatment options, and potential outcomes.

Demonstration of one's ability to appreciate the relevance of information to one's own situation is the third test of functional abilities. This includes the appreciation of the probable consequences of each treatment option for oneself. This complicated ability is difficult to assess, and oftentimes courts have found patients to be incompetent if they appear to understand information about their condition, but have not appreciated the relevance of the information to their own situation [28] For example, a patient may understand that his doctors believe that he is ill, but the patient may deny being ill despite objective evidence suggesting otherwise. This would suggest a lack of appreciation for the information.

Demonstration of the ability to reason with relevant information is the fourth test of functional abilities. This is typically conceptualized as the ability to rationally manipulate information [28], which would include treatment related information regarding risks and benefits, and one's values and preferences.

As one might expect, each of the abilities discussed above can be influenced or compromised by deficits in cognitive abilities. This fact is particularly important for consideration when one is assessing these functional abilities with older adults. Several cognitive abilities undergo age-related changes, including, for example, memory and attention [3]. In addition, information tends to be processed more slowly as we age [3]. Such deficits can impair demonstrations of capacity, particularly with regard to understanding, reasoning, and appreciation. Not only should one take these factors into consideration, but one should also be prepared to augment the performance of older adults by reducing the cognitive demands of the assessment process. For example, information can be presented in written, in addition to oral, form to reduce the demand on attention and auditory memory. Information can be presented at a somewhat slower speed to accommodate the slower information processing of older adults. Information can be broken into small units to reduce the memory load. Other accommodations can be made to address age-related visual and auditory sensory deficits. For example, information can be printed in a large font on nonglare paper. Extraneous background noise can be minimized. Lighting can be bright without glaring.

Causal Component. The causal component is the clinical or disabling condition that is likely the cause of incapacity. The effects can be transient (e.g., delirium) or long term (e.g., Alzheimer's disease). An important question is whether the problem will persist, worsen, or improve.

Interactive Component. The interactive component takes into account the specific demands of the treatment situation and how it is relevant to or interacts with the individual's functional deficits, that is, person–context interactions. In different contexts or environments, certain functional abilities may be needed for an individual to be competent to make a medical decision. It is possible that any incongruence between a patient's abilities and the demands of the situation could be addressed by either teaching the patient new decisional skills if possible or reducing the demands in the patient's life situation.

Judgmental and Dispositional Components. A judgment must be made regarding the congruency between the patient's abilities and the situation demands and supports. The judgment could be conceptualized as a matter of template matching, where the template comprises the cognitive and behavioral demands of a medical decision-making task and the decision-making context, and a match is sought between the template and the cognitive and behavioral abilities of the individual, plus any environmental supports (i.e., physical, social). To the extent that there is a mismatch, there may be diminished decision-making capacity. Lastly, it is possible that any incongruence between a patient's abilities and the demands of the situation could be addressed by either teaching the patient new decisional skills if possible or reducing the demands in a person's life situation [26]. The dispositional component constitutes the consequences of the judgment as prescribed by law [26].

This model takes into account many different aspects of a competency decision and highlights the important aspects to assess. The model helps to give shape to the construct of legal competency by structuring the important components.

Assessment Guidelines and Instruments

Two good guides for assessing medical decision-making capacity are Grisso and Appelbaum's [28] guide for physicians and other health professionals, and *Assessment of Competency and Capacity of the Older Adult: A Practice Guideline for Psychologists* published by the Veterans Administration [22]. The Grisso and Appelbaum book includes a very thorough and thoughtful discussion of relevant concepts and issues, and also contains an array of questions that can be used to ascertain medical decision-making capacity, and a copy of the MacArthur Competence and Assessment Tool-Treatment (MacCAT-T) manual. The Veterans Administration guide focuses on older adults, whereas the Grisso and Appelbaum book and the MacArthur assessment instrument are relevant for adults of all ages.

The Veterans Administration Guideline also remains a very reasonable guide for mental health practitioners who are preparing for the assessment of an individual's medical decision-making capacity. The Guidelines describe five key steps in the assessment of competency (capacity): The first step includes review of the consultation request and clarification regarding the decisional capacity in question. The second step involves consideration of informed consent and an ethical, appropriate, and valid assessment. Step three is the assessment process, which may include interviews with the patient, family, and health-care informants to gain an appreciation of the patient's values. This is followed by performance-based assessment of cognitive functioning, assessment of mental health factors, and performance-based assessment of specific decisional capacities. The fourth step includes a synthesis of data from the interviews and assessment, and a report of the findings. The results are discussed with the patient and relevant family members. Finally, the reader is encouraged to perform a follow-up evaluation that considers the impact of recommended interventions and assessment of changes in functioning. These guidelines include a very helpful algorithm for assessing decisional capacity. The questions of voluntariness and knowledge, though not formally addressed, also must be determined.

A variety of performance-based assessment instruments have been developed to aid in the assessment of medical decision-making capacity. These are not designed as stand-alone "capacimeters", but rather as one source of information that is to be used in a comprehensive assessment of capacity, which would also include cognitive and diagnostic assessment. A review of those instruments is beyond the scope of this article. The interested reader is referred to Grisso [28] and Moye *et al.* [20] for reviews of relevant forensic instruments. A listing of these and other related instruments also can be found in a handbook created for lawyers by the American Bar Association Commission on Law and Aging and the American Psychological Association [16]. Following their review of capacity assessment instruments, Moye *et al.* recommended the MacCAT-T [28] and other Grisso and Appelbaum instruments for psychiatrically disturbed populations. The Capacity to Consent to Treatment Instrument [19] is recommended for demented populations. Finally, the Hopemont Capacity Assessment Instrument [29, 30] is recommended for impaired adults in long-term-care settings.

The practice of assessment of capacity to consent to treatment has become more sophisticated and arguably more valid in recent years with the introduction of assessment instruments created explicitly to aid in the assessment of capacity. Nevertheless, judgment of practitioners remains the gold standard for capacity determination, and that judgment is moderately reliable at best. Available guides and guidelines can facilitate more thorough, and hopefully more reliable, assessments. The further development and refinement of existing assessment instruments will undoubtedly improve the psychometric properties of this first generation of instruments and enable us to assess capacity to consent with greater reliability, validity, and confidence.

Capacity Assessment

Capacity to Stand Trial

For a person living with a mental illness who has been charged with a criminal offense, the road ahead can be quite lengthy and complicated. Courts refer only a fraction of cases for an evaluation to assess a person's ability to proceed to trial, which is not surprising, given the presumption that criminal defendants are competent to stand trial [1]. If unable to participate meaningfully in the proceedings, a person is deprived of due process [2]. While approximately 95% of felony cases in the United States are resolved by a plea bargain agreement, there is currently no data that would tell us how many potentially incompetent people negotiate their way through a plea bargain agreement. As between 15 and 20% of prison and jail populations consist of individuals living with a serious mental illness, depending upon how mental illness is defined, one wonders how many are being processed or evaluated properly.

What is Competency to Stand Trial?

In the United States, the legal standard for competency to stand trial varies by state but cannot fall below federal standards as articulated in *Dusky v. United States* [3]. Dusky incorporates a two-prong test of whether a defendant has "sufficient present ability to consult with his lawyer with a reasonable degree of rational understanding and whether he has a rational as well as factual understanding of the proceeding against him" (p. 781). Ultimately, the trier of fact (usually a judge) is relied upon to interpret what capacities are sufficient to meet the legal threshold of trial competency. Competency is specific to a defendant's capacities at the time of trial, which is different from a defendant's mental condition at the time of an offense (e.g., insanity).

It is important to note that Dusky does not demand or specify any particular type of disorder, only that the person lacks the capacity to proceed with his case. The reasons a defendant is typically found to be legally incompetent to stand trial are because of a mental disorder, mental retardation, or significant medical conditions (such as brain injuries resulting in cognitive damage, delirium caused by intoxication, or an acute medical condition) that would directly impact his ability to understand the proceedings or assist in his defense. In some cases, the condition is permanent and untreatable, such as in cases of moderate or severe mental retardation or irreversible cognitive damage caused by a traumatic brain injury. In other cases, treatment of psychiatric or medical illnesses and/or education may be utilized to successfully restore a defendant's competency to proceed.

There is no gold standard that defines what makes a defendant competent. Ultimately, the trier of fact will determine which factors are relevant to trial competency, given the requirements referenced by Dusky [3] are ill-defined. For example, expectations of having the capacity to testify relevantly when a defendant intends to enter a guilty plea or accept a plea bargain offer may not be as significant in some courtrooms, while in other jurisdictions, the standard is held regardless of a defendant's legal strategy. In *Godinez v. Moran*, the US Supreme Court held that the competency standard for pleading guilty or waiving the right to counsel was the same as for standing trial [4]. Importantly, the court found that actual decisions must also be made "knowingly" and "voluntarily" [4]. The distinction between capacity and actuality is important to bear in mind. While the focus of our inquiry into a defendant's competency to stand trial will assesses his mental "capacity" or ability to make decisions about his case, it is the court's role to determine that the defendant's actual decision is made knowingly and voluntarily. The mental health consultant may ask how a defendant has made general decisions in the past to inform his opinion about the defendant's current capacities. The court must determine, generally by conducting a colloquy (or entering into a discussion), whether a defendant does "actually" understand the significance and consequences of his decision specific to his case and whether or not that decision is uncoerced.

The Legal Process of Referral, Evaluation, and Restoration of Competency to Stand Trial

The process of referring a person for an evaluation to assess competency can occur at any time prior to adjudication. The arresting officer(s), jail staff, prosecution or defense counsel, or even a family member

might initially raise concerns about a defendant's capacity to proceed, although the evaluation process will not become formal until a judicial order is signed authorizing the examination procedure. Ethical standards insist that the defendant have an attorney assigned to him. When we receive referrals where there is no identified defense attorney, we will contact the court to request an attorney be assigned before we begin our competency evaluation.

Many jurisdictions employ outpatient clinics where an evaluee might be transported from the correctional facility to a clinic for evaluation. There are fewer jurisdictions where evaluations are conducted at a hospital (e.g., a state psychiatric hospital in the United States). Many jurisdictions employ in-custody evaluations wherein the evaluator conducts the examination where the defendant is detained, whether that is in a correctional setting or a civil commitment facility. The time allotted for an evaluation to be completed varies by jurisdiction. Evaluations can also occur out of custody for defendants who are not incarcerated or who have been released on their personal recognizance.

A defendant's case is processed through the legal system based upon the category of his legal charge. For those charged with a misdemeanor or more minor offense, the potential sentencing range is generally shorter than a felony or more serious offense, which can dictate the timelines for court hearings. Persons charged with felonies may be treated differently than those charged with misdemeanors, and we encourage evaluators to clarify the statutory guidelines within their jurisdiction regarding these potential differences.

Statutory permission for time allotted to restore a defendant's competency to stand trial also varies between jurisdictions and may depend upon the crime charged or other factors (e.g., violence history). In some jurisdictions, when a person is charged with a misdemeanor crime and is found to be incompetent, the charge may be dismissed and the defendant may be released or sometimes referred for civil commitment (*see* **Civil Commitment**). Other jurisdictions may have guidelines for misdemeanant competency restoration treatment, although often for a shorter duration than for felonies. A person charged with a felony may be committed for competency restoration, again based upon the jurisdiction's guidelines, for several weeks or months. However, the indefinite commitment of a criminal defendant, because of continued legal incompetency, would violate his due process [5]. Therefore, if a felony defendant's competency to stand trial is not restored after a reasonable amount of time (pursuant to guidelines of his jurisdiction), the charges may be dismissed and he may (or may not) be referred for civil commitment. Alternatively, if competency restoration treatment is considered to be successful, the defendant will proceed to court to address the charges as any other defendant.

In *Sell v. United States* [6], the US Supreme Court addressed whether or not psychotropic medications should be administered involuntarily to treat mental symptoms so a defendant can proceed to trial (*see* **Treatment, Right to: Mental Health**). The Supreme Court identified four findings that must be satisfied prior to the authorization of involuntary treatment with psychotropic medications: (i) that a court must find important governmental interests are at stake (e.g., prosecution of the crime); (ii) that involuntary medications will significantly further those concomitant state interests because administration of the drugs is substantially likely to render the defendant competent to stand trial and administration of the drugs is substantially unlikely to have side effects that will interfere significantly with the defendant's ability to assist counsel in conducting a trial defense; (iii) any alternative, less intrusive treatments are unlikely to achieve substantially the same results; and (iv) administration of the drugs is medically appropriate, i.e., in the patient's best medical interest, in light of his medical condition [6] (p. 12–14). If these conditions are met, the court can exert judicial authorization for involuntary administration of psychotropic medications. If these conditions are not met, and the defendant is nonetheless referred for competency restoration treatment, the treatment may be limited by a defendant's refusal to accept psychotropic medications, and competency may not be restored. However, following the dicta of Sell, some jurisdictions employ either civil commitment (when the defendant presents a danger to himself or others or is gravely disabled) or a policy-driven medication override process (cf. *Washington v. Harper* [7]) as an alternative mechanism for involuntary administration of medications. The purpose of administering these medications would not be for the purposes of competency restoration treatment but for medical necessity, such as when a person presents a danger to himself or others.

The Role of the Mental Health Consultant in Evaluations of Competency to Stand Trial

Competency to stand trial is a legal standard, not a medical or mental health concept. Mental health professionals who consult with the court about a defendant's competency are in the position of needing to explain how mental health issues factor in to a defendant's ability to proceed with his case. The issue of whether or not a person is competent to stand trial cannot be answered simply or dichotomously. For example, a head-injured defendant might have adequate knowledge about court proceedings, be able to cooperate with his attorney, and have an interest in resolving his case expediently. However, he also might be unable to retain information across meetings with his attorney or demonstrate impulse control problems that would substantially interfere with his capacity to assist in his defense or appear in court appropriately, despite his interest in doing so. Similarly, a person with a psychotic disorder may have no other discernable impairment that would preclude him from comprehending his legal situation beyond a deeply ingrained delusional thought that there is a larger significance to his incarceration that will only be revealed to him after he enters a guilty plea. As the ultimate decision is legal, mental health professionals are faced with the challenge of explaining or educating the court about a defendant's mental symptoms that impact his capacity to understand, participate, and make decisions in his case.

As mental health consultants, we are skilled in establishing a person's cognitive, emotional, and interpersonal dynamics. We have been trained to assess a defendant's general overall capacities, such as his level of cognitive and intellectual functioning, his level of rationality or decision-making capabilities, his personality constructs, and how he interacts with others. We are also trained to recognize potential psychiatric symptoms or belief systems that could interfere with a defendant's ability to attend to his basic daily needs. Our role as court consultants is therefore to explain a defendant's capacities in relation to the relevant legal concepts. We are not asked to define legal terms, as this is reserved for the court and attorneys. We do need to be informed of the legal question, as this will guide our evaluation to focus on the relevant legal requirements. It is not up to the mental health consultant to translate our understanding of a defendant's capacities into legal terminology, as this determination is reserved for the judge or jury. Our role is to supply the court with information about the sorts of things a defendant can do that will demonstrate the kinds of abilities that are relevant to the legal question.

A mental health consultant will address three primary capacities that are relevant to a defendant's competency to stand trial: general capacity, decisional capacity, and particular capacities that are unique to his case. We can examine a defendant's general cognitive capacity in terms of his basic level of knowledge and about court-related matters. If a defendant presents with symptoms that would interfere with his general capacities, there is little reason to go further. For example, active auditory hallucinations might prevent someone from utilizing his intrinsic ability to attend to a court hearing or listen to his attorney, apart from his otherwise intact cognitive abilities. It is helpful to understand a defendant's baseline level of psychiatric and intellectual functioning, attention, memory, degree of rationality, and his ability to work with or interact with others to provide the context for competency-related capacities. Within this context, we are in a better position to inform the court whether a defendant's inability to trust his attorney is based upon a pessimistic view of the legal system or a paranoid delusional perception. We are also able to assist in establishing whether or not a presented claim of psychosis is legitimate and how it may or may not bear upon a defendant's case. A link must be established between a potential symptom or condition and a trial-relevant incapacity. It is not enough to say that a person with a cognitive or psychotic disorder is incompetent without relating how his condition affects his capacities.

We also examine a defendant's capacity to make decisions and whether he can apply these capacities to inform a legal decision. The manner in which people make decisions is often not based upon rational or syllogistic methods. Rather, decisions are more frequently made from emotional, reactive, automatic, or sometimes delusional states, particularly when a person is under duress or facing serious criminal charges for the first time. Consider how one may have decided on what to order the last time he/she went to a restaurant. They might have based their decision upon trying to stick to their diet or breaking their diet because they were tempted by the daily special. Understanding the process of what goes into

making general or everyday decisions will inform us of how a person will approach more critical decisions. When evaluating a defendant's decisional capacity, we need to consider how he will make decisions, in general, which can then be applied to the specific decisions he is facing in his legal case. Is the defendant capable of weighing risks and benefits of his decision? Is he able to project himself into the future after having made the decision to inform his choice? Is his factual knowledge of the case intact? Is his decision based upon a rational understanding of his available legal options? Is his decision stable over time? It is important to recognize that competency to stand trial is based upon a "capacity" to make reasonable decisions, not whether the decisions were reasonable. People are free to make unreasonable decisions, although they must have the ability to do otherwise. For example, a defendant might wish to take his case to trial despite considerable evidence against him that is certain to result in a guilty finding because he wants to have his day in court. Another defendant might decide to accept a plea bargain offer to avoid trial for emotional reasons or so he can get out of jail sooner, even when he has salient information that might hold up well at trial.

Finally, as mental health consultants, we examine a defendant's capacities as relevant to his specific case. Each case has its own unique particularities that may interact with a defendant's situation or mental condition. An individual living with a mental disorder may have a well-encapsulated psychotic delusion that does not bear upon his specific legal case and be otherwise quite capable of resolving his case as long as the case does not overlap with the delusion. For example, a defendant may harbor grandiose delusional ideation in regards to his own professional affiliations, such as believing that he has acquired a number of doctoral degrees in several different fields, and be charged with stealing food, which he does not dispute. In negotiating his way through his court hearing, the issue of his delusion about his numerous doctoral degrees may never come up, because it is not relevant to the specifics of his case. Alternatively, it may interfere with his competency to stand trial if he believes that his professional affiliations entitle him to take food without needing to pay for it. We have also seen cases where an individual may have a delusional notion about a specific entity, perhaps an electric or telephone company, which prompted him to commit arson or some other crime of property damage. He may not demonstrate any other aspects of psychosis, and once the act was committed, he no longer feels at risk. However, when faced with the legal consequences, he insists that he had no alternative but to act in the manner he did. This individual, who may meet the legal criteria for insanity at the time of the crime, might reject a mental defense because he does not believe that he was demonstrating exculpable symptomatology at all and rather insists that his attorney prove his delusional reasons. The factors a defendant weighs when considering various plea alternatives, such as whether or not to waive an insanity defense, must not only be well informed, but free of delusional ideation. A defendant may present with otherwise intact general capacities in regards to his understanding of his charges and trial process and can engage appropriately with his attorney, but for a particular element that is specific to his case that calls his decisional capacities into question. A defendant for whom an insanity defense would be a viable course of action may not wish to proceed in this manner, given the potential for a lengthier commitment to a mental institution than he would have received if imprisoned. The potential influence of existent mental symptoms in formulating this decision would need to be carefully considered, particularly if the defendant lacks insight into his mental illness or expects his attorney to present his delusional beliefs about the case. This is precisely why evaluations of a defendant's capacity to proceed must go deeper than simply reviewing a defendant's familiarity of legal terminology, his charges and the potential consequences he is facing.

Evaluation of Competency to Stand Trial

Evaluating an individual's competency to stand trial can be fairly straightforward – such as in the case of a floridly psychotic individual – or extremely complex and subtle, when considering a defendant's particular decisional capacities that are relevant to his case. A review of a defendant's knowledge about legal concepts specific to standing trial is generally included in an evaluation of his capacities, but what actually occurs in the courtroom may differ. For example, the sorts of questions a judge may ask during a colloquy may go beyond questions posed in the evaluation, such as a defendant's understanding of a specific plea agreement or conditions of release

that were not articulated at the time the evaluation was conducted.

Elements to consider when assessing a defendant's knowledge or understanding of his case include the nature and seriousness of the charge, the outcome he could face if convicted including the type of punishment whether incarceration (e.g., prison or jail) or out of custody (e.g., fines or probationary requirements), the length of sentence (commitment or community probationary requirements), the impact of a conviction (e.g., restrictions imposed by felony convictions, confinement, or permanent criminal history) or the impact of a finding of legal insanity (e.g., hospitalization, conditional release conditions, or possible incarceration in some jurisdictions following a finding of guilty but mentally ill). A defendant should be familiar with his available legal defenses and the ramifications of those choices (e.g., guilty, not guilty, no contest or Alford plea, not guilty by reason of insanity, plea bargain), as well as what evidence exists against him and what witnesses might testify to. A defendant should be familiar with the roles and function of courtroom participants, such as his attorney, the prosecutor, the judge, jury, and witnesses; and the adversarial nature of a trial, particularly the opportunity to testify and the potential risk involved in cross-examination. Most of these elements speak to the first two levels of evaluating a defendant's general competency-related capacities.

However, competency to stand trial involves more than simple knowledge of legal concepts. In working with defense counsel, a defendant's ability or capacity to cooperate, supply relevant information, manage disagreements, participate in trial strategy to the degree possible, and to understand the concept of privilege are important to consider, particularly within the context of a defendant's general capacities as outlined above. A defendant's capacity to then apply these concepts to his specific case, weigh his available legal options and communicate his choices to his attorney is what will inform a judicial determination about a defendant's competency to proceed.

An evaluation of a defendant's competency to stand trial generally includes but is not limited to a review of court documents (court order requesting the competency evaluation) and discovery information (charging documents, probable cause statement, police reports, and witness statements), interview(s) with the defendant, consultation with collateral sources (family members, medical, and mental health providers) and sometimes psychological assessments that may focus on cognitive abilities, psychiatric symptomatology or specific competency-related capacities.

The opportunity for a neutral party familiar with mental health issues to be available to observe the initial interactions of a defendant in court would greatly inform a referral for a competency evaluation. Ideally, evaluations of competency to stand trial will have defense counsel present or at least available for consultation, so that potential concerns can be raised, and the relationship between counsel and client can be observed and assessed. A defendant has a legal right to have counsel present during an evaluation; however, if the attorney cannot be available or if a defendant elects to proceed on a *pro se* basis (e.g., represent himself), this option may not be possible.

Sometimes interviews are conducted in jails under conditions a defendant might feel humiliated or offended by (e.g., through the pass-through of a jail cell door or while physically restrained) that would establish a less than neutral context for an attorney or an evaluator. Every effort should be taken to treat a defendant with respect and courtesy, given this can often set the stage for the level of cooperation and disclosure during the interview, and even have a bearing on how a defendant will present in court or impact his relationship with defense counsel. During a competency evaluation, the limitations of confidentiality should be carefully explained so that a defendant can decide whether or not to participate and the advantages or disadvantages of not cooperating with an evaluation.

It is important to consider cultural differences and level of experience with the criminal justice system in the jurisdiction a defendant is involved in. Simple lack of exposure, culturally based traditions or actions accepted by one culture that differ from the jurisdiction where the defendant is criminally charged, would not necessarily support a finding of legal incompetency if the defendant has the capacity to learn the rules of the legal system or the expectations of the society he is involved with. This may require the assistance of a court-certified interpreter or a consultation with a cultural expert to establish that an initial lack of understanding does not preclude the ultimate ability to participate.

Most often, a report is generated consolidating all of the information and supplied to the court and others as directed by the court order (e.g., defense,

prosecutor, jail mental health staff, or others), unless the evaluation is retained by defense and protected under attorney–client privilege. Reports that are detailed, objective, and include collateral information that supports the opinion posited, are generally sufficient to stand alone. However, if the issues are less clear, expert testimony may also be required to allow parties to clarify the proffered opinion or to gather additional information.

Report Writing and Testimony

The conclusions following an evaluation of a defendant's capacity to stand trial are generally communicated to the court in a report (*see also* **Report Writing for Courts**) and/or testimony. Some jurisdictions require that the evaluation includes opinions regarding a defendant's current mental condition in addition to the opinion regarding his capacity to stand trial. Reports generally include the referral question, the legal charges pending, an opinion regarding the defendant's mental condition at the time of the evaluation, and the defendant's current capacities in relation to trial. A more thorough analysis will also include developmental/biographical, clinical, medical, and criminal history information supplied by the defendant and from a variety of collateral records including medical, correctional, mental health, sometimes academic facilities, and consultations with family members, medical and mental health treatment providers, community corrections officers, defense counsel, and other sources that are familiar with the defendant. The more comprehensive the report is, the less likelihood that a mental health consultant will be called upon to testify to clarify his opinions. However, in cases of opposing expert opinions or when a defendant's mental status may be different in court from the time the examination was conducted, court testimony may be required to clarify or elaborate on the proffered opinion. When testifying, a consultant is generally asked about his professional qualifications to establish his expertise in the field, the process he utilized to evaluate the defendant including the sources of information that substantiated his opinion, and his opinion regarding the defendant's trial-relevant capacities. It should be emphasized that it is the court's responsibility to make the ultimate opinion regarding a defendant's competency to stand trial, and as mental health consultants we are responsible for describing a defendant's trial capacities.

Recommendations to the Court

Mental health professionals aid the court in understanding how a defendant's mental symptoms could impact his understanding of his case, but also dispel some potential misinformation about mental illness. A defendant is not incompetent to stand trial simply because he is diagnosed with schizophrenia or bipolar disorder. Mental health consultants serve to explain to the court how the potential symptomatology could specifically impact a defendant's trial capacity. For example, a defendant diagnosed with schizophrenia exhibiting disorganized speech would have difficulty communicating effectively with counsel. A defendant, who is in a manic episode with pressured, uninterruptible speech, may have similar difficulty communicating with counsel or testifying relevantly, whereas another defendant with schizophrenia, whose symptoms are less severe or are well controlled with psychotropic medications, may still carry the diagnosis of schizophrenia but be able to participate in a rational manner.

An often overlooked aspect of a defendant's competency to stand trial is the stability of his mental status across time and situations, which is why the ultimate decision about legal competency is reserved for the trier of fact. Differences between settings of where a defendant might consult with counsel or be evaluated for his legal competency (e.g., a quiet or less-distracting atmosphere) and a courtroom (particularly a presiding court where numerous cases are processed quickly over a short period of time) must be taken into consideration when assessing the stability of a defendant's mental status. Further, the intensity of a defendant's mental symptoms can wax and wane with time and may be less related to the behavioral environment, necessitating the mental health consultant to educate the court about the nature and course of expected mental symptoms and the defendant's specific limitations and capacities.

A mental health professional involved in assessing competency is in a good position to inform the court about conditions that may be conducive or counterproductive to a defendant's court appearance or his ability to work with his attorney. An evaluator will sometimes be faced with conflicts that exist between the defendant and his attorney wherein the difficulty communicating is not based upon a mental illness as much as characterological issues, misunderstanding, or even limited opportunities for consultation.

Depending upon the time frame of a defendant's arrest, arraignment, and opportunity to consult with counsel, it might be that a temporary condition such as intoxication or a delirium interfered with initial communication abilities. Sometimes the context and manner of the initial contact can dictate how the working relationship will follow. Additionally, sometimes, defense attorneys will change from the time of arraignment to the start of a trial, which has the potential of adding confusion and sometimes frustration for a mentally ill defendant.

The defendant's behavior in court and while consulting with his attorney can vary and it is helpful to be able to delineate which elements might be related to characterological aspects that are more volitional, as opposed to symptoms of mental or medical impairment. Collateral information from a variety of sources aid in establishing a pattern of symptomatic presentation related to a mental illness versus personality dynamics. It is recognized that nervousness or anxiety about a court appearance is customary, and only when it reaches the level of significantly interfering with a defendant's comprehension and ability to attend to his attorney or the proceedings will it require intervention.

As variations in a defendant's mental symptoms could range significantly across time and situations, the tolerance level of the court's time schedule may impact a defendant's capacity to participate, follow court proceedings or cooperate with counsel. It is essential to apprise the court of a defendant's potential limitations (e.g., attention span, ability to comprehend or process verbally presented material, and potential sensory disabilities), so that the court may decide how much time it will allow or expect from defense counsel to spend with the defendant on his case.

There has been a recent development of Mental Health Courts in the United States (*see* **Mental Health Courts**). By 2005, there were approximately 125 operational courts in 36 states [8]. All require voluntary participation by the defendant. Mental Health Courts serve as a diversion into judicially supervised community-based mental health treatment programs where charges are deferred or dismissed pending successful completion of court-ordered mental health treatment. Initially, defendants charged with felony or violent crimes were not admitted; however, a second generation of mental health courts [9] that accept felony cases is beginning to emerge.

Other Related Trial Competencies

The legal standards for competency to stand trial are the same as for competency to be sentenced, to plead guilty, to waive an insanity defense, to waive privilege, and to waive the right to counsel, as each speaks to relevant decisional capacities that are specific to a defendant's particular case. Competency to proceed on a *pro se* basis (self-representation) is every defendant's right as long as the waiver of counsel is made voluntarily and intelligently [10], although at a minimum, the defendant "must have the capacity to understand and weigh the risks and benefits of self-representation, including the risk that he could be erroneously convicted due to deficiencies of his self-representation" [11] (p. 300). Although the legal standards are the same, the decisional expectations are not and vary depending upon context [11].

While everyone who is arrested has the right to remain silent [12], a person's competency to confess or to supply information is generally not assessed at the time a statement is given. The defendant's rights are generally read to him and he may be asked to initial or sign a document signifying that he had his rights read to him, but inquiry into the extent of a defendant's comprehension of these rights is generally not pursued. Assessing a defendant's competency to confess requires the evaluator to conduct an analysis of the defendant's mental status at the time he was questioned, akin to an evaluation of mental state at the time of the alleged offense (e.g., insanity). While it may be helpful to review the legal terminology utilized in Miranda [12] (*see also* **Head Injury: Neuropsychological Assessment**) when questioning a defendant about his understanding of these terms, it is also essential to consult with collateral sources about a defendant's general cognitive and intellectual functioning and behavioral accounts of the defendant at the time he received his rights particularly if mental health symptoms were present.

The legal standard for competency to be executed similarly parallels the Dusky [3] standard of possessing a rational understanding and an ability to cooperate with counsel. There may be ethical considerations of restoring a person's competency to be executed, such as in the case where a competent defendant's

mental condition deteriorates while awaiting execution, particularly if this requires involuntary administration of psychotropic medications. It was subsequently determined that the due process clause in the US Constitution would permit involuntary treatment of serious mental symptoms if the inmate presents a danger to himself or others [7]. It is unconstitutional to execute an insane person, per the Eighth Amendment in the US Constitution [13], and as found in the US Supreme Court case of *Ford v. Wainwright* [14].

In the case of *Singleton v. Norris* [15], after finding that the Sell [6] criteria was met, the Eighth Circuit court of appeals concluded that due process would not be violated by involuntary treatment as the mandatory medication scheme that was valid under the stay of execution would still be valid when an execution date was set. This matter continues to be debated, particularly in cases where an inmate may have a factual awareness of the reason for his execution but lacks appreciation that he is being executed for retribution because of a delusional belief [16].

Capacity to Waive Insanity Defense *see* Capacity Assessment

Capacity to Waive Legal Counsel *see* Capacity Assessment

Capacity to Waive Miranda Rights

In *Miranda v. Arizona* [1, 2], the US Supreme Court ruled that any statement arising from a custodial interrogation of a suspect would be presumed to be involuntary and not admissible unless the suspect is informed of his rights to remain silent, to avoid self-incrimination, to obtain legal counsel before and during police questioning, and to obtain free legal counsel if indigent.

Litigation concerning a defendant's capacity to confess has been increasing in the criminal and juvenile courts. A confession or incriminating statement given by a suspect can greatly influence the final court

decision of a defendant's guilt or innocence. Self-incriminating statements to law enforcement, even in the absence of other incriminating evidence, often produce guilty verdicts [3]. Mental health professionals have assisted the court in assessing a defendant's capacity to have waived *Miranda* rights at the time of the interrogation. Like the evaluation to assess a defendant's legal insanity, the *Miranda*-focused evaluation involves a retrospective analysis of the defendant's mental state at the time of the police questioning. The clinician evaluates current capacity, to gain insight into the defendant's present abilities, and then extrapolates the analysis to the point in the past when the defendant had actually waived the rights [4]. In 1966, the US Supreme Court ruled in *Miranda v. Arizona* that a suspect's statement is presumed involuntary and inadmissible in court if law enforcement does not provide four warnings. These warnings include (i) the right to remain silent, (ii) that any statement can be used against the suspect in the future court proceedings, (iii) the right to the presence of an attorney before and during the interrogation, and (iv) an attorney provided free of charge if the suspect is unable to pay for one. Some jurisdictions have added a fifth warning, whereby the suspect is informed that the rights can be invoked at any time. The 1967 case, *In re. Gault* [5] applied the Miranda protections to juvenile suspects.

The terms *competency to confess* or *competency to waive Miranda rights* have been used interchangeably with capacity to waive *Miranda* rights. While competency generally refers to the legal determination by the court, capacity has to do with the individual's ability to waive the rights at the time of the interrogation.

Mental health testimony is generally presented at a pretrial suppression hearing. A forensic evaluation must be functionally based; that is, integrated with the legally relevant criteria [6, 7]. The astute clinician should break down the assessment into a determination of factors relevant to a knowing waiver, an intelligent waiver, and a voluntary waiver.

Knowing, Intelligent, and Voluntary Waiver of Rights

A mental heath professional can offer an opinion whether a waiver of *Miranda* was made knowingly and intelligently. A knowing waiver is the individual's understanding or comprehension of the rights in addition to the manner in which the rights were administered [8]. The rights can be read by law enforcement or the suspect might be given a "waiver form" to read and sign. With the latter, an assessment of reading comprehension would be important. Written *Miranda* waiver forms vary greatly in their length and complexity, from a 2.8 grade level to postcollege [9]. The readability of the waiver form can be analyzed by the Flesch–Kincaid readability formula, easily calculated with word processing programs. Comprehension can also be affected by how the rights were presented, such as a police officer handing the suspect a form with their rights and asking the suspect to sign it without explanation.

An intelligent waiver of rights involves a decision-making capacity, an appreciation of the rights based upon knowledge of the legal process. For example, a defendant may understand one has the right not to speak to the police but cannot make an intelligent use of the right to silence because of a faulty belief that invoking the right to silence would be perceived by the trier of fact as the actions of a guilty person. It must be noted that in the United Kingdom, unlike in the United States, a defendant who elects not to speak to law enforcement can have that right to silence be weighed negatively by the trier of fact. It can be assumed that the suspect has something to hide.

The mental health professional should be cautious in directly opining on the third prong of a valid waiver, the voluntariness component. In the 1986 US Supreme Court case, *Colorado v. Connelly*, the court ruled that a confession "compelled" by hallucinatory and delusional thinking was voluntarily given because the police did not take advantage of Connelly's mental state to extract the confession. There was no showing of undo influence. The court ruled that there must be a "link" between the *Miranda* waiver and inappropriate police conduct [10]. It is not a clinical issue whether law enforcement overstepped their bounds in extracting a *Miranda* waiver. Nevertheless, clinicians can assess relevant psychological factors that make an individual more susceptible to the effects of police conduct. Valuable information can be given to the court regarding such factors as the defendant's interrogative suggestibility, compliance, intelligence, anxiety, memory, and the effects of drug intoxication and sleep deprivation.

The mental health profession understands that a judicial determination of the validity of a *Miranda* waiver is dependent not only on the evaluation results

but also on the *totality of circumstances* surrounding the *Miranda* waiver. This includes the nature of the interrogation process and a defendant's individual characteristics, which may increase or reduce comprehension of the rights [11]. In that respect, there is no one IQ cutoff or a diagnostic threshold, which would automatically render a defendant incompetent to have waived rights during the interrogation.

Protocol for Miranda Capacity Evalutaion

Frumkin [4] proposes a protocol for conducting a capacity to waive *Miranda* rights evaluation. The importance of reviewing relevant third-party data cannot be overstated. The referring attorney should collect for the clinician a copy of the *Miranda* waiver form or the card from which *Miranda* was read. The mental heath professional should also obtain from the attorney, school records, work records, psychological and medical records, and any and all records which would help one interpret evaluation findings in a historical context. If it exists, it is important to review the audio or videotape of the interrogation and/or depositions of law enforcement. Although it is important for the psychologist to obtain an arrest history of the defendant, research has shown [8] no simple correlation between an arrest history and *Miranda* comprehension and appreciation.

After a review of third-party data, a thorough clinical interview is conducted including a psychosocial history and mental status examination. An essential part of the evaluation consists of obtaining the defendant's step-by-step version of what transpired with first contact with law enforcement, up through the *Miranda* waiver and subsequent statement. The goal is to get the defendant to describe how the rights were administered by law enforcement. This is needed to assess the defendant's ability to recite the rights, spontaneously from memory, and also whether the rights can be remembered immediately after they are read by the examiner or by the defendant himself (depending upon the manner in which the rights were administered by the police). It also allows an assessment of the defendant's reading and listening abilities.

Intelligence testing, such as administration of the Wechsler scales are important not only to obtain IQ scores but also to obtain scaled scores from subtests which are relevant to the types of cognitive capacities need to understand and appreciate the abstract concepts contained in *Miranda.* Reading comprehension testing is also warranted if the defendant was asked to read the rights by law enforcement. Personality testing can be useful in examining psychological variables that could impact upon an individual's ability to comprehend and process information as well as for issues relevant to the voluntariness of the *Miranda* waiver. As with any forensic evaluation, the clinician should assess the minimization or exaggeration of cognitive and/or psychopathological symptoms, (*see* **Malingering: Forensic Evaluations**).

Specialized Tests

Thomas Grisso, as part of a large federally funded research project in the late 1970s, developed four tests aimed at assisting a clinician in evaluating a defendant's capacity to make a knowing and intelligent waiver of *Miranda* rights at the time of the police questioning [8]. These tests help assess the current *Miranda* understanding and appreciation. It is up to the mental health professional to integrate this data with the defendant's history, what transpired during the police questioning from both the law enforcement and defendant perspectives, behavioral observations, and intelligence and personality testing data, to make a retrospective analysis of what the defendant would have understood and appreciated at the time of the police questioning.

The four tests are the Comprehension of Miranda Rights (CMR), the Comprehension of Miranda Rights-Recognition (CMR-R), the Comprehension of Miranda Vocabulary (CMV), and the Function of Rights in Interrogation (FRI). The CMR helps assess an individual's current understanding of the *Miranda* rights (knowing waiver). The subject is shown each of the four *Miranda* rights. After the examiner reads the right, the subject must state what the right means in his or her own words. The CMR-R is a less verbal means of helping to assess an understanding of the rights. The subject is read and shown each *Miranda* right and is then given comparison statements. The subject must state whether the comparison statement means the same or different from the *Miranda* right. The CMV requires the subject to define six presented words often found in *Miranda* warnings. The usefulness of this test is limited if few of the six words are actually contained in the *Miranda* version given by the police. The FRI measures factors

relevant to an intelligent waiver of the rights, the ability to appreciate the significance of the *Miranda* rights based upon a subject's knowledge of the legal system. It is composed of three subscales, Nature of Interrogation, Right to Counsel, and the Right to Silence. They are thought to be independent variables and scores do not correlate well with each other [8].

Scoring for the Grisso tests, as they are commonly referred, is from a test manual. The manual was derived by incorporating the work of a national panel of judges, lawyers, and legal scholars. They decided what types of responses indicated a full understanding or appreciation of the right (two-point response), what type of responses indicated partial understanding of the right (one-point response), and what type of responses indicated no understanding (zero-point response).

These tests have normative data for both adults and juveniles. Scores can be compared to individuals based on age and IQ. As Grisso and others have emphasized, the tests are to be used as an aid to assist in evaluating capacity to waive *Miranda* rights. The tests do not provide data relevant to the voluntariness of a waiver. They only help assess current understanding and appreciation, not capacity at the time of the interrogation. The tests are frequently misused by clinicians who put undo weight on the scores or the percentiles and who also do not take into consideration the limitations of the tests themselves [4, 12, 13].

Research regarding Miranda Understanding and Appreciation

Research has shown [8, 14] a strong relationship between intelligence and capacity to understand and appreciate the *Miranda* warnings. In fact, with most individuals with IQs in the borderline to mental retardation range, the *Miranda* warnings are "words without meaning" [15, 16]. There is also a relationship with age. Juveniles aged 14 and younger do not understand or appreciate the rights as well as older juveniles and adults. In fact, 23% of adults and 55% of juveniles do not understand at all at least one of the four *Miranda* rights [8].

Owing to the continued maturational growth of juveniles and evidence that during adolescence, performance improves in areas such as memory, attention, reasoning, and executive functioning, many juveniles have not yet developed the cognitive abilities to make an intelligent waiver [14]. Suspects need to have enough cognitive capacity to enable comprehension and reasoning abilities to be used to make rational legal choices.

The clinician needs to be aware of the research concerning mental disorders and *Miranda* comprehension. Mental illness, *per se*, does not automatically equate with incapacity to understand and appreciate the rights. A person with a psychosis can still have the capacity to waive their rights, as long as their mental disorder does not affect their cognitive abilities to make a knowing or an intelligent waiver. Research suggests that psychosis in conjunction with low intelligence may be a good predictor of incapacity to waive the Canadian rights [17]. Psychosis by itself was not a good predictor of one's lack of ability to comprehend the meaning and effect of the rights. No link was found between depression, anxiety, or behavior problems and the capacity to waive *Miranda* rights [14].

Voluntariness Component and Interrogative Suggestibility

The clinician can provide useful information to the court on psychological characteristics, which make a defendant more likely to be misled by police or to change responses under pressure compared to other people. This, as well as other psychological variables (such as compliance, submissiveness, coping skills, and impulse control) may also be the relevant factors the court may wish to consider when determining the voluntariness of a *Miranda* waiver. Personality tests, such as the Minnesota Multiphasic Personality Inventory-2 (MMPI-2), Personality Assessment Inventory (PAI), and the 16 Personality Factor (16 PF) may provide useful information regarding a defendant's psychological functioning and how that functioning interacts with the demands of the interrogation process (*see* **Psychological Testing**).

Interrogative suggestibility (*see* **Interrogative Suggestibility**) is defined as the extent to which an individual comes to accept messages or information communicated during formal questioning, essentially believing as true the information given. The Gudjonsson Suggestibility Scales (GSS) [18] is a specialized psychological test that can be used to identify those most susceptible to give into leading

questions and shift to different responses under pressure. The examinee thinks that the GSS is a memory test. A narrative story is read aloud and the subject is asked 20 questions about the story, 15 of the questions are misleading. The test quantifies how much the person "yields" to the leading questions, both after being asked the leading questions, and later when firmly told that errors were made in answering questions. Shift is also calculated, which is how many times the subject shifts from one response, right or wrong, to a different response. A total suggestibility score is calculated, which is the sum of the first Yield and the Shift. The ultimate determination of a suspect's capacity to waive *Miranda* rights at the time of the police questioning falls in the domain of the court. Forensic mental health professionals can provide valuable data to the court to assist in the determination whether a defendant made a knowing, intelligent, and voluntary waiver of rights.

Cardiac and Natural Causes of Sudden Death

Definitions

In the discussion that follows we have adopted the terminology used by the World Health Organization, which defines "sudden unexpected death" as that occurring within 24 h of the onset of symptoms, where natural disease or functional disorder is recognized as a cause of death. The term "sudden cardiac death" has traditionally been reserved for deaths that occur within 1 h of symptom onset. Worldwide, such deaths are almost always related, in one way or another, to the existence of ischemic heart disease. More recently, new subdivisions have been added to the original classifications. The diagnosis of "sudden unexpected death in epilepsy" is widely accepted as a distinct entity. In 1993, the US Food and Drug Administration (FDA) first developed the generally accepted criteria for the diagnosis of sudden unexpected death during epilepsy (SUDEP). To be classified as SUDEP, the patient must have a proven history of recurrent seizure but must be otherwise healthy at the time of death, with death occurring within minutes, but in the absence of seizure activity. Finally, and perhaps most important, no cause of death is apparent at autopsy. Lastly, the term sudden infant death syndrome (SIDS) is now reserved for death where no cause of death is apparent. If a cause is apparent, death is then classified as being a result of sudden unexpected infant death syndrome (SUID) or unexplained infant. Such deaths are usually cardiovascular or respiratory in nature.

Sudden deaths (excluding traumatic deaths) can be divided into four general groups:

1. *physiological or death due to genetic defect*;
2. *pathological death* due to diseases (including malnutrition and starvation), which can be slow or sudden;
3. *accidental or violent death* due to trauma, such as a wound, or poisoning, which, unless homicidal, is also accidental (for example, an addict dying from clostridia cardiotoxicity);
4. *unexplained death* when all findings are insufficient to explain its cause.

Historical Considerations

The study of sudden, unexpected deaths goes back many centuries. Leonardo da Vinci described sudden, unexpected death as *la dolce morte* (the "sweet death"), because the very speed with which it occurs tends to shorten the grieving period. Sudden death can occur in conjunction with many different diseases. Perhaps the best known example occurred in 480 B.C., with the sudden cardiac death of the soldier Philippides. He had run from Maratona to Athens in order to announce victory against the Persians. Another example occurred in 1705 when so many people died during an epidemic of sudden death in Rome that Pope Clemente XI ordered his "archiatra" (doctor in chief), named Giovanni Maria Lancisi, to undertake an autopsy investigation. The results were published under the title *De subitaneis mortibus* ("the gross anatomical findings"). He found cardiac involvement in most of the decedents. The victims described in early reports of sudden death were generally men living a life of luxury. However, this disease process soon came to involve those not so well-off [1]. Even today the pathophysiology of this disorder remains poorly understood, although there is definite progress to report (see below). Today most instances of sudden unexpected death (SUD), autopsied or not, are really cases of sudden cardiac death (SCD), a consequence of heart disease, especially coronary atherosclerosis. Obviously, this does not apply to individuals under 40, where deaths from coronary artery disease are uncommon, but deaths from cardiomyopathy are fairly frequent.

This chapter is devoted to the analysis of "any *death which is rapid (without prodrome), unexpected and/ or unforeseen, that occurs in apparently healthy people, or in ill patients during a benign phase of their disease"*. A negative history does not necessarily exclude the previous occurrence of a silent infarct, and the finding of a myocardial monofocal fibrosis, involving 10% or more of the left ventricular mass, should be considered as an acceptable sign of an old, undiagnosed myocardial infarct. It is increasingly recognized that the existence of such a scar predisposes to sudden death because of recurrent ventricular tachycardia arising from the boundaries between the scar and normal tissue [2].

For many years it was commonly held that SCD was the result of ischemia induced by the presence

of critically stenotic lesions. In fact, stenotic lesions are present less than 30% of the time [3].

Here, we review the most common natural causes of sudden, unexpected death. In the United States, more than 325 000 cases of fatal myocardial infarction occur annually [4], and most of these deaths are sudden. We also know that in North America the annual incidence of out-of-hospital cardiac arrest is approximately 0.55 per 1000 population; this implies that about 164 600 episodes of out-of-hospital cardiac arrest occur annually in the United States. The incidence in other industrialized countries is probably comparable if, for no other reason than that, the incidence of coronary artery disease varies little from one industrialized country to another. Compared with coronary artery disease, the incidence of all other causes of SCD is negligible, except in the young who do not, as a rule, suffer from coronary disease. In fact, the investigation of sudden death in the young and apparently healthy poses a difficult challenge for death investigators and is the focus of this article.

In 2001, Virmani *et al.* systematically analyzed the pathologic changes observed in a large consecutive group of young SUD victims (31–40 years) [5]. The findings are illustrated in Table 1. Nearly a decade has passed since this list was originally compiled. If it were compiled again today there would be substantial differences; the frequency of cardiomyopathy, inflammatory myocardial diseases, and ion channel disorders would be much greater [6]. The increased availability of genetic testing has substantially increased our awareness of many disorders and increased the frequency with which they are diagnosed. At the same time, some of the diagnostic categories, such as "idiopathic left ventricular hypertrophy (LVH)", probably would now be eliminated entirely because there etiology is now understood; the genetics of hypertrophic cardiomyopathy (HCM) has been largely characterized, and the explosive increase in stimulant drug abuse, with the powerful ability of these drugs to induce LVH (itself a powerful predictor for sudden arrhythmic death), is increasingly recognized [7].

Table 1 Pathologic changes in young SUD victims $n = 229$ (all aged 31–34 years)

1.	Atherosclerosis, 60%
2.	No finding, 9%
3.	Hypertensive LVH, 6%
4.	Idiopathic left ventricular hypertrophy, 4%
5.	Dilated cardiomyopathy, 4%
6.	Hypertrophic cardiomyopathy, 3%
7.	Myocarditis, 3%
8.	Sarcoidosis, 2%
9.	Aortic dissection, 2%
10.	Endocarditis, 1%
11.	Floppy mitral valve, 1%
12.	Coronary artery tunneling, 1%
13.	Right ventricular dysplasia, 1%
14.	Rheumatic mitral stenosis, 1%
15.	Anomalous coronary artery, 0.5%
16.	Coronary artery dissection, 0.4%
17.	Congenital heart disease, 0.2%
18.	Lipomatous hypertrophy, atrial septum, 0.2%

Specific Medical Disorders

Coronary Artery Disease (60%)

Table 2 shows the *percentage distribution*, the degree of maximal stenosis, and the frequency of occlusive thrombi in those with and without evidence (monofocal scarring) of previous infarction (SUD chr) compared with noncardiac patients dead from other diseases (NCA) and patients dying accidental deaths (AD).

These data clearly demonstrate that SCD from acute myocardial infarction (AMI), as the first indicator of coronary heart disease, may occur in absence of a critical stenosis (SUD 35%; AMI 11%). It is also apparent that "chronic" cases had more severe and more extensive coronary atherosclerosis, but a lower frequency of occlusive thrombus (15 vs. 40%) in AMI. The high frequency of severe coronary atherosclerosis (similar to that seen in SUD) in the control no cause apparent (NCA) and in accidental death (AD) group is also noteworthy [1].

Intracoronary perfusion with radio opaque material will demonstrate an extensive compensatory collateral system, formed by intramyocardial giant, capillarylike vessels, joining branches of the same artery (homocoronary) or branches of different arteries (intercoronary), in normal and diseased hearts. At the level of the atherosclerotic plaque, proximal and distal secondary branches may be seen communicating with a neovascularized atherosclerotic intimal (innermost) and residual lumen. The collateral system was identical in SUD, AMI, and controls. The enlargement of normal anastomotic vessels was proportional to the degree and number of critical stenosis [1].

Table 2 Percentage distribution of maximal lumen reduction and number of atherosclerotic coronary arteries with severe (> 70%) lumen/diameter sterosis

Degree of coronary stenosis %	SUD 1st 133 cases	SUD chr 75 cases	AMI 1st 145 cases	AMI chr 55 cases	NCA 100 cases	AD 97 cases
0	8	–	2	–	7	8
<50	13	–	2	2	10	21
50–69	13	7	7	–	17	32
70	16	11	21	14	11	19
80	29	18	31	20	24	14
90	20	64	37	64	31	6
Severe >70% in						
1	30	17	42	29	26	23
2	25	35	34	40	18	13
≥ 3 vessels	10	41	13	29	22	3
Occlusivethrombus	8	28	41	40	–	–

The lack of symptoms or signs of ischemia in this group of decedents clearly demonstrates the importance of collateral connections. In chronic patients, the higher frequency of critical, multiple stenotic lesions is not an indication of more severe coronary disease but, rather, evidence that the atherosclerotic process simultaneously involves the entire coronary tree. Studies by several investigators suggest that in patients with acute myocardial infarction, all three major coronary arteries are widely diseased and have multiple yellow though nondisrupted plaques, suggesting that AMI may represent a pan-coronary process of vulnerable plaques in all stages of development throughout the process [8].

However, because of the established compensatory flow from the collaterals, aggravation of atherosclerotic process does not imply clinically evident dysfunction; the presence of these collaterals raises doubts about the significance of occluding thrombi. When present, they are found only in old plaques in vessels containing a critical lumen reduction. This observation strongly suggests that existing collateral flow will nullify the effects of thrombotic occlusion, which in turn implies that the thrombus may not be the primary cause of sudden death or infarct, but rather a secondary phenomenon [1].

Natural History of Coronary Atherosclerotic Plaque in Humans

We have performed systematic, quantitative, histological examination of diseased coronary arteries of SCD victims, quantitating intimal thickness increases and lumenal reduction, and made morphometric measurements of the length, shape (concentric, semilunar), and intimal/media thickness of coronary plaques in large groups of sudden death victims: 100 acute myocardial infarcts, 208 decedents with sudden/unexpected death cases, 50 individuals with chronic coronary heart disease patients, and 97 healthy controls. This included examination of coronary sections taken from the origin of left main trunk, left anterior descending branch, left circumflex branch, right coronary artery, posterior descending branch and the middle tract of anterior descending, and marginal and posterior tracts of right coronary artery [1]. Of 3640 coronary sections, 1519 without and 1315 with a lumen reduction less than 70%, and an intimal physiological thickness less than 300 or 600 μm, respectively, we never observed fatty streaks, lipoprotein–cholesterol subendothelial infiltration, monocytes, macrophages, foam cells, platelet aggregates, fibrin-platelet thrombi, inflammatory elements, or intimal fissures.

SCD with Normal Heart (9%)

Many of these cases are a consequence of genetic aberration and, more likely than not, these particular mutations act to disrupt normal myocardial repolarization, resulting in the family of diseases known as “long QT syndromes” or “LQTS”. The QT interval represents the total duration of ventricular systole. It is controlled by the sequential opening and closing of various sodium and potassium channels during cardiac depolarization and repolarization [9]. Under normal circumstances, the QT interval should be less

than half as long as the time elapsed from one "r" wave to the next. If it is longer, then repolarization is also prolonged and the chances increase that an "r" wave will fall on a "T" wave and trigger a fatal arrhythmia. More than 80% of LQT1, 2, 3 deaths occur during exercise or after being startled, chiefly because as the heart rate increases, the r–r interval becomes shorter.

The incidence of LQTS defects is estimated at 1 : 5000, but if acquired forms of LQTS are included, the true incidence of LQTS may be closer to 1 in 1000 [10]. At least eight different genes are involved, though disorders such as idiopathic ventricular fibrillation [11], progressive cardiac conduction disease [12], and the only recently recognized short QT [13] syndrome are all very rare. There are two types of defects, depending on whether alpha or beta channel subunits of the channel are involved [14].

By far the most interesting of the mutations involves the gene for the human ether-a-go-go-related gene (HERG) potassium channel, located on Chromosome 7 and the *MiRP1* gene located on Chromosome 21. These interact to form I_{rk}, the inward rapid potassium current. If there is a defect in HERG, the resultant syndrome is called *LQT2*; if on *Mir*, it is called *LQT6*. LQT3 is due to mutations in the sodium cardiac channel SCN5A, and the resulting syndrome is commonly referred to as *Brugada syndrome*. The LQT4 syndrome is due to a mutation in the ankyrin-B protein [15]. LQT7 is the result of yet another defect in the alpha subunit of the I_{Kr} channel. No matter what the defect is, the result is the same: prolonged repolarization. Testing of patients with suspect LQTS syndromes is available commercially in the United States, but the cost is still prohibitively high [16].

QT prolongation leads to the occurrence of a lethal type of ventricular tachycardia known as *torsades des pointes* (*TdP*). The blockade of any potassium channel can precipitate torsades des pointes (TdP). Most, if not all, clinical cases of TdP are drug-induced, secondary to abnormalities of the (HERG) ion channel, the one that conducts the rapid component of the delayed rectifier KC current I_{Kr} [17].

LQT3 is a rare syndrome, accounting for less than 5% of all LQTS. It is the result of a "gain of function" mutation that causes sodium channels to remain open. Asian men suffering from the disorder known as *bangungut* (literally, "sleep death") die during nightmares [18]. Alternatively, there may be a "loss of function", and the sodium channels stay closed and the result is Brugada syndrome. LQT3 is the only "channelopathy" associated with morphological changes. Biopsy samples obtained from 18 patients who were believed to have this syndrome were found to contain detectable SCN5A mutations in only 4 patients, but structural alterations were seen in 14: right ventricular micro aneurysms in 7 patients and 4 of these also had micro aneurysms on the left. Right ventricular cardiomyopathy was present in one patient; cardiomyopathic changes were noted in three additional cases [19]. The findings reinforce the relatively recent notion that there may also be acquired forms of Brugada syndrome.

The ryanodyine receptor (Ry) is the single largest gene in the human body, with 102 exons. Death from this mutation occurs as a result of stress-induced bidirectional ventricular tachycardia, which is also called *catecholaminergic polymorphic ventricular tachycardia* (CPVT). The arrhythmia occurs because of abnormal calcium concentration variations within the individual myocytes. In this disorder, Ry is inherently unstable and prone to unpredictable failure [20]. When that occurs, the cell is flooded with excessive amounts of calcium producing electrical instability. When the Ry mutation occurs in skeletal muscle, it causes malignant hyperthermia (anesthesia-related death) and central core disease. In cardiac muscle, RYR2 mutations cause CPVT, and still other mutations in the same gene can lead to the occurrence of right ventricular dysplasia (see below) [21].

The importance of these disorders in the process of death investigation cannot be overemphasized. In a postmortem study published in 2005, LQTS genetic testing was performed in a cohort of 49 SCD cases, with an average age at death 14.2 ± 10.9 years. A combination of genetic techniques was used to identify all eight genes implicated in the pathogenesis of either LQTS (LQT1 to LQT6) or multisystem disorders involving either QT or QU prolongation. Ten LQTS-associated mutations (four novel) were discovered in the 10 SUD cases, with 20% occurring in women with an average age at death 18.0 ± 11.8 years). The activities at the time of SUD included sleep (five), exertion (two), auditory arousal (one), and undetermined (two). Sudden death was the sentinel event in two-thirds of the cases [22].

Hypertensive Left Ventricular Hypertrophy (6%)

LVH is associated with a marked increase in premature ventricular contractions and complex arrhythmias, as well as the occurrences of SUD [23, 24]. This increase is independent of all other risk factors, including even atherosclerosis. In hypertensives and athletes, LVH represents a physiologic response to increased workload, though in the hypertensives, it is a counterproductive one. Although not apparent to the naked eye, LVH is associated with decreased coronary artery reserve, decreased capillary density, and increased diffusion distance (the distance that oxygen and nutrients must traverse to reach the enlarged cardiomyocytes). As a consequence, there is relative ischemia at all times, even in the absence of atherosclerotic narrowing or increased workload. This situation predisposes to electrical instability and an increased incidence of SUD. The process of myocardial remodeling also increases the incidence of SUD. Many important myocardial changes can only be seen at the microscopic level (see below), and all of them favor the occurrence of arrhythmias. At the macroscopic level, the heart assumes a spheroid shape, leading to repolarization dispersion ("QT prolongation"), which also carries with it increased risk of SUD, probably by the same mechanisms involved in other forms of long QT. Even modest degrees of hypertrophy are associated with increased risk for SUD; therefore, it is extremely important that the heart be weighed and normalized to standard tables, such as the Mayo Clinic Nomogram [25].

Idiopathic Left Ventricular Hypertrophy (4%)

This term is outdated and should really be abandoned. If the cause of hypertrophy is not apparent, then there are really only two possible explanations: HCM (*see* section "Hypertrophic Cardiomyopathy (HCM)") and drug-induced hypertrophy. In industrialized countries, the latter is almost always a consequence of substance abuse. There is evidence that most abused stimulant drugs (cocaine, methamphetamine, and [3, 4] methylenedioxymethamphetamine (MDMA)) initiate a process of myocardial remodeling that ultimately results in LVH (Figure 1). The process involves individual myocytes and the collagen network that supports them. The process is required so that the heart can adapt to new working conditions. Part of the remodeling process is initiated by the occurrence of cell death and the activation of fetal genes, whether from ischemia, toxin, or programmed cell death (apoptosis). No matter what initiates the process, myocardial collagen content increases, as does the severity of ventricular fibrosis [26, 27].

The pattern of fibrosis resulting from stimulant abuse resembles that seen in pheochromocytoma or any other form of catecholamine toxicity, such as

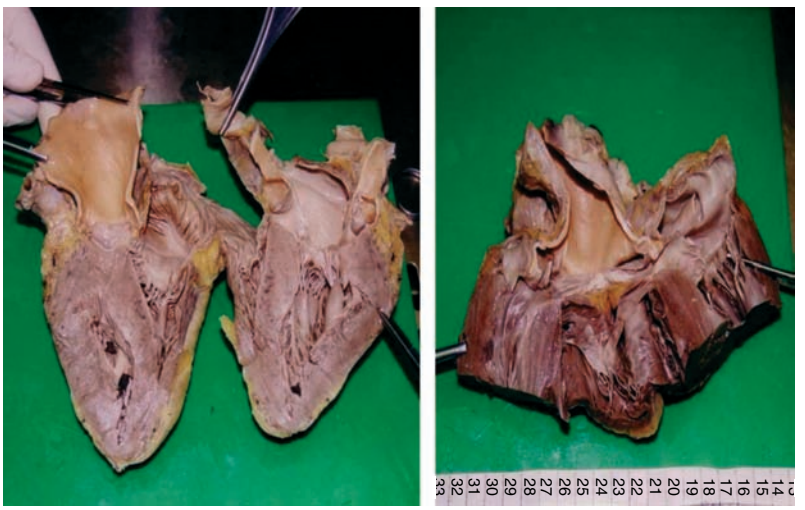

Figure 1 Left ventricular hypertrophy on "long axis" and "short axis" section

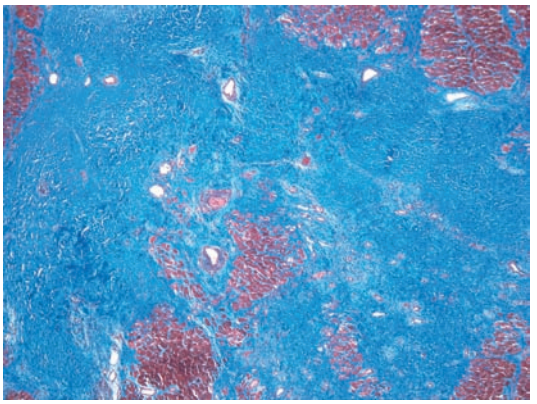

Figure 2 Dense and compact fibrosis as repair process of an ischemic necrosis (Trichromic stain)

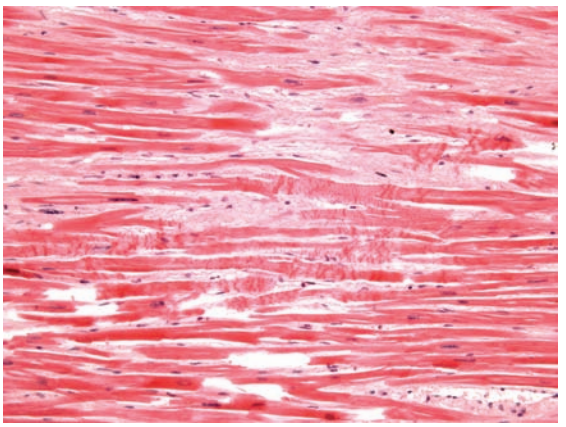

Figure 3 Microfocal fibrosis as result of catecholamine contraction based necrosis

methamphetamine or cocaine abuse. Damage to the heart is microfocal in nature and can be easily distinguished from the type associated with healing ischemic necrosis (Figure 2). When lesions are due to catecholamine toxicity, individual damaged cells are seen surrounded by normal myocytes, and damage cannot be related to the territory served by any one blood vessel (Figure 3) [28].

Hypertrophy in drug users is due to direct activation of the gene for calmodulin kinase II [29]. Other changes occur at the same time; the predominant form of myosin in the heart shifts to a slow isoform, and there is increased production of atrial naturetic factor. The rennin–angiotensin system is activated, and calcium levels within the endoplasmic reticulum decrease [30], generally reducing the cardiac output. Additional changes occur in the number and function of β-receptors (to compensate for the decreased output) while, at the same time, potassium channels controlling myocardial depolarization begin to function less efficiently [31, 32]. All these processes favor the occurrence of QT dispersion.

Dilated Cardiomyopathy (4%)

Cardiomyopathies are usually classified by their appearance (i.e., dilated, hypertrophic, and restrictive). Many etiologies are recognized, but all seem to act via identical common pathways. Dilated cardiomyopathy is by far the most common form and it is frequently responsible for heart failure. It is estimated that 400 000 cases occur in the United States every year [4]. Familial cardiomyopathy, mainly inherited as an autosomal dominant, was once considered rare, but is now diagnosed with increasing frequency. Cardiac enlargement and systolic dysfunction of one or both ventricles leading to congestive failure are the main clinical findings. Early phases of the disease are difficult to recognize; ventricular dilatation and pump dysfunction may remain asymptomatic for years and, in fact, severe pump dysfunction, with an adverse prognosis identical to that associated with dilatation, may occur with only minimal dilatation. Ventricular arrhythmias, including ventricular tachycardia, are observed in 20–60% of patients [33]. Systemic or pulmonary embolism has been reported in 3–18% of patients who have very severe forms of the disease. Echocardiography has shown that left ventricular thrombi are present in 8–60% of patients [34].

The most common pattern seen at autopsy is four-heart chambers dilatation with an increased heart weight (>500 g), despite a normal or reduced cardiac wall thickness. Microscopic examination disclosed abnormal myocytes with attenuation, edema with cloudy swelling, loss of myofibrils (colliquative myocytolysis), and often nuclear atypism. These changes are most evident in the left ventricular wall. Minimal lymphocytic infiltration with minor interstitial myocardial fibrosis is often present.

Hypertrophic Cardiomyopathy (HCM) (3%)

This disease is inherited as an autosomal dominant affecting 1 in 500 people (or about 0.2% of the general population). As such, it is probably the second

most common cause of SUD after atherosclerosis. Most never display any symptoms. Death is particularly likely in competitive athletes because their disease actually leads, albeit transiently, to improved cardiac performance with supernormal ventricular function and ejection fractions of 65–80%. HCM mutations have been identified in 14 different genes and account for more than 500 possible mutations. Most of the mutations are single nucleotide substitutions found within coding exons, intron–exon junctions, or promoter regions of the genes for β-myosin heavy chain, cardiac troponin T, or myosin binding protein-C. Those most likely to die suddenly are those with clusters of mutations in the β-myosin heavy chain gene (*MYH7*), a mutation associated with marked hypertrophy and poor prognosis [35, 36].

Not all forms of HCM result in obvious cardiac hypertrophy. In two-thirds of the cases, there is asymmetric hypertrophy of the interventricular septum, but in nearly a quarter of the cases the entire ventricle is involved. In a very small proportion of patients (approximately 10%), hypertrophy is confined to the apex. The latter pattern is much more common in Japan than in the West [37]. Traditionally, it has been presumed that when sudden death occurred in patients with HCM, it was, somehow, a consequence of myocyte disarray and fibrosis (see Figure 4). It is now clear that adrenergic stress of any sort can produce the same type of disarray and that the presence of disarray is a nonspecific finding [38]. There exists a strong association between hypertrophy and the occurrence of lethal arrhythmias due to QT dispersion [39].

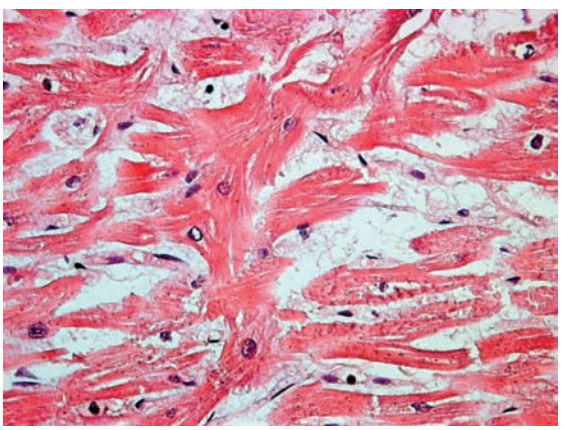

Figure 4 Myocardial disarray with interstitial fibrosis [Reproduced from Ref. 28. © American Medical Association, 1988.]

One type of HCM mutation involves α-tropomyosin and it results in little if any hypertrophy. Nonetheless, it is associated with a high incidence of SUD [40]. The incidence of this mutation is not really known since few medical examiners have the facilities to do DNA screening, leaving the final cause of death undetermined. A prototype chip, capable of detecting mutations in HCM genes, has already been developed [41], and as the technology becomes more widely available the true prevalence of this disorder should become more apparent.

Myocarditis (3%)

The type of inflammatory cell reaction elicited by the causal agent distinguishes the different forms of myocarditis. Unfortunately, the causative agent can only be demonstrated by DNA resequencing, and sometimes not even then. Acquired immune deficiency syndrome (AIDS) and iatrogenic (transplanted heart) immunodeficiency syndrome are conditions in which opportunistic infections occur frequently, and microorganisms can be seen in the myocardium. However, when the latter are not visible, a specific chemotropic cellular response may indirectly suggest the etiology of the underlying disease.

Myocarditis can be *primary* or *secondary:* it may begin within the myocardium or in other organ's systems. The etiology of myocarditis may be due to identified or unidentified causes (the term unidentified is preferable to idiopathic, especially since adequately equipped laboratories are usually capable of identifying the responsible virus) [42]. The area of involvement, either in interstitial or intercellular, can also help distinguish different types of myocarditis. In our experience (AIDS, Chagas', drug hypersensitivity), SUD is most often associated with the presence of extensive lymphocytic myocarditis. The actual cause of cardiac arrest in most instances remains a matter of speculation. For example, we have frequently observed the coexistence of myocarditis and catecholamine necrosis, suggesting that several different mechanisms were operating at the same time, including destruction (or irritation) of the intramyocardial nerves, which alters sympathetic control and induces arrhythmias.

A causal link between sudden death and limited foci of a few inflammatory cells has never

been established [43]. In the rare instances of diffuse myocarditis, cardiac arrest may be due to myocardial insufficiency consequent to massive interstitial exudation (e.g., acute rejection of a transplanted heart) or other mechanisms involving adrenergic nerves resulting in ventricular fibrillation (e.g., sudden death in Chagas' disease in which diffuse lymphocytic myocarditis and catecholamine necrosis coexist) [44].

It has only recently been discovered that patients thought to be suffering from acute coronary syndrome (ACS) may actually be suffering from a form of myocarditis where the virus exhibits an endothelial tropism. ACS is generally diagnosed by angiography, but angiographic studies of patients with florid symptoms are occasionally negative. When endomyocardial biopsies from such patients are analyzed by nested polymerase chain reaction/reverse transcriptase–polymerase chain reaction, viruses, especially Parvo viruses (PVB19 is not related to the agent infecting dogs) are often detected, even in the absence of the histological changes conforming to the requirements of the Dallas criteria [43, 45, 46]. The true extent of this problem is not known for two reasons: (i) no local medical examiner has the training to perform DNA testing and, even if they did, they do not have the equipment and (ii) more often than not the Dallas Criteria are not applied correctly. In a retrospective review of a large case series, the incidence of myocarditis based upon death certificates was found to be slightly less than 5%, with a higher incidence in males than in females. Just how much weight should be placed in these findings is a matter of important debate because histopathological reanalysis of the same listed with myocarditis in the death certificates demonstrated that only 32% of cases actually fulfilled the Dallas criteria, suggesting that the true incidence of myocarditis may only amount to a fraction of official estimates [47].

Sarcoidosis (2%)

Sarcoidosis is a multisystem disorder of unknown etiology. It is characterized by the presence of noncaseating epithelioid cell granulomas. Many infectious and environmental and genetic factors have been implicated, but none definitely identified [48]. The prognosis and clinical manifestations depend on the location and extend of the granulomatous infiltrates. At autopsy, cardiac involvement has been identified in 20–30% of sarcoid victims. When the heart is involved, a wide range of clinical manifestations are possible (conduction disorder, ventricular arrhythmias, atrial arrhythmias, pericarditis, valvular dysfunction, and congestive heart failure) [49]. However, it is unusual for patients with sarcoidosis to present with isolated cardiac involvement. In one autopsy study of sarcoid patients, cardiac involvement proved to be the cause of death in 37% of the patients [50]. In these cases, SUD is the result of ventricular tachyarrhythmia or conduction block in 25–65% of incidents. Consequently, cardiac involvement is associated with a much poorer prognosis, and the mortality rate may exceed 40% at five years and 55% within 10 years. When the disease is limited to the lungs, the survival rate is much higher.

Aortic Dissection (2%)

The new classification of aortic dissections reported by the Task Force on Aortic Dissection and by the European Society of cardiology [51] is basically a subdivision of the original classifications of Stanford and De Bakey [5]. It distinguishes five classes of aortic dissections: class 5 includes traumatic and iatrogenic aortic dissections (Figure 5).

Endocarditis (1%)

Valvular and endocardial diseases are not common causes of SUD. The frequency with which either disorder is diagnosed varies with each pathologist's practice and with the composition of the population examined [52]. Infective endocarditis involves the valvular endocardium and is associated with infected thrombotic vegetations. Any microorganism or bloodborne parasite has the potential to cause infective endocarditis. In practice, Gram-positive cocci cause myocarditis much more often than Gram-negative organisms and bacteria much more often than fungi. Usually, one organism induces the disease, but sometimes more than one is responsible (superinfection). Nosocomial infections may cause infective endocarditis. Generally, the process involves a single, native, left heart valve (usually the mitral), but multivalvular infections of left heart valves or of both right-sided and left-sided can occur under certain conditions.

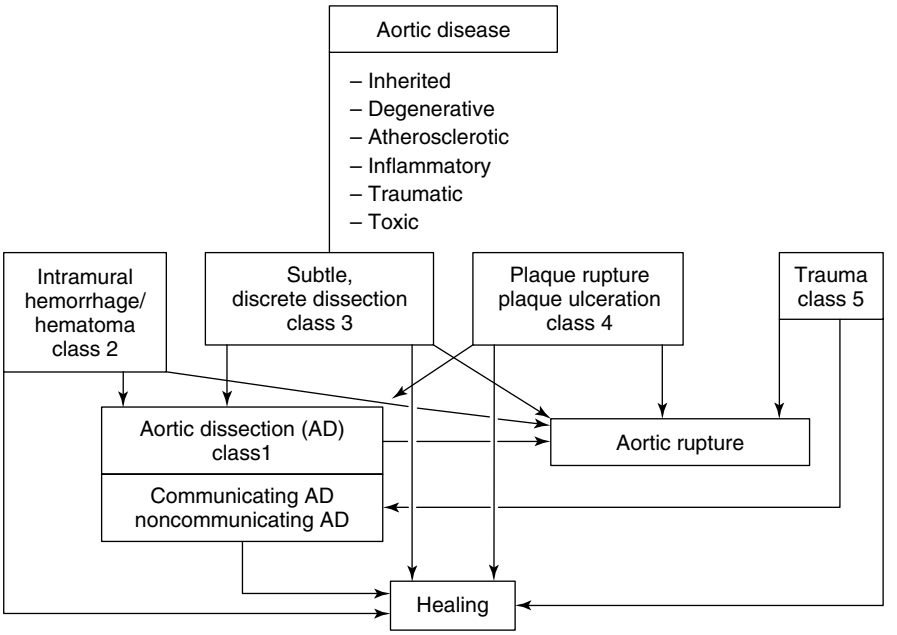

Figure 5 Schematic illustration of different aortic disease aetiologies that can result in aortic dissection including progression or regression of the disease. (Task Force of Aortic Dissection and by the European Society of cardiology [51])

Vegetations attach to the atrial aspect of an atrioventricular leaflet or to the ventricular surface of a semilunar cusp. In both instances, the distribution of the vegetation is related to the lines of leaflet/cusp closure on their flow surfaces. Valvular infection can remain localized to one cusp/leaflet or spread to a contiguous one ("kissing" lesions) or even to the chordae tendineae or papillary muscles. When that occurs, there is a good chance of papillary muscle rupture.

Sometimes, vegetations occur distant from their usual sites. If that is the case, a pathological cause will be usually evident. Microscopically, vegetations are composed of intermingled thrombus, inflammatory cells, and microorganisms; the latter sometimes form colonies. The organisms often, but not always, can be visualized in a Gram or Gomori methanamine silver stain [1].

Both the vegetations and adjacent heart valve display an inflammatory reaction that may be acute or chronic. When an infection has been present for a protracted period, healing changes may be obvious, and portions of vegetations may calcify. Often the valvular pathology found at autopsy provides a plausible explanation for a fatal arrhythmia, for example, the occurrence of myocarditis or myocardial infarction, or annular abscess with damage to the atrioventricular node [53]. In other instances, the cause of death may be impossible to determine.

Floppy Mitral Valve (MVPS) (1%)

In autopsy series the incidence of MVPS ranges from 4 to 5%. Clinical data hint at an incidence of about 2.5%, but even apparently benign cases of MVPS, in young adults, might result in sudden, unexpected death. Such cases are generally not included in hospital-based studies, which may lead to a serious underestimation of the fatal risk associated with the disease [54], and MVPS as a cause of sudden death in the young is almost certainly underdiagnosed.

Gross morphology varies with the etiology of valve prolapse, as will the mechanism of sudden death. When prolapse develops suddenly, for example, following chordal rupture or rupture of the body of an infarcted papillary muscle, then the leaflets themselves may be normal. In these cases, acute pulmonary edema may be the cause of death. In cases of myxomatous degeneration, the prolapsed valve is usually gray-white and thickened, and bulges with

a hooded appearance toward the left atrium. The bulging is best appreciated if the affected valve is viewed from the left atrial aspect before opening the left ventricle.

The endocardium on the surface of the leaflet is usually thickened by fibromuscular tissue, and tiny thrombi may be attached to both leaflet and chordae. Linear thrombi can also be formed at the base of a prolapsed leaflet in the angle between it and the adjacent atrial wall. If the thrombus becomes organized, the angle will become obliterated by fibrous tissue. Cerebral ischemic events prevalent in younger individuals were related to prolapsed mitral valves and such thrombi, but subsequent clinical studies became controversial.

In the late 1990s the first study was published, describing dysplasia of the atrioventricular nodal artery. Careful dissection demonstrated dysplasia of the artery in 18 of 24 hearts with mitral valve prolapse but in only 4 of 16 controls hearts ($p = 0.003$). Since then additional reports have been published and it appears that arterial dysplasia in mitral valve prolapse may contribute to sudden cardiac death mediated by ventricular fibrosis [55].

Coronary Artery Tunneling (Coronary Bridging) (1%)

Myocardial bridging (MB) is a congenital disorder involving a segment of a major epicardial coronary artery that runs intramural (tunneled artery) through the myocardium. The incidence in various reported autopsy series is very wide, ranging from 5.4 to 85.7%. The prevalence also varies substantially in different reports, with a much higher rate of detection at autopsy than with angiography (5–12%). The most frequent site of occurrence is the proximal half of the anterior descending branch of the left coronary artery (60%) [56].

Muscular bridging of right coronary arteries is very rare and more variable both in form and location (2.8–11.4%). The presence of tunneling is usually of no clinical significance, but myocardial ischemia, infarction, ventricular arrhythmia, and sudden death have all been reported, frequently in association with HCM and coronary atherosclerosis.

The clinical significance of MB is controversial and still very much debated. When it occurs, there is systolic compression of the tunneled segment; however, the compression remains clinically silent in the vast majority of cases. Nonetheless, there have been episodic reports of bridging-related episodic angina, tachycardia-induced ischemia, myocardial ischemia, sudden death during strenuous exercise, and malignant arrhythmia.

Angiographically, MB of a coronary artery is demonstrated by rhythmical occlusion of a segment of the artery during every systole that disappears during diastole (milking effect). If patients do become symptomatic, it is probably explained by the fact that during tachycardia diastole shortens more than systole. The literature contains reports of ischemic ECG changes, increased lactate production, and myocardial perfusion defects visible with thallium scintigraphy. An increase in sympathetic drive during stress or exercise facilitates ischemia in these individuals because increased contractility aggravates systolic and diastolic compression [56]. Recently, it has been suggested that exercise increases QT interval duration impairing coronary blood flow to the area perfused by the bridged artery, resulting in ventricular repolarization abnormalities that may increase the risk of sudden death caused by malignant arrhythmias. Repetitive ischemic episodes, even if not symptomatic, may cause patchy myocardial necrosis and fibrosis. The long-term prognosis of individuals with isolated myocardial bridges appears to be excellent, but in some cases they may cause ventricular tachyarrhythmias and SUD.

Right Ventricular Dysplasia (1%)

Arrhythmogenic right ventricular disease (ARVD) is a major cause of sudden death in the young, and it seems to be especially common among athletes. It is a type of cardiomyopathy characterized by the loss of cardiomyocytes with fibrofatty replacement (Figure 6). Three patterns of disease have been identified. In the classic form, there is isolated right ventricular disease with significant functional impairment. Disease may or may not extend to the left ventricle. Alternatively, involvement with the left ventricle may predominate, with early and prominent LV manifestations, such as sudden cardiac death, but relatively mild right-sided disease. In the third form, substantial biventricular involvement is observed. Arrhythmias are associated with all three forms [57, 58].

Both autosomal-dominant and recessive forms exist (the latter is known as *Naxos disease*, where

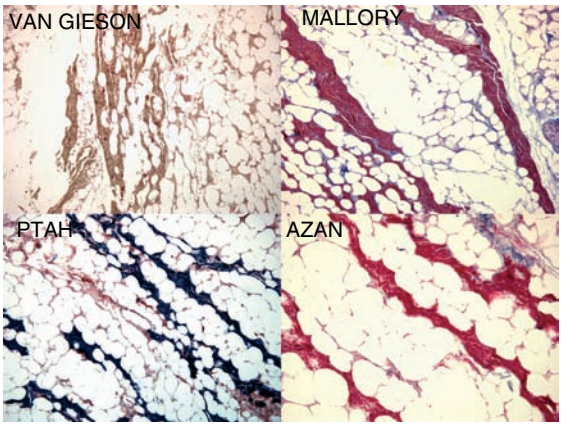

Figure 6 Histological aspect of ARVD: loss of myocytes with fibrofatty replacement (Trichromic stains)

the cardiac changes are accompanied by skin disorders) [59]. The abnormal genes responsible for this condition primarily encode desmosomal proteins, but mutations in the cardiac ryanodine receptor (RYR2) also occur (see above). The abnormal proteins produced are all components of the desmosomal intercellular junction complex responsible for maintaining tissue integrity and. The same proteins also seem to be involved in cell signaling [60].

Rheumatic Mitral Stenosis (1%)

This disorder affects women more than men and, in most instances, only the mitral valve is involved. Only occasionally there is an involvement of both the mitral and aortic valves. Tricuspid involvement is quite uncommon. Gross changes observed at autopsy are the result of organized, minute endocardial vegetations located along the lines of closure. They are formed during acute attacks that induce inflammation in various portions of the valve. This resultant scars distort the valve components. Contributing to the destruction is the deposition and organization of minute thrombi that result from the altered hemodynamics of the distorted valve. Thus, valve damage is cumulative.

The process results in shortened and thickened cusps and leaflets and this causes valvular regurgitation; fusion of the adjacent sides of cusps/leaflets at commissural areas leads to luminal stenosis, the principal change observed in tricuspid stenosis. The result is a diaphragmlike orifice with only minor associated chordal changes; fusion, thickening, or shortening of the chordae tendineae of the mitral valve result in leaflet tethering and valve regurgitation; alternatively, the chordae fuse to cause a mitral subvalvular stenosis.

Thus, a rheumatic valve may be purely stenotic, purely regurgitant, or exhibit both functional abnormalities. The histological features of a distorted valve may vary, but generally, cusps/leaflets are diffusely fibrosed, often with obliteration of their original architecture, and show increased vascularization (small, thick-walled vessels); focal lymphocytic infiltrates are often found, usually near the cusp/leaflet base. Aschoff's nodules, *per se*, are not found in cases that have smouldered for many years, but they are, on rare occasions, observed in the valves of people with active rheumatic or in areas where stenosis developed rapidly.

The secondary morphologic changes most often encountered include valvular, annular commissural, and chordal calcification. These complications are less likely when valvular stenosis developed rapidly. The deposition of ectopic calcium further distorts valve components. If they ulcerate, they may embolize their contents, causing hemolysis, or act as a site of thrombus deposition with subsequent embolization or infection. Occasionally, cardiac fibroelastoma (CPF), otherwise known as "*Lambl's excrescences*", the most common cardiac tumor, may be encountered on a valve distorted by rheumatic fever. Even though the tumor is histologically benign, it can cause life-threatening complications. The tumor is characterized by multiple papillary fronds formed by a central fibroblastic core and is surrounded by a

myxomatous layer and endothelial cells. These may embolize, leading to heart attack and stroke [61].

Anomalous Coronary Artery (0.5%)

Congenital coronary artery anomalies have a statistical incidence of 0.3–0.8% and account for 0.1–2% of all cases of congenital heart disease worldwide. At autopsy anomalous origin of the right coronary artery from the left valsalva sinus is the least common form of the anomaly observed (0.026%). In angiographic studies, the incidence of anomalous origin of right coronary from the left sinus valsalva depends on the population being studied. Although uncommon, this anomaly is frequently associated with SUD [62].

Most coronary anomalies do not result in signs, symptoms, or complications, and usually are discovered as incidental findings at the time of autopsy. Congenital anomalies of the coronary arteries present great difficulties in diagnosis because patients may be absolutely asymptomatic, though rarely the underlying abnormality can manifest itself with syncopal (fainting) episodes or even florid heart failure, which explains why the diagnosis of abnormal coronary artery origin is usually made only at autopsy examination [63].

Ischemia is usually precipitated by strenuous, prolonged effort, and this explains why a basal ECG or even a stress test ECG may be negative. Syncopal episodes are the only prodromal (early, nonspecific) symptoms. Repetitive ischemic episodes may cause patchy myocardial necrosis and fibrosis as well as ventricular hypertrophy, which eventually can elicit arrhythmias because of the malignant combination of acute and chronic substrates. This may explain why sudden death, associated with an anomalous origin of a coronary artery from the wrong sinus, may occur in adults, even though the anomaly has been present since birth.

Anomalous origin of the left coronary artery arising from the pulmonary artery is a rare but serious congenital anomaly, commonly referred to as *Bland–White–Garland syndrome*. It is quite rare and is said to account for approximately 0.25–0.5% of all congenital heart disease. The genetics is neither known nor have any risk factors been identified. Infants with the disease appear normal at birth and then display a typical downhill course. Occasionally, there may be no symptoms until the teenage years, and this is when SUD may occur, especially during exercise. Because the coronary artery is compressed by the pulmonary artery, there may be ischemia and fibrosis, sometimes extensive, is found at autopsy [64]. Fortunately, the diagnosis is easily made with newer imaging techniques.

Coronary Artery Dissection (0.4%)

Spontaneous coronary artery dissection is a rare cause of SUD. Until quite recently, it was thought to be almost exclusively a disease of peripartum period. However, a connection with drug abuse and even exercise is now recognized. More than 50 cases related to stimulant abuse have now been reported. It is speculated that increased arterial blood pressure from cocaine's inotropic and chronotropic effects combined with its direct vasoconstrictive effect leads to increased shear forces on the coronary endothelium [65]. Elevated wall stress may cause an intimal tear and the subsequent dissection of the coronary artery. If the lumen becomes occluded because of the dissection, infarction can result. Presumably the same mechanisms are operative in cases of dissection associated with intense exercise, even in the absence of coronary artery disease [66].

Congenital Heart Disease (0.2%)

In recent decades, because of dramatic improvement in surgical techniques, the types of congenital heart disease associated with SUD have changed significantly. Improved methods of medical control, more aggressive surgery, early surgical correction rather than palliation, implantation of defibrillators, and radiofrequency ablation of arrhythmic foci all have helped to improve survival rates. Severe cardiac malformations are likely to cause early death, and some of these cases will be sudden. Mortality is highest in newborns, especially in the first few days of life, and is due to the ductus arteriosus closing in cases of ductus-dependent malformations, such as ductus hypoplastic left heart syndrome, critical aortic stenosis, complete transposition of great vessels, and aortic coarctation. Mortality and the incidence of sudden death (SD) decrease with survival into early infancy. Cardiac malformations in the newborn are becoming rare in some countries, because diagnoses are now being made in early fetal life. Sometimes termination of the pregnancy follows these diagnoses. Most newborns with malformations diagnosed during

pregnancy are treated at birth and often receive early surgical palliation or corrective surgery. It should be remembered, however, that deaths in congenital heart disease subjects at any age are far more likely to be expected and protracted rather than sudden.

Lipomatous Hypertrophy of the Interatrial Septum (0.2%)

This is another rare disease characterized by the excessive deposition of fatty tissue within the interatrial septum. The reported prevalence in autopsy reports is approximately 1%, although echocardiographic studies of living patients suggest a much higher incidence. It is generally considered a disorder of the elderly and the obese; however, the prevalence of arrhythmias in these patients has been reported to be as high as 40%, and there are rare reports of SUD. Histologic examination shows that this fatty deposition is composed of mature fat with varying quantities of fetal (brown) fat, inflammation, fibrosis, and entrapment of myocardial fibers. The fatty accumulation often assumes a dumbbell shape, easily recognized in positron emission tomography (PET) scans of the living [67].
