Regardless of the elaborate methodology one can apply, in our opinion, this method should never be used alone for individualization because there are several problems which are almost impossible to overcome in the comparison between a structure with soft tissues (face) and a structure made of hard tissue (skull). The method should be used only for excluding identity if gross incompatibilities are present or establishing consistent traits, which, however, cannot lead to a judgment of certainty.

In conclusion, results always need to be carefully examined by an experienced observer. Personal individualization has to be carried out with a set of data, after having carefully evaluated the limits and the possible sources of error of each method.

One last mention should be made concerning the role of the forensic anthropologist in mass disasters [44–49]. Once again, usually forensic pathologists, odontologists, and geneticists are the main figures called in for mass disasters. However, forensic anthropology is increasingly proving to be an indispensable discipline on these occasions, particularly where mass graves (especially in the case of war crimes) are involved, where extremely fragmented or charred remains need to be identified, or in the case of open mass disasters, where the biological profile of each victim may be crucial. The presence of the anthropologist is essential from the very beginning, as has been previously mentioned: disasters such as that of the Mont Blanc tunnel, for example, have proven how important recognition of minute charred remains is at the scene of the disaster. However, the role of the anthropologist can be fundamental also in individualization. Recent articles [48, 49] comment on the role of anthropologists in the identification of victims of war crimes in mass graves, when virtually no medical or dental antemortem data is available and where genetic antemortem samples may be difficult to obtain. Once again, most authors comment that great caution is advised and that frequently individualization is achieved through the combination of history, personal effects, biological profile (sex, age, stature, etc.) and, at times, peculiar pathological traits.

Identifiler

When the 13-core short tandem repeat (STR) loci for Combined Offender DNA Index System (CODIS) entry in the United States were adopted in 1997, scientists were required to use a minimum of two tests to generate this number of results. By 2001 the sophistication of multiplex technology had improved to the point where STR multiplex systems that encompassed the full set of core loci were produced. The 15-locus AmpF*l*STR® Identifiler™ STR multiplex system (Applied Biosystems, Foster City, CA) is one such system and required the addition of a fifth fluorescent dye (PET®) and mobility modifying nonnucleotide linkers to achieve this enhanced level of performance. The enlargement of forensic STR multiplexes to coamplify up to 15 loci provides extremely high discriminating power for unmixed full profile matches. This additional discriminating power is of great practical benefit for resolving complex kinship cases such as those that occur in mass disaster identifications. It also assists to minimize the likelihood of finding adventitious matching profiles on large forensic DNA database systems. The loci typed in the Identifiler™ system are displayed in the image of the allelic ladder in Figure 1.

Image Processing and Analysis

History

From the late 1980s [1, 2], digital forensic image processing was becoming more widely used in court cases to enhance images. For still photographs, it has been used operationally in the United Kingdom at the Home Office Scientific Research and Development Branch since 1984 [3]. Fields where digital image processing is commonly used [2] are CCTV systems, document examination, fingerprint recognition, and photography.

Societies

There exist different societies that encompass forensic image processing. The SPIE [4] working group Investigative Image Processing has existed since 1999, and several conferences and proceedings have been conducted in this field. The American Academy of Forensic Sciences (AAFS) [5] has the Engineering Sciences group and there are ideas to set up a separate Digital Evidence and Multimedia group. For scientific working groups we see the scientific working group IT (SWGIT) [6] which has a liaison with the International Association for Identification (IAI). In Europe, the European Network of Forensic Science Institutes [7] has the Digital Imaging Working group and the Forensic IT Working Group.

CCTV

In CCTV we have seen developments from purely analog systems to the digital systems. For analog systems, several commercial image processing packages were developed for image processing of the video streams.

In CCTV systems, which are similar to the television systems, several standards exist: NTSC, PAL, and SECAM. For example PAL has 25 frames per second, and 50 fields per second. To have the best visual effect, the fields are composed of even and odd fields, such that the movie is more fluent. An example of odd fields and even fields is shown in Figure 2.

Analog CCTV images have to be digitized prior to processing them on a computer. When digitizing the image itself, the image is represented in the computer by a grid of numbers. The number at each grid point indicates the brightness at that point. Often a value of

Figure 1 Example of a frame that is composed of odd and even fields

Figure 2 The odd field of the frame in Figure 1

0 represents black and 255 represents white. In a color image three numbers are stored for each grid point (pixel) to indicate the red, green, and blue values at that point.

In Figure 1 an image is shown with one frame. Here we can see the odd and even lines. In Figure 2 one field of the image is shown. The license plate that is not moving is clearly readable. Here we see a time shift between the odd and even field.

In most packages image processing the next operations are found:

- contrast enhancement;
- edge filters;
- color image processing;
- deblurring; and
- measurements (such as height measurements, which are handled in the chapter).

With contrast enhancement, the information that is already there can be visualized. It is important to understand that there is no more detailed information available in an image than the grid point (pixel) that is visible in the image. For that reason zooming in does not help with a poor resolution of the image itself. This is visualized in Figure 3 with a license plate of a car. The license plate is magnified, and the limitations of the resolution and blur in the image are clearly visible.

There are possibilities to have more information if several images are available. If the target is not moving and there is noise [8] in the image, it is possible to reduce the noise and make the image itself more clearly visible. This is a possibility with a surveillance camera that stands still and captures multiple frames of an object that does not move.

Another possibility is to integrate the images of an object or a camera that moves, the super resolution method. In Figure 4 we have an example of a moving camera with some known number plates in lab environment. The images are registered first and then averaged.

There exist more sophisticated methods for deblurring, such as Wiener restoration, which is commonly used in image processing [9]. The movement and blurring filter of the movement should be known. In Figure 5 we have a known movement of the persons on their bicycles. With the known blurring function,

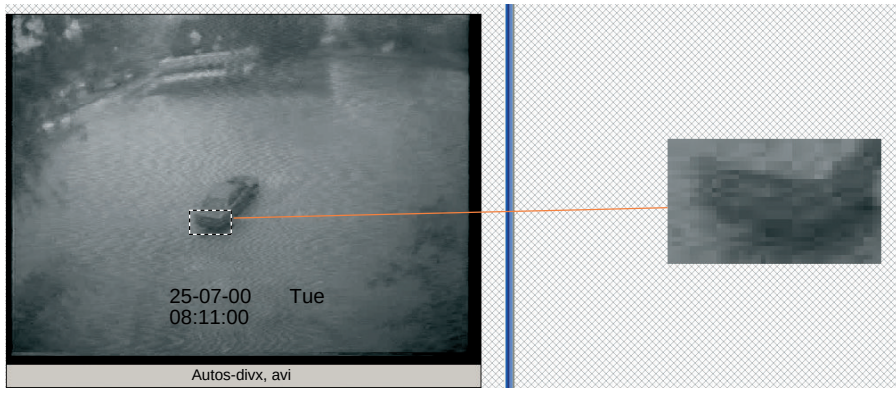

Figure 3 Magnification of a number plate of a car. On the right the selected part is magnified. It is not possible to reconstruct the number plate with this single image

Figure 4 Laboratory experiment: (a) one field, (b) super resolution image, (c) original

Figure 5 Wiener restoration of the field shown in Figure 2. The blurring function is estimated from the velocity of the bicycle

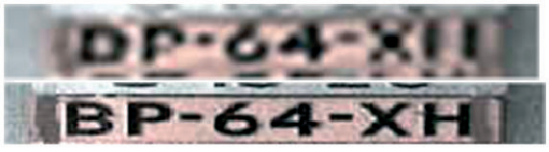

Figure 6 Laboratory experiment: super resolution with number plate in lab

the number plate on the bicycle becomes more clearly visible.

The methods should be interpreted and used with care, especially when there is digital compression in the images, which might alter the images. It is always necessary to validate the results before drawing a conclusion. For validation of test results it is important to have a large enough test set where the ground truth is known. To make a good validation, it is advisable to consult a forensic statistician. In Figure 6 we have an example of a wrong conclusion that could be drawn from these images when super resolution is used improperly.

Digital Compression

In digital systems mostly digital compression is used. For digitizing analog tapes in a forensic setting, it is always advisable to use lossless compression. In real world CCTVsystems band width and hard disk capacity cost money. This means that with compression a file with a size of 1 MB can be compressed (for example to JPEG) to 15 KB. The draw back is that we lose information. An example of images with various levels of compression is shown in Figure 7.

With video streams such as MPEG-2, MPEG-4/3GP, and many others, mostly a "lossy" compression scheme is used which compresses the video also by predicting the next frame. Also with these compression schemes one should be aware that we lose information, and alter the image. Mostly these compression schemes are optimized for the human eye.

Integrity

Questions of integrity are as follows:

- Is a specific image captured with a specific camera?

Figure 7 Different levels of compression. The size is given in the middle with a magnification of the eye under various compression ratios of JPEG

Figure 8 Example of an easy to recognize forged photograph

- With which brand/model has this image been captured?
- Has the image been altered?
- Has the digital compression altered the image?

An example of an easy to recognize forged photograph is shown in Figure 8. How can we see that the image has been altered? We might look at the next properties of the image:

- shadows
- edges
- compression artifacts
- pixel artifacts
- cut and paste artifacts
- light conditions
- noise
- original images if they are available.

When someone manipulates an image in a professional manner (and takes into account the properties above) it becomes nearly impossible to determine if the image has been manipulated. For this reason the chain of evidence should always be considered, in a similar way to other forensic evidence, before drawing conclusion.

Pixel Artifacts

Pixel artifacts can be used to examine

- if a picture has been taken with a certain camera; and
- whether two series of images taken with the same camera can be used to determine pixel artifacts.

Pixel artifacts are defects in the charge coupled device (CCD). Sometimes they are visible in the image itself, and can be used to draw a conclusion as to whether a certain image has been made with a certain camera. In coming to that opinion, it is important to have knowledge of the randomness of the pixel artifacts in a given batch of cameras and their CCDs. Since the manufacturing process of

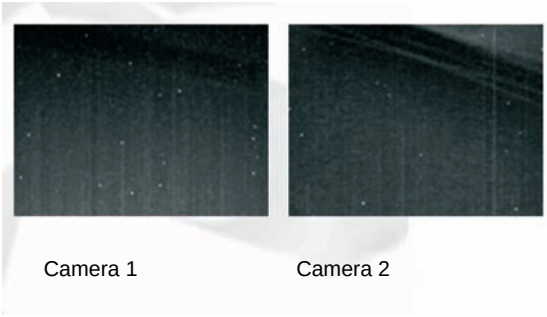

Figure 9 pixel artifacts visualized in images of two different cameras

CCDs is getting more precise, and less pixel artifacts are available, other methods such as measuring noise in the image should be considered. In Figure 9 an example of pixel artifacts is shown in an image with two different cameras. pixel artifacts are not always visible in a given image, depending on the gray level of the pixel and the surrounding pixels in a certain picture. There are methods such as averaging the images to make them clearer.

Determining the photo response nonuniformity (PRNU) [10] is an alternative approach for pixel artifacts. It is one source of pattern noise in digital cameras. An approach for JPEG-compressed images is available for download from http://sourceforge.net/projects/prnucompare/.

Background

A digital image consists of a matrix of image elements known as *pixels*. A digital image is made by means of CCDs or a complementary metal-oxide semiconductor (CMOS). The CCD of a digital camera is a matrix of light-sensitive elements. The light-sensitive elements on the CCD correspond with the pixels in a digital image.

Contamination and disruption of the light-sensitive elements can occur during the manufacture of the CCD. The result of this is that the light-sensitive elements work better or worse than the surrounding elements so that the intensity of the corresponding pixels in the image is always higher or lower than that of the surrounding pixels. These phenomena are known as *pixel artifacts*. Depending on the extent of the contamination this can occur in a cluster form whereby several connected light-sensitive elements become contaminated.

There are several studies [11–14] with various cameras of different manufacturers and with a series of cameras with successive serial numbers of the same manufacturer. Up to now show that the location of (clusters of) defects on the CCD surface are randomly distributed between CCDs. In general the pixel artifacts are clear and can be demonstrated in reproducible tests. As a result of these properties the pattern of pixel artifacts provides a kind of digital fingerprint of a camera.

Header and Footer Information. In a comparative study of digital images it is first checked whether the properties such as the format and header or footer information of the images are similar. Header or footer information of a digital image file is the information that the camera adds to an image file. This can contain information on the settings, the make and model of the camera, etc. This header or footer information is not visible in the images but can be made visible by examining the file itself. It is possible to alter the header and footer information by means of software.

The header information is a block of information that stands in the image file and precedes the block with the pixel values. Footer information stands in the block after the block with the pixel values of the image. This is shown in the graphic in Figure 10. Not all files contain header and footer information however. Files of the type JPEG usually contain header information.

Pixel Artifacts. Each digital image is formed by the actual image, noise, and any pixel artifacts. The

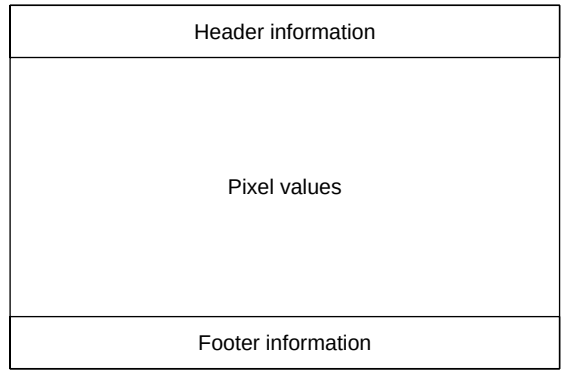

Figure 10 Schematic overview of a file

actual image and the noise differ between the images mutually made by the same digital camera at the same temperature, but the pixel artifacts are present to the same extent.

There are two investigation options:

1. Linking a digital camera to a serie(s) of image(s).
2. Comparing series of images mutually (e.g., by comparing video streams tapped from Internet traffic if the camera is not available).

In the first case, a series of test recordings is made with the camera in question, e.g., of a smooth white, gray, and/or black surface after which this set of images is used as the reference set.

In the second method, a series of images is used as the reference set. In this case, the camera is not available so that it is not possible to perform any test with camera itself.

If sufficient images are available, it is possible to find the pixel artifacts by adding a series of images (pixel by pixel) and to calculate an average. In this way changes parts of the image, the actual image and the noise, are averaged out and the consistent elements of the image, the pixel artifacts, remain behind. A filter such as a median filter, can also be used to increase the visibility of the pixel artifacts.

In some cases pixel artifacts can be seen in an image without any further processing so that only one image can be used instead of a series. It does not, however, follow that pixel artifacts are visible in every image made by the camera. Visibility depends on the object on the position of the pixel, temperature and the lighting of the image, and/or the way in which the image has been compacted.

The positions of the pixel artifacts in the reference set are compared with the positions of the pixel artifacts in the disputed images. Similar positions of pixel artifacts can be strong indication that the images were made by the same camera. Dissimilar positions can be a strong indication that the images were not made by the same camera.

Conclusions. Conclusions about the results of the investigation into pixel artifacts are reported in terms of support for the hypothesis that an image was or was not made by a certain camera. To express the extent of the support for a hypothesis some investigators make a choice from a verbal scale of "no support", "some support", "reasonable support", "much support," and "strong support" in a Bayesian framework.

The conclusions cannot be formulated quantitatively if insufficient statistical information is available to determine to what extent pixel artifacts are actually randomly distributed in the CCD or CMOS.

Comments.

- It is possible to add or remove pixel artifacts artificially by means of image processing software. The conclusions are based on the assumption that the integrity of the images is guaranteed.
- The investigation is based on the assumption that pixel artifacts are randomly distributed. To check this in the case of a specific CCD it is necessary to compare several CCDs of the same production process with each other.

Fingerprints

Several image processing methods are used for processing fingerprints [15]:

- contrast stretching;
- convolution filtering;
- separation of colors;
- dilation and erosion; and
- fast fourier transform (FFT) techniques for filtering regular patterns.

These methods are also used in combination and in local areas of the image. A question that arises when using these methods is if the methods have been validated (so that no information or minutiae are added that does not exist). Furthermore there is interest in new techniques that can be used for fingerprint enhancement with image processing (e.g., wavelet filtering).

The most common image processing methods as contrast enhancements are common knowledge, and do not have the risk of altering an image that minutiae are shown which are actually not there.

It is important to have new image processing methods validated and know what the risks are of these methods. Another issue is that the software that is used should be tested if it really does the image processing function that is requested.

More complicated methods such as FFT can degrade the image in such a way that the data can

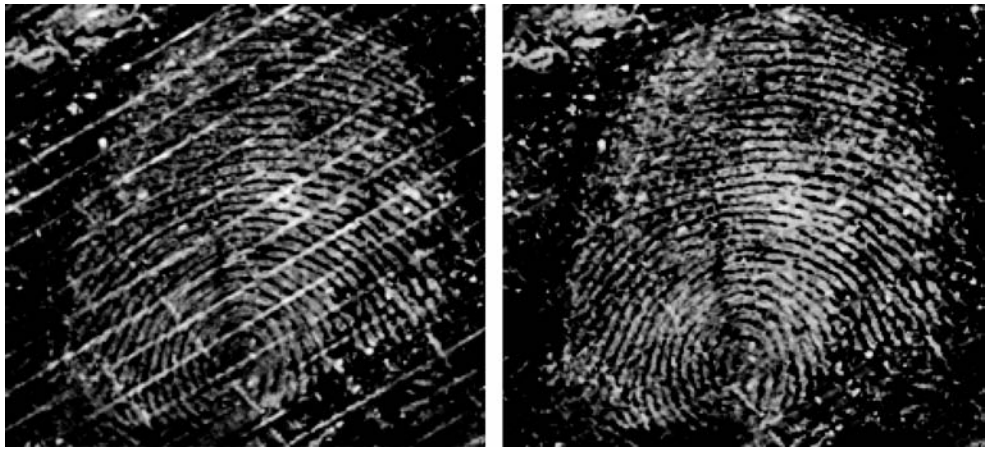

Figure 11 FFT filtering of image: (a) image with regular pattern and (b) filtered image

be altered. In 1994 this was mentioned in literature in 1993 by Watling [16] in 1995 by S. Bramble [17]. Both describe a warning on using the FFT, for instance Watling: "However one must be extremely careful when using the FFT spike boost so as not to cross the line between enhancement and restoration."

In a Daubert hearing in 1998 [18] concerning image processing of fingerprints the methods were accepted in court without much discussion. It even stated:

"The evidence in the record supports the trial court's unchallenged findings that the technique utilized by Berg has a reliability factor of 100% and a 0% margin of error and that the results are visually verifiable and could be easily duplicated by another expert using his or her own digital camera and appropriate computer software."

Which is not in agreement with the earlier publications.

In Figure 11 an example of image processing with FFT is shown. The regular pattern can be filtered out since it has a known frequency.

Documents

With documents color image processing is sometimes feasible. Examples are available from www.4n6site.com. If different colors (for example from different inks) have been used, it is possible to separate the colors and make the handwriting more clearly visible. Also on document image processing early publications suggest the limitations of image processing [19]: "However, the Laplacian filter also produced misleading answers on the other sequence problems."

Concluding Remarks

As mentioned, image processing can be used to enhance an image. This means that the limitations of the final image are limited by:

- the camera with lens system;
- the cabling between camera and recording system;
- the recording device and its settings and properties; and
- the playback device and its settings and properties.

In digital systems it is important to have the same playback software and hardware as where the images have been captured with. Since there exist many different digital CCTVsystems, a collection of players and hardware can help to speed up the examination. Also software can give a different playback results as is shown in Figure 12.

There has been much research in the field of image restoration, however in practice the usage is limited since the blurring functions are often more complicated and not known. Also the human eye compensates for many kinds of blurring functions. Measurement in images should be done with care and with enough validation as is shown in the chapter "Length measurement".

Figure 12 Two test recordings by two different cameras ((a) left camera, (b) right camera), where ten images were averaged. The positions of the pixel artefacts (white dots) are in different places

In Limine Motions and Hearings

The term *in limine* is from Latin and means "at the outset" or "at the threshold".

In US courts – and also in other countries that follow the adversary system of jurisprudence – if, either prior to trial or during a trial, an attorney wishes to challenge an opponent's expert testimony, the attorney can file a motion *in limine* asking the court to exclude the anticipated expert evidence. The predicate for such a motion is that the proponent contends the proposed evidence is inadmissible because it is either of questionable reliability or does not meet either the *Frye*, the *Daubert*, or other proof-of-reliability tests for admissibility. The purpose of the motion is to avoid inserting irrelevant and unreliable matter into a proceeding and thereby causing a mistrial.

The court, if it believes the motion may have merit, will permit the attorneys to present evidence for and against the motion. This proffer of evidence assists the judge in arriving at a reasoned admissibility decision. Hearings on motions *in limine* are always conducted outside the presence of a jury; their purpose is merely to enlighten the judge on the proposed subject matter's admissibility, or, if an advocate believes a judge's decision on the motion is in error, to create a record upon which an appeal can be based.

The moving party – the side filing the motion to exclude evidence – has the burden of presenting supporting evidence. The court will, if the motion is granted, either exclude the forensic expert's testimony or limit its scope.

The practice of filing a motion *in limine*, requesting a special judge ruling on the admissibility of certain evidence, may also be filed by an attorney who proposes to use a certain novel expertise, if that attorney anticipates strong objection to the evidence from the opposing side, and seeks a favorable ruling on the admissibility issue.

Motions *in limine* are most often filed prior to trial, so that when the trial commences, the admissibility issue will have been settled "at the outset" and there will not be any delay of the proceedings while the jury is removed from the courtroom to permit attorneys to argue the evidentiary objections. In some cases, such motions may also be filed and entertained when a trial has already commenced. In such a case, the jury will be removed from the courtroom while the judge hears the evidence on the motion.

Burns

Introduction

The possible findings in burned bodies cover a broad spectrum, ranging from minor, local, superficial burns of the skin to calcined skeletal remains without any soft tissue left and total incineration. The extent of the tissue changes depends on the temperature actually applied to the body, the time for which it is applied, the kind of transmission of the heat to the body, and other prevailing conditions. In most cases, the heat acts on the body beyond death. Consequently, the changes found are largely of postmortem origin. The effects of the heat on the body are burns of the exposed tissue, changes in the content and distribution of tissue fluids, fixation of the tissue, and shrinking processes (Table 1).

The forensic investigation of deaths related to a fire is important to determine the manner and cause of death, the vitality of the findings, and the identity of the victim. The basis of the assessment is a careful evaluation of the autopsy findings. Additional investigations, such as toxicology (e.g., determination of carboxyhemoglobin concentration, cyanide (CN) concentration, and blood alcohol concentration) or histology (particularly of the airways), may help to complete the assessment of the case.

External Findings

Among the externally discernible changes, the various stages of skin burns, the results of tissue shrinkage, and the consumption by the fire are the dominant features. In most fire deaths, the body was exposed after death to temperatures of several hundred degrees Celsius for at least several minutes, often by direct contact with the flames. Destruction may be so extensive that the less experienced tend to consider an autopsy pointless, because in their opinion it will not produce any useful findings. But this is definitely wrong: even charred torsos, with exposure of the body cavities and partial amputation of the extremities, the organs of the thorax, and abdomen, can usually still be assessed quite well, and body fluids

Table 1 Effects of heat on human bodies

Heat effect	External findings	Internal findings
Burns	Skin burns (first- to fourth-degree);	Burn injuries and destruction of internal organs and the skeletal system;
	pseudo-washerwoman's skin on palms and soles;	Edema, hemorrhages and vesicular detachment of the respiratory mucosa
	Singeing of the hair; Consumption by the fire	
Changes of the content and distribution of tissue fluid	Skin blisters	Evaporation of body fluids;
		Rupture of the abdominal wall with prolapse of intestinal loops;
		Exit of blood-tinged, foamy liquid from mouth and nose;
		Heat hematoma;
		Pseudohemorrhages in organs or cavities;
		Accumulation of fat in body cavities, vessels, or the heart
Heat fixation	Leathery, desiccated skin with brown discoloration	Hardening of internal organs and muscles;
		Fragmentation of erythrocytes
Shrinking of tissue	Tightening of the skin;	Shrinking of the internal organs up to the so-called "puppet organs"
	Heat-related tears in the skin;	
	Protrusion of the tongue;	
	Petechial hemorrhages on neck and head;	
	Pugilistic attitude	

as well as tissue samples can be obtained for further investigations.

Burns and Consumption by Fire. Skin burns are categorized into four degrees, with each degree characterizing a certain depth of the skin lesion. The categories are degree 1 (superficial burns), degree 2a (superficial partial-thickness burns associated with necrosis of the upper layers of the epidermis), degree 2b (deep partial-thickness burns associated with necrosis of the entire thickness of the epidermis), degree 3 (full-thickness burns with necrosis involving the dermis as well), and degree 4 (charring in which the heat lesion reaches deeper soft tissue layers). First-degree burns are characterized by a reddening of the skin. As a postmortem residue, a red margin may occasionally be observed. The leading sign of a second-degree burn is a fluid-filled skin blister. Second-degree burns of the palms of the hands and the soles of the feet appear as whitish discolorations of the epidermis associated with swelling, wrinkling, and vesicular detachment up to glovelike peeling. The findings resemble the so-called washerwoman's skin, as seen after prolonged exposure to a moist environment [1]. The skin in third-degree burns is firm and discolored brown.

Heat changes of the hair occur at temperatures above about 150 °C. This can be used to differentiate between burns and scalds or to indicate the approximate temperature on the skin reached in smoldering fires. The hair gets frizzy and brittle and assumes a fox-red or dark brown to black color (Figure 1). Temperatures of about 200 °C lead to the formation of gas bubbles in the shaft, at 240 °C the hair becomes frizzy due to the melting of the hair keratins, and above 300 °C charring occurs. Singeing of the head hair is usually not associated with high flames, but with a characteristic smell. In contrast to this, frizzy hair burns with high, open, and sustained flames, causing

Figure 1 Singening of the hair: the hair is frizzy and brittle and assumes a fox-red color

severe damage to the neighboring skin or mucosa [2]. The explanation for this phenomenon is the larger distance between the individual hairs, which allows better access to oxygen.

The distribution of burn injuries is seldom even and depends on various conditions. Especially, tight-fitting clothes can protect the underlying skin from burns for a long time. In the same way, it may be possible to prove a homicide by manual strangulation in a fire victim with the ligature still in place [3]. In cases of suicidal self-incineration using fire accelerants, burns may be absent from the feet and lower legs if the incineration took place while the body was in an upright position [4]. In burns caused by low heat, deep, anatomically circumscribed signs of consumption by the fire may occur (Figure 2). These are formed when the fire is maintained according to the wick principle: in those parts of the body where the skin has burned away, liquefied subcutaneous fatty tissue leaks out and maintains the fire [5, 6]. The bizarre distribution of the burn lesions in such cases has given rise to the myth of spontaneous human combustion [7, 8].

The question of to what extent the level of charring in a burned body allows drawing conclusions as to the duration of the fire is rarely asked [9]. In the literature there are a few reports on this topic, most of which refer to observations made during cremations

Figure 2 Circumscribed charring and consumption of the soft tissue of the left lower leg by a smoldering fire in a 73-year-old woman

[10–12]. These studies have shown that the course of events follows a fixed chronological order.

Some authors have proposed classifications as a tool to describe the extent and distribution of consumption by a fire [13–16]. According to our experience, the Crow–Glassman scale (CGS, Table 2) [15] is the best usable classification system. There is a clear relation to the scene of the fire. Lower degrees of destruction are found more often in fire victims recovered from buildings, whereas in car fires the extent of consumption by the fire is usually higher owing to the higher temperatures produced by these fires. Massive destruction does not only require higher temperatures but also an especially a longer duration of exposure [12, 17].

Shrinkage of Tissue. The reason why the tissue shrinks is the loss of fluid caused by the heat. Externally, it is characterized by tightening of the skin, splitting of the skin, protrusion of the tongue from the open mouth, petechial hemorrhages in the region of the neck and head, and the so-called pugilistic attitude.

The typical posture of charred bodies is called pugilistic or boxer's attitude with the arms being abducted in the shoulder joint and flexed in the elbow joint and the legs being abducted in the hip joint and flexed in the hip and knee joints (Figure 3). The reason for this phenomenon is the shrinkage of muscles and tendons caused by the heat. The flexion of the joints of the extremities is due to the predominance of the flexor muscles. This may even result in dislocation, most often recognizable at the wrists. In the same way, contracted feet may be observed, especially after advanced consumption of the legs.

Table 2 Crow–Glassman scale (CGS) of burn-related destruction of corpses [15]

Level 1	Second-degree burns, sometimes singeing of the hair; visual identification possible
Level 2	Burns of varying severity, sometimes with thermal destruction/amputation of ears, genitals, hands, or feet; visual identification may still be possible
Level 3	Consumption by the fire with partial amputation of arms and/or legs; cerebral cranium intact
Level 4	Bony lesions of the cerebral cranium; residual extremities still present
Level 5	Fragmented skeletal remains without soft tissue

Figure 3 Pugilistic attitude of a charred body as a result of the heat-mediated shrinking of the muscles and tendons

Splitting of the skin is a frequently observed phenomenon in charred bodies. It is very rare in burns of minor severity. If it appears in such cases, prolonged exposure to the heat has to be assumed. The splits have sharp edges that can be approximated, are often linear, but are occasionally also angled (Figure 4). In most cases they reach the subcutaneous fatty tissue, sometimes also the outer muscle layers. In this context, little attention has been paid to the fact that the tissue exposed in the depth of the splits is usually unburned and often not even sooted. Most likely the splits form during the cooling of the body.

Protrusion of the tongue from the open mouth is due to the heat-related shrinkage of the soft tissue of the neck (Figure 4). In the presence of severe burns on the neck and/or thorax, petechial hemorrhages may

Figure 4 Heat splits of the skin and protrusion of the tongue

occasionally be found in the lids and conjunctivae. For their formation, congestion due to the shrinkage of the soft tissue of the neck by heat or heat rigidity of the thorax while the circulation is still intact is discussed [18, 19]. So petechial hemorrhages in the region of the neck and head would have to be regarded as a vital sign.

Internal Findings

The internal findings in fire deaths are the result of a fixation of the tissue by the heat, processes of shrinking, thermal changes of the content and distribution of tissue fluids, and a rising gas pressure in hollow spaces. After the fire has opened the body cavities, direct burns occur also on the internal surfaces.

The loss of fluid and, after exposure of the body cavities, also the direct effect of the heat cause shrinking of the internal organs, which become firm, hardened, and cooked by the heat (so-called "puppet organs"). The surface of the organs becomes increasingly bosselated (formed into rounded, raised areas or knobs) and is reduced to a spongelike residual structure in the end. The tissue is meanwhile completely desiccated and disintegrates into ash at the slightest touch.

Respiratory Tract. The respiratory tract is the most important organ system for the diagnosis of vitality. Where fire fumes are inhaled, deposits of soot particles will be found. Edema, mucosal bleeding, and patchy or vesicular detachment of the mucosa in the nose, mouth, pharynx, larynx, trachea, and bronchi may be indicative of inhalation of hot gases. Often, increased secretion of mucus is observed in the air passages. This may be interpreted as an attempt to cool the surfaces of the air passages and thus as a sign of vitality, if other causes for the secretion of mucus (bronchial asthma, catarrhal bronchitis) have been ruled out [20, 21]. Damage caused to the respiratory tract by dry heat is limited more to the upper portions [22]. The inhaled hot air is sufficiently cooled down by the mucosa of the airways, so that after exposure to a "normal fire" hardly any changes are found in the medium and small bronchi [20–22].

Vessels. Intensive red discoloration of the intima of the vessels can be regularly observed in fire victims. This finding is the result of hemolysis [23] occurring at temperatures above 52 °C. Already at 48 °C erythrocytes begin to dissolve. If the circulation is still intact, the erythrocyte fragments ("fragmentocytes") can be demonstrated microscopically also in other organs, which has to be interpreted as a sign of vitality [24].

Gastrointestinal Tract. The abdominal wall protects the abdominal organs from direct damage by the

flames for a relatively long period of time. But as a result of the heating of the body, the tissue fluids boil away and the pressure inside the hollow organs and the abdominal cavity builds up, which often leads to the rupture of the abdominal wall and the prolapse of intestinal loops. Consumption of the abdominal wall by the fire further promotes the rupture. In rare cases, heat-related ruptures of the gastrointestinal organs are found, before they were directly exposed to the fire [25].

Bones. The skeleton is damaged by the fire, but it is not consumed completely. Even if it is exposed to a fire with high temperatures over a long period of time, there will usually still be remains to allow macroscopic assessment and successful determination of the species, the body measurements, and the sex as well as to identify skeletal anomalies and the presence of possible injuries [13, 26–30].

At temperatures above 700 °C, complete combustion of the organic substances with incineration and recrystallization of the inorganic matter occurs, which is called *calcination* [31, 32]. The bones are grayish-white and desiccated and disintegrate easily. The surface shows characteristic tears partly reflecting the course of the trabeculae, but often also being irregular in structure.

In charred or calcined bones, a minor mechanical strain may be enough to cause fractures. Especially in fractures localized within charred bone areas, the possibility of artifacts should be considered. But several authors have stressed that injuries sustained during life can be demonstrated even on charred or calcined bones [13, 29, 33].

In the assessment, special attention must be paid to the bony skullcap (Figure 5). In about 33% of all fire deaths, the skullcap is partially destroyed and the interior of the skull is exposed [17], which makes assessment even more difficult. Isolated fractures of the external table are seen especially in those cases where a defined area of the skullcap was in direct contact with the flames [11, 34]. Prolonged exposure to heat causes fractures of the entire thickness of the skullcap with occasional bursting of the sutures of the skull [11]. The tears in the skullcap caused by heat may radiate from a center, but can sometimes also be elliptic or circular in shape or resemble a spider's web fracture [34]. In rare cases, round or oval bone fragments may burst outward. Distinction of this finding from a gunshot injury may be difficult [35].

Figure 5 Skull cap with heat-related fractures and calcination of the tabula externa

Cranial Cavity and Brain. A frequent finding is the epidural heat hematoma. It is not a vital sign, but a postmortem effect due to the shift of fluid from the diploe and the venous sinuses when the skullcap is in direct contact with the flames. Accordingly, charring of the bony skull is usually found above the site of the heat hematoma. It is dry, crumbly, and of brick-red color. Occasionally, it may be surrounded by fat, and in rare cases accumulations of fat without extravasations of blood can also be found in the epidural space. Apart from that, the hematoma is sometimes found to be interspersed with brain tissue when the dura mater is torn as a result of shrinkage by heat [36].

Postmortem extravasates of blood may occur in all cavities of the skull including the ventricles of the brain. But, also in the brain tissue itself hemorrhages can be found as a result of the shrinkage

of tissue with laceration of small blood vessels. In these cases, distinction between postmortem and vital hemorrhages can be particularly difficult [37–39].

When the skullcap is intact, the brain of fire victims is often shrunken, and of a hardened consistency with filled sulci (grooves) on the surface. Dotzauer and Jacob described the finding as "a reduction of the brain volume associated with swelling of the internal matter" [40]. Histologically, condensation of the vessels and widening of the Virchow–Robinson spaces have been described [20, 40]. Again, this finding may be explained as the result of a loss of fluid and does not prove a vital thermal damage to the tissue.

Toxicology

In fire victims, the concentrations of carbon monoxide hemoglobin (CO-Hb), methemoglobin (met-Hb), and CN should be routinely determined in the corpse blood as part of the toxicological investigations [41–44]. Concentrations of more than 10% CO-Hb and more than $0.2\,mg\,l^{-1}$ CN in the blood suggest that fire fumes were inhaled and are to be considered as signs of vitality. A positive result for met-Hb indicates that nitrous gases were formed during the fire and were inhaled. As sole cause of death, elevated concentrations of CO-Hb and CN have to be considered especially in victims showing no or only minor heat changes on the body.

In deaths following flash fires, pulmonary tissue should also be kept as evidence to demonstrate the use of fire accelerants [45, 46]. As these substances are volatile, it is advisable to store the samples in airtight containers and to investigate them rapidly by means of headspace capillary gas chromatography mass spectrometry (GC-MS). A positive result for fire accelerants in the pulmonary tissue is also regarded as a sign of vitality.

Diagnosis of Vitality

Autopsy and Toxicological Findings. The signs of a vital exposure to the fire are summarized in Table 3. External signs that the body was exposed to heat when the victim was still alive may be the absence of burns and/or soot deposits in the corners of the eyes (so-called crow's feet), incompletely singed eyelashes, which result from squinting the eyes and, under certain conditions, petechial hemorrhages in the conjunctivae [18]. However, these findings are usually discernible only if the body was not, or was only slightly, consumed by the fire. As this is rare in deaths due to heat exposure, the internal findings are much more important than the external findings.

The most important constellation of findings to prove that the victim was alive during a fire is the combination of a CO-Hb concentration above 10% and soot deposits in the respiratory tract, the

Table 3 Signs of vitality after exposure to fire fumes versus heat

Exposure to fire fumes	Exposure to heat
Macroscopic findings	
Soot deposits in the airways	Crow's feet, incompletely singed eyelashes
Soot deposits in the esophagus	Skin blisters
Soot deposits in the stomach	Vesicular/patchy detachment of the pharyngeal mucosa or epiglottis; edematous swelling of the epiglottis; vesicular/patchy detachment of the upper esophageal mucosa
Histological findings	
Soot deposits in trachea and bronchi	Vesicular detachment of the tracheal and bronchial mucosa; pseudogoblet cells; massive secretion of mucus; nucleic elongation and palisade arrangement of the mucosal epithelium in trachea and bronchi; hyperemia and edema of the tracheal and bronchial mucosa
Toxicological findings	
CO-Hb concentration >10 %	
Cyanide concentration $>0.2\,ng\,ml^{-1}$	

esophagus, and the stomach [21] (Figures 6 and 7). In fact, these parameters show only whether the victim was exposed to *fire fumes* while alive; they are not indicative of vital *heat* exposure. Consequences of an inhalation of hot gases may be edematous swelling and vesicular or patchy detachment of the mucosa in the pharynx, the larynx, and/or the upper section of the esophagus [21, 24].

Although there is a certain relation between the vitality parameters of soot aspiration and CO-Hb, there is no reliable correlation [47, 48]. Deposits of soot in the airways should never lead to the premature conclusion that the victim died of intoxication by fire fumes. Soot particles may, under certain circumstances, occur in the respiratory tract also if burning was exclusively after death. On the other hand, the absence of soot in the respiratory tract does not allow drawing the conclusion that exposure to the fire occurred after death. Authors have pointed out repeatedly that the signs of vitality may be partly absent in cases of undoubtedly vital burning [14, 16, 21, 43, 49–52]. The significance of one vitality parameter alone is therefore limited.

Figure 6 Soot aspiration as a vital sign [Reproduced from Ref. 21. © Elsevier, 2003.]

Figure 7 Soot deposits in the esophagus as a vital sign [Reproduced from Ref. 21. © Elsevier, 2004.]

Histology. The histological signs of vitality are also summarized in Table 3. Histological examination of the respiratory tract is especially valuable to demonstrate changes due to the inhalation of hot gases. However, it should be remembered in this context that certain findings, e.g., nucleic elongation and palisade arrangement in the epithelium of the respiratory tract, may also be due to postmortem effects of heat on the body. On the other hand, other findings such as hyperemia and edema of the mucosa of the respiratory passages as well as

interstitial and intra-alveolar pulmonary edema are unspecific. Detachment of the mucosa from the epiglottis, the trachea, and the bronchi may also be due to autolysis and decomposition, although rarely in the vesicular form characteristic of thermal effects [20, 24]. The histological parameters should also be assessed only in context. According to our experience, the combination of pseudogoblet cells, increased secretion of mucus, and vesicular detachment of the epithelium is highly indicative of vital effects of heat on the respiratory system [21]. Histological findings of the pulmonary tissue in cases of rapid death may be acute congestion, interstitial and sectional intra-alveolar pulmonary edema, acute emphysema, as well as microthrombi.

Determination of the Cause of Death

The issues of vitality and cause of death are closely linked. For example, a high CO-Hb concentration in corpse blood supplies information both regarding the cause of death and the vitality. Apart from the signs of vitality, the absence of other causes of death is an essential condition for the conclusion that death was due to the fire. The diagnosis of a fire to cover up a homicide requires the presence of fatal injuries inflicted by another person *and* the absence of the classical parameters of vitality [33, 53–55].

The presence of mechanical lesions or severe pathological findings together with (seemingly) absent vital parameters may cause diagnostic problems. While in the presence of potentially fatal injuries (e.g., polytrauma following car accidents) perimortal burning has to be discussed, differentiation between peracute death due to the effects of heat and purely postmortem burning may be very difficult. In cases of this type, the CO-Hb concentrations in the corpse blood may be below 10%; the oral, pharyngeal, and laryngeal mucosa may show no heat damage; and there may be no soot aspiration. The most likely pathophysiological mechanism is a fulminant shock [24, 56–60]. But in some cases, the questions regarding the cause of death and the vitality cannot be answered definitely [14, 21, 47, 48].

Scalds

Scalds are the result of the effect of moist heat, usually hot water and/or steam, while scalding by other hot liquids, especially hot oil, is a comparatively rare picture to be examined in forensic practice. As the thermal conductivity of water and steam is much higher, they produce worse injuries than dry heat even after short exposure, as from the very beginning the actual skin temperature is considerably higher with moist heat and moist heat penetrates to deeper layers of the tissue much better than dry heat [61–64].

An actual skin temperature of 44 °C is regarded as the lowest temperature needed to cause damage to the skin; at this temperature, a second- to third-degree scald would be reached after an exposure time of 6 h [61–63]. Between 44 and 51 °C, a temperature increase of 1 °C reduces the exposure time needed for a certain degree of skin injury by half. Above 51 °C, there is no convective heat transport via the skin capillaries any more and the heat penetrates into the deeper tissue layers.

External Findings

Typical for the effect of moist heat is a uniform injury pattern of all the affected skin areas with sharply demarcated edges. Pouring a hot liquid over the skin may produce a streaklike trickle pattern. Scalds due to immersion are characterized by a straight, horizontal burn pattern corresponding to the level of the liquid. With tight-fitting clothes, the underlying skin areas may often be spared from scalding. As the temperatures applied by moist heat are usually lower than those of dry heat (water boils at 100 °C), moist heat does not produce fourth-degree skin burns (charring), heat-related exposures of body cavities, or amputations.

Internal Findings

The internal findings are unspecific. They are consequences of the shock associated with scalding [24], which can also be regarded as the cause of death. The phenomena seen after the inhalation of hot steam have been extensively described in the literature for deaths following a boiler explosion [24].

If hot steam is inhaled, the temperature hardly declines along the air passages, so that a direct thermal damage may occur even in the peripheral parts of the respiratory tract [22]. For differentiation between hot steam and dry air, the so-called “pleura sign” can be used at autopsy. If hot steam was inhaled, the parietal pleura is reddened, whereas the

Figure 8 Fourth-degree burns in a 52-year-old worker after explosion of an acid tank

costodiaphragmatic angles are pale [24]. In deaths caused by the effects of dry heat, this sign is absent even if the circumstances suggest a fire with high temperatures.

Child Abuse

Scald injuries in infants and small children are no rare events. Between 5 and 14% of the scalds occurring in children are claimed to be due to physical abuse. In scalds due to immersion, this percentage ranges probably even between 12 and 55% [65]. In all cases, it is therefore essential to clarify whether the injuries were caused by another person or could be the result of an accident.

If there are discrepancies between the localization and shape of the scalds on one hand and the given history of their origin on the other, if it is denied that they were caused by heat, if it is claimed that they were caused by other persons below the age of criminal responsibility, if pain during or after the injury is played down or denied, or if no doctor is consulted or is consulted only after a delay, all this may be indicative of child abuse.

Chemical Injury

Skin burns by chemical substances are rarely mentioned in the forensic literature. They are more frequently described under clinical aspects and occur mainly as household and industrial accidents. Chemical burns of the respiratory and gastrointestinal tract are seen both in accidents and suicides involving the intake of acid and alkaline solutions. Occasionally, child abuse is committed by forcing children to drink such substances.

The extent of the damage depends on the type of the substance taken, its concentration, amount, and time of exposure. The effect continues until the agent is removed or neutralized. Essentially, the damage is caused by coagulation (acid) or colliquation (alkaline solution) of the tissue. Alkaline solutions (most of which with a pH > 11) often produce worse injuries than acids (most of which with a pH < 2), as they liquefy the tissue and this process is not limited by protein precipitation.

Chemical injuries can manifest themselves as first- to third-degree burns. In exceptional cases they assume the appearance of fourth-degree burns (Figure 8).

As with scalding injuries, the internal findings away from the affected regions are due to shock reactions and thus unspecific.

MICHAEL BOHNERT

Ink Analysis

The Different Classes of Inks

The inks most commonly encountered on documents today are writing inks and printing inks [1, 2]. Writing inks can subdivided into at least four classes – the thick (high viscosity) inks such as those used in ballpoint pens; the fluid (less viscous) inks such as those used in rolling ball, porous plastic nib, extruded plastic tip, and felt/fiber tip pens; the gel inks; and other inks such as erasable, "dry erase", and crayon inks.

Printing inks can be divided into at least two classes – those used in impact printers such as printing presses and typewriters and those used in nonimpact printers such as desktop printers, photocopiers, and thermal printers. Those used in printing presses include offset, intaglio, letterpress (typographic), gravure, and flexographic inks while those used in desktop printers include ink-jet inks and laser jet "inks" (toners). The toners used in laser jet printers are also used in photocopiers. Black and white desktop printers use black toners while color desktop printers use color toners (usually cyan, yellow, magenta, and black, also referred to as *CYMK*).

The General Composition of Inks

All inks, including those that date back hundreds of years, consists of a colorant or mixture of colorants in a vehicle (sometimes called *a carrier, a base*, or, *in printing inks*, *a varnish*). The colorants in fluid writing inks are dyes (dyes, as opposed to pigments, are soluble in the vehicle). The colorants in viscous writing inks are mostly dyes but may include some pigments, particularly carbon black (pigments are dispersed in the vehicle). The colorants in gel ink writing were originally colored pigments but now are a combination of colored pigments and dyes.

The colorants in printing inks are pigments dispersed in a vehicle except in at least the following cases: some color ink-jet printing inks contain both dissolved dyes and dispersed pigments; some typewriter ribbon inks contain dyes mixed with the pigment carbon black in a thick slurry; and thermal printers use ribbons containing thermal dye deposited on a film (the printing process is referred to as *thermal dye transfer*).

The vehicle or carrier of any ink consists mostly of a solvent or mixture of solvents and other components. For example, ballpoint pen inks contain solvents like 2-phenoxyethanol or benzyl alcohol or a mixture of these along with resins that thicken the ink (resins give "body" to the ink and assist in making the colorant adhere to the surface). They may also contain other components, albeit at a much lower level, such as humectants or corrosion inhibitors. Ballpoint pen inks consist of approximately 25% dyes, 50% solvents, and 25% resins.

In printing ink technology, the resin is sometimes called the *binder* and one of its functions is to get the colorants to adhere to the substrate (e.g., paper). Some binders are film-forming resins such as ethylcellulose and nitrocellulose (used in screen printing inks) [3]. Some minor (i.e., low concentration), but critical components of printing inks are the drying agents.

The Reasons for Performing Ink Analysis

The forensic scientist analyzes inks for at least three reasons:

1. to determine if two inks are the same or different (and if they are the same, how rare or common the ink is);
2. to determine the origin, source, or manufacturer of an ink; and
3. to determine the date of an ink (either when that ink was first produced or, ideally and much more difficult, when that ink was placed on a document).

All these determinations, except one, require the use of reference standards. The one exception is when inks being compared are found to be different.

Of the three determinations, the most commonly performed is the comparison of inks; however, the one has received the most attention due to its difficulty is the dating of inks, particularly writing inks. There are three progressively difficult levels of doing this.

The first is to determine the "date" of the ink by following when major changes in ink formulations first occurred (e.g., the introduction of glycol-based ballpoint pen inks, of copper phthalocyanine dyes in ballpoint pen inks, of water-based inks, and of gel inks). For this, the ink is compared with reference standards representing historical changes in ink production. One often consults a table of such historical changes [1].

The second is to determine the first manufacturing date of the ink or when certain components were first used in ink. For this, the ink is compared with a comprehensive collection of reference standards (discussed below).

The third, and most challenging level, is to determine when the ink was placed on a document. One approach to estimate the age of a single ink entry is to compare the ink with itself before and after inducing age (e.g., by heating). Another way is for the questioned ink to meet a stringent, but important requirement; namely, that it be on a document bearing ink entries of known dates and made with the same ink formula as that of the questioned ink. If this is met, then one can determine the relative age of these inks and, depending on the known dates of the other entries, find date bounds that bracket the age of the questioned ink. Both the *estimated age of a single ink entry* and the *relative age of inks entries* (of the same formula and on the same paper) are discussed below.

The Need for Reference Standards

On the basis of the discussion above, not much can be done (other than to say that two inks are different) without the use of reference standards. For writing inks, dried samples of different formulae can usually be distinguished by a set of established analytical procedures [4, 5]. Samples of different batches of the same writing ink are normally indistinguishable by this set of procedures. This is because the manufacturing of writing ink requires strict adherence to its formula (recipe); any deviation can cause the ink to fail in its performance (e.g., in the way the pen writes). Writing ink formulas are also meant to be stable over the average lifetime of their use, particularly if they are in a container such as a cartridge. However, such inks tend to "age" (fade, decompose, etc.) after they are placed on paper, exposed to the elements. Andrasko and Kunicki [6] also observed that some aging (ink drying and dye decomposition) occurs near the tip of a ballpoint pen. For nonwriting inks, particularly for ink-jet inks, thermal printing inks, and toners, the same approach of collecting different formulations is normally taken for building reference collections.

There are two types of reference standards: requested standards and acquired standards. Requested standards are those that are obtained from ink manufacturers through formal requests and acquired standards are those obtained from pens, ink samples, etc., acquired, for example, from stationery stores, businesses with promotional pens, or personal collections of pens or pen writings. When requesting samples of different ink formulas from the ink industry, one always asks about the existence of formula variations via component substitution and, if

any exist, requests to see these samples if differences can be found at the forensic laboratory level (using the established set of analytical procedures).

The forensic laboratory of the United States Secret Service has the largest collection of reference samples of writing ink formulas in the world. It is known as the *International Ink Library*. Yearly, this laboratory solicits samples of new, improved, or changed ink formulas from the ink industry in the United States and most of those abroad. As of 2007, the collection consisted of over 8500 inks. It consists of four parts: the *company files* which contain manufacturing information such as the first date of production of inks; the *ink samples* which may be in bulk, in cartridges, or in writing; the *scribble sheets* which contain the dried ink on paper; and the *thin-layer chromatograms* (TLCs) which separate their dye content.

It is critical that this collection be maintained up to date in order to make forensically significant statements about what a match between a questioned ink and a standard reference ink means [4, 5]. If a questioned sample, for example, is matched to a reference standard, then one cannot eliminate the possibility that the questioned sample is the same as the reference standard. By a match between A and B is meant that their analytical profiles (determined using a given set of analytical procedures) are indistinguishable.

Features That Do Not Tend to Change with Age

Ink formulas in closed systems (e.g., cartridges) tend to be stable over the lifetime of the ink's use. Once they are exposed to air and allowed to dry, certain features change with age (covered below), but others such as their elemental profiles, optical properties, and certain colorants are more resistant. The dried inks on the scribble sheets are sufficiently stable to be used for comparisons (their stability is nevertheless periodically checked). The established set of analytical procedures used to distinguish these inks [4, 5] provides the *analytical profile of these inks*. These profiles consist of three parts: the *physical*, the *optical*, and the *chemical features* of the inks. The physical features include the type of ink (i.e., one determines whether the ink comes from a ballpoint pen or a nonballpoint pen), a feature readily determined by observing the appearance of a written line under magnification. The optical features include the ink's color, near infrared absorbance, near infrared luminescence, and ultraviolet fluorescence. The chemical features include the ink's thin-layer chromatogram viewed under visible light, ultraviolet radiation, laser illumination (with filtered viewing), and in the near infrared luminescence mode.

There are two levels of TLC examinations: the library search level (level 1) and the higher resolution level (level 2). The first involves TLC plates that are highly reproducible (due to their low sensitivity to changes in ambient or developing chamber conditions), but, as a trade of, have low resolution. These are used for developing the fourth part of library (the TLCs) and for searching the library for matches via plate-to-plate comparisons. The second involves TLC plates that are highly discriminating (high resolution), but are also sensitive to external changes. These are used to further discriminate inks that were indistinguishable at the library search level; this is done via within-plate comparisons.

To address the comparison, sourcing, and dating of an ink using a collection of reference standards, one first obtains a (level 1) analytical profile of the ink (this requires removing inks for TLC examination). This profile is compared with those from inks in the collection. All those that match (i.e., are indistinguishable) are further sorted by removing additional sample from the questioned ink and from the scribble sheets corresponding to the matching standards and performing the level 2 examination in a single plate. If a single match is found, the questioned ink is said to bear the same characteristics (at the given level of examination) as the matching standard and, therefore, cannot be eliminated as being that ink. The match approaches an identity as the collection becomes more complete and the set of analytical procedures become more discriminating. If there is information from the manufacturer of a unique component (that no other ink has), then the match is an identity. The unique tagging of inks assists in this endeavor [1].

Features That Tend to Change with Age

Once ink is exposed to the elements, then, like paints, they begin to dry [7, 8]. This drying process primarily involves the evaporation of solvents, but it can also involve the oxidation of resins, the penetration of the ink into the paper, and possibly other interactions

of the ink with the paper's chemistry and physics. Overtime, there could also be natural degradation of ink dyes or degradation induced by heat or light.

Aginsky [9] found that inks that contain high boiling solvents and a binder such as a resin (even at low levels) have the property that their solvents do not readily evaporate. In essence, as such an ink dries via solvent evaporation, it thickens and its solvents evaporate more slowly. Thus, solvent evaporation along with ink setting is the major aging process in ballpoint pen inks that is currently extensively studied. This drying process affects several measurable features (aging parameters) such as how much ink solvent remains in the ink, how much ink solvent is extractable into organic solvents of varying strength, and how fast and to what extent the ink dyes are extractable into weak extracting solvents. The section below summarizes some of these and those due to dye degradation. It should be noted that these can be used for determining the *relative age of inks* (where several inks of the same formula and on the same document are compared for their age) and the *estimated age of a single ink entry*; the latter usually involves the accelerated aging approach (where two samples of the same ink, one of which is heated, are compared).

To be useful (e.g., for comparing inks of different age), these measurements must have no dependence on the amount of ink sampled. One way of achieving this *mass invariance* is to take ratios of measurements (e.g., measurements of the same sample at different wavelengths, retention times, temperatures, etc.) each of which depends linearly on the same amount sampled [2]. Furthermore, to determine if two inks are of the same or different age, one needs to make multiple measurements, average these, and use *statistical methods* such as *significance tests* to determine if there are significant differences between the two means (averages) or not [1, 2].

Sketch of Some Ink Aging Parameters

Aging Process: Solvent Evaporation plus Ink Setting

Extraction of ink volatile components into a solvent

- Vehicle-to-dye and vehicle-to-vehicle ratios [10].
- Percent extraction of solvents into a slow extracting solvent (compute difference between an unheated and heated ink specimen, each followed by a fast extracting solvent and the results are ratioed in such a way that a percent extraction into the slow extracting solvent is obtained) [9, 10]. Comment: This mass invariant method is the one most studied and used by Aginsky. To estimate the age of an ink, he implored the induced aging approach using heat.
- Amount of solvents extracted into a fast extracting solvent (compute percentage of solvent loss when comparing an equally sampled unheated and heated sample) [9–12]. Comment: Gaudreau and Brazeau [12] modified this Aginsky method by removing the ink sample from the cuvette before sampling the extract (i.e., the cuvette is free of the sample). This method is not mass invariant so equi-sampling is imperative.

Direct measurement of ink volatile components

- Thermal desorption of ink solvents (using solid phase microextraction SPME) [13, 14]. Comment: Andrasko [14] used a SPME holder as his thermal desorption device and used it to characterize inks. This simple device can also be used to make mass invariant measurements for example, by measuring the same sample at two different temperatures and taking a ratio of these.

Extraction of ink (or of individual dyes) into a weak solvent: [1, 2, 7, 8, 15–17]

- Rate of extraction
- Extent of extraction
- Time to extract X% (e.g., 90%) of ink (or a dye) Comment: The changes that this approach measures cease after three to four years while those of the mentioned above cease after one to two years.

Extraction of nonvolatile and noncolored vehicle components

- Solvent extraction [10]
- Thermal desorption using SPME [18]. Comments: Bügler *et al.* [18] characterized inks via their resin (which volatilize at high temperature) and solvent components; however, it can also be used to make mass invariant measurements (see comment above regarding the use of SPME by Andrasko [14]).

Surface reflectance vs. subsurface reflectance using polarizing light microscopy [11]

Comment: This surface vs. subsurface reflectance phenomenon is based on the ink drying (solvent evaporation).

Discoloration of ink when exposed to gaseous organic bases [10]

Comment: In this reversible phenomenon, as the ink ages (solvent evaporates) the ink becomes more resistant to discoloration.

Ratio of infrared peaks [19]

Comment: The changing infrared peaks involve the OH, CH, and CO groups and are believed to be from the evaporating solvent. For the ink studied, the ratio of these changes seems to cease after 10 to 20 years.

Aging Process: Dye Decomposition

Follow the demethylation process

Crystal Violet → Methyl Violet → Tetramethyl Para Rosaniline → others. Comment: Using high performance liquid chromatography (HPLC), Andrasko [20, 21] observed dye degradation for inks exposed to light, but also for inks stored in the dark (albeit the rate is slower). Using desorption ionization mass spectrometry (MS) Grim *et al.* [22–24] explored similar changes. Other who have applied desorption ionization MS include Weyermann *et al.* [25] and Ifa *et al.* [26] who basically used it to characterize inks.

Ink Comparison and Interpretation

Introduction

The forensic examination of ink is usually performed for identification, comparison, or dating purposes [1–6]. The identification and the comparison processes aim at inferring the identity of the source [7] of an ink specimen, while the dating exercise focuses on the determination of the time of a particular entry on a document. The dating process is not a straightforward one and was discussed by many [8–14] and is still the subject of research. It is not the topic of this article, which focuses on comparison and identification of ink in forensic science.

The distinction between the identification and the comparison processes lies in the number of sources that are considered during the examination:

- The identification process aims to determine the source of a questioned specimen from a reference library [15]. In this process, a large number of potential sources are considered in a first step. On the basis of chosen characteristics of the questioned specimen, one (or several) control samples, similar to the questioned specimen, is (are) selected from the library. Information, which was collected on this (these) control sample(s), is then used to provide intelligence information in the course of the investigation.
- The comparison process endeavors to assess if a questioned specimen ink originates from one or a restricted number of particular sources [16]. In this process, a few sources are considered and the weight of the evidence represented by the (non-)differentiation between the questioned specimen and the control ink is evaluated and reported, usually for Court purposes.

Most of the principal techniques developed in the field of analytical chemistry were or are used to analyze inks in the forensic context. Recommended techniques focus on the detection and comparison of dye components and are described in [15, 16]. Other techniques focusing on the various components of inks, such as dyes, pigments, solvents, resins, preservatives, binders, surfactants, etc., were reported [17–19]. Neither the identification, nor the comparison process necessarily favors any of the various analytical techniques.

Definition of the Source of an Ink in the Forensic Context

There are several ways to define the source of an ink. They all depend to a great extent on the structure of the ink commercial market. The market is influenced by two phenomena: (i) emergence of new suppliers and new products and (ii) cost savings:

1. In the past decades, demand for writing instruments has generated an explosion of ink formulations, each of which may contain dozens of chemical components. In addition, the appearance of products manufactured in emerging

economies, in traditional Western markets, certainly contributes to the diversity of available ink formulations.

2. The very same increasing demand and globalization effect have pushed ink producers and writing instrument manufacturers to adopt highly efficient manufacturing processes to minimize production costs and maximize profits. In the last decade or so, many writing instrument manufacturers have merged or were bought by other companies. Notwithstanding, it is now very common for the inks and for the different components of writing instruments to be manufactured by different, unrelated and independent producers, which are also driven by economic factors. Ink producers are tempted (i) to minimize the development costs of an ink formula by selling batches of ink from the same formula to different writing instrument manufacturers and (ii) to reduce the production costs of a given ink as much as possible by replacing components of this ink formula with similar but cheaper ones if available. This is done providing that this manipulation does not affect the characteristics of the ink that are important to writing instrument manufacturers.
   Conversely, instrument manufacturers, influenced by market prices, might be tempted to put different inks in a given brand/model of instruments during the production life of a model as new, but cheaper, inks with the required characteristics become available.

Forensic ink examiners are hence faced with a considerable diversity of combinations between ink formulations and writing instrument brands/models when attempting to identify the source of questioned ink specimens. This variety is certainly an asset from the point of view of a forensic investigation; however, it renders the maintenance of ink databases and the interpretation of forensic ink analyses very challenging. Attempts have been made by some manufactures to introduce chemical tags in the composition of their ink, in order to identify them [20, 21]. However, the process was never really adopted by manufacturers because of costs and, in return, was never very successful because of the low adoption level among manufacturers.

From the description of the ink market, it can be seen that the source of an ink can be defined in various ways. The definition of what "source" is required (e.g., manufacturer, instrument) in a particular circumstances, impacts on both the comparison and the identification processes. In both processes, the meaning intended by the "source" defines the degree of detail of the answer provided by the examiner at the end of his examination. In an identification process, the significance given to the source of an ink constrains the construction of databases by defining precisely which control sources need to be referenced. In the comparison process, it defines the level of information on the ink market that needs to be available to the examiner (e.g., the number of manufacturers producing ink with the same formula, the number of production batches indistinguishable from each other, and the number of instruments carrying ink indistinguishable from each other).

Traditionally, the following meanings are attributed to the concept of source in forensic ink examination:

1. The source can be defined as an ink formulation. The demonstration of the identity of source of ink samples in this context is purely a matter of qualitative identity (i.e., the similarity of the intrinsic characteristics of the samples [7]) and is demonstrated by the nondifferentiation of the characteristics of their composition. In the identification process, samples from the different ink formulations need to be referenced in ink collections.
2. The source can be defined as an ink manufacturer. The demonstration of the identity of source of ink samples in this context is performed in two stages; at first the qualitative identity between the samples is confirmed, then the identity of the manufacturer is inferred from information such as the number of ink manufacturers using the same formulation, the size of their respective production, the geographical area, or the market shares of instrument manufacturers supplied by them, etc. In the identification process, samples from all the inks produced by the ink manufacturers need to be referenced. All changes of any ink component by any of the manufacturers need to be recorded in ink collections.
3. Since claims of the possibility to measure batch-to-batch variations have been reported [22–24], the source can also be defined as a particular production batch. The definition of the source of an ink sample is, in this context, a refined

situation of the definition in (2) above. The identity of source is inferred following the same logical path as before. At first the qualitative identity of two samples is demonstrated. In a second stage, the identity of the production batch is inferred. This inference takes into account the number of batches that remains identical to each other when using the considered analytical technique to detect batch-to-batch variations. In this situation, samples from every batch from all manufacturers need to be referenced in ink collections for identification purposes.

4. The source can be defined as a brand/model of writing instrument. As in (2) and (3) above, the identity of source of two samples is inferred from the qualitative identity between the two samples and from the information available on the number of instruments of this particular model/brand that contain an identical ink. The constitution of ink collections in this situation is far more complex than for the three aforementioned cases. Samples from all brands/models need to be collected. This needs to be performed only once in most situations. However, should the ink composition of any of the brand/model change, a new sample for that brand/model needs to be referenced.
5. Finally, the source can represent a particular instrument. As for (2), (3), and (4) mentioned earlier, the identity of source is inferred by demonstrating the qualitative identity between the two samples and from the number of writing instruments that have an ink similar to the samples and are available at the time when the questioned document was created. The constitution of reference collection, in such situation, would obviously prove to be impossible in an identification context, since one would have to sample every writing instrument during the manufacturing process.

Ink Identification

More practically, in ink identification, the source of a specimen is normally defined as the brand/model of an instrument as in (4) mentioned earlier, although information regarding formulation (as in 1) or the manufacturer (as in 2) is also often reported. The number of ink available to consumers has a direct consequence on the establishment and maintenance of ink collections. Furthermore, the possibility, either of writing instruments of different brands to have the same ink or of writing instruments from the same brand/model to have different inks, is decreasing the efficiency of the ink identification process. Most of the time, it appears impossible to obtain, retain, classify, and search exhaustive information on all of the brands/models of writing instruments and on their corresponding ink formulations, at any given time of their production lifetime. The very few reference ink collections, which have been set up over the past decades, prove to be far from exhaustive, although the size of some of them can be quite impressive [8, 25, 26]. Nonetheless, despite these difficulties, ink collections are still maintained and their technology upgraded [27]. Recent search simulations have shown a high identification rate for randomly selected specimen inks [28] and demonstrated that these collections are very useful tools to forensic investigations.

Ink Comparison

In a first step, the ink comparison process aims at verifying the qualitative identity of two ink sample. Such qualitative identity is based on the level of concordance of the characteristics of the samples and the possibility to explain the discordance between them. Modifications of inks on paper due to environmental conditions have been reported [13, 15, 16, 29–35] and needs to be taken into account when assessing the qualitative identity of two ink samples. This can be achieved empirically, or statistically by assessing the likelihood of the qualitative identity for a set of environmental conditions.

In a second step, the comparison process aims at weighting the evidence represented by the qualitative identity of two samples. It should be noted that in most cases, the absence of qualitative identity leads the simple rejection of the hypothesis that the two samples originate from the same source. The comparison process usually considers the source of an ink as being a particular instrument, as in (5) above. Obviously, the ideal result of the comparison process would be to link the questioned ink to the sole writing instrument under consideration to the exclusion of all others. Unfortunately, such a goal is unrealistic. While, in most cases, demonstrating the qualitative identity between ink from a questioned entry and an alleged source is a rather straightforward process,

linking writings on a document to a single given writing instrument, to the exclusion of all others, can only be achieved using some sort of statistical inference. Indeed, with respect to context in (5), modern mass-production processes result in the production of hundreds of thousands of writing instruments containing inks with the same properties, which, at first, cannot be ruled out as being the source of the questioned writings.

For example, a particular batch of ink may fill 100 000 pens. Every one of those pens would contain exactly the same ink, and thus it would be impossible to say that one of them was used to write the questioned document to the exclusion of all 99 999 others on the basis of the sole analysis of ink evidence. The evidential value notably depends on the total number of writing instruments produced containing similar inks. The weight of the evidence represented by a link established between a questioned ink specimen and a control ink, which was produced in a very small amount and used to fill only 100 000 pens, is more informative than a similar link, established between a questioned specimen and a blue ball-point pen that was manufactured at several million exemplars.

No frequency study has ever been reported on the availability of the various inks. From the structure of the ink market, it appears that data on the specificity of given inks is difficult to obtain. Indeed, a frequency study performed on a given market would not necessarily be representative of the structure of another geographical market and the measured frequencies are likely to vary significantly in time. Furthermore, the need to be able to measure, store, retrieve, and compare ink data at different times and locations requires a quality assurance system that is not available at the moment [27]. Finally, a frequency study would only provide a broad estimation of the specificity of a considered ink in a given case, since the evidential value really depends on the availability of the ink to the potential writers, at the time of the creation of the questioned document.

Since the specificity of the considered ink would need to be determined in every case, the last evaluative stage is usually not performed at all [16].

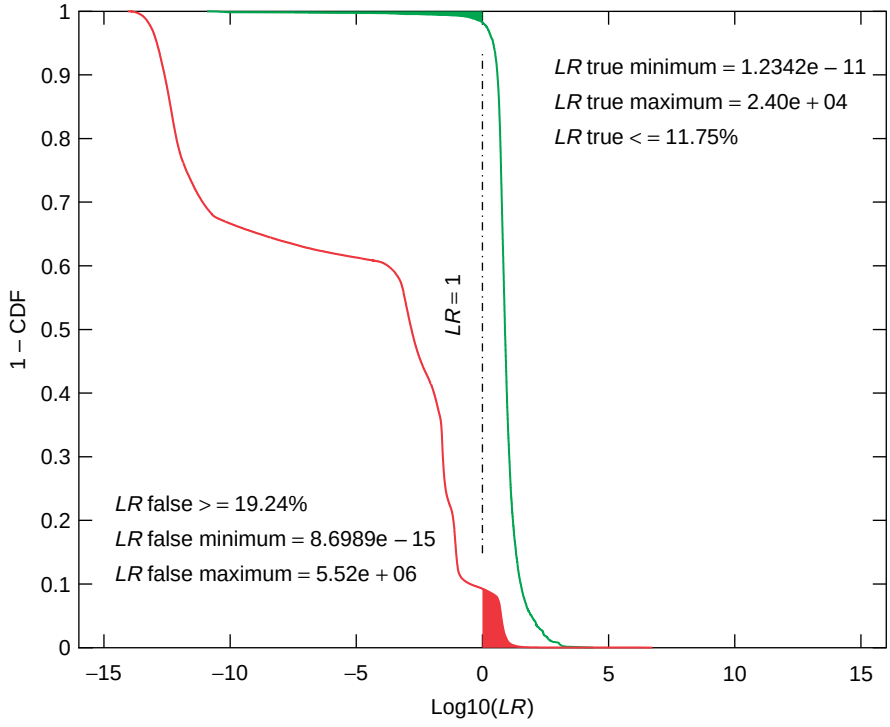

Figure 1 Simulations of the evidential value of a BIC® ink under various environmental conditions. It is possible to observe that the green curve is close to the separation line likelihood ratio ($LR = 1$), indicating a weak evidential value

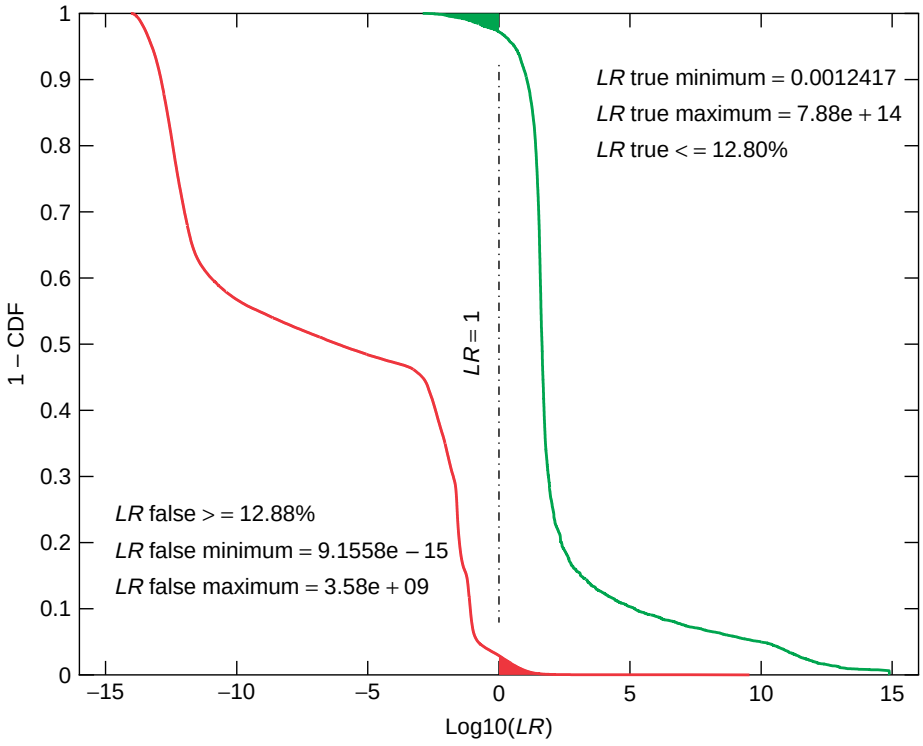

Figure 2 Simulations of the evidential value of a Pentel® ink under various environmental conditions. It is possible to observe that the green curve is located further away from the separation line ($LR = 1$), indicating, as a result, a generally higher evidential value

Thus, the result of a comparison between a questioned ink and a given writing instrument is reported as the (non-)differentiation of their respective chemical profile.

In very few cases, is it useful to define the source of an ink as in (1), (2), (3) or (4). However, in these contexts, the value of the information provided by the ink examination is limited given the number of corresponding instruments that can be considered.

Conclusion

Forensic ink analyses have been performed routinely for the last hundred years. Nevertheless, little has been written on the interpretation of the outcome of forensic ink analysis. The complexity of the relationships between ink producers and instrument manufacturers, reinforced by the rapid evolution of these relationships, has prevented the collection of exhaustive data. While such data could be used to inform probabilistic framework for the interpretation of ink evidence, such as the widely accepted likelihood ratio framework [36], the current absence of these data let forensic ink examiner with no other choice than to report the (non-)differentiation of questioned and control ink samples. Nonetheless, recent technological improvements, such as the digital acquisition and automatic comparison of ink data, render the collection and comparison easier, at different times and locations of these data [27]. This technology allows identifying ink specimen more efficiently and also the constitution of specific frequency datasets for the evaluation of ink evidence in comparison processes. The use of such technology already shows promising results. Indeed, simulations demonstrate that it is possible to measure the individual specificity of different inks, while taking into account environmental conditions (Figures 1 and 2).

Insanity *see* Temporary Insanity

Insanity: Defense

Criminal laws in Western society are designed to identify those persons who should be held responsible for actions contrary to societal rules and subject to appropriate punishment. This concept is well entrenched in our moral codes and appears in early biblical and philosophical writings. From a legal perspective, how to codify those factors that exculpate one's responsibility for criminal conduct raises important issues. For example, a person who unintentionally hits another person in the midst of a violent seizure does not seem to warrant criminal sanction. Similarly, a two-year-old girl who scratches her 14-year-old brother should not be punished in the same way as when her older brother commits a similar act. In these scenarios, the legal system recognizes that not all actions call for legal determinations of guilt or identical subsequent punishments. The question of how the law might draw the line between those who are found responsible for their actions and those who are not the subject of great debate and central to the concept of the insanity defense [1].

Under United States law (which has its origins in British common law), to be found guilty of criminal conduct, one must have committed an illegal act, also referred to as an *actus reus* combined with the *mens rea*, or guilty mind, that accompanies the act [2]. Without a finding that both elements were present at the time of the crime, the defendant should not be held legally responsible. The Not Guilty by Reason of Insanity (NGRI) defense stands for the proposition that although there are some individuals who have committed an *actus reus*, they are not blameworthy because their mental illness prevents them from forming the requisite *mens rea*. Therefore, the appropriate response for such persons is treatment rather than punishment.

Although the public may believe that the insanity plea is an "easy way out" of the criminal justice system, the defense is infrequently raised and rarely successful. For example, the insanity defense is raised in less than 1% of all felony cases [3] and in the United States, on average, defendants are found NGRI only one out of every four times the defense is raised [4]. Furthermore, individuals who are found criminally insane are typically involuntarily committed to a forensic psychiatric facility for an indefinite period of time. Although the criteria for release from the hospital into the community are defined by each jurisdiction, the person's risk of future dangerousness is generally a significant factor in deciding whether or not he or she is appropriate for release.

Insanity Tests

Different legal standards of insanity have been proposed in an attempt to define when and how a person's mental illness should legally excuse their criminal acts. One of the earliest standards arose from the case of *Rex v. Arnold*,, in which Justice Tracy held that for a man to be found insane he must be "totally deprived of his understanding and memory, and doth not know what he is doing, no more than an infant, . . . a brute, or a wild beast . . ." [5]. Under this stringent test, the individual has to be so mentally disturbed that they do not even know what they are actually doing.

Subsequent cases decided by the English courts proposed other operational definitions for insanity.

One such case involved Mr. James Hadfield, an Englishman charged with treason after he attempted to shoot King George III while the King was entering the theater. Mr. Hadfield had the delusion (*see* **Delusions**) that God was going to destroy the world unless Mr. Hadfield killed the King and then was sacrificed through a legally sanctioned execution. At his trial, Mr. Hadfield's attorney, Thomas Erskine, argued for a finding of insanity. Lord Erskine proposed that the test of insanity should take into account whether the act was the "offspring of a delusion", rather than the act of a person who was like a "wild beast" and had lost total control [6]. This successful defense resulted in Hadfield's acquittal by reason of insanity and the subsequent passage of the Criminal Lunatics Act of 1800; one of the earliest legislative efforts to articulate aspects of the insanity defense [7].

In the aftermath of the Hadfield case, a new test for insanity arose from the trial of Edward Oxford. In 1840, Mr. Oxford was acquitted on grounds of insanity after he had attempted to assassinate Queen Victoria. The instructions to the jury indicated that Mr. Oxford should not be held responsible if a "controlling disease" made him unable to resist his actions. This standard became known as the "*Irresistible Impulse" insanity standard*, though its consideration was not limited to "impulsive" or sudden acts. Under this standard, a person could have the cognitive faculties to know what they were doing and the wrongfulness of their actions, but nevertheless be found "insane" because their mental disorder resulted in their inability to resist the impulse to commit the crime [8].

The United States briefly adopted the "Irresistible Impulse" standard in the mid-twentieth century in the Federal housebreaking case of Monty Durham [*Durham v. United States*, 214 F.2d 862 (1954); see also as amended in *United States v. Brawner*, 471 F.2d 969 (1972)]. The Durham standard proved controversial, and critics pointed out that there seemed to be no way to distinguish between an "Irresistible" impulse that was or was not resisted; thus, it could be argued that any action actually taken was, by definition, irresistible. Many jurisdictions still have a component of this standard, and mental health practitioners apply clinical data to help the court in its determinations on the issue of one's capacity to conform conduct at the time of an alleged criminal act based on symptoms of mental disease or defect.

One of the most famous and widely adopted tests of insanity is known as the *M'Naghten rule*. Daniel M'Naghten was a Scottish wood turner who attempted to murder Sir Robert Peel, a prominent leader of the Tory Party whom Mr. M'Naghten believed was persecuting him. By mistake, Mr. M'Naghten shot and killed Peel's secretary. At his trial, Mr. M'Naghten was found NGRI. Owing to the resulting public outrage, Queen Victoria ordered the 15 Law Lords of the House of Lords to compose a new, and presumably, more stringent standard. The result of their efforts became known as the *M'Naghten standard*, which stated the following:

> "To establish a defense on the grounds of insanity, it must be proved that, at the time of the committing of the act, the party accused was laboring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing; or if he did know it, that he did not know he was doing what was wrong" [9].

The M'Naghten test is often referred to as a "*cognitive" test of insanity* because it specifies that the person will not be found insane if they know the nature and quality and wrongfulness of their acts. Some jurisdictions have modified this test by substituting the words appreciate, understand, or distinguish the word "know".

In contrast to the more stringent M'Naghten standard, the New Hampshire case of *State v. Pike* (1869) formulated an insanity standard known as the "*product test*". This test is significantly more lenient than the M'Naghten standard and reads, "No man shall be held accountable, criminally, for an act which was the offspring and product of mental disease" [10]. The product test allows a defendant to be found criminally insane if their behavior results from their mental disease, even if they knew their actions were wrongful. The product test has not received broad acceptance and is the insanity standard only in New Hampshire and the Virgin Islands [11].

In 1955, the American Law Institute (ALI) produced the Model Penal Code, which also included a proposed insanity test. This ALI insanity test includes both a cognitive and volitional prong and reads as follows:

> "A person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the criminal conduct or to conform his conduct to the requirements of the law" [12].

Although the ALI test of insanity was utilized by federal courts and approximately half of the states during the 1980s, the acquittal by reason of insanity of John Hinkley for his attempted assassination of President Ronald Reagan resulted in sweeping changes in both the federal and state statutes. As a result, many states eliminated the volitional prong from their insanity defense and returned to the stricter M'Naghten standard. In 1984, Congress passed the Insanity Defense Reform Act, which resulted in a new federal test of insanity that closely resembles the original M'Naghten test. Under this test, a person is not criminally responsible, if "As a result of a severe mental disease or defect, he was unable to appreciate the nature and quality or the criminality of his acts" [13].

Assessing Criminal Responsibility – The Forensic Interview

When preparing for an evaluation of a defendant's criminal responsibility, the expert should first clarify if he or she is appointed by the court or retained by the defense or prosecution. Although the examiner should always strive for honesty and objectivity regardless of whom has retained him or her, opinions rendered by a psychiatrist hired by the defense are not always disclosed to other parties. Before proceeding, the evaluator should carefully review the relevant statute as well as any case law that interprets the statutory language. The expert should also request collateral records to include police reports, witness and victim statements, booking and jail records, past psychiatric and medical records, police records of prior crimes, educational and work records, as well as audio or videotapes of confessions and 911 telephone tapes. Other evaluator's opinions may also assist in reviewing the consistency of the defendant's presentation. However, the examiner should first determine if any prior psychological examinations are prohibited from their review.

An evaluation of criminal responsibility involves an assessment of the defendant's mental state at the time of their alleged offense. Therefore, the evaluator should schedule their examination as soon as possible in order to observe the defendant's mental status in close proximity to the crime. Prior to conducting the evaluation, the defense attorney should be notified of the impending interview. In some situations, the defense attorney may request to be present during the assessment and may obtain a court order allowing them to do so. If this situation occurs, the evaluator should request that the defense counsel should not interrupt the examination or instruct the defendant how to respond to questions.

Prior to beginning the interview, the evaluator should inform the defendant who requested the evaluation, that the assessment is not confidential, that they are not acting as the defendant's treating psychiatrist, and that the defendant's statements may appear either in a written report or in deposition or court testimony. The evaluations may be audio or videotaped but such recording is not mandatory unless required by the court.

The examiner typically takes a broad bio-psychosocial history, which may be important to understand the defendant's background leading up to the instant offense. Key areas to review include past psychiatric history and prior hospitalizations, family psychiatric history, educational history, any history of learning disabilities or mental retardation, and the defendant's social and relationship history, particularly as related to any of their crime victims. The defendant's drug and alcohol history is also critically important, particularly during the months and days leading up to the instant offense. Finally, understanding the defendant's prior legal history can assist in determining if the defendant has a pattern of criminal behavior that may be unrelated to the presence, if any, of a psychiatric disorder.

Taking the Defendant's Account of the Offense

In assessing criminal responsibility, an evaluator generally begins by asking open-ended questions related to the alleged offense(s). Sample questions may include statements such as "Tell me what happened" or "What were you thinking and feeling before, during, and after your alleged crimes?" Through this technique, the examiner encourages the defendant to communicate their own thought processes regarding how the events unfolded. The examiner follows with more detailed questions that review the events in the weeks, days, hours and minutes leading up to and including the offense.

Rather than simply obtaining an account of "what happened", however, the evaluator must also determine if the defendant had a mental disorder at the

time of the offense and the relationship, if any, of the mental disorder to their criminal acts.

With regard to specific lines of inquiry, the evaluator typically asks questions to assess whether the defendant understood the nature and quality of his or her behavior at the time of the crime. For example, the evaluator might ask the defendant to explain what he was specifically thinking with regard to each action that comprised their criminal behavior. When evaluating a defendant's knowledge of wrongfulness, the examiner should review steps that the defendant took to plan and prepare for the crime as well any evidence to suggest that the defendant attempted to escape or avoid detection. Specific efforts to avoid detection that suggests knowledge of wrongfulness includes wearing gloves or a disguise during a crime, concealment of a weapon, waiting until the cloak of darkness, threatening to kill the witness if they go to the police, and giving a false name or alibi when questioned by the police. Examples of hiding evidence that indicate a knowledge of wrongfulness include wiping off fingerprints, washing away blood from the crime scene, destroying documents, or hiding a body [14] [15].

Although the above actions may suggest the defendant understood that their actions were wrongful, the evaluator should specifically query the defendant as to his or her understanding of both the legal and moral wrongfulness of their behavior. For example, this inquiry might include questioning a defendant as to why he threw a gun down a gutter or disposed of gloves that he was wearing. If the defendant responds that he threw these items away because he knew the police might arrest him, this answer might signify that he understood that his actions were legally wrongful. If, however, the defendant also describes a delusional belief that he needed to kill his neighbor in order to save the world from evil forces and was attempting to avoid arrest to continue this moral crusade, his psychotic beliefs may also render him unable to know the moral wrongfulness of his acts, despite his understanding that his behavior might be misinterpreted as wrongful by others.

Specific evidence that the defendant understood his actions were wrongful include statements by the defendant to the examiner that he knew his actions were wrongful at the time of the crime, notifying the police that a criminal act had occurred, and expressions of remorse or guilt immediately following the crime. At some point during the examination, the evaluator should ask questions such as "At the time of the crime, did you know that what you were doing was against the law?" or "Was there anything that made you think that what you were doing was a right thing to do?"

In those insanity tests that include a volitional prong, the assessment of the defendant's ability to conform their conduct or to resist a criminal impulse may be more challenging. First, if a defendant's mental disorder renders them unable to know their actions are wrongful, he or she may have no reason to actually conform or alter their conduct. In assessing a defendant's ability to refrain from criminal behavior, Rogers [16] has suggested examining the defendant's capacity to delay their actions, plan, organize, to consider alternatives, and to act differently in the face of potential negative consequences. Another method to assess a defendant's ability to refrain is sometimes referred to as the "*policeman at the elbow" test.* Under this line of questioning, the defendant is asked if they would have changed or stopped their behavior if a policeman was nearby, i.e., at their elbow. In general, individuals, who would stop their behavior if a policeman were to come on the scene, demonstrate the capacity to conform their conduct to the law should they choose to do so [3].

A defendant's account of an alleged offense is a retrospective account, and one that may be obtained at any point after an alleged offense. Therefore, the information the defendant provides may be a distorted or a self-serving account of what actually occurred. For example, a defendant who acted while floridly psychotic may have some confusion regarding their recollection of what he or she was thinking and feeling at the time. Even if a defendant describes events in their entirety and with a solid understanding of their symptoms, the evaluator must attempt to incorporate collateral data to help gain a fuller picture of what the defendant may have actually been experiencing.

Forming the Sanity Opinion

There are three important areas to review when rendering an opinion on a defendant's criminal responsibility. First, the evaluator must establish if the individual had a mental disease or defect at the time of the crime. The expert should determine what mental disorders qualify for consideration of insanity

through reviewing the governing statute and relevant case law. Psychiatric illnesses characterized by psychotic symptoms or significant cognitive impairment are the most common types of mental disorders that reach the threshold for consideration of the insanity defense. In some jurisdictions, certain disorders are specifically excluded and may include all personality disorders or antisocial personality disorder. In addition, voluntary intoxication alone may also be excluded as a qualifying mental illness. The examiner should become very familiar with detecting signs of malingered mental illness, particularly faked hallucinations or delusions [11].

Secondly, the expert evaluates whether or not there is a relationship between the defendant's mental symptoms and their alleged criminal actions. It is important to specifically review the motive for the defendant's behavior as well as their thoughts and feelings before, during, and after the crime. The evaluator should also screen for the presence of a rational alternative motive, such as stealing money for drugs or killing someone in a jealous rage. Such motives are often unrelated to the person's mental illness and generally exclude the person from further consideration of an insanity defense if they are the sole driving force for the criminal behavior [11].

Finally, the examiner must apply the relevant insanity test when evaluating the relationship between the person's mental disorder and their alleged acts. Under a M'Naghten test of insanity (i.e., cognitive standard), the evaluator reviews if the defendant knew what they were doing or understood that their actions were wrong, even if they had a qualifying mental disorder. Consider the case of a paranoid schizophrenic who burns down their neighbor's home because they believe the neighbor is demon possessed and is casting spells that would soon destroy the world. Despite their mental illness, this defendant may have understood that they were starting a fire to burn an inhabited dwelling (i.e., the nature and qualify of their acts) while at the same time believed that their actions were right because they were saving many lives from demonic destruction. Some jurisdictions allow consideration of insanity if the person's mental disorder resulted in the belief that their actions were morally justified, despite knowing that their actions were wrong in the eyes of the law.

When applying volitional tests of insanity, the examiner must carefully review if the person's mental disorder rendered them unable to control their behavior, even if they knew their actions were wrongful. Evidence that may indicate that the defendant had the ability to refrain includes stopping their behaviors when detected by someone during the course of the crime or deferring their actions until a more advantageous opportunity arises [11].

Summary

The insanity defense is based on the premise that some mentally ill individuals are not legally culpable due to their underlying illness and therefore should not be criminally punished. Tests of insanity have evolved over time and vary significantly by jurisdiction. Evaluators must conduct a careful retrospective analysis of the defendant's mental state at the time of the offense and use available collateral data to determine whether or not the defendant meets the specific test of insanity.

Introduction

The literature dealing with the interpretation of "printed" documents is very limited. An article published by Souder [1] first highlights a theory of probability applied to two imaginary typewritten documents.

In general the absence of published literature reflects the absence of formal guidelines to help a scientist in assessing the relationship between a questioned document and a printing technology. Everything is left to the expert's judgment based on his experience or by invoking the random nature of a set of observations. This lack of formal guidelines is well exemplified by the following quote:

> Therefore, although all such marks on two photocopies may not much, a reasonable number that can be easily superimposed, by the use of either photographic transparencies or a comparison projector, is clear proof that the same machine has been used in the production of both. Their random nature indicates that chance match is extremely unlikely [2], p. 160.

With the massive availability of different printed documents, the forensic document examiner is more than even faced with the obligation of identifying different printing technologies. Detailed information about the identification of the printing technologies is beyond the scope of this article and the reader should refer to the specialized literature.

Generally every printout, independently from the printing technology, may present manufactured characteristics and acquired characteristics (individual characteristics). The manufactured characteristics may be defined by the type of ink (or printing material) used and the morphology aspect of the printout under the stereomicroscope. The manufactured characteristics refer to *class characteristics*, in the sense that all printed documents issued from a specific technology will share the same characteristics. For example, all the electronic typewriters equipped with a Brougham 10 daisy wheel will share the same class characteristics such as font design, size, and spacing.

Individualization intervenes when we can demonstrate that every object belonging to a defined class can be distinguished from the others on the basis of individual characteristics, provided that these exist. Individual characteristics are also described as acquired characteristics. This second definition is more elegant because brings in the notion of time. Indeed, time and usage of a certain object can provoke unique accidental deformations allowing its individualization.

It is obvious that the origin or the source of every manufactured or acquired characteristic should be carefully identified and explained. To simplify the reading, the author will focus the interpretation of printed documents on two technologies: typewriting and electrophotography. Table 1 lists a number of manufactured and acquired characteristics that may be encountered within the above-mentioned printing technologies.

A logical approach to help the scientist in the formal interpretation of such evidences is to assess the results in a likelihood ratio (LR) format. The main advantage of this approach is to invite the scientist to consider his results in the light of at least two

Table 1 List (not exhaustive) of manufactured and acquired defects encountered within typewriting and electrophotography

Printing technology	Manufactured characteristics	Acquired characteristics
Typewriting	Types of printing	Misalignments
	Typebar	Horizontal
	TypeBall	Vertical
	Typewheel	Rotational
	Design, size, and spacing of typeface	Typeface defects
Electrophotography	Roller marks	Random defect from the glass platen
	Types of toners	
	Single or bicomponent	Repetitive defect from
	Organic composition	OPC drum
	Inorganic composition	Fuser rollers
		Grabbing rollers
		White divots [3]

propositions. The following three examples aim to show the application of this approach.

Typewriting Example

An anonymous letter was typewritten with a mechanical typewriter having a 254 spacing and a cubic type font design. According to the limited questioned material, the exact cubic font type could not be identified. The letter "p" has a broken bulb defect that has been identified by the expert as an acquired defect. Indeed, in order to interpret these findings properly, the examiner should exactly understand the mechanical causes of the "p" defect. A mechanical typewriter showing the same manufactured and acquired characteristic is seized. The question is what the evidential value of this correspondence? To approach this question, there is the need to define the results, the propositions at hand and assign the LR.

- Define the evidence results $E = (E_1, E_2, E_3)$ as
  E_1: mechanical typeface with 254 spacing,
  E_2: cubic typeface, and
  E_3: acquired defect on letter "p".
- Define the propositions H_p: hypothesis for the prosecution and H_d: hypothesis for the defense:
  H_p: the seized typewriter is the origin of the anonymous letter and
  H_d: another typewriter is the origin of the anonymous letter.

The population defined by the generic term "another typewriter" is dictated by the case circumstances. In this case, it could be any other typewriter including all kind of type font and type printing mechanism. The LR becomes

$$LR = \frac{\Pr(E_1, E_2, E_3|Hp)}{\Pr(E_1, E_2, E_3|H_d)} = \frac{\Pr(E_1|H_p)}{\Pr(E_1|H_d)} \times \frac{\Pr(E_2|E_1, H_p)}{\Pr(E_2|E_1, H_d)} \cdot \frac{\Pr(E_3|E_1, E_2, H_p)}{\Pr(E_3|E_1, E_2, H_d)} \quad (1)$$

$$LR = \frac{\Pr(E_1, E_2, E_3|H_p)}{\Pr(E_1, E_2, E_3|H_d)} = \frac{1}{f_{Mechanical\ \&\ 254}} \times \frac{1}{f_{Cubic|Mechanical\ \&\ 254}} \cdot \frac{a}{b} \quad (2)$$

A search into the "TYPE" database [4] allows knowing the frequency of mechanical typeface having a 254 spacing (= 13%, there are 622 mechanical typefaces out of a total of 4683 typefaces) and using a cubic typeface style (= 3%, there are 22 mechanical cubic typefaces).

The probability a must be evaluated considering the reproducibility of the acquired defect among the reference known samples. Let us say that the defect is always reproducible, so $a = 1$.

The probability b must be evaluated considering the frequency of the acquired defect. Because we do not have the appropriate database, we may subjectively evaluate or use a reference data such as the study by Gayet [5].

Equation 2 becomes

$$LR = \frac{\Pr(E_1, E_2, E_3|H_p)}{\Pr(E_1, E_2, E_3|H_d)} = \frac{1}{0.13} \cdot \frac{1}{0.03} \cdot \frac{1}{0.44} \approx 582 \quad (3)$$

The findings are about 582 times more likely if the seized typewriter is the source of the questioned letter than if originated from another typewriter.

Photocopier Example

A blackmail message was sent to the police department menacing the building's total destruction. The message was determined as being a photocopy. A further examination of the recto of the photocopy showed two acquired marks of different size and shape (suggesting scratch glass platen marks). Investigators were able to rapidly locate a suspect and at his home a photocopier producing the same two acquired marks was found.

- Define the results of your evidence $E = (E_1)$ as
  E_1: two acquired defects.
- Define the propositions:
  H_p: the seized photocopier, at certain time, is the origin of the blackmail message; and
  H_d: another photocopier is the origin of the blackmail message.

The fact that the questioned document was printed using a photocopier (as opposed to any other printing device) is not considered important in the assessment of the case hence the device *photocopier* appears in both the propositions. The same approach had been adopted in the previous example with regards to the *typewriter*.

The likelihood becomes

$$LR = \frac{\Pr(E_1|H_p)}{\Pr(E_1|H_d)} = \frac{1}{f} \quad (4)$$

The numerator has been set to 1 because of the persistency and reproducibility of the defects under the case circumstances (i.e., no replacement of the glass platen).

f is the probability of finding two marks at the same position (X, Y) on the glass platen. We can assume that we may distinguish only marks separated by 2 mm (that is only an assumption, in reality we can distinguish marks with relative distances smaller than 1 mm), so on an A4 document (210 mm × 297 mm) we have 105 × 148.5 squares of size 2 mm. So, if we assume that the characteristics are uniformly acquired on the glass platen surface, the probability to find the same 2-mm mark on another copier is $1/105 \times 148.5 = 0.000064$. To be more conservative this probability should be multiplied by 4. In fact, depending on the position of the document to be copied on the glass platen, the same defect on the glass platen can generate four different positions of the marks on the resulting photocopied document. So our probability will be $0.000064 \times 4 = 0.000256$.

If we assume that each mark could be considered as independent, we can square the probability so that in our scenario of two marks we obtain $0.000256 \times 0.000256 = 6.55 \times 10^{-8}$.

$$LR = \frac{\Pr(E_1|H_p)}{\Pr(E_1|H_d)} = \frac{1}{f} = \frac{1}{0.000256 \times 0.000256}$$
$$= \frac{1}{6.55 \times 10_{-8}} = 15'258'789 \quad (5)$$

In this simple case, we obtain a very high LR. The findings are about 15 million times more likely if the seized photocopier is the source of the blackmail letter than if originated from another photocopier. It should also be noted that in our case we do not take into account the chemical toner composition, neither the shape nor the orientation of the marks that would surely lower the probability.

Laser Printer Example

Consider a laser printed A4 contract showing two repetitive defects (1 mm) along the page. A repetitive artifact is a printing quality defect that has a pattern which reappears on the printed page at regular intervals. It results from physical damage to or contamination of a rotating unit such as a charging roller, an organic photoconductor (OPC) drum, or a fuser. Measuring the distance between the repetitive defects allows inferring the rotating unit circumference. The vertical distance between each repetitive defect was 94-mm. An HP LaserJet 4000 showing the same printing defect is seized. This laser printer has an OPC drum circumference of 94 mm.

- Define the results of your evidence $E = (E_1, E_2)$ as
  E_1: a OPC drum with a 94-mm diameter and
  E_2: two acquired repetitive defects
- Define the propositions:
  H_p: the seized HP LaserJet 4000 printer has printed the contract; and
  H_d: another Laser printer has printed the contract.

The likelihood becomes

$$LR = \frac{\Pr(E_1|H_p)}{\Pr(E_1|H_d)} \frac{\Pr(E_2|E_1, H_p)}{\Pr(E_2|E_1, H_d)} =$$
$$\frac{1}{f_{94\text{-mm OPC}}} \cdot \frac{1}{f_{\text{defects}}} \quad (6)$$

where f_{94}-mm OPC is the probability of finding a laser printer equipped with a 94-mm OPC drum. This probability was assigned to 0.22 in reference to a database [6].

Where f_{defects} is the probability of finding two repetitive defects at the same position X on a 94-mm OPC drum. Consider a defect that is present on a drum with a circumference of 94-mm and a drum width of 210 mm (the width of an A4 page). The probability of this defect occurring in the same horizontal position and any radial position on another drum of this size is 0.0047 (or 1 in 210).

Now considering we have two defects of this size occurring on two different horizontal X positions on the drum, then the probability is squared. Again, we assume that the defects are independent authorizing the frequency multiplication.

$$LR = \frac{1}{0.22} \cdot \frac{1}{0.0047 \times 0.0047} = 205'769 \quad (7)$$

The findings are 205'769 times more likely if the seized laser printer is the source of the questioned letter than if originated from another laser printer. Again, the chemical toner composition, neither the

shape nor the orientation of the marks were taken into account that surely increase the LR value.

Conclusion

In the above three examples, the subjective "identification" approach was formalized adopting a logical framework assigning the results in a LR format. This interpretation methodology invites the scientist to consider his results in the light of at least two alternative propositions that are mutually exclusive. It mainly provides a support to properly evaluate the evidence in a particular case with impartiality, but it can also provide a help to the decision through the probabilities quantification involved in the LR.

Introduction

In comparing fibers, hairs, paint chips, glass fragments, toolmarks, soil samples, bloodstains, and other forms of trace evidence, it is common to speak of "matches" and "exclusions". If two samples do *not* match (and if the match criteria cannot produce false negatives, and if there has been no police or laboratory misconduct or error), then the samples cannot have come from the same source. But testimony that the samples match has an additional wrinkle. For instance, even if two DNA samples are identical, it is logically possible that someone else has the same DNA profile and is the source. Likewise, the fact that a bullet fragment from a crime scene and a bullet found in a defendant's residence have similar elemental compositions does not necessarily mean that they came from the same box of ammunition, the same melt of lead, or some other unit of production [1, 2]. Because such matches are not within the experience of ordinary judges and jurors, the legal system normally expects expert witnesses to assist the factfinder by providing further information or conclusions about how a match should be evaluated. This article describes the law concerning the manner in which the significance of a laboratory finding of a match may be described.

Probabilistic Statements

Frequencies and Random Match Probabilities

Courts routinely admit estimates of how infrequent the matching features are in the general population [3, § 12.4.1]. Such quantities indicate the probability that a randomly selected sample in a defined population would have the matching type if that sample were *not* the source. The underlying logic is that if the match is unlikely to arise under this hypothesis, then the match is unlikely to be coincidental. Thus, the random match probability, as forensic scientists usually call it, is essentially the same as the statistician's p-value – the probability of finding an outcome at least as extreme as the one observed when the null hypothesis is true.

It has been argued that very small random match probabilitites are unfairly prejudicial or misleading. One potential danger is that the jury will think that it gives the probability that the match is random. A random match probability of 1%, for example, might be misreported or misconstrued as a 99% chance that the trace originated from the defendant. This is an example of the *fallacy of the transposed conditional* (also known as the *prosecutor's fallacy*) [3, § 12.4.1(b)(1)].

Some American courts have intimated that transposition by the expert or prosecutor could constitute reversible error, and one federal court of appeals granted postconviction relief partly on this ground [3, § 12.4.1(b)(1)]. Likewise, courts in England and Australia have reversed convictions when the judge's summation contained the fallacy. In reversing rape convictions in *R. v. Doheny*, [1997] 1 Cr. App. R. 369, 374, the English court of appeals suggested that to avoid transposition, an expert presenting DNA evidence should give the jury the frequency and then "say how many people with the matching characteristics are likely to be found in the United Kingdom – or perhaps in a more limited subgroup, such as, for instance, the Caucasian sexually active males in the Manchester area". This proposal has not been well received [4, 5], but much of the criticism seems overdrawn [3, § 12.4.1(b)(2)].

Likelihood Ratios

Some statisticians do not regard random match probabilities as a suitable measure of probative value. One alternative is to use a likelihood ratio to express how much the data support one hypothesis compared to another [6–8]. Indeed, the likelihood ratio can be generalized to describe the degree of support that measurements of a continuous variable, such as the refractive index of a sheet of glass, gives to competing hypotheses. Framing the issue in terms of likelihoods eliminates the need for an arbitrary cutoff point for declaring a match, and it is particularly useful when the numerator (the probability of the match when the suspect is the source) is not assumed to be 1 [2, 9].

Likelihood ratios have been introduced in a growing number of criminal cases [3, § 12.4.2(b)]. They are routinely quoted in civil and criminal cases in which the parentage of a child is relevant. In these contexts, the likelihood ratio is called the *paternity index* [10].

Posterior Probabilities

Neither the likelihood ratio nor a frequency gives a judge or jury the quantity that it ultimately seeks – the probability that a given hypothesis is true. That probability can be obtained according to Bayes' rule by combining a likelihood function with a prior probability function. Efforts to do so, however, have met with a mixed reception in the courts. Articulating the prior probability is the major sticking point. Several approaches have been discussed in the case law and legal literature: (i) applying a uniform prior distribution across the suspect population; (ii) assuming that prior probability is one-half; and (iii) producing a list of posterior probabilities for a broad range of priors.

Assuming a Uniform Prior in an Enumerated Population. In rare cases, it is possible to enumerate a suspect population. For example, in *State v. Klindt*, 389 N.W.2d 670 (Iowa 1986), the prosecution sought to prove that a torso found in the Mississippi River was the remains of a woman named Joyce Klindt. Investigators narrowed the possibilities among a list of missing persons in four nearby states to four women. A statistician computed likelihoods based on immunogenetic markers and other information about these women and applied these to a uniform distribution of prior probabilities for the four missing women. At the murder trial of Joyce Klindt's husband, the statistician testified that "[b]ased upon the likelihood of the concurrence of these factors among the missing

women, . . . the probabilities were over ninety-nine percent that the torso was Joyce Klindt's rather than any of the other three." *Id*. at 671.

The defendant objected to this testimony, but the objection was "basically that the underlying data was [sic] not sufficiently established." *Id*. The Supreme Court of Iowa quickly disposed of this claim upon determining that the data used to derive likelihood ratios were reliable. However, the court did not discuss the statistician's assumption that the prior probability with respect to each woman was 1/4.

Assuming a Prior of One-Half. In thousands of paternity cases, a posterior "probability of paternity" is calculated using a likelihood ratio (involving genetic information on the mother, child, and alleged father) and an arbitrarily chosen prior probability of 1/2. In these cases, the expert normally makes no effort to examine other possible fathers and to ascertain the prior odds for each such man. Rather, the alternative hypothesis usually is taken to be that a single "random man" is the father and that the prior probability of this hypothesis is 1/2. Testimony as to the resulting posterior probability, with or without disclosure of the prior odds, usually has been admitted with little appreciation of the nature of the computation [11]. The Supreme Court of Oregon, however, disapproved of the practice of using fixed prior odds. It announced in *Plemel v. Walter*, 735 P.2d 1209 (Or. 1987), that experts who desired to testify to a posterior probability could do so only by presenting a comprehensive table of prior and posterior probabilities, leaving it to the jury to decide which, if any, prior odds to use [12].

Bayesian computations also are used in criminal cases in which the defendant is alleged to be the father of a child or fetus resulting from rape or incest as well as in homicide cases involving missing bodies, and a few other offenses [13]. Although here too the use of the arbitrary prior probability of 1/2 often is not challenged, several courts have reversed convictions based on such testimony. The leading cases are *State v. Spann*, 617 A.2d 247 (N.J. 1993), and *State v. Skipper*, 637 A.2d 1101 (Conn. 1994). In *Spann*, a guard at a county jail was convicted of sexually assaulting a woman incarcerated there. human leukocyte antigen (HLA) tests involving the woman's child showed an exclusion probability of 99% and a paternity probability of 96.55%. On cross-examination, defense counsel established that the 96.55% figure presupposed a prior probability of 50%, but the expert characterized this premise as "neutral", "purely objective", and "one of the beauties of the test". 617 A.2d at 252. The prosecutor argued in summation that "guilt. . . . is proved to a mathematical certainty by carefully applying an objective scientific technique to the hard facts of this case." *Id*. at 249.

The Supreme Court of New Jersey held that the prosecution's portrayal of the posterior probability was unfair and that the failure to explain what effect other prior probabilities would have had on it was misleading. In dictum, the court stated that "the expert's testimony should be required to include an explanation to the jury of what the probability of paternity would be for a varying range of such prior probabilities, running, for example, from. 1 to. 9." *Id*. at 254.

In *State v. Skipper*, 637 A.2d 1101 (Conn. 1994), defendant was charged with various offenses arising from a sexually abusive relationship that he initiated with the young daughter of a neighbor. DNA testing performed on an aborted fetus, the girl, and the defendant resulted in a likelihood ratio of 3496 and a corresponding paternity probability of 99.97%. Unlike *Spann*, the prior probability of 1/2 was never disclosed, even on cross-examination. Instead, an expert "explained" that "[t]he calculation is . . . simply a conversion of the paternity index to the percentage. So, it's 99.97 is basically 3500 to 1, which is odds . . . expressed as a percentage." *Id*. at 1105.

The court held that this expert evidence was inadmissible and reversed the defendant's conviction. It stated that "[t]he assumption that there is a substantial possibility that the defendant had intercourse with the victim . . . raises serious concerns in sexual assault cases. It is antithetical to our criminal justice system to presume anything but innocence at the outset of a trial." Indeed, the opinion suggests that any nonzero prior probability – no matter how small – undermines the presumption of innocence:

> Whether a prior probability of 50 percent is automatically used or whether the jury is instructed to adopt its own prior probability, when the probability of paternity statistic is introduced, an assumption is required to be made by the jury before it has heard all of the evidence – that there is a quantifiable probability that the defendant committed the crime.

Id. at 1107–08 (footnote omitted).

The *Skipper* opinion, however, fails to explain why or how the presumption of innocence means

that the prior probability is zero. The conventional understanding of the "presumption" is that the mere fact of a criminal charge may not be considered supportive of guilt; hence, if the government adduces insufficient evidence at trial to permit a reasonable jury to conclude beyond a reasonable doubt that defendant is guilty as charged, the "presumption" is not overcome, and defendant is entitled to a directed verdict of acquittal [14]. Another interpretation is that *ab initio*, "the defendant should be thought no more likely than anyone else to be guilty" [15–17].

Varying the Prior Odds. Although American courts are divided as to the admissibility of posterior probabilities derived via Bayes' rule with undisclosed prior probabilities – particularly in criminal cases [13] – no appellate opinion holds that it is impermissible to permit testimony about the impact of the trace evidence on the prior probability. This testimony could take two forms. In the first, the jurors are invited to select the prior probability on the basis of the other evidence in the case, and to use the trace evidence according to Bayes' rule to deduce a posterior probability. This approach was employed by the defendant in *R. v. Adams* [1996] 2 Cr. App. R. 467, and, on retrial, [1998] 1 Cr. App. R. 377. The Court of Appeal denigrated such te stimony as "a recipe for confusion, misunderstanding and misjudgment." 1 Cr. App. R. at 384. Similar remarks can be found in American cases, although these are dicta since no such presentation was used. For example, People v. Nelson, 48 Cal.Rptr.3d 399 (Ct. App. 2006), *aff'd*, 185 P.3d 49 (Cal. 2008). This condemnation seems overstated, but the approach is criticized in more detail in [5], pp. 67–71.

In the second approach, no juror is asked to settle on a single figure for the prior probability, but only to inspect a table of prior and posterior probabilities to appreciate the power of the trace evidence [11]. This variable-prior-probability method avoids certain logistical, psychological, and jurisprudential difficulties that confront the juror-choice-of-prior-probability method. Jurors may not be very skilled at translating their impressions of the nonstatistical evidence into a single number; unless they actually articulate this number before learning of the trace evidence, they may be tempted to double-count the trace evidence by including it to some extent in the prior probability estimate; and arriving at a single number for the posterior probability would invite a comparison to a threshold probability required for conviction – a quantity that is difficult and perhaps undesirable to articulate [18].

Categorical Opinions

Experts often are asked for opinions, not numbers. The basic question then becomes: When should opinions about the impact of the trace evidence be admissible? These characterizations might range from the relatively uninformative statement that two samples are "consistent" with each other (or that they "match," or that the suspect "cannot be excluded") to pointed descriptions of the value of the match (e.g., "strong evidence of a common source") or of the infrequency of the matching features (e.g., a "very rare" type, or a "unique" match).

"Consistent-with" Testimony

For some types of trace evidence, such as hair fibers, toolmarks, and handwriting, little or no frequency data have been compiled. Some experts therefore describe the striking similarities between the samples, report that they match, and leave it at that. Indeed, in response to doubts about the ability of analysts to ascertain authorship on the basis of handwriting samples or to determine that a "rolled" fingerprint and a "latent" print come from the same person, a few courts have confined experts to testimony about the existence of the match [3, § 12.5.1].

The difficulty with this approach is obvious – the jury has no experience with which to judge how probative the esoteric characteristics are. Intuition and the experience of forensic examiners suggest that the failure to exclude the defendant surely is relevant – hair fibers and toolmarks, for example, are variable – but this variation has not been quantified. Consequently, the juror presented merely with testimony that the defendant or the material in his possession is consistent with the trace is hard-pressed to know what to make of the match.

As such, testimony that stops after reporting a "match" arguably is unfairly prejudicial. However, opposing counsel should be able to put the evidence in perspective by pointing out that for all that the expert has said, the trace might have come from anyone in the courtroom. If the evidence is indeed relevant and if the risk that the jury will be unduly impressed can be readily countered, then testimony

that the sample from the defendant is "consistent with" the trace should be admissible despite the difficulty in ascertaining just how incriminating the evidence is.

It also could be argued that the testimony of a match without substantial data on the frequency of the matching characteristics is not sufficiently scientific to be admitted under the standard of scientific validity adopted by the US Supreme Court in *Daubert v. Merrell Dow Pharmaceuticals, Inc*, 509 U.S. 579 (1993). However, the analyst may be able to declare matches and nonmatches accurately, and even without systematic study of population data, it may be clear to scientists that the outcomes are at least somewhat probative. The question for the law is then whether the trace evidence is of sufficient assistance to justify its admission despite the risk that it will be overvalued. Under American and English law, the finding of a match should be admitted unless the jury will give so much weight to the evidence that its prejudicial impact substantially outweighs its probative value.

Qualitative Expressions for Probability and Likelihood Ratios

The conclusion that testimony about the matching nature of two samples often should be admissible notwithstanding the lack of systematic data on the population frequencies conflicts with a line of cases that rely on the general-acceptance standard of *Frye v. United States*, 293 F 1013 (D.C. Cir. 1923), to hold that a DNA match is inadmissible unless the expert gives a numerical frequency [3, § 12.5.2]. But these cases confuse a question of science with an issue of law. What should be well established in science is that the methodology has some reasonable individualizing power. How the findings made with a generally accepted technology should be presented to achieve a satisfactory balance between probative value and prejudice is a quintessentially legal question, not a scientific one. Where empirical knowledge justifies characterizing a matching type as "rare," "extremely rare," or the like, the expert should be permitted to say as much. See, e.g., State v. Bloom, 516 N.W.2d 159, 166–67 (Minn. 1994); [19].

Somewhat more problematic are statements from the expert that the evidence is "weak", "good", "very strong", etc., intended as a description of the likelihood ratio for the evidence. If the expert makes the actual meaning of these phrases clear by providing the underlying likelihood ratio, then it is not obvious that they add much to that more precise numerical statement, although neither is any great prejudice apparent [9], p. 57. Yet, if it is not made clear that the expressions are merely descriptions of the likelihood ratio, whether the jury will make reasonable use of them is questionable. In that situation, the balance of probative value and prejudicial effect could favor exclusion.

Uniqueness

The most extreme case of a purely verbal description of the infrequency of the matching features arises when those features are said to be unique (or the defendant is said to be the source). Uniqueness, the condition where there is one and only one occurrence of the particular features in a population, is impossible to prove directly for an infinite population [20], but scientific research and common experience have led to judgments of extreme rarity for a few types of trace evidence. For example, courts have taken "judicial notice" of the uniqueness of fingerprints.[a]

Sometimes an expert's claim of "uniqueness" is not generally accepted or adequately established by scientific research. In these situations, the opinions should not be admitted under the *Frye* or *Daubert* standards. However, "[t]here is no 'bright-line' standard in law or science that can pick out exactly how small the probability of the existence of a given profile in more than one member of a population must be before assertions of uniqueness are justified . . . " [21]. When a great number of samples have been compared to one another and shown to be distinct, and when the process that gives rise to the population is known to involve an infinitesimal probability of generating a duplicate type for each unit or individual in the population, courts should allow an opinion of probable uniqueness along with, or instead of testimony about the vanishingly small random match probability [3, § 12.5.3].

End Notes

[a.] The doctrine of judicial notice permits a court to accept as true a fact that is not subject to reasonable dispute. The application of the doctrine to fingerprinting, however, was successfully contested in *United States v. Mitchell*, 365 F.3d 215, 252 (3d Cir. 2004).

DAVID H. KAYE

Interpretation: Low Template DNA

Introduction

The term *low template DNA* (LTDNA) has become the preferred term to describe any sample where there are a few DNA molecules present [1]. The term has been coined to avoid confusion with low copy number (LCN), which rather describes one particular enhancement technique. LCN has become synonymous with elevated PCR cycle technology [2–5]. In modern forensic laboratories, an analyst using the term *LCN* usually means amplification using 34 cycles probably with a duplication and consensus strategy for LTDNA samples The connection between LTDNA and 34 cycles is valid in part, but not comprehensively useful. It may be possible to obtain profiles from trace DNA amplified at 28 cycles (or indeed any other cycle number) and equally not all 34-cycle work is done on truly trace DNA. Equally there are other ways to increase the sensitivity of the analysis than elevation of the number of short tandem repeat (STR) amplification cycles, for example nested PCR [6, 7], MiniSTR [8] and whole genome amplification (WGA) [9, 10], post-PCR clean-up, and enhanced injection volume [11].

Despite being developed in the LTDNA context at least some of the concepts discussed in this chapter have application to all profiles, regardless of

the amplification strategy, wherever profile quality is compromised because of presumed low template number. Equally, 34-cycle amplification may produce profiles that appear to suffer none of the compromising aspects.

Increasing the number of PCR amplification cycles from 28 allows the amplification of less than 100 pg of total genomic DNA. It is expected that 3.5 pg contains one haploid DNA template, therefore 100 pg should equate to approximately 30 haploid templates or 15 diploid templates. With LTDNA analysis, results may be less reproducible compared with analysis involving more than 100 pg of DNA, and analysis may be more prone to contamination. However, the quantification step in DNA amplification is not completely accurate at low levels. The consequence of this is that quite often the LCN technology is applied to samples that give a low quantification result but which produce reproducible profiles with large peaks and no apparent signs of any compromise to quality.

Profile Quality

The low template number and increased amplification cycles may affect the morphology of LTDNA profiles [12]. The most noticeable effects are observed in/on dropout, heterozygote balance ratios, and stutter size. There are two postulated causes for this: sampling from low-level templates and stochastic effects in the early amplification rounds. When the template number is small, it is possible that each allele is unequally represented in an aliquot from the sample. Equally, if the number of templates is small, a stutter event or nonamplification in the early rounds of amplification can have a marked effect on the amount of final allelic and stutter products produced. However, as the heights of the peaks in the profile increase, the performance of 34-cycle amplification approaches that of 28-cycle amplification with normal template levels. For ultra trace work, it is impossible to completely remove the possibility contaminant alleles.

Heterozygote Balance and Dropout

If the sampling and amplification of template were perfect for each strand of haploid DNA template, then the two peaks of a heterozygote should be of equal height or area (hereafter height). However, in all PCR work some variation is induced in the resulting peaks' heights. For 34-cycle low template work, the induced variation is larger. There are two terms in common usage to describe heterozygote balance. These are

$$Hb = \frac{\text{height of the smaller peak}}{\text{height of the larger peak}} \quad \text{or} \qquad (1)$$

$$Hb = \frac{\text{height of the higher molecular weight peak}}{\text{height of the lower molecular weight peak}} \qquad (2)$$

The latter contains more information (the order of the alleles is kept) whereas the former is in more common usage. For 28-cycle full template work it is expected that the heterozygote balance (defined the second way) is expected to lie approximately between 0.5 and 2.0. For LTDNA work, it can be anywhere between 0 and infinity. A heterozygote balance of 0 or infinity is equivalent to the event of allelic dropout.

The distribution of *Hb* for LTDNA templates amplified at 34 cycles shows the expected peak slightly below 1, which arises from the slight tendency for lower molecular weight alleles to amplify better (Figure 1).

It is usually possible to examine empirical data from known heterozygotes to determine a peak height above which dropout has not been observed. This is often termed the *homozygote peak height threshold guideline* and may be of the order of 3000 rfu, although each laboratory would need to determine their homozygote peak height threshold as part of their validation. Therefore, if a single peak at a locus is present at a height greater than the threshold it is potentially possible to rule out dropout and designate the locus as homozygous.

Stutter Size

Stutter peak heights (relative to the size of the associated allele peak) can be bigger for low template 34-cycle work. This is thought to occur because a stutter in an early round of amplification has a proportionally larger contribution to the final product if there are few templates (Figure 2).

A stutter guideline is often defined below which a peak may be composed completely of stutter product. This does not mean that it must all be stutter, it is still possible that part of the peak is allelic, but that there is no need to invoke the presence of an allele to explain

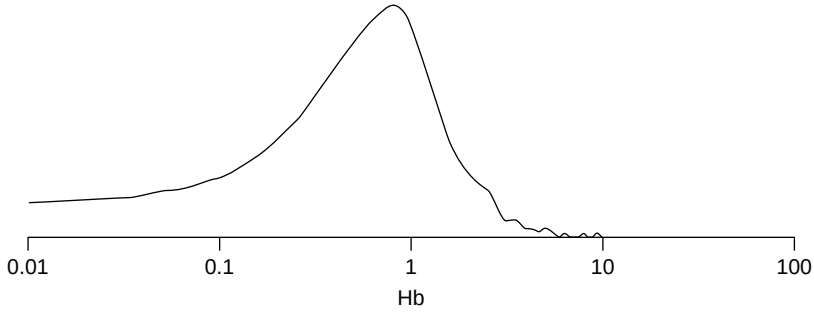

Figure 1 Distribution of the frequencies of *Hb* values for a set of $N = 1688$ heterozygote profiles obtained after 34 cycles [13]

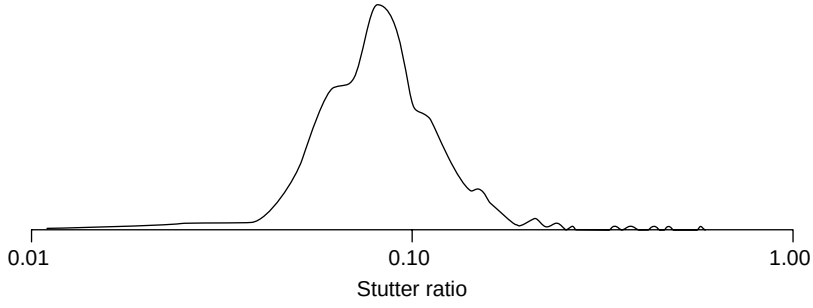

Figure 2 Distribution of the frequencies of *stutter ratio* values for a set of $N = 844$ loci heterozygote profiles obtained after 34 cycles [13]

the peak. Just because a peak could be stutter does not mean that it is stutter. Given the greater variance in stutter ratio at LTDNA levels, broader criteria are often used than for 28-cycle work with good template levels. Each laboratory should determine their own stutter guidelines as part of their validation. Application of these guidelines should always be undertaken in conjunction with duplication to report consensus profiles and should be done before looking at the reference profiles.

Contamination/Drop-in

It has been proved impractical to completely eliminate the possibility of laboratory-introduced contamination in LTDNA work, even when strict conditions of cleanliness are in place. Many readers would respond to this statement with deep concern. However, it is also impractical to eliminate the possibility of contamination of samples at the scene or at other stages of the evidence chain. It is of utmost importance for every forensic laboratory to minimise the possibility of gross contamination of the crime sample with the suspect's sample. It is also important that the laboratory adopts protocols that minimize the opportunity for the introduction of DNA from analysts involved in the collection or analysis of samples and the potential contamination from laboratory based sources, such as nonDNA free plasticware [14]. This can be achieved through appropriate training and good laboratory practices together with the establishment of elimination databases for staff and other relevant personnel. Further, confidence in the "health" of the laboratory can be gauged from appropriately targeted environmental monitoring. Regular environmental testing of surfaces assists in determining when a more through deep clean of these surfaces is required.

Most contamination events observed in LTDNA profiles appear to be a single allele or a few alleles, often of small peak height. The term *drop-in* has

been coined to describe this phenomenon. Drop-in rates for an operational LTDNA laboratory should be constantly monitored and the laboratory should be able to demonstrate that their drop-in rate is low. This may typically be within a range of 1–3% per locus or even less. By regular monitoring of the drop-in rates, any unacceptable rise can be easily observed. Appropriate investigations into the cause of the increase and appropriate cleaning can be initiated. The interpretation procedures recommended by Gill and Buckleton [15] are very robust to contamination events of this type, as long as the possibility of introducing the suspect's DNA is eliminated and the drop-in rate does not exceed 30% per locus.

The Interpretation of LTDNA Profiles

LTDNA profiles, single stain or mixtures, may be interpreted using a frequentist or likelihood-ratiobased approach [16]. The usual strengths of the likelihood-ratio approach also apply to LTDNA work and are not repeated here. However, for those people philosophically opposed to, or constrained not to use such an approach, there are still valid ways in which the profiles may be interpreted.

It is often impossible to assign the source of a trace DNA sample to a particular body fluid or cell type. Nor is it likely to be straightforward to state when or how the DNA was deposited. Difficulties include demonstrated secondary transfer [5, 17–19].

Any case that involves prior contact between persons of interest in an investigation is likely to be unsuitable for LTDNA analysis. The possibility of prior contact is to be considered along with other information relevant to the case, before LTDNA analysis was attempted [20].

As the reporting of the number of DNA contributors to LTDNA profiles cannot always be undertaken with the same degree of confidence as the reporting of 28-cycle profiles, a caveat regarding the assumption of contributor number is usefully included as part of the reporting regime.

Typically scientists interpreting LTDNA work operate at what has been termed the *sublevel 1 level of propositions* [21–24].

Using the Bayesian approach two propositions are formed that align with the prosecution and defense viewpoints.

H_p: the DNA in the crime stain is from the suspect and

H_d: the DNA in the crime stain is from someone else.

The use of the term DNA rather than blood, semen or saliva, is what makes this a sublevel 1 set of propositions.

The current interpretation strategies are based upon replicate amplifications. This requires that a LTDNA sample is amplified at least twice. This approach improves the reliability of the technique considerably and ameliorates most of the perceived negative aspects. Interpretation may proceed via what is termed the *biological* or the *statistical* model.

The Biological Model

The biological model uses a "consensus" approach. A "consensus profile" is developed by "scoring those alleles that appear in two or more of the replicates but not at similar heights in the negative controls". This consensus should be developed before the reference samples are examined. The consensus profile many contain zero, one, two, or more alleles per locus. In some instances, it can be difficult to determine whether the resulting consensus profile arises from one or more individuals. Peak height imbalance is less reliable in this determination than in normal template work. The decision as to how many individuals are present in the consensus profile is one of the more problematic decisions in LTDNA casework.

If there are between zero and two alleles per locus in the consensus profile, it is normal to treat the profile as unmixed.

For example, Table 1 shows two amplification results for a sample; replicate 1 and replicate 2, and the resulting consensus profile generated prior to consideration of the results from the corresponding extraction negatives.

The next step is to consider the DNA profiles from the extraction negative associated with the sample. If duplicated alleles are sighted in the extraction negatives that correspond in height to those in the consensus profile generated for the sample, then these alleles are removed from the profile. These duplicated alleles could indicate a contamination event rather than a random spurious drop-in event.

In the example in Table 2, the alleles in the extraction negative profiles correspond in height to

Table 1 Amplification results from two replicates of the same evidential sample

	D3	vWA	D16	D2	D8	D21	D18	D19	TH0	FGA	Amel
Rep 1	15,16	16	11,12,13	18,19	11	30,31	18	14	6,7,8	20,23	X,Y
Rep 2	15	NR	11,13	18	10	30	19	14	6,9	20,23	X
Consensus	15,0	NR	11,13	18,0	NR	30,0	NR	14,0	6,0	20,23	X,0

Where "NR" means no result, 0 is a code that signifies that an unseen allele may be present (F in the United Kingdom) and "Rep" means one replicate amplification of sample

E Neg 2	–	15,17	–	–	–	27	–	–	9	–	–
Report	15,0	NR	11,0	18,0	NR	30,0	NR	14,0	6,0	20,0	X,0

those in the consensus profile. The presence of the D16 13 allele and the FGA 23 allele results in these two alleles being removed from the consensus profile.

If the peak heights of alleles in an extraction negative profile are markedly smaller in height than the peak heights of corresponding alleles in a consensus profile, then the reporting scientist may conclude that the alleles detected in the extraction negative could not have contaminated the sample. Therefore, in these circumstances it may be appropriate for the reporting scientist not to delete alleles from the consensus profile of the sample.

An assumed single source stain is interpreted/assessed statistically using either the match probability or the likelihood-ratio approach. In many cases, those loci with one allele present, say allele a, cannot be assumed to be homozygous. In such cases, the "2p" rule is typically applied. This rule assigns the match probability as either $2p_a$ using the product rule where p_a is the allele probability for allele a, or preferably one of a number of variants that include the subpopulation correction [25]. These are

$$\frac{[2\theta + (1-\theta)p_a]}{(1+\theta)}\left(2 - \frac{[3\theta + (1-\theta)p_a]}{(1+2\theta)}\right)$$

One of these variants, for a homozygous defendant of type *aa* is

$$\frac{2[2\theta + (1-\theta)p_a]}{(1+\theta)}$$

and

$$\frac{[\theta + (1-\theta)p_a]}{(1+\theta)}\left(2 - \frac{[2\theta + (1-\theta)p_a]}{(1+2\theta)}\right)$$

for a heterozygous defendant of type *ab*. This is often approximated as

$$\frac{2[\theta + (1-\theta)p_a]}{(1+\theta)}$$

The biological model reduces the replicates to a consensus profile and in doing so is wasteful of evidence. This tends to be conservative if H_p is true but is not conservative if H_d is true (this statement is universally true of all transformations or reductions that waste evidence). Of most concern are the situations where the suspect is an *ab* heterozygote and

- one replicate is *ab* and the second replicate is *ac* and hence the consensus profile shows the *a* allele. There is an additional nonreplicated *c* allele.
- each replicate is *a* and hence the consensus profile shows the *a* allele and no others. The situation is at its most extreme if the *a* peaks are near, but just below, the threshold.

If caseworkers are vigilant for these situations the biological model is expected to operate in a conservative manner under most realistic circumstances. However, the perceived deficiencies led to searches for methods that utilize the evidence more thoroughly.

The Statistical Model

The only model currently available that attempts to use information from the LTDNA profile more thoroughly is termed the *statistical model*. This treats the alleles as either present or absent, and also models dropout, drop-in, and stutter as binary events. This model may be used to explore the robustness of the biological model or substituted for it in casework. The only forensic service currently using this model in casework is the FSS in the United Kingdom. In that service it is embodied in the software LoComatioN [26].

While this model does make more comprehensive use of the information, it still wastes some. Specifically the treatment of the alleles as present or absent wastes the information inherent in peak height. It is still unclear how large this loss is when LTDNA profiles are considered, as peak height is a much less reliable indicator.

If there are more than two alleles at some loci then it is likely that the profile will be treated as a mixture. DNA profile morphology including relevant peak heights in the replicates of a sample and the number of alleles observed at each locus across the multiple amplifications should always be considered when determining the likely number of contributors to the DNA profile. When peak heights are small, the relative heights of peaks are virtually uninformative in mixture analysis. Such mixed profiles should be classified as uninterpretable.

If there are multiple contributors, it may be possible to separate the contributions into major and minor components. In such a sample, the peak heights of one DNA component is markedly greater than the peak heights of other DNA component(s) in the sample and the profile of the major DNA component is consistent between two replicate profiles.

For some mixed profiles, it may be appropriate to condition on a known DNA contributor to the sample, for example, if the sample is from an item of worn clothing. By conditioning on the wearer's DNA profile it may be possible to determine the profile of any additional DNA contributor, provided this profile is consistent between two replicates and well above any background DNA that may also be present.

The Statistical Model Theory

As noted, the statistical model, first proposed by Gill *et al.* [27] considers three separate phenomena as follows:

C: the event that an allele appears at a given locus in the crime sample as a result of contamination/drop-in. The complement to this event is denoted by $\bar{C}$ with $\Pr(C) = 1 - \Pr(\bar{C})$.
D: the event that a given allele "drops out" because of stochastic variation in the amplification. The complement to this event is denoted by $\bar{D}$ with $\Pr(D) = 1 - \Pr(\bar{D})$.
St: the event that a band has been caused by stuttering of an adjacent allelic peak.

In general, we have replicates $R_1, R_2, \ldots, R_n$ although in practise n is generally 2. We proceed using the notation given in Curran *et al.* [28]. Under any given proposition, H, we have three sets to consider:

T – the alleles of those people who are known (i.e., they have been identified and have contributed DNA to a sample that has been typed) and who are assumed to have contributed to the mixture.
V – the alleles of those people who are known but who are assumed to have not contributed to the mixture.
U – the alleles of the unknown contributors.

The contents of the sets T, V, and U are dependent on the proposition under consideration (H). We wish to calculate

$$\begin{aligned}&\Pr(R_1, R_2, \ldots, R_n, T, U, V \mid H)\\ &= \Pr(R_1, R_2, \ldots, R_n \mid T, U, V, H)\\ &\quad \times \Pr(T, U, V \mid H)\end{aligned} \tag{2}$$

When the number of unknown contributors to the stain is nonzero, the set U may contain more than one mutually independent genotype, therefore this becomes

$$\begin{aligned}&\Pr(R_1, R_2, \ldots, R_n\ T, U, V \mid H)\\ &= \sum_j \Pr(R_1, R_2, \ldots, R_n \mid T, U_j, V, H)\\ &\quad \times \Pr(T, U_j, V \mid H)\end{aligned} \tag{3}$$

where U_j is the jth possibility for genotypes (or more specifically alleles) of the unknown contributors. The net effect of the hypothesis H is to dictate the elements of T, V, and U, therefore in the following steps we assume that H has been accounted for. Furthermore, if the set U is nonempty (and contains m elements) then it is possible to simplify (1) for computation to

$$\Pr(T, V) \sum_{j=1}^{m} \Pr(R_1, R_2, \ldots, R_n \mid T, U_j, V) \times \Pr(U_j \mid T, V) \tag{4}$$

In most circumstances the union of the sets V and T remains the same in the numerator and denominator in which case we can cancel the term $\Pr(T, V \mid H)$. Using the assumption that the replicates are independent of each other, this expression becomes

$$\sum_{j=1}^{m} \left[\prod_{i=1}^{n} \Pr(R_i \mid T, U_j, V) \right] \Pr(T, U_j, V) \tag{5}$$

Furthermore, the replicate information does not depend on people who have not contributed so that $\Pr(R_i \mid T, U_j, V) = \Pr(R_i \mid T, U_j)$

$$\sum_{j=1}^{m} \left[\prod_{i=1}^{n} \Pr(R_i \mid T, U_j) \right] \Pr(T, U_j, V) \tag{6}$$

Expression (4) allows us to reduce the problem into two nested but discrete steps: evaluation of the genotype probabilities and evaluation of the probabilities of the replicates with respect to genotype information.

Assessing Genotype Probabilities

The evaluation of the genotype probabilities, with the inclusion of population substructure, is given in Curran *et al.* [28]. There is one minor difference in that the possible values for the unknown contributors are not constrained in the same way. In general mixture interpretation genotypes of unknown contributors are restricted to alleles that have appeared in the crime scene sample. Furthermore, the set of unique alleles observed in the known contributors, T, and any unknown contributor combination must be equal to the set of unique alleles observed in the crime scene sample. For example, if the scene has alleles $C_g = \{a, b, c\}$ then the combination of $T = \{a, b\}$, $U = \{c, c\}$ is allowable whereas $T = \{a, b\}$, $U = \{b, b\}$ is not because it does not explain the presence of the c allele. With the possibility of drop-in, such a restriction must obviously be removed. Furthermore, allelic dropout allows the proposal of alleles that have not been seen in the crime scene sample. From a computational and practical point of view, it is useful to have some mechanism for generating candidate genotypes for the unknown contributors. One possibility is to allow the choice of drawing $2x$ alleles from the set of unique alleles observed in all of the replicates, where x is the number of unknown offenders.

Finally, there can be good reasons for not using all possible genotypes such as particular combinations being inconsistent with the estimated mixing proportion of the sample, or inconsistent with preferential amplification rules. See Gill *et al.* [29] for a deeper discussion of these issues.

Assessing Replicate Probabilities

In a manner similar to mixture interpretation, assessing replicate probabilities can be made easier by partitioning replicate information into a number of disjoint sets.

Firstly, we collapse T, U_j into a set of unique alleles G_g, For the time being let us regard G_g as a set of unique alleles for a particular combination and let R be a particular replicate, then $\Pr(R_i \mid T, U_j) = \Pr(R \mid G_g)$. We can evaluate this probability by constructing three sets:

1. The alleles that have dropped out Δ (delta).
2. The alleles that have not dropped out ρ (rho).
3. The potential contaminants/drop-in peaks or stutter peaks/alleles χ (chi).

Using this notation we can now define our three sets

$$\begin{aligned} \Delta &= G_g \ \{R|G_g\} \\ \mathrm{X} &= R \ \{R|G_g\} \\ \mathrm{P} &= R \ \{\mathrm{X} \cup \Delta\} \end{aligned} \tag{7}$$

where "\" is the set exclusion operator. The set $\{\mathrm{X} \cup \Delta\}$ is a conventional set in that it doesn't contain duplicated elements. From these sets we can write down the probability of any replicate, given any genetic combination using the following rules:

1. For every element of P write $\Pr(\bar{D})$.
2. For every element of X write $\Pr(C)p_i$ where i is the ith element of X and p_i is the probability of the ith allele in the population. If $X = \phi$ then write $\Pr(\bar{C})$.
3. For every element of Δ write $\Pr(D)$.

There are two additional factors that should be considered in our rule regarding the elements of the set of contaminants, X. The first is the concept of ordering. Consider a situation where X contains more than one element, e.g., where the replicate contains alleles 13, 14, 15, and the putative genotype for the one unknown contributor is 13,13. In this case X would contain alleles 14 and 15. There is no particular reason to think that the order in which these contaminants were "added" has any relevance, therefore we must account for the possible orderings of these alleles – in this case we should multiply the probability by a factor of two. In general, if X contains k alleles, then there are $k!$ possible arrangements. The second factor that we might consider is the effect of population substructure. However, we argue that the allele probabilities for contaminants are more likely to be related to sources within the laboratory rather than the population of the offender. In arguing so, we admit then, that using the population frequencies for the contaminant alleles are probably incorrect and that treating contamination events as independent on an allele by allele basis is also incorrect. However, they suffice as an approximation.

Conclusion

LTDNA interpretation is considered the hardest DNA evidence type to interpret and is undertaken by the most experienced analysts after extensive training. Analysts would have spent some time interpreting simple stains before moving on to mixtures and LTDNA cases [30].

It is acknowledged that in many cases it is difficult to associate a LTDNA DNA profile to its DNA source (e.g., semen, blood, or saliva), because of the small amounts of cellular material present in the sample. In addition, owing to the extreme sensitivity of the analysis, we can expect to obtain DNA profiles from trace biological material left for reasons unconnected with the facts under investigation. In other words, the relevance of such profiles is usually more difficult to establish compared with the relevance of DNA profiles obtained from rich samples extracted from visible biological stains. Research has shown that trace DNA can be obtained following primary, secondary, or tertiary transfer.

There have been expressions of concern in the literature and courts about the reliability of LCN work [31]. LTDNA technology had been offered originally as an investigative tool to the police, typically in cases where no names were offered for investigation or in cases reopened by the UK Criminal Case Review Commission. The transition from an investigation tool (aiming at generating leads for further investigation through the national DNA database) to evidence presented in court has not been straightforward. The recent ruling and discussion following the Omagh trial highlighted issues of contamination and the reliability of the technique [32–35]. In the aftermath of the Omagh bombing decision, a report commissioned by the Home Office has supported the validity of the technique [1]. The Forensic regulator has recommended some very sensible ways forward [36].

Since LTDNA analysis began in the late 1990s there has been considerable improvement in both profile quality and in the control of, and understanding, of the different sources of contamination that may occur. LTDNA analysis is costly, when compared with other examinations, and is usually reserved for targeted cases.

If careful attention is given to training, good scene, storage, and laboratory practice, robust interpretation guidelines and care in presenting appropriate caveats then LTDNA analysis can take its place as a forensic tool.

Interpretation: Observer Effects

Introduction

The term *observer effect* generally describes circumstances in which the results of an observation are affected by the observer. In physics, the term has been used to describe circumstances in which the act of observation changes the phenomenon being observed, as where measurement of electrical current in a circuit changes the current flow. By contrast, in the social sciences and in forensic science, the term is used to describe circumstances in which the observer's preconceptions or motives influence conclusions drawn from data [1]. The preconceptions and motives are thought to influence the *perception and interpretation* of the evidence rather than changing the evidence itself. Observer effects are sometimes also called *examiner bias* [2, 3] although it important to note that the "bias" entailed in the phenomenon may occur without the observer intending or even being aware of it [4, 5].

Observer effects are closely related to *context effects* and the two terms are sometimes used synonymously [4]. The term *context effect* originated in psychology and has been used to describe circumstances in which the perception of a stimulus is affected by the surrounding context, as where a gray object looks lighter against a dark background than against a light background (see, e.g., http://web.mit.edu/persci/people/adelson/checkershadow_illusion.html). In forensic science, the term *context effect* has been used more broadly to describe situations in which the results of a forensic analysis are affected by the circumstances in which it is performed, and particularly by the information available to the analyst, as when an analyst becomes more likely to identify a latent print as that of a suspect when told that another analyst has already made the identification or when told that other evidence indicates the suspect made the print. The "other evidence" might be said to provide a "context" that changes the analyst's interpretation of the data contained in the prints. Alternatively, the "other information" might be said to have changed the analyst's expectations about the data and hence to have induced an *observer effect*.

The same phenomenon is sometimes described as *confirmation bias*. In psychology and cognitive science, the term *confirmation bias* refers to a human tendency to evaluate evidence in a manner that supports or confirms one's preconceptions, such as a tendency to search out and give more weight to evidence that supports a favored hypothesis than to evidence that contradicts it [5]. In forensic science, the term *confirmation bias* has been used in a manner that is roughly interchangeable with the terms *observer effect* and *context effect* [6, 7].

Underlying Psychological Phenomenon

Underlying all of these terms is a basic phenomenon of human psychology – the tendency of observers to interpret data in a manner consistent with their expectations and desires. The existence of this phenomenon is well established – it has been called *one of the most venerable ideas of traditional epistemology* as well as *one of the better demonstrated findings of twentieth century psychology* [8]. An early discussion of the

phenomenon can be found in the writings of Francis Bacon, who commented in 1620 that

> The human understanding when it has once adopted an opinion draws all things else to support and agree with it. And though there be a greater number and weight of instances to be found on the other side, yet these it either neglects and despises, or else by some distinction sets aside and rejects, in order that by this great and pernicious predetermination the authority of its former conclusions may remain inviolate [9].

Even earlier, Julius Caesar famously noted men's tendency to "believe quite readily that which they wish to be true" [10]. In the twentieth century, psychologists confirmed the existence and strength of these phenomena with innumerable experiments in which people's interpretation of a variety of stimuli, data, and forms of evidence were shown to be influenced by preconceptions and desires. The effects are greatest when the underlying data are somewhat ambiguous and when observers are influenced by strongly held expectations and motives. Extensive reviews of this literature are found in [1, 4, 5, 8, 11, 12].

The most relevant studies relate to the interpretation of scientific data. Like everyone else, scientists have a tendency to interpret data in a manner that supports theories that they favor. The tendency of academic scientists to cling to pet theories, well past the point at which such adherence could be justified by the evidence, has been widely noted [13–15]. In his iconic book *Galileo's Revenge: Junk Science in the Courtroom* [16], Peter Huber traced several false scientific theories to misinterpretation of data arising from uncontrolled observer effects. A scientist who is committed to a pet theory inevitably (and unconsciously) interprets data in a manner consistent with that theory. By Huber's account, uncontrolled observer effects are one of the hallmarks of junk science (*see* **Interpretation: Legal Perspective**).

Minimizing Observer Effects

Allowing preconceptions to influence the interpretation of data is said to be the "cardinal sin for the formal, pure scientist" [8]. Accordingly, when scientists must rely on subjective judgment to interpret the results of an experiment, they routinely take careful steps to mask or shield the person interpreting data from extraneous information that might improperly influence the interpretation. For example, scientists in most fields use "blind" or "double-blind" procedures when relying on subjective judgment to interpret data. Blind procedures are also widely used for peer-review of scientific articles, for grading of written examinations, and for other functions for which it is important to minimize observer effects.

The field of forensic science has been criticized for failing to take adequate steps to minimize observer effects [1, 4]. Through communications with police, lawyers, and other experts, forensic scientists often are exposed to information that may influence their expectations and perhaps even their hopes and desires about what a particular examination might reveal [1]. Moreover, when performing examinations forensic scientists often rely in part on subjective judgment to evaluate potentially ambiguous data [17]. Even seemingly objective procedures like DNA testing sometimes require analysts to use subjective judgment to resolve crucial ambiguities and hence could potentially be influenced by observer effects [3, 18–21]. Yet forensic scientists rarely take steps to shield themselves from extraneous information – i.e., information unnecessary for making a scientific assessment – when making comparisons or interpreting test results [1] (*see also*, **Threat Assessment: School**; **DNA: Degraded Samples**).

The difference between forensic science and other scientific fields may stem in part from uncertainty about what types of information are necessary and relevant to a forensic science assessment. In some forensic disciplines consideration of nonscientific evidence is not only accepted but required by professional norms. For example, fire investigators are trained to consider whether a suspect had a motive for setting a fire when deciding whether to classify a fire as arson [22] (*see also* **Fire and Explosion Investigations: Overview**; **Fire: Scene Investigation**). There have been reports of forensic scientists relying on nonscientific evidence in other disciplines as well, such as a DNA analyst who defended a "match" that implicated the defendant in a rape case by saying: "I know I am right. They found the victim's purse in [the defendant's] apartment" [21]. In 1997 the US Justice Department's Office of Inspector General reported that FBI explosives experts had relied on extraneous evidence when making key scientific determinations in a number of important cases [23]. In the first World Trade Center bombing in 1993, for example, FBI examiners had relied on the

fact that the suspects had access to urea nitrate to reach the conclusion that urea nitrate had been used to make the bomb. The Inspector General condemned this reasoning as circular and biased. The FBI laboratory management agreed and pledged to take steps to ensure that the problem never happened again. Academic commentators have been unanimous in condemning the use of such nonscientific evidence as a basis for scientific conclusions [1, 6, 7, 17, 18]. They argue that the role of the forensic scientist is to offer conclusions derived from a scientific discipline, not to offer conclusions based in part on analysis of other evidence in the case (*see* **Fire and Explosion Investigations: Overview**).

Forensic scientists have become more aware of the importance of addressing observer effects as a result of a high-profile error by the FBI's fingerprint identification unit in the Madrid train bombing case [6, 7, 24]. Three highly trained FBI latent print examiners, and a well regarded independent examiner, all identified a latent print associated with the Madrid bombing as having come from Brandon Mayfield, a resident of Portland, Oregon. The error came to light when Spanish authorities determined the latent print actually matched an Algerian suspected terrorist. The FBI acknowledged the error and apologized to Mr Mayfield. In a subsequent analysis, the agency attributed the error in part to *confirmation bias*. After an initial erroneous identification, each subsequent examiner was fully aware that the latent print had previously been matched to Mayfield. This knowledge may have led them to place too much weight on similarities between the two prints while ignoring or discounting discrepancies.

Empirical Studies of Observer Effects in Forensic Science

Empirical studies have confirmed that observer effects can influence the interpretation of latent prints, leading to errors [25–28]. For example, in one clever study, psychologists asked five highly experienced latent print examiners to compare pairs of prints [26]. The examiners were not told that they had previously individualized these pairs (i.e., found them to match) during casework. Each examiner was instead told (incorrectly) that the prints were those that the FBI had erroneously matched in the Madrid train bombing case. Although they were instructed to "ignore all the contextual information and focus solely on the actual prints", three of the five examiners changed their previous judgment of "match" to "no match" and a fourth changed from "match" to "cannot tell". Only one of the five examiners consistently maintained that the prints were a "match". In other words, after exposure to "extraneous information" suggesting that the prints should *not* match, four of five examiners reached a different conclusion than they had reached previously when comparing the same prints.

Studies in other forensic science domains have also found evidence of observer effects on examiners' judgments [29]. Research on the precise mechanisms by which observer effects influence interpretation are just beginning to emerge [30]. Additional research in this important area is clearly needed.

Case Managers and Sequential Unmasking

There are a number of procedures for minimizing observer effects [1, 4, 31]. One method is to separate various laboratory functions and assign them to different people. A *case manager* who is fully informed of the facts of the case decides what to test and how to test it; a *laboratory analyst* who is "blind" to extraneous information analyzes and interprets the test results. To the extent possible, the analyst remains "blind" to extraneous information, such as information about the legal consequences of the judgment and nonscientific evidence in the case, when deciding whether samples "match". Once the analyst interprets and records the test results, the *case manager* (who is aware of the broader facts of the case) is then responsible for placing the test results in context and assessing the compatibility of forensic observations with various theories of what occurred.

Another approach is simply to perform the analysis and evaluation of various samples in a sequence so that analysis and interpretation of early samples cannot be influenced by knowledge of the later samples. Evidentiary samples, which are generally more difficult evaluate, are analyzed first, before the analyst knows the features of the reference samples. For example, fingerprint examiners can decide whether a latent print is interpretable and which features of the latent print constitute reliable data before knowing whether those features are consistent or inconsistent with a reference print. Similarly, DNA analysts

can decide which "alleles" in an evidentiary sample profile are real and which are spurious before knowing whether those alleles match up with a suspect's. Information required to draw an ultimate conclusion is "unmasked" when needed but the analyst performs as much work as possible while "blind" to unnecessary facts [31].

Interpreting Expert Opinions: History of

Introduction

The underlying principle of interpretation is the achievement of the best assessment of the uncertainty associated with the comparison of evidence found at the scene of the crime and evidence found in association with a suspect.

Interpretation in forensic science has a long history, dating back to comments made by classical scholars. See Aitken and Taroni [1], Robertson and Vignaux [2] and Sheynin [3] for appropriate references.

Records were scanty until the mid-nineteenth century. In his book on the emergence of probability, Hacking [4] describes how Leibniz in the seventeenth century wrote about the relationship between probability and the law. A probabilistic analysis of the cumulative force of circumstantial evidence was given by Bernouilli [5]. The calculus of probabilities was applied to problems including the presumption of death, the value of annuities, marine insurance, the veracity of testimony, and the probability of innocence by his nephew, Bernouilli [6].

From the mid-nineteenth century till the 1940s, interpretation in forensic science was concerned mainly with the determination of a relative frequency of a characteristic of interest. In the war years of the 1940s, the logarithm of the likelihood ratio, known as the *weight of evidence*, was used in Bletchley Park by code breakers. The role of the likelihood ratio in interpretation in forensic science did not emerge until the publication of a seminal paper by Lindley [7], though the philosophy had been expressed in a report for the Dreyfus case by Darboux, Appel, and Poincaré [8].

Early forensic scientists recognized that adequate data and consideration of the case as a whole should be used to reach a decision regarding the value of forensic scientific evidence. Their points of view were generally compatible with a Bayesian framework [9]. Bertillon wrote that experts must be prepared to present evidence in a numerical form and not just as an opinion. He also considered the presentation of results without other information pertaining to the inquiry as a methodological error, an early consideration of the differing roles of the likelihood ratio and the prior odds in the assessment of evidence.

In the 1960s in a series of papers, Kingston and Kirk [10, 11] and Kingston [12–14], discussed the role of statistics in forensic science (or criminalistics). These were predated by Kirk [15] in which Kirk stated that "(p)robability is the very keynote of interpretation of all physical evidence". A distinction has been made between *individualization* and *identification*. The process of addressing the issue of whether or not a particular item came from a particular source is termed "individualization". "Criminalistics is the science of individualization" [16]. An "identification" is, more correctly, defined as "the determination of some set to which an object belongs or the determination as to whether an object belongs to a given set" [12]. However, established forensic and judicial practices have led to "individualization" being termed "identification". The establishment of an identification of a suspect or defendant with a criminal is an opinion on the issue of interest to the court and outside the remit of the forensic scientist. The step from probabilities relating to evidence to probability relating to identity has been termed a "leap of faith" [17].

The problems that may arise when numbers are introduced into a court of law are discussed at length in Tribe [18], in response to an article by Finkelstein and Fairley [19] with a response by these authors to the article by Tribe in Finkelstein and Fairley [20]. For example, in an issue which is still a matter of debate, Tribe raises the concern that a very low relative frequency for a characteristic may "dwarf all efforts to put it into perspective". This concern "pervades all cases in which the trial use of mathematics is proposed".

Current research and development on interpretation concentrates on ideas known as *Bayesian*, named after the nonconformist minister Reverend Thomas Bayes, FRS (1702–1761). The paper in which the principles of the reasoning that has come to be known as *Bayesian inference* was espoused was published posthumously in 1763 [21–23].

The history of interpretation may be considered, roughly in chronological order, in the four stages of relative frequencies, discriminating power, significance probabilities, and likelihood ratios. A brief description of errors in interpretation follows. The article finishes with a short comment on the role of Bayesian networks in interpretation in forensic science.

Relative Frequencies

The relative frequency of a characteristic has been used as a measure of the strength of evidence for many years, since at least the mid-nineteenth century. The relative frequency in a sample has been used as an estimate of the probability of the characteristic being present in a member of the population of which the sample is representative.

An early example of the use of a relative frequency in law was to query the authenticity of signatures on wills [24, 25]. The use of probabilistic and statistical evidence in the Howland will case is probably the earliest instance of their use in American law. The evidence related to the agreement of 30 downstrokes in a contested signature with those of a genuine signature. It was argued that the probability of this agreement if the contested signature were genuine was extremely small; the probability of observing two spontaneous signatures with the number of overlaid strokes observed in those two signatures was estimated as $(1/5)^{30}$. Hence, the contested signature was a forgery, an example of a transposed conditional and a leap of faith.

Later examples in which the relative frequency of a characteristic in some background or relevant population was used as evidence include the Dreyfus case, the *Collins* case [26] and, in the present day, cases involving DNA profiling. In all the examples, the smaller the frequency, the stronger is the support provided by the evidence for the prosecution proposition.

Propositions may be at one of three levels known as *source, activity, and crime* [27]. Examples of prosecution propositions at each level include the following:

Source: the defendant's DNA was at the scene of the crime;

Activity: the defendant assaulted the victim;
Crime: this is close to the activity level but includes nonscientific evidence as to whether a crime occurred.

The decision-making processes in forensic science that were used in the early 1960s were contrasted with a statistical approach to evidence evaluation by Kingston and Kirk [10] who advocated the use of statistics in forensic science. They commented that the emphasis for a high quality of interpretation of evidence should be upon a formal system rather than on the subjective opinion of an individual (such as an expert witness); a comment that still has considerable relevance.

It was recognized in the 1960s that there are four aspects to the accurate collection and interpretation of data: planning, randomness, independence, and uncertainty [10]. Some updated comments are appropriate.

- *Planning:* Data have to be collected properly to ensure that any analysis based on them may be meaningful. Meaningful results do not arise from the application of statistical analyses to data that have been collected poorly or in an inappropriate manner.
- *Randomness:* It is necessary to make a careful study of the type of evidence that is likely to appear so that the population selected from which a sample is taken and from which background information is derived is one which is equivalent to a random sample. The experimenter is under reasonable control of the choice of the sample but is not under control of the evidence. A true random sample is rarely achievable in the context of forensic science and, in such a situation, inferences have to be made from what is known as a *convenience sample*. This approach is defended by Evett and Weir [28]: "(i)n the last analysis, the scientist must also convince a court of the reasonableness of his or her inference within the circumstances as they are presented as evidence".
- *Independence:* Independence is not necessary before a statistical analysis may be used. In practice, dependence should be assumed and any assumption of independence justified.
- *Uncertainty:* The existence of uncertainty means a statistical analysis must be used. The existence of uncertainty places a limitation on the appropriateness of any decisions made and validates the contention that a statistical approach offers the best solution to the problem.

Discriminating Power

Discriminating power was developed as an answer to the problem of the determination of the quality of a method for distinguishing between two samples from different sources. If an analysis of characteristics of a sample from a crime scene and of a sample recovered from a suspect failed to distinguish the two samples as originating from different sources, it was necessary to know how strong this outcome was as evidence that the samples came from the same source. These problems were of considerable interest to forensic scientists in the late 1960s and in the 1970s; see, for example, theoretical work in Parker [29, 30], Jones [31] and Smalldon and Moffat [32]. Early experimental attempts to answer these questions have been described in Tippett *et al.* [33] for fragments of paint, and in Gaudette and Keeping [34] for human head hairs.

Two individuals are selected at random from some population. The probability that they are found to match with respect to some characteristic (*e.g.*, blood profile or paint fragments on clothing or head hairs) is known as the *probability of nondiscrimination* or the *probability of a match*, PM. The complementary probability, that is, the probability that they are found not to match with respect to this characteristic is known as the *probability of discrimination* [31] or *discriminating power*, DP [32] such that $DP = 1 - PM$. Gaudette and Keeping [34] provided an estimate of the probability that hairs "selected at random" from two individuals are indistinguishable. This probability can be thought of as an average probability. Its value can be used as a broad guideline to indicate the effectiveness of the evidential type in general, but its use as the value of the evidence in a particular case could be very misleading.

Significance Probabilities

The role of significance probabilities in evidence evaluation is best discussed by means of an example. The example chosen is that of a broken window and the characteristic of interest is the refractive index. A fragment F of glass is found on the clothing of a suspect. Let θ_0 be the value of the parameter,

representing the mean refractive index of the broken window. This is the assumed constant.

Let X be the refractive index for F. It is assumed that if F came from a window of refractive index θ, then X is such that

$$X \sim N(\theta, \sigma^2) \tag{1}$$

there being variation in the refractive index within a particular window. The question is whether F came from the window at the crime scene. If this is so, then θ will be equal to θ_0. The converse may not be true.

An argument based on significance probabilities is as follows. Suppose $\theta = \theta_0$. The deviation of an observation x from the mean θ of the distribution is measured in terms of the probability of observing a value for the random variable X as extreme as x, in relation to θ_0.

The supposition that $\theta = \theta_0$ may be referred to as the *null hypothesis*, conventionally denoted by H_0. If H_0 is true,

$$X \sim N(\theta_0, \sigma^2) \tag{2}$$

The probability $\Pr(|\ X\ | > x)$ is the probability of what has been observed (x) or anything more extreme if H_0 ($\theta = \theta_0$) is true (and hence, as discussed above, that F came from the window at the crime scene). The phrase "anything more extreme" is taken to mean anything more extreme in relationship to an implicit alternative hypothesis that, if H_0 is not true, then $\theta \neq \theta_0$.

The probability of what is observed or anything more extreme, calculated assuming the null hypothesis is true, is known as the *significance probability*. It may be thought to provide a measure of the compatibility of the data with the null hypothesis. It is conventionally denoted by P. A small value of P casts a doubt on the null hypothesis. Certain values of P have been used to provide values known as *significance levels* at which a scientist decides to act as if the null hypothesis is false. Typical values are 0.10, 0.05, and 0.01. Thus, for example, a value x of the refractive index for which $P < 0.05$ would be said to be *significant at the 5% level*. The expression for P may be written more explicitly in the notation of conditional probability as

$$P = \Pr(|\ X\ | > x \mid \theta = \theta_0, \sigma) = 0.01 \tag{3}$$

A small value for P would seem indicative of the falsity of the null hypothesis, but it is not the probability that the null hypothesis is true. It is incorrect to use the value for P as the probability that the suspect was at the crime scene. The transposed probability

$$\Pr(\theta = \theta_0 \mid \ \ |\ X\ | > x, \sigma) \tag{4}$$

would be much more useful, but this is not what has been calculated. The relationship between equation (3) and equation (4) is similar to that between the probability of the evidence given the suspect is guilty and the probability that the suspect is guilty given the evidence. The interpretation of the first of the last two probabilities as the second is the fallacy of the transposed conditional.

Significance probabilities also *combine* in a different way from the probabilities of events. For characteristics which are dependent, it is possible that the significance probability of the joint observation may be greater than either of the individual significance probabilities. For example, it is possible that the individual significance probabilities are both <0.05, but the combined significance probability >0.05.

The significance probability is the output of the first part of a two-stage process [35] which models some processes used by forensic scientists from then until the present day. If the outcome of the significance test is significant, then the piece of evidence which is being compared with the crime scene is deemed not to have come from the crime scene. If the outcome is not significant, then the piece of evidence which is being compared with the crime scene is deemed to have perhaps come from the crime scene. This leads to an effect known as the *fall-off-the-cliff* effect (credited in [36], to Smalldon). A comparison which is significant at the 4.9% level leads to an exclusion of the evidence and one which is significant at the 5.1% level leads to the continuation of the evidence in the investigative process. The second stage is one of assessment of the rarity of the similarity. If the similarity is of a rare characteristic, then the evidence is stronger than if it is of a common characteristic.

Likelihood Ratio

The likelihood ratio is the ratio $\Pr(E \mid H_p)/\Pr(E \mid H_d)$, which converts prior odds $\Pr(H_p)/\Pr(H_d)$ in favor of the prosecution proposition (H_p) relative to the defense proposition (H_d) into posterior odds

in favor of the prosecution proposition, given evidence E, $\Pr(H_p \mid E)/\Pr(H_d \mid E)$. A brief historical review is given here. A detailed description of the role of the likelihood ratio is given in a separate entry.

An interesting and somewhat prophetic comment was made by Parker and Holford [35]. The two-stage approach follows, they said, the traditions of forensic scientists. Interestingly, they then went on to make the following remark.

> We could (therefore) set up an index R whose numerator is the likelihood that the crime hair comes from the suspect and whose denominator is the likelihood that it comes from the population at large. In ordinary language one would then assert that it was R times more likely for the hair to have come from the suspect than from someone drawn at random from the population. But a statement of this nature is of rather limited use to forensic scientists, by-passing as it does the similarity question altogether [35].

Note that these are posterior probabilities about the source of the evidence and not about the relative likelihood of the evidence under prosecution and defense propositions.

The logarithm of the likelihood ratio is known as the *weight of evidence* [37] as it is possible to write the odds form of Bayes Theorem in a log-odds form, which is additive and the logarithm of the likelihood ratio may be thought of as weights in the two pans of the scales of justice.

The use of the odds form of Bayes Theorem to evaluate evidence is extended to include the feature of missing evidence by Lindley and Eggleston [38]. The idea of considering a restricted population, as on an island, for theoretical developments of evidential evaluation, a context known as the *island problem*, was introduced by Eggleston [39], Following the publication of various papers by [7, 40, 41], the 1980s saw a flourishing of the development of related ideas, led by Evett. See, for example, Evett [42] which discussed the question "What is the probability that this blood came from that person?", Evett [43] which provided a "quantitative theory for interpreting transfer evidence in criminal cases", Evett [44] which considered the two-trace problem, and, Evett [45] which considered the evaluation of DNA profiles in the case where the defense is "It was my brother". Review papers by Evett include Evett [46] and Evett [47].

Relationship of Significance Probabilities to Likelihood Ratio

As an illustration of the relationship of significance probabilities and the likelihood ratio, consider a characteristic X of interest. The prosecution and defense propositions are H_p and H_d. The mean of X at the crime scene is θ_0 and the distribution of X at the crime scene is $N(\theta_0, \sigma^2)$. For X from an unknown source, of unknown θ, assume that the unknown θ has a normal distribution with mean θ_0 and variance τ^2, where, typically, $\tau^2 \gg \sigma^2$. Then,

$$f(x \mid H_d) = \int f(x \mid \theta)\ f(\theta)\ \mathrm{d}\theta \tag{5}$$

and so

$$(X \mid H_d) \sim N(\theta_0, \sigma^2 + \tau^2) \tag{6}$$

With $\tau^2 \gg \sigma^2$, the distribution of $(X \mid H_d)$ is approximately $N(\theta_0, \tau^2)$. Thus, the likelihood ratio is

$$\begin{aligned} V &= \frac{f(x \mid \theta_0, H_p)}{f(x \mid H_d)} \\ &= \frac{(2\pi\sigma^2)^{-1/2}\ \exp\left\{-(x-\theta_0)^2/2\sigma^2\right\}}{(2\pi\tau^2)^{-1/2}\ \exp\left\{-(x-\theta_0)^2/2\tau^2\right\}} \end{aligned} \tag{7}$$

Consider $\tau = 100\ \sigma$. Let $z^2 = (x-\theta_0)^2/\sigma^2$ be the square of the standardized distance between the observation x and the mean specified by the null hypothesis, θ_0. Then,

$$\begin{aligned} V &= 100\ \exp\left(-\frac{z^2}{2} + \frac{z^2}{2\times 10^4}\right) \\ &\simeq 100\ \exp(-z^2/2) \end{aligned} \tag{8}$$

For example, for measurements of refractive indexes, consider $x = 1.518540$, $\theta_0 = 1.518458$, $\sigma = 4\times 10^{-5}$, $\tau = 4\times 10^{-3}$. Then $z^2 = 2.05^2$ and $P = 0.04$, which, at the 5% level, would lead to rejection of the hypothesis that the fragment of glass came from the window at the scene of the crime. However,

$$V = 100\exp\left(\frac{-2.05^2}{2}\right) = 12.2 \tag{9}$$

a value for V that is supportive of H_p against H_d. Such an apparent contradiction between the two approaches is not a new idea and has been named Lindley's paradox (see, for example, [40, 48]).

Errors

As the procedures for the interpretation of scientific evidence developed, many examples of erroneous interpretations of scientific evidence in the law arose. Probably the most famous is that of the prosecutor's fallacy [49], also known as the *fallacy of the transposed conditional*. The fallacy is to equate the probability of finding evidence on an innocent person with the probability that the person on whom that evidence is found is innocent. In practice, it is not possible to derive the second probability from the first without knowing the probability of the person being innocent before the evidence was presented and without knowing the probability of finding the evidence on a guilty person.

A related fallacy is the defense fallacy [49]. Given a probability, p, of finding the evidence on an innocent person, the defender's fallacy then multiplies this probability, p, by the size of a relevant population, say N, to obtain the expected number of people Np with the evidence in that population. It is then argued that a large value of Np renders the evidence meaningless as the accused is only one amongst Np people. However, in rebuttal, before the evidence was presented, the accused was one of N people. The evidence has reduced the pool of potential criminals from N to Np and is therefore of some worth.

Another statistic, while not an error but difficult to interpret, is that which gives the probability of the existence of more than one person with the evidence under consideration, conditional on the existence of one person (the accused) with the evidence. As an example of its use, the court in *Collins* apparently concluded that, if a random item sampled from a large population belongs to a rare type, then the probability of at least one more item of that type in the population is about 0.41. While not an error, this is not a very helpful statistic in that it is not possible to combine this result with other evidence to assess the value of the combined evidence.

Another error is the numerical conversion error. Given a characteristic with probability p, the use of the numerical conversion error is to argue that one has to test $1/p$ people before observing another person with the characteristic. For example, if $p = 0.01$, $1/p = 100$. However, the probability of observing another person with the characteristic in 100 people is $1 - (1 - p)^{100}$, which equals 0.634. Further examples are given in Aitken and Taroni [1].

Bayesian Networks

The use of deterministic networks for legal analysis had been proposed in the 1930s [50]. It was not until the late 1980s that a statistical theory was developed and applied to forensic scientific examples.

Propositions and evidence are represented by nodes in a graph. Edges in the graph correspond to direct associations between the nodes joined by the edge. Nodes that are separated by other nodes are said to be independent conditionally on the intervening nodes. Conditional probability tables and probability density functions are needed to complete the construction of a network. Once evidence is known, the status of the corresponding node is switched from uncertain, with associated probabilities, to certain, where one and only one outcome has a probability of 1, while the others have a probability of zero. This process is known as *instantiation*. The probabilities associated with other nodes are adjusted accordingly. Initial work may be found in Aitken and Gammerman [51] and in Dawid and Evett [52]. A review of work up to 2005 is given by Taroni *et al.* [53].

Interrogation

Scholars and police detectives often distinguish between interviews and interrogations. The goal of an interview is to gather information relevant to a criminal investigation, whereas the goal of an interrogation is to persuade a suspect to admit to committing or participating in a crime [1–2]. Once detectives have concluded (correctly or incorrectly) that a suspect is guilty of committing a crime, they deploy several psychologically powerful interrogation techniques to move the suspect from denial to confession.

Historically, physical and psychological torture have been the primary tools of interrogators and, in many countries, torture remains a standard interrogation technique [3]. In the United States, at least through the early 1930s, police used the "third degree" – routinely beating, threatening, and abusing criminal suspects in the pursuit of confessions [4]. As a result of the Wickersham Commission Report in 1931 [5] and a number of Supreme Court cases beginning with *Brown v. Mississippi* [6], physical abuse of suspects began to decline in the 1930s and by the 1960s, appeared to be rare in the United States [7]. As a substitute for physical and psychological abuse, police began to develop increasingly subtle and sophisticated psychological interrogation techniques.

In 1940, W.R. Kidd published *Police Interrogation*, the first police interrogation manual, instructing police on the new science of modern interrogation. In 1942, Fred Inbau published the first edition of his seminal interrogation manual, *Lie Detection and Criminal Interrogation.* With John Reid and others, Inbau revised and expanded this training manual through several revisions. The most recent edition – *Criminal Interrogation and Confessions* by Inbau, Reid, Buckley, and Jayne – was published in 2001. The Chicago-based firm, *Reid and Associates*, transformed these manuals into a training program and, in 1974, began offering seminars to police and security professionals across North America. More than a quarter million police have now been trained in the Reid Method of interrogation. Undoubtedly, many more police officers have either read the Inbau *et al.* manual, or have learned Reid tactics by observing or working with other interrogators. Research confirms that these tactics are frequently used by detectives in the United States [8–10].

If a suspect is in police custody, police are required to issue the well-known *Miranda* warnings prior to interrogation, informing the suspect that he has the right to remain silent, the right to appointed counsel, and that anything he says can be used against him in court [11]. Surprisingly, *Miranda* has proven to be only a minimal safeguard against coercion. The overwhelming majority of suspects (estimates range from 78 to 96%) relinquish their rights and thus appear to consent to interrogation [12].

In practice, police have devised several strategies to elicit waivers to the *Miranda* warnings. These include reading the *Miranda* warnings in a quick, confusing or perfunctory manner; de-emphasizing or minimizing the significance of the *Miranda* warnings; obscuring the adversarial nature of the police-suspect interaction; and telling the suspect that the interrogator can help him only if he first waives his *Miranda* rights [13].

Police interrogators persuade a suspect to confess by manipulating his perception of the nature and gravity of his immediate situation, the limited choices available to him, and the consequences that follow from each of these choices. The interrogator labors to convince the suspect that admitting culpability is the best and most sensible course of action. First, the suspect's resistance is broken by causing him to perceive that he is trapped and that his situation as hopeless [14]. The interrogator leads the suspect to believe that his guilt can be objectively demonstrated to the satisfaction of any reasonable person; that this fact is indisputable and cannot be changed, that there is no way out of his predicament, and that his fate is already determined.

Alone in the interrogation room with one or more police officers, the suspect is repeatedly accused of committing the crime. The interrogator is likely to express unwavering confidence in these assertions of guilt, ignoring or cutting off any of the suspect's denials or objections. This is likely to have the effect of causing the disoriented suspect to believe that he bears the burden of proving his innocence. If the suspect offers an alibi, the interrogator may attack it as inconsistent, implausible, contradicted by all the case evidence, or simply impossible – even if none of these characterizations is true. Perhaps the most powerful tool that police use to convince the suspect that his situation is hopeless is to confront him with objective and irrefutable evidence of his guilt – whether or not such evidence actually exists.

American law permits interrogators to pretend they have evidence when they do not, and police often confront suspects with fabricated evidence such as nonexistent eyewitnesses, false fingerprints, make-believe videotapes, false polygraph results, etc. [15]. Confronted with real or fabricated evidence, many suspects conclude that conviction and imprisonment are inevitable, and decide that there is no choice but to confess.

During the next phase of interrogation, the detective seeks to create the impression that confessing will actually improve the suspect's otherwise hopeless situation. Interrogators emphasize their discretionary power to favorably influence the suspect's case and describe how unfavorably his case is likely to be perceived by key players in the justice system: prosecutors, jurors, or a judge. The interrogator's message to the suspect is that he will be charged with a less serious crime and receive a shorter prison sentence if he accepts responsibility, admits guilt, and expresses remorse [16]. Conversely, continued denial will result in a more serious charge and a longer prison sentence. Detectives suggest that the suspect is dependent on the interrogator's help and can only be released from the pressures of interrogation by confessing [14].

To clear the path for an admission, interrogators suggest honorable or sympathetic reasons why the suspect might have committed the crime. For example, interrogators may suggest that instead of premeditated murder, the suspect was acting in self-defense, or that he accidentally killed the victim. In interrogation manuals, this technique is known as using "themes" [2]; [17]. These "themes" are actually hypothetical scenarios or rationalizations that morally, psychologically, and legally downplay, excuse, or justify the suspect's act. Interrogators use such scenarios to make a suspect comfortable with making an admission, and to persuade him that if he makes an admission, he (with the interrogators' help) can control how his admission is framed for relevant audiences (i.e., prosecutors, judges, juries, his friends and family, the victim's friends and family, and perhaps the media). Scenarios can be a subtle yet powerful inducement. They work by shifting blameworthiness from the suspect being interrogated to another person, or to the social circumstances that caused the act, or by redefining the act itself. Delivered against the backdrop of the techniques that have preceded them – social isolation, accusations of guilt, attacks on denials, evidence ploys, etc. – these scenarios are intended to motivate the suspect to admit the crime because he is being offered a chance to mitigate his punishment by choosing the less incriminating of two bad explanations.

The tactic of reframing the interrogation as an "opportunity" simultaneously misrepresents the role of police as allies instead of adversaries, and suggests that interrogators can and will help the suspect to minimize the consequences of his crime. Interrogators may explicitly tell a suspect that they can help him by how they write up their report following questioning, or by what they tell the prosecutor prior to charges being filed, or by how they testify before a judge or jury at trial. Interrogators may also offer to help a suspect in ways that extend beyond the criminal justice system, such as arranging for counseling or help from social services. Of course, the catch is

that these benefits can only be realized if the suspect complies with the interrogators' demands for an admission. Police often imply that this "opportunity" for the suspect to "tell his side of the story" is time-limited and will vanish once the interrogation ends.

Effective psychological interrogation is an incremental, cumulative process. Through tactics that rely on deception, manipulation, and coercion, the interrogator gradually restructures the psychological context within which the suspect makes the decision about whether or not to confess. A suspect may enter the interrogation room confident that he will never agree to make an admission. However, once the suspect has been convinced that he will almost certainly be arrested, convicted, and punished, his assessment of his immediate situation and his decision-making calculus are likely to change such that confessing may be seen as the only available means of improving his prospects [15].

The modern interrogation process is designed to break the resistance of a rational person who knows he is guilty and to persuade him that the benefits of confessing outweigh the costs [14]. The presumption is that the suspect under interrogation is guilty and will, at least initially, steadfastly deny his guilt. This presumption of guilt should be based on solid evidence. However, it is sometimes based on little more than a detective's intuition. Acting as a sort of human lie detector, interrogators may mistakenly evaluate the suspect's verbal and nonverbal behaviors as indicative of guilt and then subject an innocent person to coercive interrogation techniques [18]. Indeed, Inbau *et al.* caution that interrogation techniques should only be used when a detective is certain of the suspect's guilt, not as a means of establishing guilt without corroborating evidence. However, once a detective has misclassified an innocent person as guilty, he is likely to resort to coercive interrogation techniques [19]. Further, because no credible evidence is likely to exist against an innocent suspect, getting a confession becomes even more important than usual – police detectives desperately need a confession to successfully build a case, especially in high profile and capital prosecutions [20]. Unfortunately, most interrogation training manuals give little thought to how the methods they advocate sometimes lead innocent suspects to confess. Instead, police trainers and interrogators, in the face of abundant empirical evidence to the contrary [21], assert that their methods will only produce confessions from the guilty. The central research issue is no longer whether police-induced false confessions exist, but why they occur and what can be done to prevent them.

Several "best practice" reforms have been proposed to increase the number of true confessions while decreasing the number of false ones. Videotaping of interrogations may be the single most important policy reform available. Videotaping creates an objective, comprehensive, reviewable record of what occurred in the interrogation room. When a videotape is available, triers of fact do not need to guess who is telling the truth about what happened during a disputed interrogation. Videotaping opens police practices up to the possibility of external scrutiny, and because interrogators know they may be scrutinized, they are less likely to use the psychologically coercive and improper interrogation techniques that are the primary cause of false confessions in America [15]. Lawyers, judges, jurors, and experts should be able to evaluate not only what was said and how it was said, but also to see the rich array of nonverbal cues (e.g., facial expressions, gestures, posture, personal space, and gaze). At the time of this writing, seven states and District of Columbia have laws requiring police to record interrogations in their entirety in some or all criminal cases, and many police departments have begun to voluntarily record interrogations [22].

Ideally, the entire interrogation should be videotaped; both the suspect and the interrogator should be visible, and the video should carry a time/date stamp. Recording the entire interrogation ensures that we do not rely on partial, selective, or biased records of what transpired. Too often, police videotape only the final, damning confession. To evaluate whether a confession is coerced or contaminated, we need to be able to examine the interaction that culminated in a confession. The requirement that both the suspect and the interrogator be visible follows directly from research demonstrating that only such an inclusive camera focus minimizes biased interpretations about the coerciveness of the interrogation [23]. Finally, including a time/date stamp on the recording ensures that there is an accurate accounting of not only the length of the interrogation but also the length of breaks or gaps in the interrogation process.

A second important reform is the use of social science expert testimony in cases involving a disputed

interrogation or confession. There is now a substantial and well-accepted body of scientific research on this topic, and case law supports the admissibility of such expert testimony [24]. If a factually disputed confession is introduced at trial, the jury will want to know how an innocent person might possibly have been made to confess falsely, especially if to a heinous crime. Most people appear to believe that an innocent person will not falsely confess to police unless he is physically tortured or mentally ill [25–26]. The purpose of expert testimony at trial is to provide an overview of research on interrogation and confessions to assist the jury in making a fully informed decision about what weight to place on the defendant's confession. By educating the jury about the existence, psychology, causes, and indicia of police-induced false confession, social science expert witness testimony at trial should reduce the number of confession-based wrongful convictions.

Police interrogation is an essential investigative activity, but it requires careful monitoring and regulation if we are to trust the voluntariness and reliability of the admissions produced by this inherently manipulative process. In a democratic society that places a high value on individual rights, fair procedures, and just outcomes, custodial interrogation is likely to remain controversial. We must be careful to give police the tools they need to help convict the guilty, while simultaneously putting safeguards in place to protect the innocent.

Interrogative Suggestibility

Law enforcement uses a variety of psychologically sophisticated techniques to extract confessions from those whom they believe are guilty of an offense. The Reid Technique [1] is the most widely taught procedure on how to extract confessions from suspects using legally sanctioned methods (*see* **Interrogation**). Unfortunately, certain individuals are particularly susceptible to police influence (*see also* **Eyewitness: Suggestibility of**). When these police techniques are used on vulnerable individuals, it becomes more difficult for the suspects to assert their Miranda [2] rights to remain silent, seek the consultation of an attorney before or during the interrogation, or to request one if indigent (*see* **Capacity to Waive Miranda Rights**).

If law enforcement should have known that a suspect was particularly vulnerable to not knowing or appreciating rights, such factors may be relevant to the voluntariness of the *Miranda* waiver or the voluntariness of the confession. Suspects, even if guilty, may be at high risk for being incapable of asserting their rights and resisting police demands. A confession may be suppressed, if based on the *totality of circumstances* [3], the court believes a defendant was unable to make a knowing, intelligent, or a voluntary waiver of his rights or that the confession itself was not voluntary.

Types of False Confessions

Additionally, there are some individuals who do not commit the offense or not to the level to which they are being accused. Some of these suspects are quite susceptible to police influence and to giving false or erroneous accounts of their participation in the offense. A false confession is defined here as one in which an individual admits to a crime or overemphasizes or mischaracterizes his or her involvement in the crime. It is more common for an individual to overstate his or her role in a crime than to confess to a crime they had no involvement in, but both of these do occur. Not only do suspects sometimes falsely confess to crimes that they did not commit, but also they do so quite regularly [4].

It is impossible to estimate the rate and frequency of false confessions because we do not know who is genuinely guilty of the act and who is not. Retractions happen in both true and false confessions, and include so-called confessions, which a defendant says the law enforcement falsely created. We know that innocent defendants are sometimes wrongly convicted. They are later exonerated by DNA evidence or when the truly guilty party is apprehended. Estimates of false confessions vary depending upon the research design and how the term *false confession* is operationalized. States do not keep a record of the number of suspects annually interrogated, how many of the interrogations result in a true confession, false confession, or no confession, and how many of those are charged with a crime and eventually are found guilty. False confession estimates range from a low of fewer than 30–60 false confessions per year [5] to reports as high as 600 [6].

Types of False Confessions

There are numerous models conceptualizing the categories of false confessions. Kassin and Wrightsman [7] describe three types of false confessions. *Voluntary false confessions* are given without pressure from police. An individual willingly goes to the police to falsely confess to a crime because of the morbid need for notoriety, to protect a friend or relative, or a

pathological need to be punished. *Coerced-compliant false confessions* result from the use of psychological, physical, or environmental pressures by police to extract a confession. In these situations, a suspect may falsely confess to achieve some immediate goal, such as to end the stressful interrogation, to go home, or to get less punishment.

Because the suspect knows he did not commit the crime, a retraction of the confession is likely once the suspect is out of the interrogative environment. *Coerced-internalized false confessions* are when the suspect, who has been subjected to intense police interrogative procedures, such as the use of the Reid Technique, comes to believe or internalize that he or she committed the crime for which they have been accused. This happens most frequently with individuals who have some memory lapse for their behavior at the time of the offense, often due to psychosis or drug intoxication. Law enforcement gets the suspect to believe that they have incriminating evidence (i.e., witnesses, fingerprints, polygraph results). The suspect, who does not really remember what transpires, internalizes the police version of the crime. Individuals who give this type of false confession are highly suggestible.

McCann [8] added a fourth type of false confession, the *coerced-reactive false confession*. The individual is pressured or induced to confess by some other person other than law enforcement. The pressure may come from an abusive husband who threatens to harm if the wife does not confess; or from a gang member who threatens the individual's family if he "does not take the rap".

There are other models of how false confessions can be conceptualized. Ofshe and Leo's model [4] emphasizes the levels of police coerciveness and makes a distinction with the temporal stability in a suspect continuing to falsely believe he or she committed a crime.

In reality, false confessions may not fall within discrete categories but rather overlap with each other. None of these models adequately account for false confessions due to the interaction of police with defendants who have psychotic thinking or the impact of the physical environment (i.e., prolonged isolation, and restraints) [9]. Also, some suspects internalize guilt without being coerced to do so.

Interrogative Suggestibility Construct

Gisli Gudjonsson coined the term *interrogative suggestibility* as the extent to which an individual comes to accept messages or information communicated during formal questioning, whereby that individual comes to believe that information given is essentially true [9, 10]. This construct is different from suggestibility related to hypnosis, which primarily deals with motor processes [11]. According to Gudjonsson, there are three prerequisites with interrogative suggestibility. The suspect must be *uncertain* as to the correct answer to a question. The subject must believe that the interviewer's intentions are genuine and constructive and not involving deception. This is referred to as *interpersonal trust.* Finally, there is an *expectation* component. The subject is reluctant to declare what he does not know because he thinks the interviewer believes that the subject knows the answer.

Interrogative suggestibility appears to be the main component of the coerced-internalized false confession, although there is some relationship to other types of false confessions. The suspect is *uncertain* of his participation in an alleged offense. Law enforcement tells the suspect they have proof that he was involved in the offense due to alleged incriminating data, such as failing a polygraph and/or fingerprint matches. When the police tell the suspect they know he committed the crime but are allowing him the chance to tell his side of the story, which is oftentimes suggested to the suspect by law enforcement as an alternative to the more morally reprehensible version already discussed by them, the suspect believes the officer's statement that it is in his own interest to confess. Thus, interpersonal *trust* is established. The suspect is also hesitant to continue to state he does not know whether he committed the offense because there is the *expectation* that he should know. The theory of interrogative suggestibility is also applicable to the formal interview of witnesses and victims [10].

Gudjonsson Suggestibility Scales

The Gudjonsson Suggestibility Scales (GSS) [9, 10] provide the mental health professional with an objective method to help assess interrogative suggestibility. There are two versions of the GSS, and both have the same format, scoring, and administration. The differences between the versions are the narrative

story presented to the subject and the standardized questions about the story. The GSS is presented as a memory test. The subject is asked to read a narrative story containing 40 facts. A subject is only given one version of the test. After the story has been read, the subject is asked to narrate everything he could remember about the story". After 50 min have elapsed (or immediately for someone with poor initial recall), 20 questions are asked, 15 of which are designed as leading or misleading. One obtains a Yield 1 score based on the number of leading questions given in to by the subject. The subject is then firmly told that a number of errors were made (regardless of actual performance), that the questions will be repeated, and he or she needs to be more accurate. After the questions are repeated, the examiner calculates the number of times the subject has given in to the second round of leading questions, for a Yield 2 score. Shift is also measured. This is the extent to which a subject has changed his response, right or wrong, to a different response. Yield 1 and Shift scores are then summed to produce a Total Suggestibility (Total GSS) score. Yield 1, Yield 2, Shift and Total GSS scores can then be compared to an appropriate normative group (e.g., adults or juveniles).

Interrogative Suggestibility Research

The GSS was developed using population groups from Iceland and Great Britain. This should not present a problem in the use of the test with populations from the United States. Although there were some ethnic differences in suggestibility scores, the differences were minor compared to other sources of variance [12]. Even so, the GSS has proved useful in providing relevant behavioral samples as how a defendant gives in to leading questions and shifts from one response to a different response under pressure [13]. There have been inconsistent findings concerning gender and suggestibility [9] as measured by the GSS, showing no simple correlations.

Age has also been shown to have an influence on an individual's suggestibility. Children below the age of 12 have been shown to be more suggestible than adolescents. They had higher Yield and Shift scores. Yet by age 12 and older, adolescents were no more likely than adults to give in to leading information. They were more likely to change to a different response when given negative feedback compared to adults. By age 17, there were no differences in either Yield or Shift types of suggestibility compared to older individuals [9].

Numerous research studies summarized by Gudjonsson [9] have shown an inverse relationship between intelligence and interrogative suggestibility. Individuals with mental retardation and others of low intelligence are more suggestible than those with higher intelligence. In particular, people with mental retardation are substantially more likely to change their answers in response to feedback that is even friendly, as opposed to feedback that is unfriendly or neutral [14, 15]. Memory is also correlated with suggestibility [9]. The faster the memory deteriorates, the more suggestible the person becomes. Individuals who have poor memory do not trust their own judgments and rely more on what others tell them. An individual is thus more prone to give in to misleading information. Shifting from one response to a different response is more associated with interpersonal and social–psychological factors.

Research has also shown that poor assertiveness, evaluative anxiety, state anxiety, and avoidance coping strategies are related to suggestibility. More chronic forms of anxiety may also be related [16].

Research has shown that prior criminal convictions decrease the individual's suggestibility [9]. It is assumed that the prerequisite of interpersonal trust is no longer as potent in those who have prior negative experiences with law enforcement. Sleep deprivation is also correlated with suggestibility, particularly after negative feedback [17–19]. The longer the sleep deprivation occurs, the higher the suggestibility becomes. The relationships of suggestibility with sleep deprivation combined with state anxiety are important components when considering police interrogation procedures. Mental illness *per se* is not correlated with suggestibility [9].

Related Constructs

Mental health professionals can provide relevant data to judges and juries regarding psychological factors which heighten the risk of a specific defendant producing an involuntary waiver of rights and/or a false or coerced confession. This assessment is case-specific and thus, it is important to integrate a

defendant's vulnerabilities with interrogation tactics and techniques actually used. Case law [20] allows the jury to hear such testimony to help them to decide how much weight to give to a defendant's confession.

In addition to a comprehensive clinical interview and review of third party data, psychological testing provides useful information regarding a defendant's reality testing, judgment, functioning under stress, impulse control, accommodation, assertiveness, and interrogative suggestibility.

Gudjonsson states that *compliance* is another psychological construct that is related to false confessions. Compliance differs from suggestibility in that compliance does not require a private or internal acceptance of the proposition or request, that is, the defendant may confess or give a statement about the crime, even though he does not believe or agree with what is said [9]. Compliance is more directly related to the coerced-compliant type of false confession. Although suggestibility and compliance are two different constructs, research has shown a modest correlation between the two [21, 22]. An evaluation of interrogative suggestibility is warranted even in those cases where there is no doubt the defendant knew whether or not he committed the offense. Since most police interrogations involve some misleading or leading questioning and some pressure for the suspect to change their answers, information regarding a defendant's susceptibility to those procedures is relevant.

A third construct specified by Gudjonsson that is related to confessions is *acquiescence*. It is the tendency to act in accordance with the wishes of others, to affirm information, regardless of the content [23]. Gudjonsson [9] reviewed the research which shows only weak correlations between acquiescence and suggestibility. There was little correlation between acquiescence and compliance.

Gudjonsson has shown [9] that those who falsely confess obtain higher GSS scores than those who do not. A high score on the GSS does not signify a false confession though. A highly suggestible individual may confess accurately about a crime. A low suggestible individual may falsely confess. In addition to the GSS, the use of personality tests such as the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) and 16 Personality Factor (16 PF) can help the clinician assess compliance and acquiescence and integrate those constructs with other aspects of an individual's psychological functioning at the time of the interrogation. As suggestibility is correlated with intelligence and memory, intelligence testing is usually warranted.

Intersecting Lines: Documents

Introduction

In the study of questioned documents, it may be important to determine the order of execution of certain elements of a document. One of the most common sequencing problems is the order of intersecting writing lines. In both criminal investigations and civil litigation, the order of intersecting lines can take on great importance. For example, one party to a contract may be accused of altering the document by wrongly adding a handwritten notation. If this handwritten entry intersects a signature (*see* **Handwriting and Signatures, Comparison of**) or other text, a forensic document examiner may be asked which came first, the signature/text or the handwritten notation. The answer to that question may determine whether the contract has been altered (*see* **Alterations: Erasures and Obliterations of Documents**).

Line intersection problems have concerned document examiners for more than 100 years. In 1901, Ames discussed an optical illusion that is familiar to every document examiner. That is, when a dark ink and a lighter ink cross each other, the darker ink will almost always appear to be on top regardless of the actual sequence of execution. He also discussed another phenomenon well known in his time – writing ink flowing into a previously written line as the first line crosses the second [1].

Since Ames' time, forensic document examiners have continually conducted research into the problem of line sequencing. Early writers were generally pessimistic regarding the potential success of determining the sequence of intersecting ink lines [2], and over the years many examination methods were proposed. Some of these methods are more reliable than the others; however, no method will allow every question to be answered [3]. It is imperative that sequencing problems be approached with caution. Most document examiners will agree that "substantial, repeated intersections of two writings offer a higher probability of success than a single, indifferent intersection . . ." [4].

There are no books dedicated to the forensic examination of line intersections. Texts on the general topic of forensic document examination dedicate only a small amount of space to the subject. Most of the information regarding the examination of line intersections is in forensic science journals and unpublished conference papers. Some of these papers provide conflicting information. Some of the methods found in these articles and papers are rarely, or perhaps never, used in actual forensic casework.

While line crossings often involve ink from writing pens, sequencing problems may also involve computer-printed text, typewritten entries, paper folds, and handwriting indentations. When line crossings involve the same or similar writing or printing mediums, they may be termed *homogeneous line intersections*. When different mediums intersect one another, the term *heterogeneous line intersection* is appropriate [5].

Microscopic Examination

Numerous methods have been proposed to determine the sequence of intersecting ink lines. In 1996, Poulin

published a review of more than 30 methods [6]. For forensic document examiners, nondestructive methods of examination are always preferable; however, some methods used to examine line intersections are destructive to the document. Perhaps the best-known nondestructive technique used to determine the order of writing strokes is an examination of the intersecting lines using a stereo binocular microscope. The separate optical paths of this microscope provide a three-dimensional image, which is essential in the microscopic study of line crossings.

Document examiners use both vertical and oblique illumination in conjunction with the microscopic examination of a line intersection. When vertical lighting is used, the presence or absence of a specular reflection is important [7, 8]. In some heterogeneous line crossings, such as when certain inks cross a carbon-film-typewritten or laser-printed character, a specular reflection may be observed if the ink is on top (Figure 1). Conversely, the lack of a specular reflection may be indicative of the ink being underneath [9, 10].

Oblique lighting, also referred to as *grazing or side lighting*, is useful in studying the groove caused by a writing stroke. Interruptions of the writing groove can sometimes be used to determine the order of the writing strokes. On occasion, a pen will skip when it hits the groove of the initial stroke. This causes a gap in the second line, which also provides evidence of the sequence of writing. An accumulation of excess ink can occur on the far edge of an underlying writing groove when crossed by a second pen. When different colored inks cross, particles of the first ink may be carried away by the second. Sometimes an ink line narrows when it crosses the groove of an existing writing line [11].

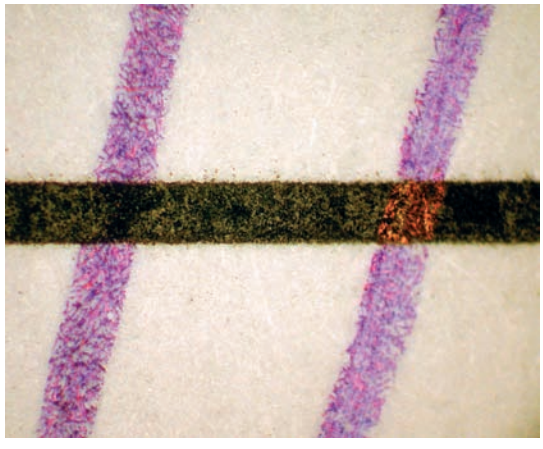

Figure 1 Microscopic examination of line intersections with vertical illumination showing, on the right, a specular reflection at the point of the intersection indicating that the ballpoint pen ink is on top of the toner. The intersection on the left does not display a specular reflection. For this intersection, the ink is underneath the toner

Typically, document examiners conduct microscopic examinations of line intersections at relatively low magnification (60× and below). Higher power magnification (125–500×) has also been used to determine sequence of execution when lines do not intersect in the traditional sense. For example, laser-printed and photocopied documents are covered with scattered toner particles that are invisible to the naked eye. Aginsky reported on a microscopic technique used to determine whether the stray toner particles are below or above ballpoint pen ink writing [12].

Another microscopic technique involves the use of the scanning electron microscope (SEM) [13–15]. This method can be effective with some types of line intersection problems, but can also be destructive to the document. Depending on the type of SEM used, sample preparation may require extraction of the line crossing from the document, as well as a coating of the line crossing with a conductive material. The latter can be avoided with the latest generation of SEMs (environmental SEM (ESEM)). The SEM can also be used in conjunction with the Kromekote paper technique discussed below [16, 17].

Lifting Method

One somewhat destructive technique is the use of Kromekote paper to lift an image of the line intersection [18]. Kromekote paper is a highly glossed coated paper. The technique is reportedly effective with ballpoint pen crossing when two or more line crossings are available for examination. The technique is not reliable with fluid inks and pencil strokes, but some researchers have reported success with other mediums (*see* **Writing Instruments and Printing Devices**). The technique requires placement of a small piece of Kromekote paper over the suspect line intersection. Pressure is applied to the back of the Kromekote paper using a heated tacking iron. In some variations of the technique, the application of cold pressure, pressure, and steam, as well as the use

of solvents, is involved. Photographic paper has been used in the place of Kromekote paper [19].

If performed correctly, a portion of the ink at the line intersection is transferred to the Kromekote paper. A careful study of the lifted intersection provides information regarding the sequence of the line crossing by observing the edges of the intersection. Other lifting methods, such as the wax lift method [20], have also been used.

The Kromekote method, as well as other lifting methods, should be used only after a careful microscopic examination of the suspect intersection. It may not be possible to conduct an effective microscopic examination after the Kromekote method is conducted.

Infrared Examination Methods

Forensic document examiners commonly use various nondestructive lighting techniques to differentiate inks (*see* **Ink Analysis**). One of these techniques relies on electronic imaging systems capable of "seeing" into the near-infrared region along with various bandpass and longpass filters, as well as a high intensity light source. Using this equipment, some inks can be observed to luminesce, while other inks do not. Utilizing another technique, some inks will transmit light, effectively becoming invisible.

The sequence of inks cannot be determined on the basis of the general appearance of a luminescing ink crossing a nonluminescing ink. In some cases, a luminescing ink below a nonluminescing ink will appear to be on top and *vice versa*. For this reason, infrared techniques have limited usefulness in line sequencing problems.

If a nonluminescing ink crosses a luminescing ink while the latter is still wet, it may be possible to see some of the luminescing ink that has been carried away along the nonluminescing ink line (Figure 2). This technique is useful in determining whether the nonluminescing ink was written last [21]. The examiner must ensure that the luminescing ink has not merely bled into the nonluminescing ink line. Of course, this technique would not be useful with a homogeneous ink crossing, and if the luminescing ink has dried, it is unlikely that this effect can be observed. Also, note that in the illustration there is an optical illusion that makes the luminescing ink appear to be uppermost. A variation of this technique involves the use of a laser to generate the luminescence in the ink [22]. If the ink from a porous tip pen transmits light, and the pen crosses a pencil writing, it may be possible to see particles of graphite carried away in the ink line [23].

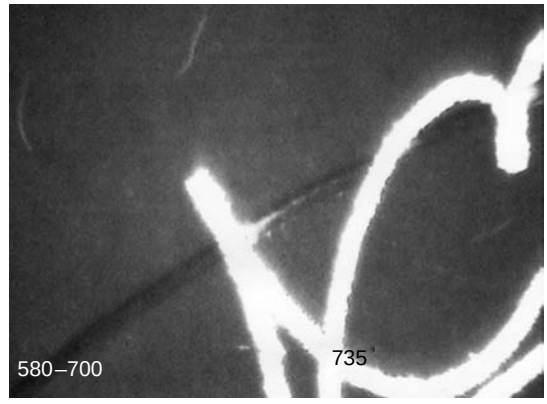

Figure 2 Image showing ink crossings that are observed using an infrared luminescence technique. The underlying freshly written and luminescing fluid ink has been pulled along the ink line of the uppermost and nonluminescing ink

Radley reported a "waisting effect" that sometimes occurs when a nonluminescing ballpoint ink crosses a luminescing ballpoint ink. This effect is the result of the second pen entering the groove of the first ink line, which can cause the crossing stroke to have an hourglass-like appearance at the point of the intersection [24].

Paper Folds

It is often possible to determine whether an ink line that intersects a paper fold was written before or after the paper was folded (*see* **Paper Analysis**). An ink line written prior to a paper fold will generally have a smooth and continuous appearance, although, in some cases, a break in the writing line occurs due to wear and tear at the fold.

When the writing line crosses a previously existing fold, the point of the pen may skip for a short distance prior to returning to the paper. In addition, an accumulation of excess ink may appear at the point where the pen point hit the fold (Figure 3). When a fluid ink is used, the ink may flow into the paper fold [25].

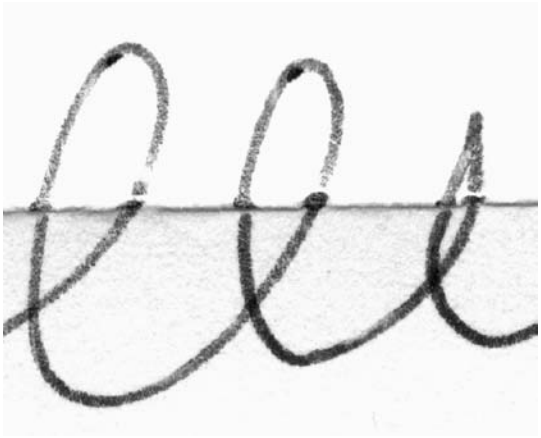

Figure 3 Paper folding prior to ballpoint pen writing. An accumulation of ink appears in the area where the point of the pen hit the fold. In addition, a break in the writing line appears where the point of the pen skipped prior to returning to the paper

Ink and Toner Intersections

Laser printers and electrostatic photocopiers are ubiquitous in our business culture. These machines make documents by using a toner to construct the text on the paper. The toner is a powder that is fused to the paper by heat and pressure. It stands to reason that questions regarding the sequence of ink and toner intersections are common.

Some aspects of ink and toner line intersections were discussed in the section of this article discussing microscopic examinations. Another frequent method of examining ink and toner intersections involves scraping away the toner at the point of the intersection. Obviously, this method is destructive to the document. One might expect that if ink is found under the toner, then the ink was placed on the paper first. If no ink is found, the writing occurred after the document was printed or copied. In actual forensic casework, it is not so simple.

Research has shown that fluid inks can soak through the toner and into the paper below [26]. An analogy would be pouring water over a pile of gravel. The water would run through the empty spaces in the gravel and soak through to the ground. At a microscopic level, laser-printed text is somewhat porous. Fluid inks may soak through to the bottom, giving the impression that the ink line was made first. This is less likely to occur when ballpoint pen inks, which are more viscous, are used. Because of this soaking-through phenomenon, caution must be used when interpreting the results of this method.

Ink and Typewritten Text Intersections

Most modern typewriters use correctable carbon film ribbons. The typewritten characters are created by the pressure of the typeface striking the film of the ribbon. It has been previously mentioned that a ballpoint pen ink over carbon film ribbon will cause a specular reflection. The specular reflection indicates that the writing ink is uppermost.

Document examiners have also used the scraping method discussed in the previous section regarding toner [27]. The same cautions apply. Fluid ink can soak through the carbon film to the paper below giving the false impression that the writing came first. Another drawback with the scraping method is the risk that ink below the carbon film might be removed during the scraping process. This is more likely to occur with ballpoint pen inks since these inks do not soak into the paper fibers like fluid inks.

Since carbon film ribbons are designed to be removable from the paper surface, another method of examining ink and carbon film intersections involves lifting the carbon from the paper with an adhesive tape or a correction ribbon.

Electrostatic Detection Apparatus Technique

The electrostatic detection apparatus (ESDA) is a device that is used to detect indented writing impressions on paper. When writing occurs on one sheet of paper with another sheet underneath, indented writing impressions are created on the sheet below. Mohammed demonstrated that the ESDA is useful for sequencing inkjet printing and indented writing impressions. He found that the ESDA is not useful in sequencing laser printing and writing impressions [28]. The ESDA has also been used to sequence writing impressions with ballpoint pen writing [29, 30]; fiber tip, porous tip, and rollerball pen writing [31]; and writing made with highlighter ink [32].

Other Techniques

A study of the embossing on the reverse side of paper may provide information as to which writing line

crossed another first. One study reported successful results on more than 90% of 300 line crossings [33].

Researchers in Taiwan have applied chromaticity measurements and clustering techniques [34] as well as the CIELAB uniform color system and sample duplication [35] to the problem of line intersections.

Laser profilometry, a technique that produces a 3D topographical representation of a line intersection, has a high degree of accuracy under testing conditions. It also has the advantage of being nondestructive [36, 37].

Attenuated total reflectance-Fourier transform infrared (ATR-FTIR) techniques have been successfully used on line sequencing problems involving laser printer toner from two different models of laser printers, as well as toner and writing ink sequencing problems [38, 39].

Time-of-flight secondary ion mass spectroscopy (ToF-SIMS) has been used to assess the sequence of heterogeneous ink crossings by measuring the secondary ion mass spectra of the inks [40].

Atomic force microscopy (AFM), a type of scanning probe microscopy, reportedly produces qualitative results comparable to those from scanning electron microscopy without the drawbacks associated with many versions of the SEM [41].

Ipse Dixit Testimony

This is a Latin term, meaning "he said it himself". It refers to a statement wherein the speaker is the sole authority for its truth or assertion. When dealing with forensic evidence, the phrase may be used where an expert witness asserts that the methodology

used in examining evidence is sound, reliable, and replicable, but, upon further request, fails to provide evidence for this assertion. In jurisdictions that follow precedents such as those embodied in *Daubert v. Merrell Dow Pharmaceuticals (1993) (see* ***Daubert v. Merrell Dow Pharmaceuticals****), Kumho Tire v. Carmichael* (1999) (*see* ***Kumho Tire v. Carmichael***), or *General Electric v. Joiner* (1997) (*see* **General Acceptance Test for Novel Expert Evidence**), the courts will ordinarily not allow self-serving assertions of reliability to be received in evidence. The court precedents referred to provide, specifically, that *ipse dixit* evidence is insufficient to prove the reliability of a technique or methodology in the absence of proof of experimentation by other scientists, the existence of data bases, and a peer review literature compelling a belief in the conclusion of accuracy.

The Supreme Court of the United States, in *General Electric v. Joiner,* made the point specifically when discussing the difference between the reliability component required for admissibility of the evidence by *Daubert*, which may be affected by methodological error in a process or technique, and an expert witness or practitioner's erroneous conclusion, which would affect the qualifications of the witness but not necessarily the soundness of the underlying technique. The Court added, however:

> [C]onclusions and methodology are not entirely distinct from one another. Trained experts commonly extrapolate from existing data. But nothing in either *Daubert* or the Federal Rules of Evidence requires a district court to admit opinion evidence which is connected to existing data only by the *ipse dixit* of the expert. A court may conclude that there is simply too great an analytical gap between the data and the opinion proffered.

Judicial Notice of Scientific Principles and Facts

Judicial notice is a legal principle applicable primarily, though not exclusively, in common law, adversary system jurisdictions (*see* **Adversary Systems of Justice**). It is a rule of judicial economy and convenience, designed to save time in litigation, whereby a court may "judicially note" the truth and accuracy of a fact, thereby relieving the party who has the burden of proof of that fact from having to present evidence of it. Judicial notice, then, is a substitute for evidence (*see* **Expert Opinion in Court: Civil Law Jurisdictions (France, Germany, Italy, and Spain)**).

When a court takes judicial notice of a fact, the opposing party is often also prohibited from presenting evidence of its untruth. It would indeed reduce the judicial process to a mockery if a litigant were permitted to offer proof that the Eiffel Tower is located in Berlin!

Most jurisdictions that sanction use of the rule place limitations on the type of facts that a judge can note judicially (*see* **Evidence: Rules of**). The common law has always permitted courts to take judicial notice of legislative facts and law, such as constitutions, statutes, decisional law, and regulations in effect within their jurisdictions, as long as these legal principles are published and capable of easy verification. A court is not required, however, to note the laws of foreign jurisdictions.

As to adjudicative facts, courts can take judicial notice of

(i) matters of common knowledge;
(ii) facts capable of certain verification; and
(iii) scientific principles.

Matters of common knowledge must be generally known to the public residing in the jurisdiction where the court sits. If the trial judge personally happens to be familiar with a fact that is relevant to the case, but that is not generally known in the jurisdiction where the court sits, the court cannot take judicial notice of that fact. Whatever party would like the fact to be considered as evidence in the case must present supporting evidence of it. Examples of commonly known matters are most geographical and historical data that are relevant to a particular case. Examples are: that certain streets within the city run in north–south direction; that traffic on a particular avenue runs one-way in westerly direction; that Washington DC is the capital of the United States; that Massachusetts was one of the original thirteen states of United States; that the Eiffel Tower is located in Paris, France.

The category of facts capable of easy verification applies to anything that can be readily found and

verified by reference to an almanac, a calendar, or a reliable compilation of data generally considered to report its data accurately. These facts need not be commonly known to the general public. Examples of such facts include the state of the moon on a particular hour of a day; the main telephone number of a company or institution in the city; the weather conditions on the day that an incident occurred; an electrical malfunction that caused the power to be interrupted at a particular time.

Of greatest interest to forensic scientists is the third category of judicially noted facts: well-established scientific facts the accuracy of which is generally beyond doubt. Some scientific facts are truly beyond doubt. Examples would be: that the earth is a sphere and not flat; that the sun rises in the East and sets in the West; that the "big bang" theory is the prevailing scientific view of the origin of the universe; that radar principles permit the reliable measurement of speed [1, 2].

On the accuracy of some scientific facts (*see* **Scientific Method Compared to Legal Method**), however, courts in different jurisdictions may have inconsistent views. In many older precedent-setting court decisions, it has been held that the digits of each finger or thumb bear unique friction skin ridge characteristics [3]. This reasoning was thereafter also extended by some courts to the uniqueness of small areas of a latent fingerprint. A more recent influential and well-reasoned court decision held that while the original part of the equation – ridge structure uniqueness – can be properly noted, courts should not take judicial notice of the fact that a particular partial or blurred latent finger mark of an unknown person can be positively matched to that of a known person [4].

When scientific principles underlying certain forensic techniques are truly beyond question, their widespread acceptance is seldom contested in court. The issue of judicial notice of the principle may never be presented to a judge. However, when it comes to the application of certain principles to the facts of a specific case, a court will rarely be in a position to take judicial notice of the specific result.

Examples are easy to find. Deoxyribonucleic acid (DNA) forensic applications rest on Nobel-prize winning scientific principles about the molecular nature of DNA, researched and articulated at Cambridge University in the United Kingdom by scientists James Watson and Francis Crick in 1953 [5]. Between these underlying principles and the ultimate opinion of an expert witness evaluating the "match" of a known and unknown biological specimen lie myriad steps, each of which may require subjective evaluation by the expert subject to error or misinterpretation. The results of these applications are not appropriate fact for judicial notice by courts. In all those and most other forensic applications, a qualified witness must present proof and opinion evidence about the results of an analysis specific to the case in point.

Jury Decision Making *see* Mitigation Testimony

Jury Dynamics

The right to a trial by jury, guaranteed by the Sixth Amendment to the Constitution for criminal cases and the Seventh Amendment for civil cases, entrusts juries to make some of the most complicated and profound decisions of civic life. How well laypeople are able to function in these roles is a question that

has vexed attorneys, judges, defendants, plaintiffs, victims, and indeed, the general public since the founding of our democracy (*see* **Jury Instructions on Expert Testimony**; **Hearsay Evidence**).

Of particular concern is how jurors make decisions in tough cases – criminal cases in which the evidence is neither so weak as to warrant outright dismissal nor so compelling as to induce a guilty plea, and civil cases where the evidence seems evenly balanced between the two sides.

The Verdict on Jury Verdicts

Over the past few decades, social scientists and legal scholars have begun to understand what goes on behind the closed door of a jury deliberation room. The empirical evidence – gathered by way of interviews of jurors and judges, archival research, experimental field and simulation studies, and most recently, by observing jury deliberations – suggests that juries function reasonably well. Several findings lead to that conclusion. First, judges tend to agree with the jury's verdict in the vast majority of cases [1, 2]; second, in criminal cases, the strength of the evidence is a stronger determinant of a jury's verdict than the extralegal factors such as personality or demographic characteristics of the jurors themselves [3, 4]; and finally, in civil cases, jurors' damage awards are related to the extent of documented injuries and losses, as they should be [5]. Several recent and comprehensive reviews of empirical research on juror and jury decision making [6, 7] detail these and other auspicious findings.

But despite the empirical research showing that jurors and juries make defensible (and usually, quite reasonable) decisions, there are lingering suspicions that, on occasion, they might not be up to the task. One concern focuses on jurors' attention to and reliance on information that is unrelated to case facts brought to light during the trial. Another concern has to do with biases that jurors bring with them into courtrooms and the prospect that those biases distort the ways that they process evidence.

The Effects of Extralegal Information

Jurors should base their verdicts only on the evidence deemed admissible in court, but do they? Information that is legally irrelevant to the decision required of them is termed as *extralegal information*. A criminal defendant's appearance, personal characteristics, and propensity for wrongdoing constitute extralegal information, yet research shows that such extralegal information can indeed influence jurors' judgments. For example, mock jurors who learned about an alleged sex offender's previous criminal acts perceived the crime victim as more credible and the defendant as more likely to be guilty than did jurors who were not so exposed [8]. Trial-related information in the media is another source of extralegal information to which jurors are exposed. Empirical studies based on juror interviews and experimental techniques that systematically vary the kind of extralegal information that jurors hear have shown that such pretrial publicity can bias jurors' in-court decisions [9, 10].

Frequently, extralegal information is conveyed by one side or the other in the courtroom. When this occurs, judges typically instruct jurors to disregard this so-called inadmissible evidence so that it does not distort their reasoning or mislead them, resulting in an incorrect verdict. On other occasions, judges instruct jurors that they may use certain evidence for one purpose (e.g., to assess a defendant's credibility) but not for another (e.g., to determine guilt). Although commentators have expressed skepticism about jurors' ability to follow these instructions [11] and US Circuit Court judge, Learned Hand, described the instructions as "recommendation[s] to the jury of a mental gymnastic which is beyond, not only their powers, but also anybody else['s]" [12], most judges assume that jurors can follow these directives.

A recently conduced meta-analysis (a quantitative technique that combined the results of 175 individual studies – primarily simulation studies – to identify reliable patterns in the data) examined the effects of inadmissible evidence on jurors' decision making and the efficacy of judicial instructions to disregard it [13]. The meta-analysis showed that jurors' verdicts were slanted in the direction of the inadmissible evidence; i.e., when the evidence favored the prosecution, guilty verdicts increased; when it favored the defense, guilty verdicts decreased. Further, judicial admonitions to disregard inadmissible evidence fell on slightly deaf ears: both proprosecution and the prodefense biases remained even after the judge instructed jurors to disregard the evidence, though the lingering effect of inadmissible evidence was reduced when the judge gave a rationale for his or her decision by stating, for example, that the evidence was

hearsay, not reliable, or without bearing on the case. The biasing effects of inadmissible evidence are also reduced when the judge issues a reminder at the conclusion of the trial to disregard any evidence so deemed. In general, though, jurors apparently have difficulty in ignoring information they believe to be reliable and probative, especially if they also think that it will lead to a just verdict [14].

Distorted Evaluations of Trial Evidence

Judges often remind jurors that their verdicts should be determined only with reference to the evidence and the legal instructions, and should not be influenced by bias, prejudice, or emotion. Appellate courts presume that jurors follow these mandates.

But is it realistic to expect any human to come into such a formal, institutional setting as a trial completely devoid of preexisting sentiments, inclinations, or expectations? Obviously not. Shari Diamond asks us to consider the differential reactions of two hypothetical jurors as they ponder the claims of a plaintiff in an automobile accident lawsuit. The first juror believes that many plaintiffs are excessively litigious and that they pursue frivolous claims in order to line their pockets. The second juror is decidedly more sympathetic; he has a brother who experiences excruciating pain as a result of a soft tissue injury. Diamond suggests that both of these jurors are simply allowing their experiences and commonsense knowledge of the world (and not any overwhelming prejudice or bigotry) to follow them into the courtroom. Psychologists and other social scientists who scrutinize the behavior of jurors are beginning to understand some of the subtle effects that these values and experiences have on jurors' reactions to trial evidence [15].

One way that subtle biases can influence fact-finding is by distorting how jurors interpret evidence as they hear it. In particular, when a juror already tends to favor one side in a case, new evidence tends to be distorted by this predecisional bias so that it is interpreted as supporting the currently favored verdict [16].

In one study, mock jurors who were given case facts, opening statements, witness affidavits, and instructions not to reach "hasty opinions or conclusions" then got successive pieces of evidence and indicated, for each item, whether it favored the plaintiff or defendant and which verdict they tended to favor. Finally, they were asked to choose a verdict. Regardless of the side that jurors favored, they tended to interpret new evidence as supportive of their preferred verdict, perhaps because doing so provided coherence and closure. Doing so meant that they did not have to grapple with inconsistencies and contradictions in the evidence.

Is there a way to counter the effects of these biases? Researchers suggest that an additional pretrial instruction from the judge reminding jurors to avoid even the slightest predecisional leaning might have some ameliorative consequences.

Effects of Jury Deliberations

Much of the empirical research on fact finders in trial settings focuses on individual jurors' cognitive and affective responses to trial-based and extralegal information. But verdicts are not determined by individuals; they result from a deliberative process during which jurors theoretically pool their knowledge and opinions to reach a verdict that reflects a consensus perspective. The extent to which jury decisions are influenced by the process of deliberating is unclear, however. Some data suggest that jury verdicts can be predicted simply by considering the distribution of predeliberation preferences [1] whereas other data show that verdicts can be significantly influenced by the process of deliberation [17]. For example, verdicts in criminal cases tend to show a leniency bias; i.e., the jury's verdict is often more lenient than would be predicted from individual, predeliberation sentiments, suggesting that the arguments of proacquittal jurors must have been persuasive in the jury room.

Laws prohibiting the observation of jury deliberations are in place in all states and the federal court system, though a recent study of jury reform included limited filming of actual deliberations [18]. This means that to understand the process by which individual jurors reach consensus, one must rely on mock jury methodology. This was the research paradigm that Samuel Sommers used to examine the effects that a jury's racial composition has on its decision making [19]. (Sommers and his colleague, Phoebe Ellsworth, had previously determined that individual white jurors tended *not* to be prejudiced in judging the case of a hypothetical black assault defendant so long as race was a salient issue in the case. However, when the "race card" was not played, white jurors were more likely to convict a black defendant

than a similarly described white defendant, suggesting that racial prejudice is still a factor in juror judgments [20].)

In particular, Sommers wondered whether diversity in the composition of the jury could offset the effects of individuals' prejudicial beliefs. He showed a condensed sexual assault trial to juries that consisted either of all-White members or of four White and two Black members. He filmed and analyzed the content of the deliberations and determined that all-White and diverse juries differed in some very important ways. All-White juries made more factual errors than diverse juries yet were less likely to correct inaccuracies than were diverse juries. They also considered fewer case facts and were less likely to discuss race-related issues than were diverse groups.

Perhaps more surprising was Sommers' finding that many of these effects were a result of differential behavior by White jurors, rather than the influence of Black jurors. White jurors on diverse juries were more likely than their counterparts on homogeneous juries to discuss controversial race-related issues. They also raised more case facts and made fewer factual errors. These data tell us something important about juries and the ways that social scientists study them. They tell us that representation of diverse members of society on a jury is not solely a moral and legal ideal, but that it can enhance the process of decision making. They also remind us of the importance of evaluating jurors both as individuals and as collective members.

Helping Jurors and Juries Perform Better

Empirical research on juror and jury decision making has revealed that in many cases, jurors competently perform their duties [17, 21]. However, in addition to concerns about pre-existing bias and prejudice improperly influencing juror decision making, there are also concerns about jurors' ability to handle evidence in complex civil litigation (e.g., antitrust litigation, and class action lawsuits which can involve hundreds of plaintiffs and multiple defendants) as well as complex scientific evidence in some criminal cases (e.g., DNA evidence involving statistical probabilities) and civil cases (e.g., scientific evidence involved in patent litigation). Rather than eliminating jury trials or replacing juries comprised of citizens with juries comprised of experts (sometimes referred to as *blue ribbon juries*), social scientists and legal scholars have found that revising court procedures can reduce the impact of pre-existing biases and assist jurors in evaluating complex evidence. The result has improved the performance and satisfaction of juror and jury.

Reducing Pre-Existing Juror Bias and Prejudice. It is natural for jurors to come to trial with pre-existing attitudes and knowledge about the world and, on occasion, knowledge about the present case. Identifying juror bias and prejudice and determining whether it is likely to interfere with a criminal defendant's right to trial by an impartial jury, as protected by the Sixth Amendment, is the duty of the attorneys representing the parties and the judge overseeing the case. The questioning of members of the jury pool prior to trial (i.e., the voir dire process) provides the opportunity to detect bias and prejudice and remove jurors who are deemed unable to be impartial.

The questioning can be conducted in a group setting or with individual jurors and can be carried out by the judge and/or the attorneys. Potential jurors tend to respond more candidly and completely when questioned by attorneys rather than the judge [22]. Individualized, as opposed to group, questioning of potential jurors also increases the likelihood of honest, candid, and complete answers from jurors, particularly when the questions involve matters of a sensitive or private nature [23]. Individual questioning also helps to avoid potential tainting of the jury pool (e.g., by means of a juror describing pretrial publicity or voicing particularly strong opinions about one of the parties) or of jurors conforming to the group by providing answers that seem to be "correct" or "appropriate" and that do not deviate from the norm [24, 25]. Having potential jurors complete pretrial, supplemental juror questionnaires is another way of attempting to gather candid information from them about potentially problematic biases and attitudes [26].

Assisting Jurors' Comprehension and Memory. Trial procedures that improve jurors' comprehension and memory of the evidence and the applicable law include providing preinstructions to jurors, allowing jurors to take notes during trial, and providing jury instructions in plain English.

In most jurisdictions, the trial judge has the discretion to include at least some information on

the law that will govern the case in the preliminary instructions provided to jurors at the beginning of the trial. These instructions include the basic principles of law that will govern the trial and an explanation of the role and responsibilities of the jury. Such instructions have been found to provide jurors with a framework that helps them to organize trial facts in ways that improve their understanding and memory of the case [27, 28].

Another procedure proposed to improve jurors' memory for trial evidence is allowing them to take notes during trial. Although judges in some states are required to inform jurors that they may take notes during trial, it is more often the case that juror notetaking may be permitted or prohibited at the judge's discretion. Initially courts were concerned that jurors who took notes would be distracted by notetaking and miss ongoing testimony and that, in addition, jurors who took notes might have some unfair advantage over non-notetakers during deliberations. Empirical studies of juror notetaking have shown no effect on jurors' comprehension or memory, but they have also found no evidence to support the concerns about juror distraction or unfair advantage during deliberations [29, 30].

However, compared to non-notetakers, jurors who took notes during trial have rated themselves as more attentive, more involved in the trial, better able to keep up with the proceedings, and more satisfied with the final verdict [30, 31].

Jurors are asked to combine the case facts with the relevant law to decide on a verdict, but understanding the jury instructions on the applicable law can be daunting for laypersons with no formal legal training. The language used in the instructions as well as the way in which the instructions are organized can make it difficult for jurors to comprehend or recall the law on which they have to rely to decide the case. Drafting jury instructions in ways that avoid abstract statements of legal principles and eliminate unfamiliar terminology, avoid awkward grammar, use case-specific language when referring to parties and pieces of evidence, and organize the instructions hierarchically in terms of legal tests and criteria can result in significant improvements in jurors' comprehension of the instructions [32, 33].

In general, then, the verdict on jurors and juries is cautiously optimistic. Although biases and predilections sometimes influence jurors' determination of the facts and application of the law, judges and other court personnel can institute structural and procedural changes to address these concerns and to render jurors' decision making more rational and predictable.

EDIE GREENE AND CHRISTINA STUDEBAKER

Jury Instructions on Expert Testimony

In trials conducted in adversary system jurisdictions (*see* **Adversary Systems of Justice**) where the fact finder is a jury composed of ordinary citizens, such as in the United States, Canada, the United Kingdom, and other commonwealth countries, the jurors will "deliberate" and then render their verdict after they have heard and seen all of the evidence that was presented by both sides in the case. Before the jurors commence their deliberation, however, the judge must "instruct" the jurors in the law that applies to the issues in the case. These instructions deal with burdens of proof and a number of other legal concepts. Among these concepts are the rules by which jurors are to judge evidence that may be in conflict, or which they have difficulty in accepting as true.

In most jurisdictions, the jurors will be told that they must determine what happened. In doing so, their role is to judge the credibility of all the evidence they have seen and heard. They will further be told that they may accept, in whole or in part, each item of evidence presented to them, or they may reject such evidence, in whole or in part, if they find it to be unconvincing or not worthy of belief. One of these instructions also deals with how jurors should evaluate expert witness testimony.

The instruction on the weight of the evidence is particularly important when opinion testimony is in conflict. While jurisdictions may differ on how such instructions are worded, a typical instruction on the evaluation of expert testimony will be as follows:

> You have heard the testimony of experts in this case. The credibility or worth of the testimony of an expert witness is to be considered by you just as it is your duty to judge the credibility or worth of the testimony of all other witnesses you have heard or evidence you have seen. You are not bound to accept expert testimony as true if you find it unconvincing, and you may weigh and credit testimony of expert witnesses the same as that of other witnesses, and give it the weight to which you think it is entitled.[a]

It is also permissible for the judge to supplement the standard expert witness jury instruction by a special provision more applicable to a particular case. In many jurisdictions, in charging the jury, the judge

may not refer to the testimony of any particular witness and may not single out certain testimony or evidence. In other jurisdictions, however, these restrictions do not apply and a judge may single out expert witnesses or evidence that needs to be specifically addressed by the jury.

Forensic experts will note that their opinion testimony is not entitled to a greater weight than that given to ordinary fact witnesses merely because they are experts. Jurors are permitted to ignore expert opinions that they do not believe or testimony that is unconvincingly presented. Jurors are likely to ignore opinion testimony they do not understand or where the witness does not explain scientific principles upon which an opinion is based in a credible manner. Other factors that influence jurors in how much weight to give to an expert's testimony are as follows: the qualifications of the witness; the appearance and presentation of the expert; possible bias or personal interest of the expert, his facility of expression and clarity of thought, as well as the comportment during cross-examination. Most jurors attach great persuasive weight to these factors in their credibility judgment of all testimony, including that of forensic experts.

While jurors are free to attach such weight to expert forensic testimony as they feel it deserves, they cannot go beyond the evidence seen and heard in the courtroom. Thus, it would be improper for jurors to perform their own investigations. The discovery, at any time during the trial, that jurors conducted experiments on their own, or, during a recess, went to the crime scene without being required to do so by the trial judge, is certain to result in a mistrial being declared. That is why judges typically instruct juries to use *only the evidence heard in court* to inform their deliberations.

Juvenile Justice: Adolescent Development

In 2005, in a landmark decision, the US Supreme Court outlawed the death penalty for offenders who were younger than 18 when they committed their crimes (*see also* **Death Penalty and Age**). The ruling

centered on the issue of culpability or criminal blameworthiness. Unlike competence, which concerns an individual's ability to serve as a defendant during trial or adjudication, culpability turns on the offender's state of mind at the time of the offense, including factors that would mitigate, or lessen, the degree of responsibility.

The Court's ruling ran counter to a nationwide trend toward harsher sentences for juveniles. Over the preceding decade, as serious crime rose and public safety became a focus of concern, legislators in virtually every state had enacted laws that lower the age at which juveniles could be tried and punished as adults for a broad range of crimes. This and other changes have resulted in the trial of more than 200 000 youths in the adult criminal system each year [1].

Proponents of the tougher laws argue that youths who have committed violent crimes need more than a slap on the wrist from a juvenile court. It is naive, they say, to continue to rely on a juvenile system designed for a simpler era, when youths were getting into fistfights in the schoolyard; drugs, guns, and other serious crimes are adult offenses that demand adult punishment. Yet the premise of the juvenile justice system is that adolescents are different from adults, in ways that make them potentially less blameworthy than adults for their criminal acts.

The legal system has long held that criminal punishment should be based not only on the harm caused, but also on the blameworthiness of the offender. How blameworthy a person is for a crime depends on the circumstances of the crime and of the person committing it. Traditionally, the courts have considered several categories of mitigating factors when determining a defendant's culpability. These include the following:

- impaired decision-making capacity, usually due to mental illness or disability;
- the circumstances of the crime – for example, whether it was committed under duress; and
- the individual's personal character, which may suggest a low risk of continuing crime.

Such factors do not make a person exempt from punishment – rather, they indicate that the punishment should be less than it would be for others committing similar crimes, but under different circumstances.

Should developmental immaturity be added to the list of mitigating factors? Should juveniles, in general, be treated more leniently than adults? A major study by the MacArthur Foundation Research Network on Adolescent Development and Juvenile Justice now provides strong evidence that the answer is yes.

The MacArthur Study of Juvenile Culpability

The study of juvenile culpability was designed to provide scientific data on whether, in what ways, and at what ages adolescents differ from adults.

Many studies have shown that by the age of 16, adolescents' cognitive abilities – loosely, their intelligence or ability to reason – closely mirrors that of adults. But how people reason is only one influence on how they make decisions. In the real world, especially in high-pressure crime situations, judgments are made in the heat of the moment, often in the company of peers. In these situations, adolescents' other common traits – their shortsightedness, their impulsivity, their susceptibility to peer influence – can quickly undermine their decision-making capacity.

The investigators examined the age differences in a number of characteristics that are believed to undergird decision making and that are relevant to mitigation, such as impulsivity and risk processing, future orientation, sensation-seeking, and resistance to peer pressure. These characteristics are also thought to change over the course of adolescence and to be linked to brain maturation during this time. The subjects – close to 1000 individuals between the ages of 10 and 30 – were drawn from the general population in five regions. They were ethnically and socioeconomically diverse.

The study's findings showed several characteristics of adolescence that are relevant to determinations of criminal culpability. As the accompanying figure indicates, although intellectual abilities stop maturing around age 16, psychosocial capability continues to develop well into early adulthood (Figure 1).

Short-Sighted Decision Making

One important element of mature decision making is a sense of the future consequences of an act. A variety of studies in which adolescents and adults are asked

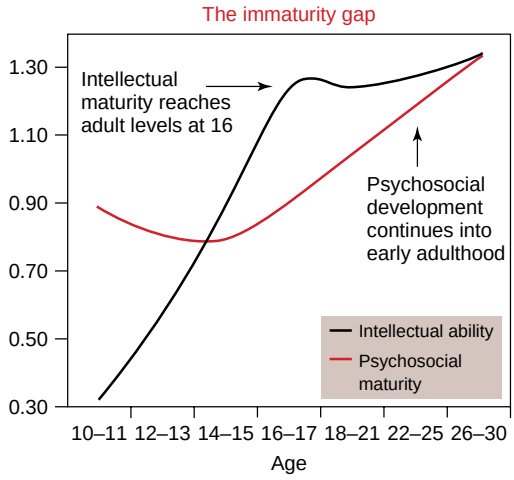

Figure 1 Developmental course of intellectual and psychosocial development

to envision themselves in the future have found that adults project their visions over a significantly longer time, suggesting much greater future orientation.

These findings are supported by data from the network's culpability study. Adolescents characterized themselves as less likely to consider the future consequences of their actions than did adults. And when subjects in the study were presented with various choices measuring their preference for smaller, immediate rewards versus larger, longer-term rewards (e.g., "Would you rather have $100 today or $1000 a year from now?"), adolescents had a lower "tipping point" – the amount of money they would take to get it immediately as opposed to waiting.

How might these characteristics carry over into the real world? When weighing the long-term consequences of a crime, adolescents may simply be unable to see far enough into the future to make a good decision. Their lack of foresight, along with their tendency to pay more attention to immediate gratification than to long-term consequences, is among the factors that may lead them to make bad decisions.

Poor Impulse Control

The network's study also found that as individual's age, they become less impulsive and less likely to seek thrills; in fact, gains in these aspects of self-control continue well into early adulthood. This was evident in individuals' descriptions of themselves and on tasks designed to measure impulse control. On the "Tower of London" task, for example – where the goal is to solve a puzzle in as few moves as possible, with a wrong move requiring extra moves to undo it – adolescents took less time to consider their first move, jumping the gun before planning ahead.

Network research also suggests that adolescents are less sensitive to risk and more sensitive to rewards – an attitude than can lead to greater risk taking. The new data confirm and expand on earlier studies gauging attitudes toward risk, which found that adults spontaneously mention more potential risks than teens. Juveniles' tendency to pay more attention to the potential benefits of a risky decision than to its likely costs may contribute to their impulsivity in crime situations.

Vulnerability to Peer Pressure

The law does not require exceptional bravery of citizens in the face of threats or other duress. A person who robs a bank with a gun in his back is not as blameworthy as another who willingly robs a bank; coercion and distress are mitigating factors. Adolescents, too, face coercion, but of a different sort.

Pressure from peers is keenly felt by teens. Peer influence can affect youths' decisions directly, as when adolescents are coerced to take risks they might otherwise avoid. More indirectly, youths' desire for peer approval or their fear of rejection may lead them to do things they might not otherwise do. In the network's culpability study, individuals' reports of their vulnerability to peer pressure declined over the course of adolescence and young adulthood. Other network research now underway is examining how adolescent risk taking is "activated" by the presence of peers or by emotional arousal. For example, an earlier network study, involving a computer car-driving task, showed that the mere presence of friends increased risk taking in adolescents and college undergraduates, though not adults [1].

Although not every teen succumbs to peer pressures, some youths face more coercive situations than others. Many of those in the juvenile justice system live in tough neighborhoods, where losing face can be not only humiliating but also dangerous. Capitulating in the face of a challenge can be a sign of weakness, inviting attack, and continued persecution. To the extent that coercion or duress is a mitigating

factor, the situations in which many juvenile crimes are committed should lessen their culpability.

Confirmation from Brain Studies

Recent findings from neuroscience line up well with the network's psychosocial research, showing that brain maturation is a process that continues through adolescence and into early adulthood. For example, there is good evidence that the brain systems that govern impulse control, planning, and thinking ahead are still developing well beyond age 18. There are also several studies indicating that the systems governing reward sensitivity are "amped up" at puberty, which would lead to an increase in sensation-seeking and in valuing benefits over risks. And there is emerging evidence that the brain systems that govern the processing of emotional and social information are affected by the hormonal changes of puberty in ways that make people more sensitive to the reactions of those around them – and thus more susceptible to the influence of peers [2].

Policy Implications: A Separate System for Young Offenders

The scientific arguments do not say that adolescents cannot distinguish right from wrong, or that they should be exempt from punishment. Rather, they point to the need to consider the developmental stage of adolescence as a mitigating factor when juveniles are facing criminal prosecution. The same factors that make youths ineligible to vote or to serve on a jury require us to treat them differently from adults when they commit crimes.

Some have argued that courts ought to assess defendants' maturity on a case-by-case basis, pointing to the fact that older adolescents, in particular, vary in their capacity for mature decision making. But the tools needed to measure psychosocial maturity on an individual basis are not well developed, or it is possible to distinguish reliably between mature and immature adolescents on the basis of brain images. Consequently, assessing maturity on an individual basis, as we do with other mitigating factors, is likely to produce many errors. However, the maturing process follows a similar pattern across virtually all teenagers.

Therefore, it is both logical and efficient to treat adolescents as a special legal category – and to refer the vast majority of offenders under the age of 18 to juvenile court, where they will be treated as responsible but less blameworthy, and where they will receive less punishment and more rehabilitation and treatment than typical adult offenders. The juvenile system does not excuse youths of their crimes; rather, it acknowledges the development stage and its role in the crimes committed, and punishes appropriately.

At the same time, any legal regime must pay attention to legitimate concerns about public safety. There will always be some youths – such as older, violent recidivists – who have exhausted the resources and patience of the juvenile justice system, and whose danger to the community warrants adjudication in criminal court. But these represent only a very small percentage of juvenile offenders. Trying and punishing youths as adults is an option that should be used sparingly.

Legislatures in several states have begun to reconsider the punitive laws enacted in recent decades. They have already recognized that prosecuting and punishing juveniles as adults carries high costs, for the youths and for their communities. Now we can offer lawmakers in all states a large body of research on which to build a more just and effective juvenile justice system.

Juvenile Justice: Transfer to Adult

Through much of the twentieth century, the juvenile court was the primary legal forum to respond to children who broke the criminal laws. With the rise in youth crime beginning in the late 1970s, legislators and commentators spoke ominously of a nation under siege by a rising generation of violent young criminals. These fears led many Americans to blame the juvenile court and demand that legislators "get tough" with violent and chronic young offenders.

In response to recurring epidemics of youth violence over the past three decades, 46 states made significant changes in laws that lowered the age and broadened the circumstances under which young defendants could be prosecuted in the criminal courts. Prosecution in the criminal court was designed to punish young offenders more harshly and for longer periods of time, thereby deterring them and other youths from further crimes.

But have these efforts been effective? Does the prospect of harsher sentences and adult time deter youth from committing crimes? Although there are strong proponents on each side of the argument, new evidence has raised questions about the effectiveness of the new laws.

Several studies have examined whether the prosecution of adolescents as adults reduces crime and recidivism. Two studies capitalized on unique conditions in the New York Metropolitan area, where the laws of two states, New York and New Jersey, span the border of a single metropolitan area. On the New York side of the border, juveniles as young as 13 are charged in adult court, while on the New Jersey side, nearly all cases of juvenile offenders below the age of 18 are processed in juvenile court. By comparing similar offenders in the two settings who were arrested and charged with the same felony offenses during the same time period, the researchers were able to determine whether treating juveniles as adults in the legal system is an effective deterrent to crime.

They find that adolescents processed in the New York adult courts were more likely to be rearrested. They were rearrested more often and more quickly and for more serious offenses, and they were reincarcerated at higher rates than those in the New Jersey juvenile courts. The results suggest that harsher sentences and adult punishments are ineffective deterrents to crime among the juveniles in this sample.

Teens Prosecuted in Adult Courts at Greater Risk of Repeat Offenses

The study examined more than 2000 adolescents who committed one of three types of serious crimes (aggravated assault, armed robbery, burglary) during 1992 and 1993. The youth were tracked through 1999 to determine rearrest rates for several types

of crimes. By using the two groups from the same metropolitan area, with similar economic opportunity, access to weapons, drug use, gang influences, and other influences on crime, any differences in rearrest between the two groups can be assumed to be due to the different court systems. The rearrest rates were calculated after controlling for time on the street.

Table 1 shows that youth prosecuted in the adult courts in New York were 85% more likely to be rearrested for violent crimes than those prosecuted in the New Jersey juvenile courts, and 44% more likely to be rearrested for felony of property crimes. The odds of rearrest were greatest for those youths with no prior arrest record who were prosecuted and sentenced as adults. Only for one type of crime, drug offenses, were youths in the adult courts less likely to be rearrested. The chances of being reincarcerated were 26% greater for youths prosecuted as adults. When the researchers compared the number of each type of offense during the follow-up period, the results were nearly identical.

Youths who received lighter sanctions – those whose cases were either dismissed or who received lighter sentences – also were less likely to be rearrested; this was true in both states. In other words, teens whose cases are diverted from court or dismissed are less likely to be arrested again. More work is needed to determine whether this stems from the courts' ability to identify those youth at greater risk for reoffending and to give them a sanction, or if the mere fact of a sanction causes an adolescent to feel more like a criminal and then act more like one after release.

The research also showed that longer sentences did not reduce the likelihood of rearrest either in the juvenile or the adult court. But, the research did show that a history of prior arrests and rearrests is a reliable predictor of future rearrests. So too are several demographic factors: males are more likely to be rearrested than females, and African-Americans are more likely to be rearrested than other race-ethnicities. More study is needed to determine whether these differences stem from different behaviors of the individuals in the groups or from different arrest policies.

Table 1 Odds of rearrest and reincarceration for adolescents in adult court relative to the juvenile system[(a)]

Recidivism measure	Statistical significance	Odds ratio relative to juvenile system
Any rearrest	ns	–
Violence	0.00	0.85
Property	0.00	0.44
Weapon	Ns	–
Drug	0.00	0.65
Reincarceration	0.05	0.6

Teens in Adult Corrections Face Harsher Settings and Experience More Developmental Problems

In a related study, the same research team, network researchers compared the correctional experiences of 425 adolescents placed in juvenile versus adult correctional facilities in 2000–2001. This research sought clues that might explain why adolescents adjudicated and sentenced in the criminal courts often have higher rearrest rates and are more often returned to jail or prison. The research used a similar design in which youth in juvenile corrections were compared with matched samples of youths in nearby states where they were incarcerated as adults. The incarcerated youths were interviewed within three months of their scheduled release date and asked about their correctional experiences, the therapeutic and rehabilitative services they received, and their mental health and social outcomes. Four states were included in the study, each with varying programs and facilities where teenage offenders were incarcerated. The experiences of youth in juvenile correctional facilities in New Jersey and California were compared with those of similar groups of youth placed in adult correctional facilities in New York and Arizona.

The results suggest clear differences in the therapeutic and service contexts of each of these settings. Figure 1 shows that youths placed in adult correctional settings reported significantly weaker correctional climates along four critical dimensions: fairness, counseling and therapeutic services, educational and job training services, and program structure, compared with matched groups of youths placed in juvenile facilities. At the same time, the juvenile facilities were more chaotic. Adolescents in the juvenile programs reported higher rates of witnessing violence and violent victimization. They also reported higher rates of involvement in several types of crimes

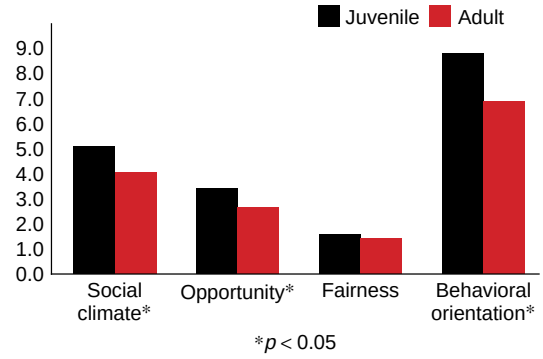

Figure 1 Institutional climate by correctional system

while incarcerated as well as more drug use. Despite these unruly settings, they reported greater feelings of safety compared with youths placed in adult settings. This paradox may reflect the social networks that were dominant in the two different types of placements, older criminal offenders in more organized prison gangs were the dominant social group in the adult facilities, compared to the loosely organized groups of peers that populated the juvenile facilities.

This greater sense of danger, then, perhaps explains the higher rates of mental health problems reported by youths in the adult facilities. Figure 2 shows that the current levels of mental health symptoms of youths in adults corrections were significantly worse on two dimensions of mental health functioning compared with rates reported by youths in juvenile facilities. The significant dimension includes the important Global Severity Index, a scale that spans all of the dimensions of mental health in this assessment tool.

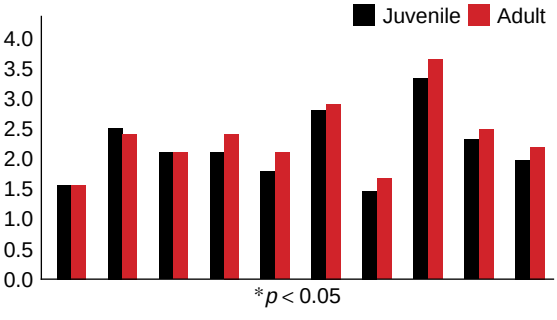

Figure 2 Current mental health functioning by correctional system

The same youths also reported higher rates of three dimensions of posttraumatic stress disorder. Figure 3 shows that youths in adult corrections had higher rates of the same types of mental health problems experienced by soldiers returning from war and survivors of natural disasters.

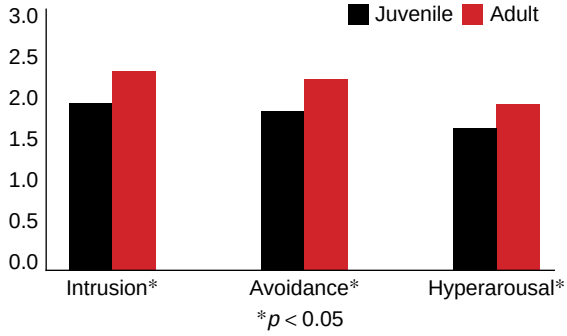

Figure 3 posttraumatic stress disorder (PTSD) symptoms by correctional system

There were also differences across the juvenile corrections facilities. Youths placed in larger juvenile justice facilities with a wider age range of inmates had outcomes similar to that of youths placed in the adult facilities. Youths sentenced as adults who spent some time in juvenile facilities before being administratively transferred to adult placements experienced fewer mental health problems and reported better service environments. These differences suggest that the size and diversity of populations in correctional placements are important dimensions of the correctional experience that interacts with the broader adult–juvenile legal categories to shape the correctional experiences of youths punished as adults.

Policy Implications

Policymakers and others advocating for harsher youth sentences argue that the threat of "adult time for adult crime" is a sound deterrent. The first study, however, shows the opposite: recidivism among 15- and 16-year olds prosecuted in adult courts in New York is actually more common and more serious than it is in New Jersey, which refers adolescents who have committed similar offenses to juvenile courts. Youths sentenced in the criminal courts in New York

were more likely to be rearrested, their rearrests were more frequent and their new offenses more serious, and they were more likely to be reincarcerated within a few years.

The study also suggests that the longer sentences in adult courts are not responsible for the differences in rearrest rates or in correctional outcomes. Rather, the second study finds that the adult courts may expose adolescents to harsher incarceration settings and less effective probation supervision in the criminal justice system. One reason may be that a felony conviction has a more harmful effect on subsequent employment, citizenship, or other positive adult roles, factors that otherwise could lessen the tendency to return to crime. Another possibility is that prosecution in an adult court communicates to the adolescent that he or she is unsalvageable, and hence repeat offenses become a self-fulfilling prophecy. A third reason is the stark differences in correctional experiences for those youths who are incarcerated as adults. Not only do they receive fewer and weaker services but also they are confined with adult offenders during the critical developmental period of the transition from adolescence to adulthood. This environment obviously has its effects on mental health. However, also, teens in adult corrections have limited exposure during this critical developmental stage to a broader set of social norms and a more diverse behavioral toolkit from the wider social networks of family, school or work, and community. Network researchers are not the only ones to reach these conclusions. Studies in Florida, for example, show similar elevated risks of rearrest for juveniles in adult court, and similar toxic environments for those youths placed in adult correctional facilities.

Authority for transfer decisions should be returned to juvenile court judges who can consider individualized criteria other than age and offense in determining how to prosecute an adolescent. Policies that result in a wholesale transfer of adolescents from juvenile to adult courts often fail to deter repeated instances of serious and violent crime. Although some of the most extreme cases may still need to be prosecuted in adult court, these should be the exception and not the rule. However, return of decision-making authority to judges must be accompanied by new models for decision making. In the past, judges have not been able to consistently identify the most serious offenders, and there has been a tendency toward harsher sentencing that often reflected racial discrimination. If new models are not offered to judges, the same problems recur. What is needed is a better method to distinguish between cases in which the community must be protected from predatory youth and those in which delinquent youth must be protected from negative effects of incarceration.

Kumho Tire v. Carmichael

Facts and Issues Summarized

Plaintiff Patrick Carmichael brought action in a federal court in Alabama against the manufacturer of a tire that blew out as he was driving his minivan on July 6, 1993. One passenger was killed and others were severely injured in the accident. Plaintiff's expert witness, an engineer referred to as *a tire failure analyst*, claimed the tire's defective manufacture resulted in the blowout that caused the accident. The analyst based his testimony on a "visual and tactile inspection".

The defendant, Kumho, moved to exclude the testimony on grounds that it did not satisfy the admissibility requirements of Federal Rule of Evidence 702 (*see* also **Expert Opinion: United States**) and the *Daubert* (*see* also ***Daubert v. Merrell Dow Pharmaceuticals***) criteria. The district court agreed with the defendant and granted summary judgment for the defendant.

An intermediate appellate tribunal – the Court of Appeals for the Eleventh Circuit – reversed the trial judge's decision and remanded the original action for trial, holding that the trial judge should not have applied the *Daubert* factors because these guidelines applied only to scientific evidence. The plaintiff's expert, by contrast, offered his opinion based on acquired experience in working for a tire manufacturing company [1].[a]

On further review, the US Supreme Court had to decide if *Daubert*'s judicial gatekeeping role pertained only to expert testimony based on science or to all forms of expert testimony. Also at issue was how the *Daubert* factors had to be applied in the evaluation of the reliability of an expert opinion, and what the judges were to do if these factors did not squarely fit the type of expertise involved.

In reversing the decision of the intermediate appeals court, the Supreme Court held that trial courts have an obligation to consider both relevancy and validity of all challenged expert testimony. The Court also reiterated, as it had done in the previous *Daubert* decision, that the *Daubert* criteria were to be used flexibly. If specific factors had little relevance to a particular occupation or expert discipline, a trial court was free to exercise its discretion in utilizing other criteria for determining whether the proffered evidence was sufficiently reliable to satisfy admissibility standards. Finally, the Court held that the trial court had not abused its discretion in excluding the evidence in this case.

Discussion and Its Importance to Forensic Scientists

Prior to the Court's *Kumho Tire* decision, several trial courts had held that *Daubert*'s reliability standard

and the factors guiding its application only applied to "scientific" expert testimony and did not apply to skill-based opinions. Other trial courts had held to the contrary and applied the full panoply of *Daubert* factors in evaluating expert opinions. This had resulted in some occupations waging what might be referred to as *science wars*.

Some occupational specialties that had been traditionally referred to as *offering scientific evidence* had vigorously maintained that they were *not* involved in "science" *per se* for the precise purpose of avoiding application of Daubert standards, when its practitioners feared they could not meet the Supreme Court standards. Other disciplines, by contrast, had strenuously maintained that they were engaged in "science" despite the tortured nature of some arguments they presented.

This, in turn, had led to disputes among experts and legal scholars about *Daubert's* meaning of the terms "science," "scientific knowledge," the "scientific method," "forensic science," and similar descriptive terms. By deciding that the *Daubert* reliability standard applied to all forms of expert testimony, the Supreme Court rendered all of these arguments irrelevant in the future[b] *Kumho Tire* also addressed the issue of whether trial judges were required to apply the *Daubert* factors rigorously to experience – or skill-based expertise. The Court's opinion clarified that the enumerated factors of "testing," "peer review," "error rates," and "acceptability in the relevant scientific community" were merely flexible guidelines for trial judges. If they applied to a specific occupational speciality and would be helpful in evaluating the reliability of opinions it generated, the factors certainly could be used. But the Court also recognized that "The *Daubert* factors do *not* constitute a definitive checklist, or test". Because the gatekeeping function must be tied to the particular facts of a case, trial judges have wide latitude of discretion and must use criteria that are appropriate to each case. The opinion of the Court stated:

> *Daubert* is not to the contrary. It made clear that its list of factors was meant to be helpful, not definitive. Indeed, those factors do not all necessarily apply in every instance in which the reliability of scientific testimony is challenged. It might not be surprising in a particular case, for example, that a claim made by a scientific witness has never been the subject of peer review, for the particular application may never previously have interested any scientist. Nor, on the other hand, does the presence of *Daubert*'s general acceptance factor help show that an expert's testimony is reliable where the discipline itself lacks reliability, as, for example, do theories grounded in any so-called generally accepted principles of astrology or necromancy [2].

How were these criteria applied to the facts in the *Kumho Tire* case? The trial court had concluded that the plaintiff's expert was not based on an approved methodology, which it found to be unreliable. The Supreme Court approved of this determination.

On the specific *Kumho Tire* issue of whether overdeflection had caused the tire's tread to separate from its steel-belted carcass, the relevant issue was whether this particular expert had sufficient specialized knowledge to assist the jurors in deciding that fact. The trial court did not dismiss out of hand the expert's visual and tactile inspection methodology, but found a lack of connection between his testimony and the particular matter at issue. While the expert claimed his method was accurate, the Court noted that nothing requires a trial court to admit opinion evidence that is connected to existing data only by the *ipse dixit* of the expert.[c] It did not find this necessary connection and thus, the trial judge's ruling was determined as not being an abuse of discretion.

The *Kumho Tire* decision is important to forensic scientists not only for its determination at all forms of expert testimony must be shown to lead to reliably valid opinions, whether science-based or obtained through experience or special skills, but also that specific disciplines can no longer rely on the fact that older court decisions long accepted expert conclusions in a particular field. Courts can relitigate the admissibility of a certain type of evidence if a credible case can be made by a litigant that there has never been an adequate scientific inquiry into the validity of the assumptions on which this field has rested its conclusions in the past.

Thus, despite the fact that decades of judicial precedent may exist in a particular forensic discipline, the underlying lack of validity on which expert opinions rest may be relitigated. This has in fact happened, in the United States and elsewhere, when dealing with such venerable expert opinions as those offered by handwriting experts, firearm and toolmark examiners, fingerprint experts, fire investigators, bitemark specialists, trace evidence analysts, and other disciplines. The results of these challenges are discussed within the topics on each discipline.

End Notes

[a.] The facts and procedural history are set out in the Court's opinion. For another commentary discussing the path in the courts as standards moved from *Frye*, through *Daubert* to *Kumho Tire*, see: Sanders, J., "*Kumho and How We Know*," (2001), Law & Contemp. Probs. [Spring/Summer] at 373. See also, Savage, D.G., Putting the Brakes on Junk Analysis," (1999), ABA J. [May] at 38 and Saks, M.J., "Banishing Ipse Dixit: The Impact of Kumho Tire on Forensic Identification Science," (2000), Wash. and Lee L.Rev. (Summer).

[b.] The Court stated, [I]t would prove difficult, if not impossible, for judges to administer evidentiary rules under which a gatekeeping obligation depended upon a distinction between "scientific" knowledge and "technical" or "other specialized" knowledge. There is no clear line that divides the one from the others. Disciplines such as engineering rest upon scientific knowledge. Pure scientific theory itself may depend for its development upon observation and properly engineered machinery. And conceptual efforts to distinguish the two are unlikely to produce clear lines capable of application in particular cases". *Kumho Tire*, 526 U.S. at 148, 119 S.Ct. At 1174.

[c.] This reference in the Court's opinion was to an earlier decision expounding on *Daubert*, namely: *General Electric v. Joiner*, 522 U.S. 136, 118 S.Ct. 512, 139 L.Ed.2d 508 (1997), in which the Court used the *ipse dixit* language to illustrate the analytical gap between method used and opinion reached. See, in this regard, the separate articles on *General Electric v. Joiner* (*see* ***General Electric v. Joiner***) and *Ipse Dixit* Testimony (*see* ***Ipse Dixit* Testimony**; ***General Electric v. Joiner***; ***Ipse Dixit* Testimony**).

Learned Treatises as Evidence

Qualified experts who testify in court are expected to be familiar with published books, pamphlets, and periodicals that are part of the witness's recognized professional literature. A lack of familiarity with the literature is a reflection on the competence and believability of an expert witness. This is not to assert that everything published in a particular field must be known and remembered by a person testifying as an expert. However, in every profession there are certain standard publications that all experts are expected to have read and studied.

In adversary system jurisdictions, statements of an author of learned publications can be used by a cross-examining attorney if these statements conflict with opinions the expert offered on direct examination.

That opportunity of impeaching the expert is explored in a different article (*see* **Cross-Examination of Experts**). No "hearsay" impediment exists when a text is used to impeach the credibility of an expert on cross-examination. Cross-examination testimony is not offered for the truth of what it contains, but only to reflect on the credibility of the speaker, by the cross-examiner's attempt to show there are others in the expert's profession who hold contrary opinions **(***see* **Hearsay Evidence**). The prohibition against the use of hearsay does not pertain in civil law jurisdictions. It is a rule that is peculiar to evidentiary systems based upon the common law of England.

Rules against the use of hearsay evidence generally were originally conceived because of a special feature of adversary system jurisdictions. The feature is that a person against whom oral or written evidence is introduced must have a right to confront and cross-examine its maker. During the development of evidentiary law, it came to be recognized that some hearsay offers special guarantees of trustworthiness that compensate for the inability to produce the declarants as witnesses. These special circumstances gave rise to the creation of a number of exceptions to the rule against the use of hearsay.

In American jurisdictions that follow a rule similar to that contained in Federal Rule of Evidence 702, (*see* **Federal Rule of Evidence 702**), there exists an exception that permits learned treatises to be used, not only to impeach, but as substantive evidence of what the publication asserts. The theory for recognizing a learned publication exception is that the authors, while not in court, are persons who, by the recognition and status they have achieved in their disciplines, have staked their professional reputation on the accuracy of statements contained in the treatise or article.

As in the introduction of physical and documentary evidence, it is necessary to present oral evidence laying a foundation before a learned treatise or text can be used during a court proceeding. Laying the foundation requires testimony by the proponent's expert that the text is recognized as authoritative in his profession. In the alternative, authoritativeness may be elicited from an opponent's expert as well, by eliciting an admission on cross-examination as to its professional recognition. In those rare cases where a text is so well recognized that most persons know of it, a court may even take judicial notice of its authoritativeness (*see* **Judicial Notice of Scientific Principles and Facts**).

After the reliability of a publication is established, the relevant passage of the learned text can be read to the jurors, who may receive it as substantive evidence of the truth of its assertions. Jurors will, however, not be permitted to read the text themselves or take the publication to the jury room during deliberations.

It is always permissible for the party against whom a passage of an authoritative published text is offered to dispute the accuracy or currency by presenting expert testimony that the text read by the opponent is either not the current edition and is therefore outdated, that it no longer represents prevailing scientific opinion on the issue, or that other experts hold differing views.

Length Measurement

Introduction

With the growing number of security cameras in the public and private domain, more and more incidents are recorded. In forensic practice, facial comparison of the perpetrator to the suspect is not always possible, the quality of the images being too poor, or the face of the perpetrator not being visible. In

these cases, it may, nonetheless, be possible to make an estimation of the body height of the perpetrator. Figure 1 shows an example of an image from a robbery of a cinema for which a height estimation of the perpetrator was requested. The results can be used to exclude or gather evidence against suspects and, as such, are interesting to the police, judges, and lawyers.

In this article, we first describe typical difficulties that arise when making height measurements in images. After this, we give an outline of four methods for height estimations, mentioned in literature. The section "Validation of the Measurements" addresses the question how results of the measuring process can be validated. How the evidential value of height estimations could be determined and reported is described in the section "Evidential Value (Likelihood Ratios)". The sections "Possible Future Research" and "Conclusions" describe the respective issues.

Typical Difficulties

Performance of height measurements in forensic casework is more involved than in a lab context. This is caused by different factors. First of all, the focal point of a surveillance camera is usually not known. The same applies to the position and orientation of the camera, which may have changed after the incident. The parameters can be retrieved by means of camera calibration, which will be described below.

Figure 1 Case example: questioned image. A height measurement was requested of the person in the oval

Secondly, surveillance cameras often have a lens distortion, the phenomenon in which straight lines appear as curved in the image. This results in deformation of people and objects in the image.

On the camera image in Figure 1, a few other problems can be seen, typical for closed-circuit television CCTV-images, which make it difficult to measure the height of the perpetrator. Circumstances such as lighting and the camera position may not be ideal. Also, resolution of an image may not be high because of limited storing capacity. A small number of pixels is a restriction on the accuracy of body height measurements.

Finally, the features of the perpetrator themselves influence the measurement. The suspect's pose, footwear, and headwear all affect the measured height. Heights are normally measured including footwear and headwear. More details are given below.

Camera Calibration

When a 3D object is projected on an image, the world and pixel coordinates of the object are related by a set of parameters such as the focal length of the lens, the size of the pixels, and the position and orientation of the camera. 3D measurements on a 2D image can be done after these parameters have been determined. This process is known as *camera calibration* and can be done in different ways.

A classical method is based on measurements of 3D coordinates of points on the scene that correspond to points on the image. In Ref. [1], a different technique is proposed, for which a planar pattern must be shown to the camera at different orientations. In the absence of a calibration object or knowledge about scene points, an estimation of the camera parameters can be found using the motion of a walking human as in Ref. [2].

Lens Distortion

Camera calibration is based on an ideal pinhole camera. The main problem with this approach in forensic applications is that surveillance cameras usually have significant lens distortion. Therefore, besides resolving the camera calibration parameters, the lens distortion problem must also be addressed.

A good method to correct for lens distortion is by placing a reference board with a raster in front of the camera. In Ref. [3], lines are selected that

should be straight in the image. The distance between the line through the end points and the middle point is computed to obtain a measure for the distortion. With software such as Mathematica, this distortion measure can be minimized and a corrected image can be created. Software packages such as PTLens correct for lens distortion automatically.

Questioned Person

Besides difficulties in body height estimation caused by the camera, there are those caused by the questioned person or perpetrator himself. As in Figure 1, perpetrators usually do not stand up straight in front of the camera, but will be walking, running, standing, or in other natural poses. This has to be taken into account, because stance influences the measured height [4]. Even standard standing measurements, for example, in doctor's surgeries, exhibit about 2-cm difference between natural and upright stance [4], and walking and running can cause even more differences in the height of the top of the head [5]. The amount of vertical displacement increases with speed.

Another factor that affects the measured height of a perpetrator is the thickness of shoe soles and headgear [4]. Here, a difference of up to 3 cm is reported between different shoe soles, excluding high heels.

Methods

In the literature, four different methods for making height measurements in camera images are given. These are described here, with their benefits and disadvantages. All methods are based on photogrammetry (literally: measuring in photographs), either on a single image or on different images taken from different sides and angles.

For every method, we attempt to report the uncertainty of the results. Unfortunately, this is seldom reported accurately. We reproduce the uncertainties as stated by the authors referred to. These values cannot be compared with each other, because they are all given in different measures. Additionally, the camera images and circumstances of the test scenes were diverse.

Reverse Projection Photogrammetry

An initial approach to performing height measurements in images that can be used when the original camera is available [6, 7] is the following. Using the same camera system, under identical circumstances as during the capture of the questioned image (same position, tilt, and focal length), an image is produced of an ordinary ruler of known height and proportions, placed at the same position as the questioned person (Figure 2). Position and orientation of the camera are checked using fixed reference points in the scene. The height distribution on the ruler is clear and with the same distortion as the questioned image, and hence the height of the questioned person may be read off the ruler. The method is referred to as *reverse projection photogrammetry* and used, e.g., by the Federal Bureau of Investigation (FBI).

(a) (b)

Figure 2 Security camera image of a perpetrator (on the left) and a reconstruction image of a ruler at the same location (on the right)

A problem connected to this method is [7] that it is not straightforward to identify whether the ruler is placed correctly at the spot of the questioned person, and results might be sensitive to deviations in location, especially when the image is distorted. In Ref. [6], height measurements of reference persons are mentioned, but the results are not included. The method is fast and easy, and therefore certainly useful for investigational purposes.

Single View Metrology (Vanishing Points)

The following method is, e.g., used in the United States of America (FBI) and in the United Kingdom (Home Office Scientific Development Branch).

When some knowledge of the scene is available, height measurements can be done on a single image, without the need of the original camera or camera calibration. Essential for a height measurement by single view metrology are

- a reference height of an object in the scene
- a set of vertical parallel lines
- two sets of horizontal parallel lines, in different directions.

As lines that are parallel in 3D will converge at a vanishing point when projected on an image, a vanishing point can be constructed by extrapolation of two parallel lines. All vanishing points of lines on a plane together form a vanishing line (or horizon). The construction of the plane vanishing line and a vertical vanishing point together with a reference height makes it possible to compute a height on the image [8]. In Figure 3, an example is shown of this method for making height measurements.

In Ref. [8], an uncertainty analysis can be found of the measurements. The measurement errors depend on the operator's uncertainty in locating the vanishing points, the top of the head, its projection on the ground plane, and a scale factor. In Ref. [4], it is shown that training the operators in locating the correct points on the top of the head and on the floor can reduce the uncertainty in measurements. The introduction of more reference heights may also reduce the uncertainty. In Ref. [8], the uncertainty in the height measurement of a man standing straight in an office is estimated on an image corrected for lens distortion. Here, a 99.7% confidence interval (3 standard deviations) was reported of ±3.9 cm around a mean, which reduced to ±3.5 and ±3.3 cm when two or three reference heights were used,

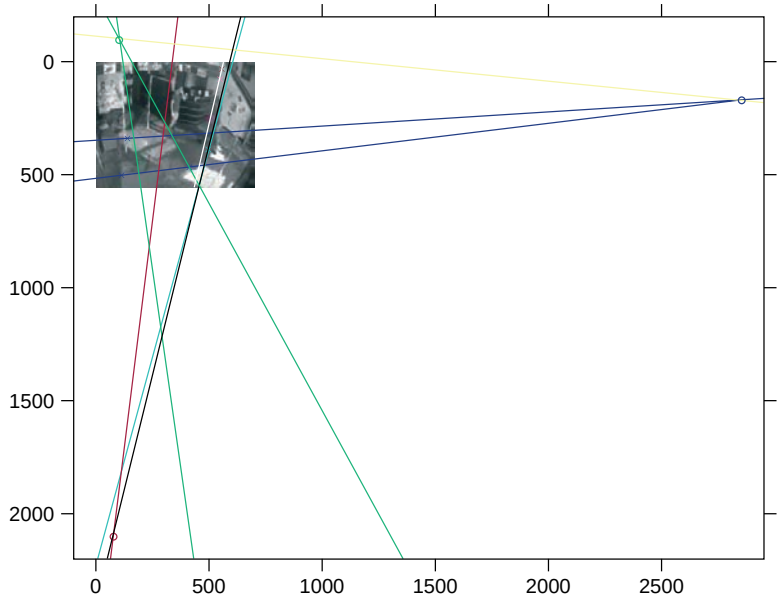

Figure 3 Illustration of modeling of the scene using vanishing points (reproduced with kind permission from J. Tighe, Home Office Scientific Development Branch, UK)

respectively. Measurements of the same test person on another image, recorded simultaneously from a different angle, resulted in a higher uncertainty of ±5.0 cm. This illustrates that the point of view may influence uncertainty.

An advantage of single view metrology is that it is fast, easy, and cheap. Applicability in casework is not always clear because enough parallel lines and a reference height must be visible on the image. Also, a correction for lens distortion may be needed, because lines are not always straight on the image. When radial distortion in an image is not minimized, it will introduce another uncertainty in the measurement.

3D Modeling of the Perpetrator

In the technical note [7], a description is given of how anthropometric measurements were performed on surveillance images from a bank robbery scene by making a 3D model of the perpetrator. The 3D model was consecutively held against images of a suspect.

For this method, in principle, different images of the perpetrator are needed, taken simultaneously by different cameras. The cameras are first calibrated by placing targets on the crime scene and taking photos with a digital camera. These measured points are imported in photogrammetric software such as Photomodeler Pro or RolleiMetric, and are used as control points for the calibration of the security cameras (including calculation of the location and orientation). With the information of the cameras, the software can calculate the 3D coordinates of concurrent points that are indicated in the different surveillance images. By indicating specific points, such as joints, on the different images of the perpetrator, three human models are created and some bodily measures calculated, among which is the total body height (including a helmet). Validation measurements were done on fixed objects, of which the error was less than 1%. Obviously, the errors will be greater for persons, because clothes can make it difficult to indicate the location of the joints. Validation measurements comparing a perpetrator with a suspect are given, but they seem inappropriate.

Applicability of the above in casework is troublesome, as images from different cameras are required. When there is footage from only one camera, there is a way to make use of information about the vertical plane the questioned person is standing in, as described in Ref. [7]. Of course, in casework this information may not be available as well.

3D Modeling of the Crime Scene

A fourth method of making height measurements in images is through the construction of a 3D model of the crime scene. This can be done in different ways. A technique that is often used is by means of photogrammetric software. As described previously, this software makes use of the fact that 3D coordinates of points can be measured by making photos of it from different positions. When a sufficient number of common points is identified on each image, a 3D model of the scene is made.

Instead of using photographs, a laser scanner can be used for the construction of a 3D model of the scene. In that case, a laser beam is sent to the scene from different angles. From all the points that reflect the laser beam, a point cloud will be obtained. Since the direction of the laser beam is known and the distance to every point is proportional to the time of flight of the laser beam, the 3D coordinates of the points can be known.

Next, a human operator links the scene points to the corresponding points in the questioned image. This makes it possible to determine the position, rotation, and focal length of the camera taking the images. This procedure of finding the right camera parameters is referred to as a *camera match*. Using the camera information, a virtual camera can then be placed in the 3D model of the room, looking at the model from the same perspective as the real camera at the real crime scene. Figure 4 shows a screen shot of the software 3dsMax, on which a 3D model of a simulated crime scene can be seen, together with its projection on a questioned image.

On the basis of the 3D model and camera parameters, in software such as 3dsMax it is possible to measure heights and distances on the image. The height of a person can be measured by placing a cylinder in the scene, from feet to the top of the head, or by creating human models (so-called *bipeds*) that can be adjusted to the stance of the person. The process of making measurements is depicted in Figure 5.

A description of the method using a high-resolution digital camera images is given in Ref. [9]. An uncertainty analysis of this method is given in section “Validation of the Measurements”. An advantage of this method is its wide applicability in forensic casework, since a 3D model of the crime scene can always be made, independent of the surveillance camera and the available images. A disadvantage is that

Figure 4 Example of a 3D computer model and its projection on the image (bottom right)

Figure 5 Example of performance of a height measurement using either a cylinder (on the left) or a biped (on the right)

taking the pictures or carrying out the laser scan is time consuming and expensive.

Validation of the Measurements

As for every measurement in real life, for each height estimation, an error is made; that is to say, measured heights are always estimations of actual values. Whatever method is used to measure body height, the key issue is the precision of the measurements. What is needed is a proper estimate of the accuracy of the height measurement on the person in the image.

The solid way to investigate this seems to be by doing validation measurements on test persons of known height, under more or less identical circumstances. This will make it possible to carry out a sound analysis on the measurement error.

We describe a standard operating procedure for the validation of height measurements used at the Netherlands Forensic Institute, based on the method of 3D modeling of the crime scene. The procedure consists of

1. carrying out a "reconstruction" at the crime scene, and
2. performing a statistically sound analysis of the results.

The end result will be a confidence interval for the perpetrator's height.

The validation procedure is based on the method of 3D modeling of the crime scene, but this is not essential. When using another method, the analysis can be performed comparably.

Reconstruction

The reconstruction consists of positioning test persons of known heights at the crime scene, in the same stance as the perpetrator, using the same camera. In the lab, the height of the test persons in the images is measured, which gives an idea about the accuracy of the measurement process.

The conditions under which control measurements take place must be similar to the original conditions. This means that the same camera must be used for the recording, so that the resolution and the lens distortion will be the same. It is also important that the camera is in the same position as before. This can be checked by placing an overlay of (characteristic lines of) the scene onto the new camera image. An example of this method is shown in Figure 6, in which the camera has been rotated after the crime scene was recorded.

By marking the location of the feet of the perpetrator on the overlay, the test persons are positioned such that the location and pose are more or less the same as the perpetrator's. The images of the test persons are captured, and their heights are measured in the same way as the perpetrator's.

Numerical Evaluation

Variation between actual and measured heights is introduced by the following factors:

1. creation of the 3D model;
2. finding of camera position, orientation, and focal length;
3. presence of lens distortion at the location of the perpetrator in the chosen image;
4. pose of the perpetrator in the chosen image;
5. presence and height of headwear and footwear; and
6. interpretation of head and feet in the images by the operators.

This variation may be decomposed into a systematic part and a random part. The systematic part is caused by variation in the modeling of the scene of crime (points 1, 2, 3) and difference in pose of test persons, as well as headwear and footwear (4, 5). Manual intervention by operators in the process (6) results in a random part of the variation.

From a statistical point of view, it makes sense to concentrate on the "total error" made in each particular height measurement, actual minus measured height, and assume it is normally distributed with certain mean (systematic error) and variation (random error). The mean and variation are estimated

Figure 6 Questioned image (on the left) next to reconstruction image (on the right). Following the overlay, it is clear that the camera has rotated after the incident

on the basis of outcomes for test persons. As the actual heights of the test persons are known, the average measurements on the test persons show whether there is a systematic error in the results. The measured height of the perpetrator must be adjusted with this error. The variation in the measurements is then used to determine a confidence interval for the height of the perpetrator.

Using 3D crime scene models, systematic errors found in casework go up to over 10 cm. However, because in these cases the perpetrator did not stand up straight, the systematic error may, e.g., be explained by the loss in height caused by his pose. Hence, this does not automatically mean that the measurement is not reliable. More problematic is a high variation in the measurements, which results in a large confidence interval. In casework, for 95% confidence intervals the band widths encountered reach from 5 up to 20 cm.

Evidential Value (Likelihood Ratios)

When height estimation is used as evidence in court, it is relevant to quantify its evidential value. This is not realized by a confidence interval. In fact, given a confidence interval and a suspect height, one cannot go much further than check whether the second is contained in the first. However, this is highly dependent on the chosen significance level, which is naturally somewhat arbitrary.

In literature [10], it has been described how evidential value can be quantified by means of so-called likelihood ratios (LRs). LR expresses numerically how rare the resemblance/difference is between a suspect's height and the confidence interval of the estimated height of the perpetrator.

In Ref. [11], a thought experiment is described about LR calculation for heights using witness statements. A theoretical foundation for the calculation of the LR based on population parameters and validation measurements on suspect and test persons has been described in Ref. [12].

There are different factors that influence the size of the LR. When the perpetrator's and suspect's heights do not match, the LR will be low and vice versa. Consequently, when the confidence interval is large, it will be more common to find a resemblance, so in that case the LR will also be low. Therefore the variation of the measurements must be low to retrieve a high evidential value. However, when the perpetrator is very tall or very small compared to the rest of the population, it is uncommon to equal the height, which may result in a high LR.

Possible Future Research

A question that arises is how much of the behavior of the estimation error is determined by the situation (camera, pose, lens distortion, resolution) and how much it behaves independently. This can be examined by testing methods on images from different cameras, and experiments investigating the latter will be valuable.

What is needed is a statistically sound comparison of the results in forensic casework of the four different methods. Points of interest are correctness and width of confidence intervals. Next to this, it is interesting to know in what percentage of the cases the individual methods are applicable.

It is furthermore interesting to look at the effect of radial distortion on measurements. Comparisons can be made between measurements on distorted images and measurements on the same images after correcting for lens distortion. The position of the measured people on the image might also influence the result.

Finally, further research is needed on the practical implementation of the calculation of numerical LRs for height measurements. This is important for the communication and translation of the evidential value of findings to judges, police officers, and the like. A typical problem in this respect is how to acquire proper databases of heights for fixed subpopulations.

Conclusion

Typical complicating factors in the process of body height estimation in digital images are, on one hand, camera parameters such as location, orientation and lens distortion; and, on the other, pose, footwear and headwear of the questioned person. Methods used in the literature include single view metrology (on the basis of vanishing points) and 3D modeling of either the perpetrator or the crime scene.

In all papers mentioned, except [8], validation of results has been limited. For any method used, results need to be validated by doing a reconstruction with persons of known heights posing in front of the same

camera, in the same pose as the person in the questioned image. The systematic and random error made in measurements is then modeled, and confidence intervals for the questioned person's height can be determined.

LRs quantifying evidential value on the basis of population parameters and validation measurements need to be studied in more detail. Moreover, dependency of results on the cameras needs to be studied, and the different methods need to be compared in actual casework.

Acknowledgments

The authors would like to thank John Tighe of HOSDB for his cooperation on the part on single view metrology.

Light Bulbs and Filaments: Examination of

Introduction

While night road traffic represents only about 20% of daytime traffic, one-fourth of all road accidents and more than one-third of all serious accidents (up to 50% in some instances) occur at night time [1, 2]. This imbalance is mainly due to a lack of visibility from drivers. Drivers assumed to be at fault sometimes claim that they did not see the other vehicle, alleging that the other vehicle's lights were not turned on. In many instances, the other driver, who claims that he/she was driving with the lights on, contests this. Therefore, during the investigation of a road traffic accident, law

enforcement personnel are sometimes required to determine whether the lights of a vehicle were on or off at the time of the accident [3]. While special units of uniformed police officers investigate most road accidents, criminalists at the forensic laboratory, who may not go to the scene, often perform the examination of light bulbs. However, a thorough light bulb examination must include examinations of the scene, the vehicle, and the different items of evidence at the laboratory. Thus, it is fundamental that both the field investigator and the criminalist communicate properly [4]. Only by including the circumstances of the case in the interpretation of the results, one can guarantee that the different observations made on the evidence are exploited to their full potential [5].

Light Bulb Types

A vehicle lighting system has to fulfill two main goals: to allow the driver to see the road ahead and to allow other motorists to see the vehicle. While all light bulbs are devices that produce light when electrically energized, it is possible to find three main types of light bulbs in modern vehicles: incandescent light, arc-discharge light, and light-emitting diodes (LEDs).

Incandescent Light

This is still the most widespread system found on vehicles. It is being slowly replaced by LED (mostly for rear and indication lights) and arc-discharge lights (for low and high beams). There are two main types of incandescent light bulbs: regular and halogen types, which are shown in Figure 1.

The heart of such light bulbs is the tungsten filament, which has a diameter of less than 0.1 mm and produces light by incandescence when energized. In the regular type of incandescent light bulb, the volume inside the glass globe is under vacuum to prevent the filament's oxidation. In time, tungsten slowly evaporates and deposits on the glass inner wall, thus the lifetime of the bulb is limited. The efficiency of such a bulb is about 2%. In the halogen type of incandescent light bulb, the globe is made of quartz, and the inner volume is filled with a halogen gas (usually iodine or bromine). As a result, tungsten does not deposit on the inner wall and the lifetime of the bulb is highly increased. Its efficiency usually reaches about 3.5%.

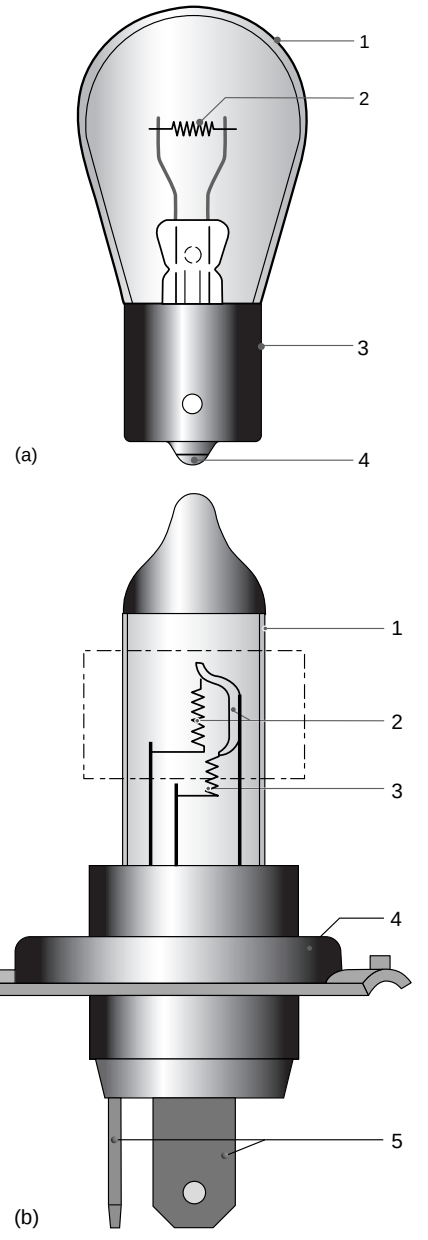

Figure 1 (a) Schematic of a regular incandescent light bulb: (1) glass globe, (2) tungsten filament, (3) metal socket base, (4) electrical contact. (b) Schematic of a halogen incandescent light bulb: (1) quartz globe, (2) low beam filament with cap, (3) high beam filament, (4) metal socket base, (5) electrical contacts. [Automotive lighting technology, windshield and rear-window cleaning, Robert Bosch GmbH, Plochingen, Germany, 2nd edition, 2003, Figures 3 and 4 [Reproduced with permission from Robert Bosch GmbH. © 2003.]

Halogen-type light bulbs are only used for high power (~40 W and more) headlights such as low/high beams and fog lights. While regular incandescent light bulbs are used for all other purposes, such as taillights and park lights. In some older vehicles and/or low-end vehicles, they can be found as low/high beam headlights.

Note that a light bulb may have more than one filament, as shown in Figure 1(b). In this case, it is used as low/high beam combination, but it can also be used for other purposes such as park/brake light.

Arc-Discharge Light

In arc-discharge or high-density discharge (HID) light bulbs, an arc passes through a gas (usually xenon with metal halides), which produces light. Thus, no filaments are present. This type of light bulb presents very little wear and, thus, a very long lifetime, and its efficiency is increased to about 22%. Nonetheless, it requires complex electronic control of the potential applied to the bulb. It remains extremely expensive and is found on high-end vehicles and as an option in many middle class vehicles. It is exclusively used for low/high beams.

Light-Emitting Diode (LED)

In a LED, a semiconductor diode emits light when a current passes through it. LEDs present no wear, an extremely long lifetime, a high resistance to mechanical shock, and an efficiency of up to 15%. LEDs are under constant development and are used on vehicles more frequently everyday, mostly to replace taillights and interior lights. Future developments will likely lead to the use of LEDs as headlights.

Failure Mechanisms

Recent research in forensic sciences has not been able to identify failure mechanisms for determining the condition of a light bulb at the time of its breakage when it is not equipped with a filament. Only the incandescent-type light bulb has a filament and, thus, can be examined to generate meaningful forensic results. Therefore, this discussion is limited to the incandescent-type.

The light produced by the incandescence of the filament is caused by heat generated by the flow of electrical current (Joule's effect). The filament can reach temperatures up to approximately 3000 °C [6]. The filament is placed in an inert atmosphere because it would completely burn if exposed to air at that temperature. As a result, the filament breaks differently depending on whether or not it is energized and whether or not the glass bulb is compromised.

From a failure mechanism perspective, it is important to consider whether the filament is energized or not. Then, it is clear that a mechanical shock has occurred; otherwise, there would be no mechanical stress applied to the light bulb and no failure would occur. When the filament is energized, several situations can occur. If the glass breaks, but the filament does not rupture immediately, the filament burns in the air and produces tungsten oxide until it opens [7]. Because of Joule's effect, the thinner the diameter of the filament, the more resistance it has and the more heat it generates; thus, the faster it will burn. As a result, one section of the filament usually disappears until it ruptures. The rupture pattern consists of two filament ends exhibiting decreasing diameters to the point of rupture and a globular appearance, as shown in Figure 2(a). This is accompanied by significant production of tungsten oxide crystals. If the glass breaks and the filament ruptures immediately upon glass breakage (due to the same shock), then the fracture is constituted of two ends of the same diameter, and the fracture surface will be globular in appearance (also called *melted fracture*) as shown in Figure 2(b) [8]. Usually, no tungsten oxide crystals are present on the filament, however there is usually some bluing or light oxidation at its surface. Nevertheless, when the filament is on at the time of the glass breakage, small glass particles deposit on the filament, melt on it, and solidify into spherical shapes (see Figure 2c).

If the globe does not break, then the filament does not come into contact with air. Thus, no oxidation of the tungsten occurs. However, the energized filament can rupture, in which case the fracture melts. If the filament is not energized, with or without glass breakage, the fracture will be brittle, as shown in Figure 2(d).

Forensic Approach

Limitations

It is important to understand that the forensic examination of a light bulb may reveal two things:

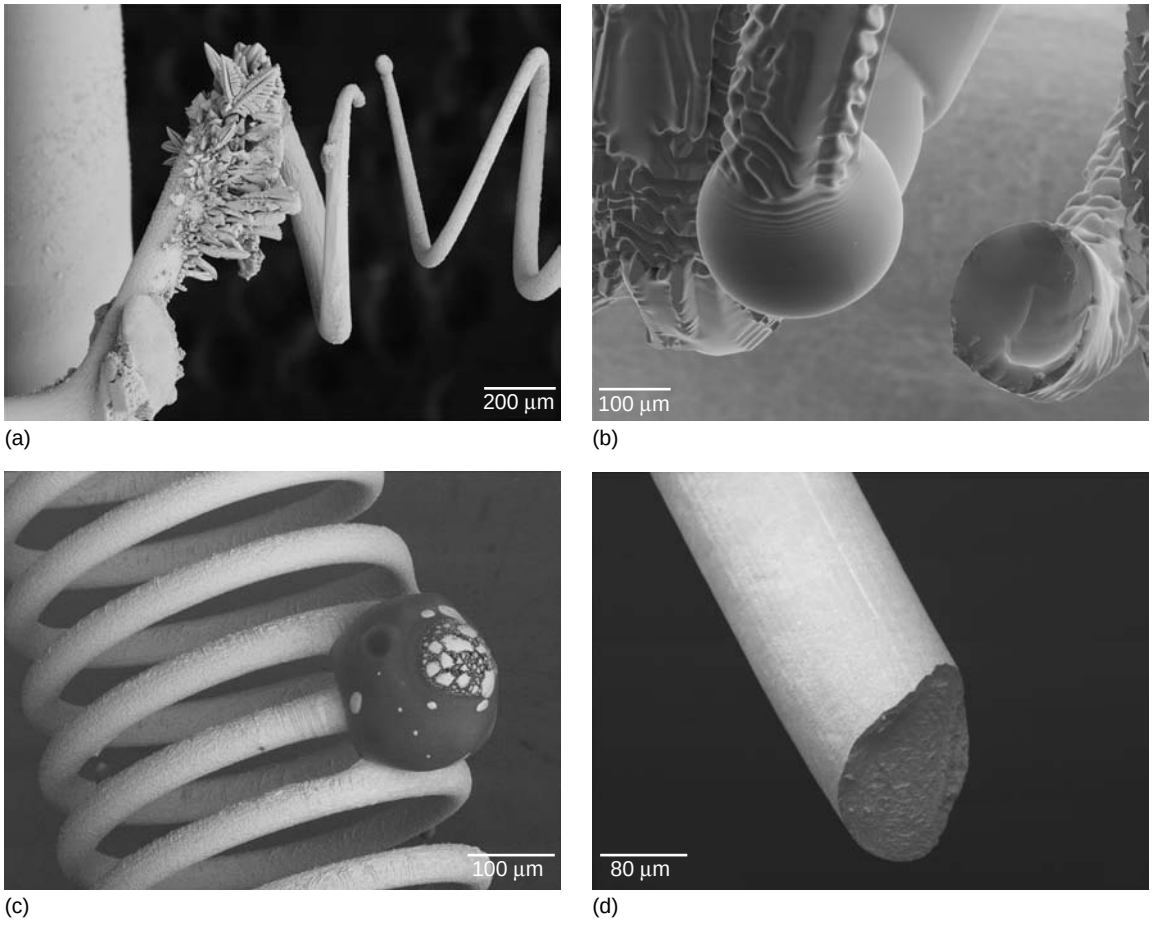

Figure 2 (a) A melted fracture due to burning of the filament in the air. Note the diminishing diameters before the fracture. (b) Melted fracture due to mechanical shock while the filament is energized. (c) Glass beads resulting from the globe breakage while the filament is incandescent. (d) Brittle fracture due to a mechanical shock while the filament is cold (not energized) [Reproduced with permission from SwissForensic.]

- Whether or not the filament was energized at the time of the glass globe breakage.
- Whether or not the filament was energized at the time of its rupture.

As a consequence, it is crucial not to confound the time of the glass breakage (or filament rupture) with the time of the accident [9]. While these two (or three) events could occur simultaneously, they could also be completely separate and independent events. It is not uncommon to observe vehicles driving on the road with either a broken taillight or headlight, or simply with one light not working. Therefore, the criminalist can generally not testify to the condition of the light bulb at the time of the accident, but rather at the time of the glass breakage or filament rupture. Although this limitation may affect the strength of the conclusion, it is often unavoidable. Of course, there are exceptions, notably when the scene and vehicle examinations have been thoroughly conducted and all evidence retrieved, and/or if the exact condition of the lighting system (including all light bulbs) was known just prior to the accident.

Overall Investigation

The forensic investigation involving the examination of light bulbs to determine whether they were on or

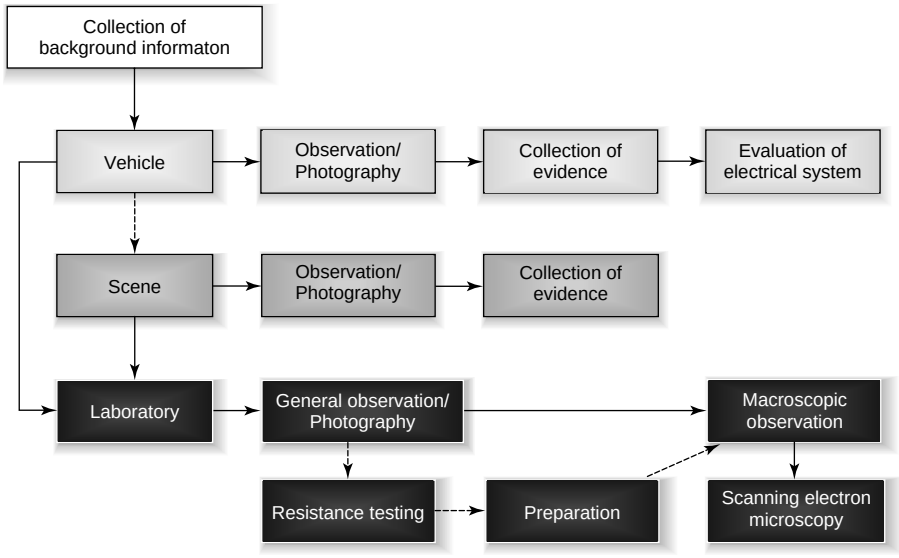

Figure 3 The different steps of the forensic examination of light bulbs

off at the time of an accident is conducted according to the steps shown in Figure 3.

First, it is crucial to obtain background information about the case and the testimony of the first responders at the scene, in particular, to understand who did what. For example, if a police officer tried to turn on the lights at the scene, this will greatly influence the outcome of the interpretation [10].

Scene Examination

The examination of the scene where the accident occurred should not be neglected. Even though the scene may have been "examined" by police officers in an attempt to reconstruct the accident, they may not have looked for light bulb remains. Often, if a light assembly has been damaged by mechanical shock, small pieces could have fallen and may remain on the ground. The search for these pieces is difficult and must be conducted meticulously. Photograph the scene along with any traces of impact. Note and photograph the position of any found items prior to removal. Be extremely gentle when moving them, because very tiny crucial pieces of evidence may be lost. Also remember that foreign materials, which have nothing to do with the vehicles involved, may be found on the accident site. This is particularly true in countries or places that are known not to be clean, where objects may remain on the side of the road for many months or years.

Vehicle Examination

When examining the vehicle, first ensure that the vehicle is properly identified [11]. Second, observe and note the position of the contact and (light) switches. Measure and record the remaining battery potential using a voltmeter. Then, thoroughly examine the fuse box. Check the integrity of each fuse. Record any abnormality or missing fuse. Be careful because many modern cars have two fuse boxes, usually one in the passenger compartment and one under the hood. Next, carefully observe and photographically record all damages to the vehicle. This is very important for interpreting the results. Sometimes the vehicle may have been damaged prior to the accident. If the damage is not consistent with the dynamics of the accident or if there are serious indications of aging, such as rust, then it is probably anterior to the accident in question. In any case, it is important to determine what damage resulted from the accident and what did not. Finally, examine and photograph all the light assemblies.

Then collect all damaged light assemblies, if possible, or, at least, the light bulbs. Additionally, it is good practice to collect all other light assemblies,

too, because they may bear some pertinence later in the investigation. For example, the rear brake light may reveal information about whether the vehicle was braking or not. When a filament is hot, it distorts more easily. As a result, if the shock was of sufficient force, the brake light filaments may be distorted, while the rear fog light filaments, if they were off, would not distort. This provides baseline information to the investigator regarding the force of the shock and the level of distortion expected. Also include the dashboard light bulbs, because these contain very tiny filaments, which distort very easily. As a result, it may be possible to determine which indicator light was on or off at the time of the shock.

Once all of the pertinent light bulbs have been collected, test the electrical lighting circuit using a multimeter. Use service manuals whenever necessary to identify the proper functioning of the lighting system. Then, verify light sockets to determine whether the circuit presents any modifications and/or abnormalities. At the end of the vehicle examination, the criminalist must have a clear documentation of the damages to the vehicle, the conditions of the light assemblies and light bulbs, and a full comprehension of the vehicle's lighting system.

Laboratory Examination

Before performing any manipulation on a light bulb, take a general photograph. One must always remember that filaments are extremely fragile and small titbits of important evidence can be lost from a bulb if not properly handled. Taking general photographs of light bulbs is never easy because of the reflection on the glass. The combined use of a polarization filter and diffuse lighting provides good results. Use a brightly colored background, either blue or pink, Post-It notes are extremely helpful.

Then, carefully observe the light bulb using a macroscope (magnification up to 40×). Note the condition of the glass and any cracks or abnormalities. Then, observe the filament(s), note their conditions and photograph them whenever possible. Carefully observe the contacts for any damage and irregularities. Finally, record all identifying marks. It is important to obtain the brand and model of the light bulb and its specifications. Further information may be obtained from the manufacturer.

Then, measure the resistance of the filament at the contacts using an ohmmeter. A normal resistance should range from 34 mΩ (for 5-W bulb) to 420 mΩ (for 60-W bulb) on a 12-V system. Often, it is possible to see whether the filament is open or not; however, sometimes, it is only possible to observe this through a resistance measurement.

It may also be necessary to remove the glass from the bulb. Proper macroscopy, or even electronic microscopy, requires the direct observation of the filament and its fracture surfaces. This cannot be achieved through the glass. To remove the glass from a regular incandescent-type light bulb, score the bottom part of the bulb with a file close to the metal base. Then, locally heat the glass at the score with a small flame. Finally, place a drop of water on the score. The rapid contraction of the glass due to cooling will break the bulb evenly along the score, thus allowing for a clean removal of the bulb. For the halogen type, wrap the bulb in paper towels and slowly squeeze it in a vice, until it breaks. The breaking is quite violent, so be very gentle when conducting this operation, and particularly when unwrapping because small pieces of filament can be lost.

Then, observe the filament in detail. If it is open, carefully locate and observe the fracture surfaces and photograph them. Check the filament for the presence of oxidation (bluing), tungsten oxide, and, most importantly, glass beads. Whenever possible, observe the filament with a scanning electron microscope. This allows for a significant improvement in the observation of the fracture surface. The presence of glass beads can also be easily pinpointed on the filament, and elemental analysis capabilities allow for the identification of glass and tungsten oxide.

Interpretation of the Results

Because the failure mechanisms of incandescent light bulbs are known, it is possible to determine the state of the light bulb at the time of the breakage as a function of its condition after the breakage. Figure 4 can aid in the interpretation of light bulb examination results in most instances. The first dichotomy depends on the condition of the glass. The second dichotomy is based on the filament's condition.

If the glass is intact and the filament is broken, the fracture surface is determinant. If the fracture is brittle (cold fracture), then the light bulb was off; if the fracture is melted (hot fracture), then the light

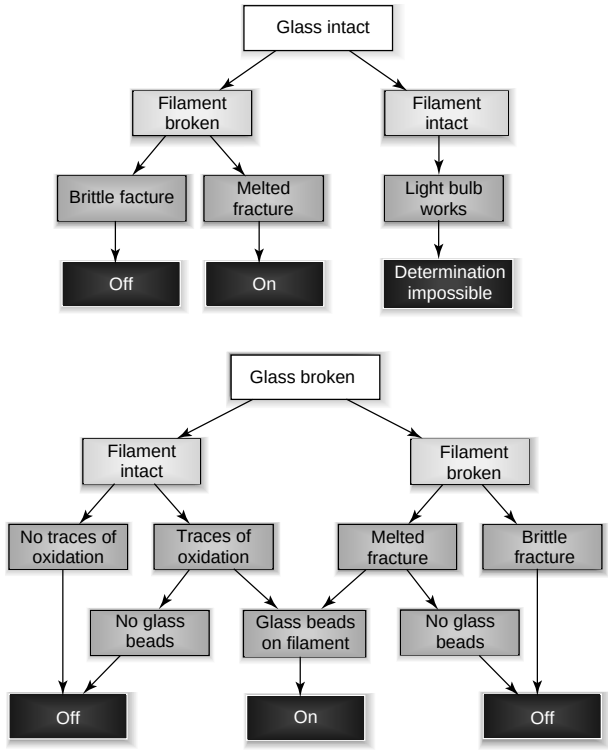

Figure 4 Scheme of the aid to the interpretation of light bulb examination results

bulb was on. When both the glass and the filament are intact and the light bulb still works, then the determination is impossible.

Things become slightly more complicated when the glass is broken, because if the light bulb is energized after glass breakage, further damage to the filament could occur. The criminalist must then take this possibility into account when interpreting the results. If the filament is intact, it is important to determine whether there are traces of oxidation. If the filament is clean and presents no traces of oxidation, this means that the light bulb was off at the time of glass breakage and was not energized afterward. If traces of oxidation are present, then it is important to determine whether glass beads are present on the filament. While there may be cases in which no glass beads would deposit on the filament when this one is on at time of glass breakage, only the presence of glass beads on a filament is a true indication that it was energized at the time of glass breakage. So, if no glass beads are present on a filament, which exhibits oxidation traces, it is likely that it was turned on after glass breakage. As a result, one cannot conclude that it was energized at the time of glass breakage. When the filament is broken, the fracture surface is determinant. If the fracture is brittle, the filament was not energized because it was cold. If the fracture is melted, then it means that the filament could have been energized at the time of breakage, or at some point after the breakage. Again, at that point, glass beads as well as the fracture surface, are decisive [12]. If they are present, the light bulb was on, if no glass beads are present, then the light bulb was likely off at the time of glass breakage.

Low Copy Number DNA

Introduction

The late 1990s saw the advent of short tandem repeat (STR) DNA testing (*see* **DNA**). STR tests combine the sensitivity of a polymerase chain reaction (PCR)- based test with great discriminating power (quadrillions or quintillions of randomly chosen, unrelated individuals may need to be compared before two are found to have the same DNA profile) (*see* **Short Tandem Repeats**). PCR is a procedure that allows a small amount of DNA (which by itself would not be enough to type) to be amplified into an amount large enough for typing. It does this by making billions of copies of DNA fragments from a polymorphic area (or areas) of the genome. PCR is

not a genetic test itself, but merely a tool to increase the amount of genetic material that is being tested.

The amplification of DNA takes place in a test tube. The DNA that is extracted from each sample is placed in a separate tube, along with a mixture of primers, enzymes, and other reagents. The tubes are then placed in a machine known as a *thermal cycler*, which can control their temperature precisely while going through a series of heating and cooling cycles. Each cycle has three steps that are repeated 28 times (in conventional DNA profiling as recommended by the widely used Profiler Plus and SGM+ test kits), doubling the number of copies of the target DNA each time, and ultimately producing literally billions of copies. The amplified DNA, which was initially like a needle in a haystack of other DNA, is amplified to the point that there are far more needles than hay and those needles can then be characterized relatively easily.

Applied Biosystems, the manufacturer of the popular Profiler Plus and SGM+ test kits, recommends that a starting quantity of DNA should be between 1.0 and 2.5 ng (1 ng = 1×10^{-9} gm) in order for their kits to produce accurate and reliable results. A diploid human cell contains roughly 6.6 pg (1 pg = 1×10^{-12} g) of genomic DNA such that 1 ng of human DNA comes from approximately 152 diploid cells. Use of more than 2.5 ng of DNA template is known to give rise to a variety of issues that can complicate the interpretation of DNA test results including: the presence of off-scale peaks; split peaks (such as those that arise due to a technical artifact known as +A; *see* Figure 1); and imbalance in the height of peaks between loci. Use of less than 1.0 ng of template DNA is also known to give rise to a set of issues that can complicate the interpretation of DNA test results including: imbalance of the height of peaks within loci; imbalance of the height of peaks between loci; and allelic drop-out (Figure 1) and drop-in.

Stochastic Effects

Walsh *et al.* [1] recognized even before PCR-based DNA tests became popular that use of quantities of DNA below the recommended 1.0 ng starting amount could be problematic. "Stochastic" effects (sometimes also referred to as "preferential amplification") are at the heart of the problems associated with small quantities of template. These stochastic effects essentially arise from sampling errors that can occur when very few samples are made (much like those that might happen when blindly drawing black and white beans from a bag – a small number of draws, but not a large number, might suggest that all the beans in the bag are black even though they account for only 50% of a large number of beans in the bag)

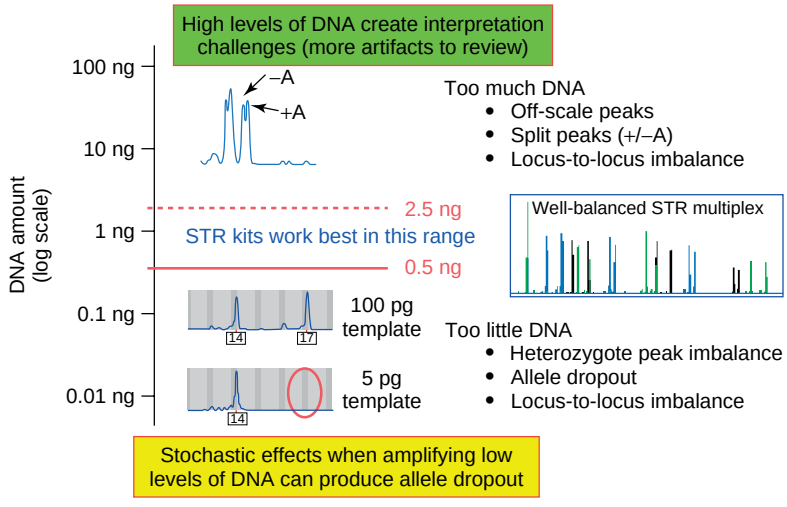

Figure 1 Impact of using nonoptimal amounts of template DNA for PCR amplification. [Derived from a presentation by Dr John Butler (US National Institute of Standards and Technology, Office of Law Enforcement Standards) at the Midwestern Academy of Forensic Sciences annual meeting in Indianapolis, Indiana on October 11, 2006]

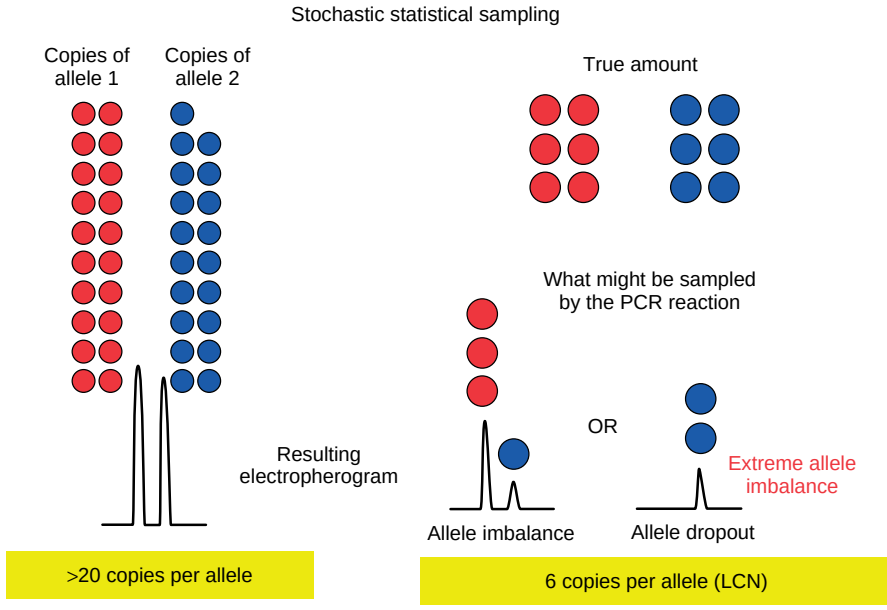

Figure 2 Stochastic statistical sampling during PCR amplification. When more than 20 copies of an allele are being amplified at the start of a PCR amplification it is unlikely that sampling errors will result in a large difference in the number of copies that are made of two different alleles. Sampling errors are much more likely to occur when fewer copies of the alleles are present at the start of the process. [Derived from a presentation by Dr John Butler (US National Institute of Standards and Technology, Office of Law Enforcement Standards) at the Midwestern Academy of Forensic Sciences annual meeting in Indianapolis, Indiana on October 11, 2006]

(Figure 2). With starting quantities of DNA arising from fewer than 150 human cells (and conceivably as few as five to ten cells), it is possible that one of two alleles at a locus will be amplified by the PCR process more than its counterpart (resulting in peak height imbalance or even allelic drop-out). It is also possible that stray alleles originating from just a few contaminating cells could be amplified preferentially, just by chance, relative to those that actually come from an evidence sample (resulting in allelic drop-in). Another commonly observed stochastic effect associated with small amounts of starting DNA template is an increase in the prevalence of a technical artifact known as "stutter" (which occurs when the enzyme responsible for making copies of the STR regions either slips forward or back during the amplification process and makes a copy that is either one repeat unit shorter or longer, respectively, than what was actually present in the template DNA). Quite simply, if there is not enough starting quantity of DNA prior to the time the PCR is started, the PCR process can produce results that are inaccurate and unreliable.

Avoiding Stochastic Effects

Because of the widely appreciated problems associated with stochastic effects in low copy number (LCN; sometimes also referred to as Low Template DNA or LTDNA) testing, the Applied Biosystems STR test kits normally fail when less than 125 pgs of DNA (that from roughly 20 diploid human cells) are used at the start of the process. This feature of the test kits specifically seeks to avoid these problems at the "stochastic limit of quantitation" (an amount of template that causes the chance of stochastic effects to be so likely as to make the test results incorrect) for the kits. The Technical Working Group on DNA Analysis and Methods (TWGDAM) validation of the AmpFISTR Blue test kit [2] explored the use of 27 and 30 PCR amplification cycles. This validation study for the test kit that was the precursor of the Profiler Plus and SGM+ test kit ultimately settled upon using 28 cycles so that quantities of DNA below 35 pg gave very low or no peaks – explicitly to avoid situations where peak imbalance results in

only one detectable allele from a heterozygous pair and concerns regarding trace contaminants could be minimized. It was assumed that 35 pg constituted an "analytical threshold".

Increasing the Sensitivity of Sensitive DNA Tests

One of the easiest ways that a PCR-based test can be made more sensitive is by simply increasing the amount of DNA replicating enzyme present and/or the number of PCR amplification cycles that are employed (Figure 3). One of the principal proponents of ultrasensitive DNA tests, the UK Forensic Science Service (FSS), in fact derives the increased sensitivity of their LCN tests primarily by increasing the number of rounds of PCR amplification to 34 cycles (six more than what is recommended by the manufacturer for the conventional use of the test kit that they use). Others have endeavored to generate information from lesser amounts of starting material by splitting samples and analyzing them multiple times and/or by purifying DNA from samples in different ways. While the details of these methodologies differ, they all suffer from stochastic effects due to the sampling errors (and ease of contamination and transfer) that small amounts of starting material entail. As a safeguard against the expectations of allelic drop-in (essentially, the presence of signal from unknown sources of contamination) and exaggerated stutter that increases in sensitivity brings, most laboratories

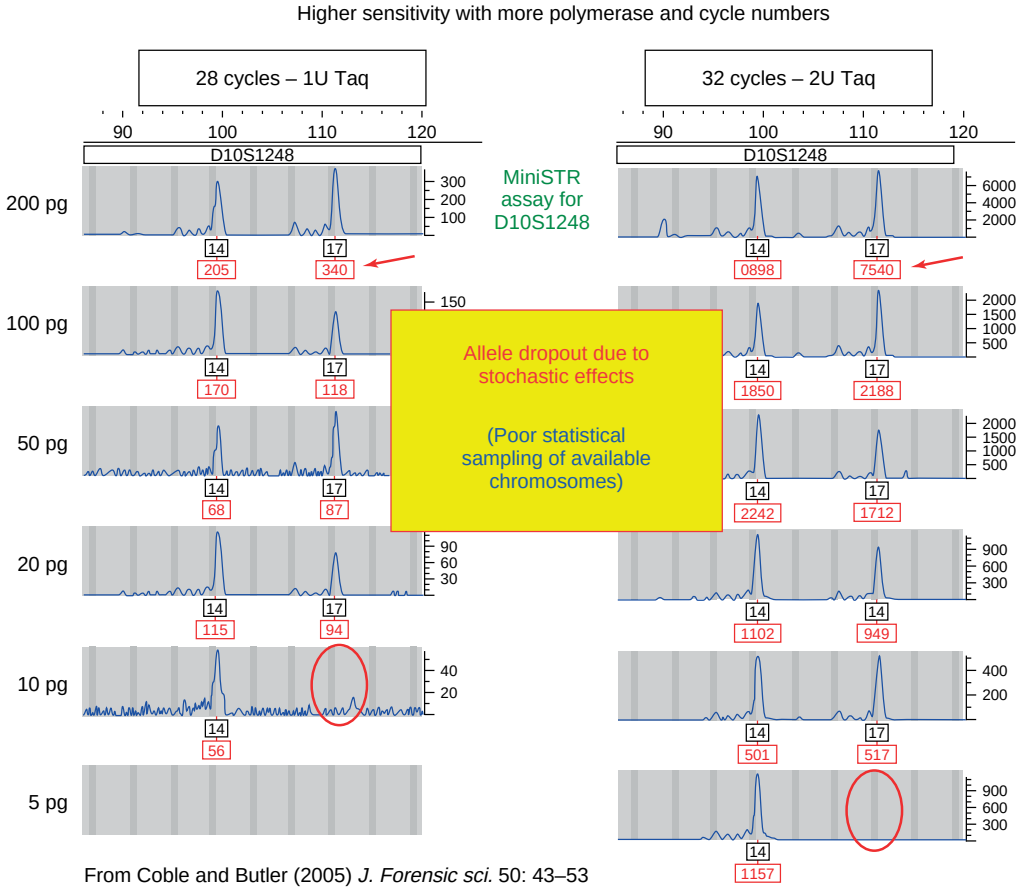

Figure 3 Higher scobnsitivity with more enzyme and rounds of PCR amplification. [Derived from a presentation by Dr John Butler (US National Institute of Standards and Technology, Office of Law Enforcement Standards) at the Midwestern Academy of Forensic Sciences annual meeting in Indianapolis, Indiana on October 11, 2006 (see also [3])]

that endeavor to perform analyses with less than recommended amounts of DNA template generate what are known as "consensus profiles". In such a consensus, a particular signal needs to be observed at least twice in multiple analyses of a sample before it is determined that the signal is associated with the sample rather than a contaminant. The reliance upon consensus profiles, especially when samples are analyzed only two times, actually results in an increase in the likelihood of problems associated with allelic drop-out which, in turn, results in reductions of the statistical weight attached to loci where only one allele is observed.

Increased Problems of Persistence and Transfer of DNA

Even under the very best of circumstances (virtually the opposite of those that require ultrasensitive DNA testing to be attempted), the presence of a DNA profile usually says nothing about the time frame or circumstances under which the DNA was transferred to an item. Further, the chance of "innocent" DNA transfer greatly increases as the amount of starting material for DNA profiling tests becomes smaller (e.g., [4]). Quite simply, even if one's DNA is found to be associated with an article of evidence, the great sensitivity of low template DNA testing causes very real problems to arise regarding both how and when that DNA was transferred.

DNA in quantities at LCN levels can be easily transferred (*see* **Transfer: DNA**; **Trace Evidence: Transfer, Persistence, and Value**) from one article to another (e.g., from evidence sample, onto the analyst's laboratory coat or gloves, then to another evidence sample; or by having been stored together in a single package) – without the contributor having any knowledge that the transfer(s) has occurred. No DNA tests are currently able to distinguish between secondary transfer (such as the transfer of DNA through contamination events) or DNA present due to direct contact with an object. Similarly, DNA tests are not currently capable of distinguishing in any way between the presence of DNA due to contamination (such as could very easily occur through storing or opening the objects in the same location as items obtained from an individual) or direct contact between an individual and the object. Given that LCN analyses can conceivably generate results from as little material as a few cells of an individual, the only way to be confident that results have not been obtained solely through contamination is to demonstrate conclusively with chain of custody (continuity) records that contamination is not even remotely possible. The greater the possibility of persistence and/or transfer of DNA from and between people and items, the greater the reduction in the probative value of DNA test results.

The Differing Paradigms of Conventional and LCN Testing

Conventional DNA profiling's greatest strength ultimately comes from its great ability to *either* include or to exclude an individual as a possible contributor to an evidence sample. In conventional PCR-based DNA profiling, the presence of alleles in an evidence sample that are not observed in a suspect and/or the presence of alleles in a suspect that are not observed in an evidence sample that is unlikely to have experienced allelic drop-out would normally exclude a suspect as a possible contributor to an evidence sample. But, because LCN testing operates at or beneath a stochastic limit of quantitation for a PCR-based amplification system, any number of such differences between evidence samples and a suspect's reference can be easily (and reasonably) attributed to allelic drop-out, allelic drop-in, or other stochastic effects (Figure 4). At the very least, each of these factors can lead to alternative interpretations of the evidence and, consequently, to a compounded reduction of the probative value of the test results (*see* **Mixture Interpretation: DNA**).

In conventional forensic DNA analysis, attempts are made to exclude a suspect, and only after failing to exclude, inferences are made regarding the rarity of the observed DNA profile. However, the statistical interpretation of LCN test results is significantly complicated by the expectation of stochastic effects. While inherent flexibility of interpretation of LCN testing results may be useful for the generation of investigative leads to which no statistical weights need to be attached, that flexibility of interpretation makes it unsuitable for establishing proof that an individual was directly associated with an evidentiary sample (let alone, what the time frame and circumstances of such an association may have been).

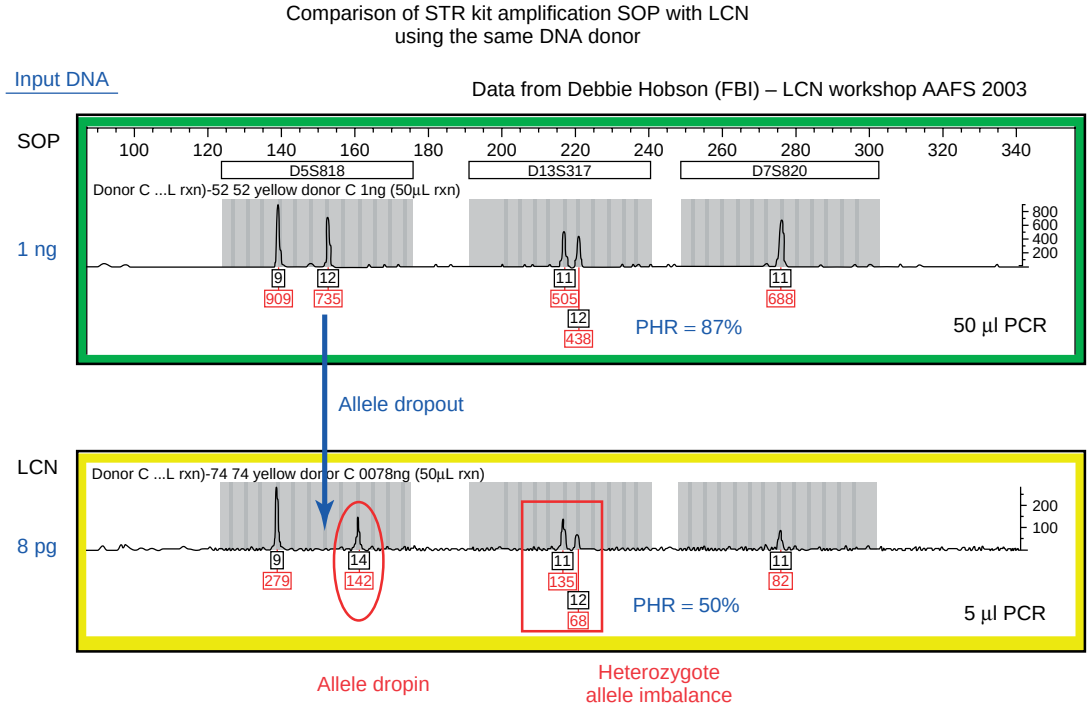

Figure 4 Comparison of conventional STR amplification and LCN amplification with the same test kit and source of human DNA. With conventional STR testing the true DNA profile of an individual can be determined directly from an electropherogram. LCN testing of the same individual with the same test kit gives rise to a significantly different electropherogram. [Derived from a presentation by Dr John Butler (US National Institute of Standards and Technology, Office of Law Enforcement Standards) at the Midwestern Academy of Forensic Sciences annual meeting in Indianapolis, Indiana on October 11, 2006]

Utility of Ultrasensitive DNA Tests

There is significant and ongoing debate regarding the utility and proper use of ultrasensitive DNA tests. A challenge to the reliability of LCN DNA profiling in the trial of Sean Hoey in Belfast Crown Court in Northern Ireland [5] prompted the United Kingdom's new Forensic Science Regulator to commission a review of low template DNA profiling techniques. That review [6] was released on 12 April, 2008 and concluded that the technologies collectively called low template DNA profiling are "robust" but accepts that what was offered as evidence in Sean Hoey's trial was not sufficient to establish the validity of the technique. The review also enumerates 21 recommendations (including the development of a consensus on the interpretation of test results and that more work be done to establish "best practices" for interpretation) that should be undertaken to improve the methodology. There are in fact things about LCN approaches upon which the reviewers and critics do agree. For instance, the International Society of Forensic Genetics similarly concludes that there is "a significant need for continuing education and research into" LCN reporting [7]. Also, Budowle *et al.* [8] caution that "Publicizing the potential of the application of LCN typing without describing its limitations may cause misunderstanding" which is consistent with the review's recommendations 1, 3, and 13. But given Budowle *et al.*'s [8] conclusion that "The method cannot be used for exculpatory purposes," the review's ultimate conclusion that LCN testing is "fit for purpose" leaves the important but unanswered question of "what *is* that purpose?"

Summary

Budowle *et al.* [8] observed that "Because of the successes encountered with STR typing, it was inevitable

that some individuals would endeavor to type samples containing very minute amounts of DNA." However, the stochastic effects associated with small amounts of template (e.g., allelic drop-out and drop-in, exaggerated peak height imbalance and stutter) coupled with the diminished ability to ascertain the tissue source of DNA samples or how long they have been associated with an article reduce the weight that can be attached to the finding of an ultrasensitive DNA profile match.

Interpretation: Low Template DNA

Luminol

Introduction

Ever since its forensic potential was first reported in 1928 [1], luminol (5-amino-2,3-dihydro-1,4-phthalazinedione or 3-aminophthalhydrazide, Figure 1) has been utilized for the detection of latent bloodstains during investigations involving violent crime. This use is based upon the emission of light when a reagent containing luminol and hydrogen peroxide is applied to the suspect stain, the resulting glow being due to the reaction of luminol with hemoglobin. The key events in the discovery, study, and use of luminol as a forensic reagent are presented in Figure 2. Despite the age of this presumptive test, there is still significant interest in the forensic community due to its high sensitivity and lack of damage on genetic material, allowing subsequent DNA analysis (*see* **DNA**). This interest has resulted in a number of recent publications, including modifications to the technique [2, 3], a new, commercially available formulation [4, 5], and studies on its performance as a forensic test [6, 7]. Recently, the authors carried out a comprehensive review of the forensic application of the luminol reaction as a presumptive test for latent blood detection, upon which this article is substantially based [8].

Luminol

Chemical and Physical Properties

The key chemical, physical, and toxicological characteristics of luminol are summarized in Table 1 [9, 10]. In relation to its use as a forensic reagent, solutions of luminol are very sensitive to light and the presence of metal cations; typically the solutions are

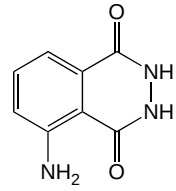

Figure 1 Chemical structure of luminol

stable only for periods of 8–12 h. Luminol, both in the pure form and in solution, is also thermally unstable, and therefore should be protected from high temperature [11].

The key property of luminol as a reagent for forensic science is its ability to undergo reactions which produce light. This phenomenon is termed *chemiluminescence* [12]; the fundamentals of which have been comprehensively reviewed in a number of textbooks and articles in recent years [13–16].

Table 1 Chemical, physical, and toxicological properties of luminol [9, 10]

Names	5-Amino-2,3-dihydro-1, -phthalazine-dione, *o*-aminophthalyl hydrazide, 3-aminophthalic hydrazide
Molecular formula	$C_8H_7N_3O_2$
Molecular mass	177.16 amu
Melting point	319–320 °C
pK_{a1}	6.74
pK_{a2}	15.10
Solubility in water	<0.1 g 100 ml^{-1} at room temperature
Physical properties	Yellow crystalline solid (grainy crystals)
General properties	Stable at room temperature, sensitive to light, combustible, incompatible with strong oxidizing agents, strong acids, strong bases, strong reducing agents, emits light on reaction with oxidizers (chemiluminescent)
Safety information and potential health effects	The toxicological properties have not been fully investigated in humans; mucosa irritation has been described: eyes, skin, respiratory tract, and gastrointestinal tract (with nausea, vomiting, and diarrhea). No data available about chronic effects. More information available at The National Toxicology Program (The National Institute of Environmental Health Sciences, NC, USA); Website http://ntp.niehs.nih.gov/index.cfm

Chemiluminescence

The luminol reaction is an example of direct chemiluminescence, which can be represented by:

$$A + B \longrightarrow [I]^* \longrightarrow \text{Products} + \text{Light} \qquad (1)$$

where A and B are reactants and $[I]^*$ is an excited-state intermediate. The excited-state intermediate returns to the ground state by a variety of routes. The light emitted has differing degrees of intensity, lifetime, and wavelength, with the latter parameter covering the spectrum from near ultraviolet, through the visible and into the near infrared.

The intensity of the chemiluminescence emission observed from a reaction depends upon both the reaction rate and the efficiency of the process generating the excited-state species. The use of very sensitive detectors and the almost complete absence of background emission have allowed the monitoring of even inefficient chemiluminescence reactions, such as the oxidative ultraweak chemiluminescent reactions in living cells [17].

The efficiency and wavelength of a chemiluminescence emission are greatly affected by the environment in which the reaction takes place. For solution-phase chemiluminescence, the factors that will affect the reaction are similar to those affecting normal fluorescence and phosphorescence.

For most analytical purposes, it is the chemiluminescence emission intensity (I_{CL}) that is measured, either as an integral over the lifetime of the emission or as a transient response. It is a function of both the efficiency and the rate of the reaction:

$$I_{CL} = \Phi_{CL}\left(\frac{dC}{dt}\right) \qquad (2)$$

where dC/dt is the rate of reaction (molecules reacting per second). Chemiluminescence reactions can occur very rapidly (<1 s) or extremely slowly (>1 day), according to the reaction and the conditions.

The Luminol Reaction

Luminol chemiluminescence has recently been reviewed by Barnett and Francis [13]. The excited-state intermediate has long been established as the 3-aminophalate dianion (Figure 3) [13]. In aqueous

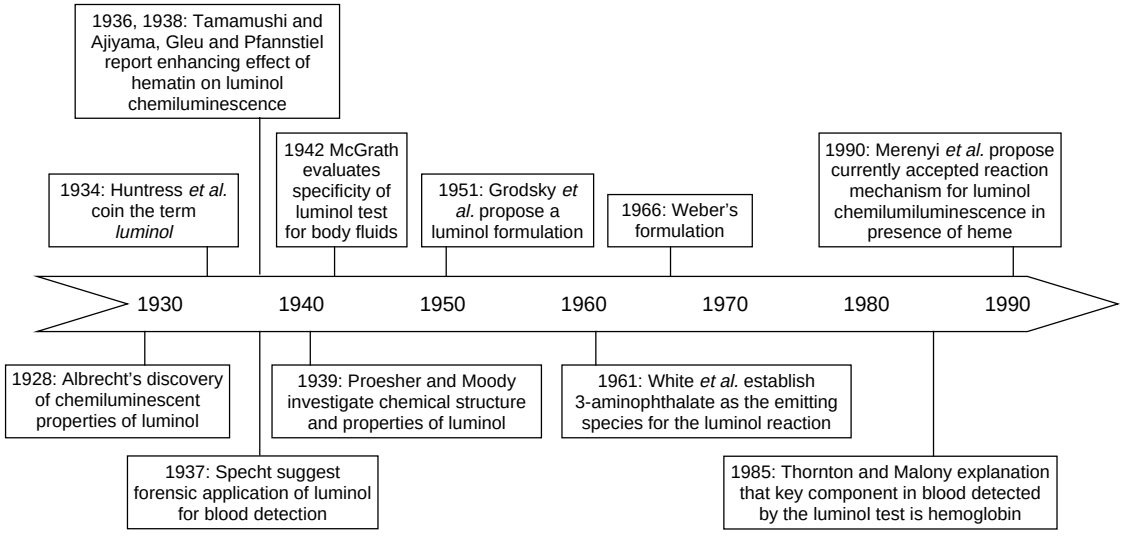

Figure 2 Key events in the discovery, study, and use of luminol as a forensic reagent

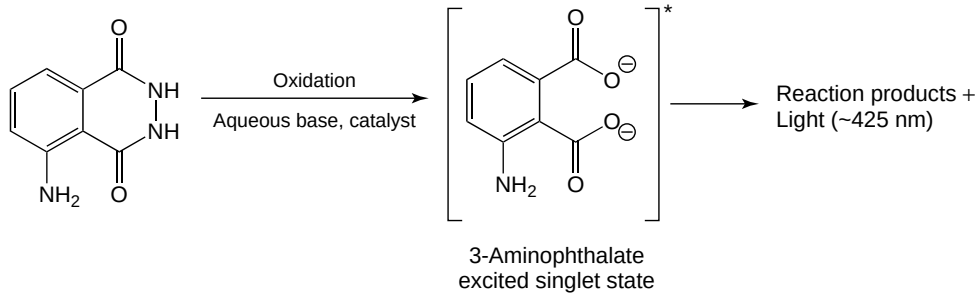

Figure 3 Luminol chemiluminescence reaction [Reproduced from Ref. 13. © Elsevier, 2005.]

solutions, the light observed ranges between blue-violet and blue-green, although the spectral range of emission is often rather broad and the observed maximum is dependent on several parameters of the reaction [18, 19]. This can include the presence of blood itself, which strongly absorbs at 420 nm, and may provide an inner-filter effect, thus shifting the observed maximum emission of luminol chemiluminescence to about 455 nm [3].

The light-producing pathway for the oxidation of luminol is a complex, multistep process and is dependent on several factors. These include pH, temperature and ionic strength of the reaction medium, and the reactive species that can be present in solution and interact with luminol, metal catalyst, or hydroxide ions [13]. For the luminol reaction, the exact role of the catalyst, which is required when the reaction is carried out in basic aqueous solution, and the reaction intermediates are not completely characterized. It is known that a wide range of other transition-metal catalysts and metal complexes catalyze the reaction. The optimum conditions of pH for the reaction depends on the identity of the catalyst used and varies between pH 8 and 11 [20], thus suggesting a multiplicity of potential catalysis mechanisms.

The luminol reaction mechanism has been the subject of significant discussion, and many suggested pathways have been postulated [21–29]. The current understanding of the probable reaction mechanism accounting for a number of findings from the aforementioned authors has been reviewed by Barnett and Francis [13]. A simplified scheme of the currently most accepted mechanism is presented in Figure 4 and is based on this work and on previous research by

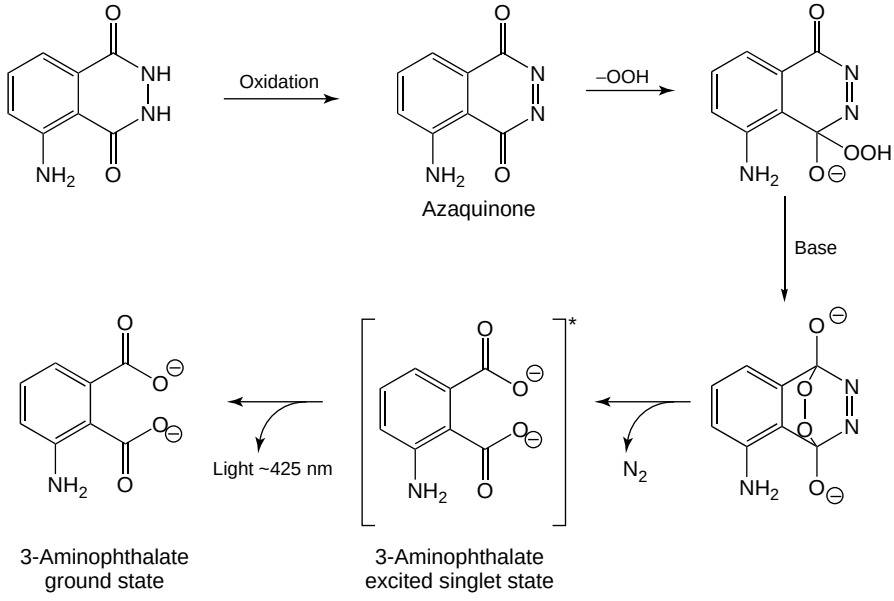

Figure 4 Simplified postulated reaction mechanism for luminol chemiluminescence

Merényi and collaborators during the 1980s [22–27]. For a more detailed discussion of the mechanism, the reader is directed to the authors' earlier review and references therein [8].

The key component within blood thought to be responsible for eliciting chemiluminescence with luminol is the iron-containing metalloprotein hemoglobin. This is the oxygen-carrying molecule found in the erythrocytes of all vertebrates and some invertebrates and is responsible for the red color of blood. Once outside an organism and deposited on a substrate, hemoglobin degrades [30], with the iron present within the molecule being oxidized from Fe^{2+} (ferrous) to Fe^{3+} (ferric). These ferric heme derivatives show the same catalytic properties and capability of participating in two-electron redox cycles as peroxidases, which are widely distributed especially in vegetables, their activity is termed a *pseudo-peroxidase* or *peroxidase-like*. This activity is commonly employed as the basis for many presumptive tests for blood, including luminol [29–33].

When a luminol formulation is applied on a bloodstain, ferric heme groups are able to catalyze both the decomposition reaction of peroxide and the oxidation of luminol and other substrates by peroxide [34–37]. These reactions are thought to happen as a result of the ability of the hydroxy–ferric–porphyrin (OH –Fe^{3+}–P) hematin group within hemoglobin to undergo a two-electron oxidation to a hydroxy–ferryl–porphyrin radical (OH –Fe^{4+}–P), which can return to the ferric porphyrin hematin state in two one-electron reduction steps *via* the hydroxy–ferryl–porphyrin (OH –Fe^{4+}–P) hematin group (Figure 5) [28, 37–40]. The catalytic process thus cycles between these three oxidation states of the hemoglobin, with the stable resting state being the ferric hematin. Alternative catalytic cycles and oxidizing species have been proposed (e.g., see Thornton and Maloney [28]), but the above cycle is now accepted by most researchers [37, 41].

The Luminol Reaction as a Presumptive Test for Blood

Operational Use

Luminol can be used to detect the presence of minor, unnoticed, or hidden bloodstains. It can disclose distribution, allowing bloodstain pattern evaluation and occasionally enabling the investigators to reconstruct some of the events of a crime by visualizing these patterns [42, 43]. Compared to other chemical-based

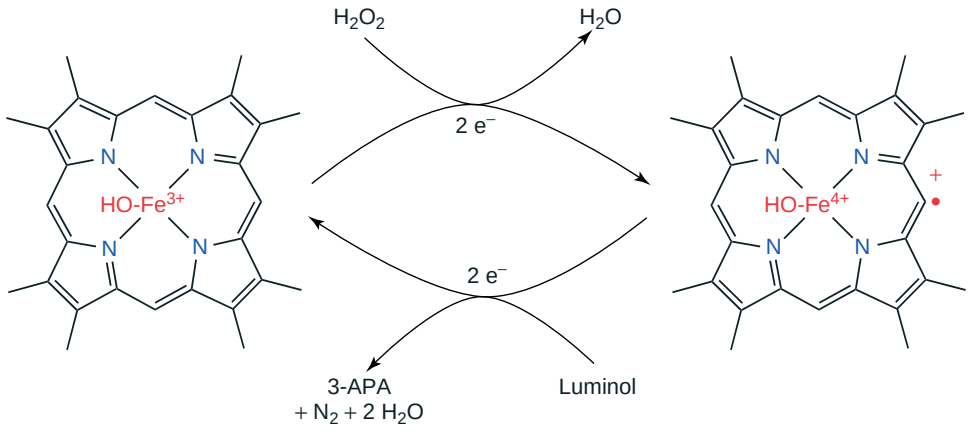

Figure 5 Iron redox cycling between different oxidation states when hematin is formed and sixth coordination position is occupied by –OH (P, porphyrin). In alkaline conditions and in the presence of a medium-strong oxidant such as hydrogen peroxide, the hydroxy–ferric–porphyrin (OH–Fe^{3+}–P) hematin group undergoes a two-electron oxidation to a hydroxy–ferryl–porphyrin radical (OH–Fe^{4+}–P)

tests and physical techniques for the detection of blood at crime scenes, luminol has the advantage of high sensitivity [7, 44, 45]. A recent evaluation reported that the luminol test could detect blood to a dilution of 1 : 100 000 [6]; earlier studies have reported that blood diluted down to a level of $1 : 10^6$ (1 μl of blood in 1 l of solution) was capable of being detected [33, 46, 47]. In addition, the luminol test does not significantly damage genetic material, especially when modern polymerase chain reaction (PCR) techniques are employed to analyze microsatellite DNA (*see* **DNA**). Only moderate adverse effects have been noted when other DNA testing procedures or serological markers were commonly used for identification purposes [6].

While several preparations of luminol have been described, including patented luminol molecule modifications or luminol blood-dependent chemiluminescence enhancers [28, 48], the formulations described by Grodsky *et al.* [47] and Weber [40], continue to be the most extensively used by forensic practitioners. This is due to their good performance, simplicity of preparation, low cost, and ready availability of the ingredients. These protocols are summarized in Table 2.

Regardless of the preparation, luminol solution is usually directly sprayed in completely dark environments. The light obtained can be photographed or filmed while the luminescent areas are marked in order to allow their detection once the light emission has faded [33, 49]. Examples of images of luminal-treated latent bloodstains are presented in Figure 6. Amplification of the luminolchemiluminescent emission by means of intensified cameras has been reported in a forensic context [28, 50] but is not in general use at crime scenes. Pretreatment of the surfaces possessing the stains with 2% hydrochloric acid (HCl) has been recommended by some authors [51, 52]. However, others have reported that this appears to decrease sensitivity by raising the background chemiluminescence level [42]. Acid treatment may also have a deleterious effect on subsequent DNA typing [33].

Owing to the potential irritant and harmful effects of luminol formulations (Table 1), and their application as aerosols, particular care has to be taken when conducting forensic testing for blood. Suitable personal protective equipment (goggles, respirators, gloves, and protective clothes) should be used by the operators when luminol is sprayed, and the area investigated should be ventilated after luminol application. The number of people assisting the operations should be limited to those strictly necessary [33].

Collection of the stains for further laboratory testing follows bloodstain location and photographic documentation, the method of collection depending on the nature of the substrate on which the stain is located (*see* **Biological Swabs**).

Table 2 Protocols for forensic luminol formulations

	Grodsky *et al.* [47]	Weber [40]
1.	Dissolve sodium perborate (3.5 g) in deionized water (500 ml) with stirring	Dissolve sodium hydroxide (8 g) in deionized water (500 ml) with stirring (stock solution A)
2.	Add luminol (0.5 g) and sodium carbonate (25 g) to the sodium perborate solution and stir until dissolved	Dissolve luminol (0.354 g) in the previously prepared sodium hydroxide solution (62.5 ml) with stirring (stock solution B)
3.	Decant solution into vaporizer or sprayer and use immediately	Dilute 30% hydrogen peroxide solution (10 ml) in deionized water (490 ml) (stock solution C)
4.		To prepare test solution mix 10 ml of each of the three stock solutions together and decant resulting mixture into a vaporizer or sprayer and use immediately
Note	Weighed out reagents can be kept for extended periods in plastic or glass containers prior to dissolution in water, luminol requires protection from light	Stock solutions can be stored in glass or plastic solutions at or below 4 °C away from direct light for extended periods

Factors Influencing the Use of Luminol

While the luminol test itself is relatively simple, interpretation of results is more challenging. Factors that should be taken into consideration include the physical structure of the substrate upon which the bloodstains are found, the chemical composition of the substrate possessing the stains, and any other substances present on the substrate.

Physical Nature of Substrate. The first issue confronting the forensic practitioner when using the luminol test at a crime scene is a consideration of the physical nature of the substrates possessing the stains [33, 42, 53]. Substrates can be divided roughly into two groups: absorbent materials and nonabsorbent materials.

Absorbent materials encompass substrates such as carpeting, leather clothes, fabric clothes, roof linings, blankets, and also irregular, porous surfaces such as

wood-finish paneling, walls, and interstitial spaces between tiles or wood objects. These materials often can retain significant amounts of blood, maintaining relatively undegraded for many years. This is due to the rapid drying of blood, especially in domestic or covered environments, thus preventing its degradation by environmental biological agents such as bacterial hydrolytic enzymes. In addition, these substrates can protect blood from physical or chemical environmental agents such as solar radiation, moisture, and water, or cleaning attempts after the crime has been committed [33, 42]. It is possible with these substrates to apply multiple applications of the luminol reagent, without the risk of excessively diluting the stains, in order to best visualize and to successfully photograph the bloodstain pattern [33, 42].

Nonabsorbent substrates such as nontextured linoleum, vinyl, tile, glass, metal, and many others present more difficulties both in the reagent application and in the quality of chemiluminescence. These substrate surfaces are unable to effectively retain and store blood and, moreover, cannot prevent its degradation especially by physical and chemical agents. As clearly demonstrated by Lytle and Hedgecock [42], these surfaces are fairly easy to completely clean, and a mild washing attempt by water and soap leads to the removal of the bloodstains yielding almost nonexistent reaction with luminol. A further complication is that the application of luminol solutions to nonabsorbent surfaces can lead to the bloodstain pattern running, owing to the limited retention of the resulting solution by the smooth surface. [33]. Particular care should therefore be used when dealing with these substrates, particularly when they are nonhorizontal, in order to avoid the loss of the stains. Investigators should first use a minimum amount of luminol solution by rapidly spraying, preferably with a nebulizer, the suspected area, and avoiding further applications quickly photograph the emission [33, 42, 53].

Influence of Interfering Substances. There is a wide range of environmental, pharmaceutical as well as domestic and industrial substances that are able to affect luminol blood-induced chemiluminescence (Figure 6). False-negative results have not been described in the forensic literature; however, there are some substances that may suppress luminol chemiluminescence which could possibly come into contact with blood. These include polyphenolic derivatives [26, 54, 55] such as tannins, which are widely present in wood, and some amino acids [56]. More problematic are those compounds that provoke intensification or generation of a chemiluminescence emission even if blood is not present, leading to false-positive results. Owing to the possible presence of these substances at the crime scene, the luminol test must not be considered sufficiently specific to permit an unequivocal identification of blood [47, 53, 57–59]

Those compounds that generate luminol chemiluminescence, or enhance the luminol emission in the presence of bloodstains, can be divided into three major categories (Figure 7):

1. compounds showing a catalytic true peroxidase or peroxidase-like activity;
2. compounds with a high oxidizing capacity towards luminol; and
3. compounds with a complex chemical composition with an undefined action mechanism towards luminol mixture.

The first group encompasses inorganic or bioinorganic species and represents the major source of interferences with the forensic application of luminol. These compounds often show excellent catalyzing properties in redox reactions and are widely distributed in the environment and in plants. These substances include free metal ions, in most cases included in inorganic compounds such as rust or soils; biological complexes between metal ions and organic components (such as metal-porphyrins, and including bacterial or plant pigments) often within protein structures; and enzymes belonging to the oxidoreductases class such as horseradish peroxidases.

Commonly encountered examples of the second category of interferents are sodium hypochlorite, potassium permanganate, and iodine. These species are present in many household and industrial chemical solutions, including insecticides, cleaning agents, disinfectants, or antiseptics [53, 60–62].

The final category of interfering substances covers a range of compounds that can be found in materials such as domestic and commercial oils, various glues, carpets, sinks, automobile seats, paints, and varnishes, and many kinds of soils [11, 33, 63, 64]. These substances are often able to catalyze the luminol reaction almost as effectively as blood, but owing to their complex chemical composition, the exact

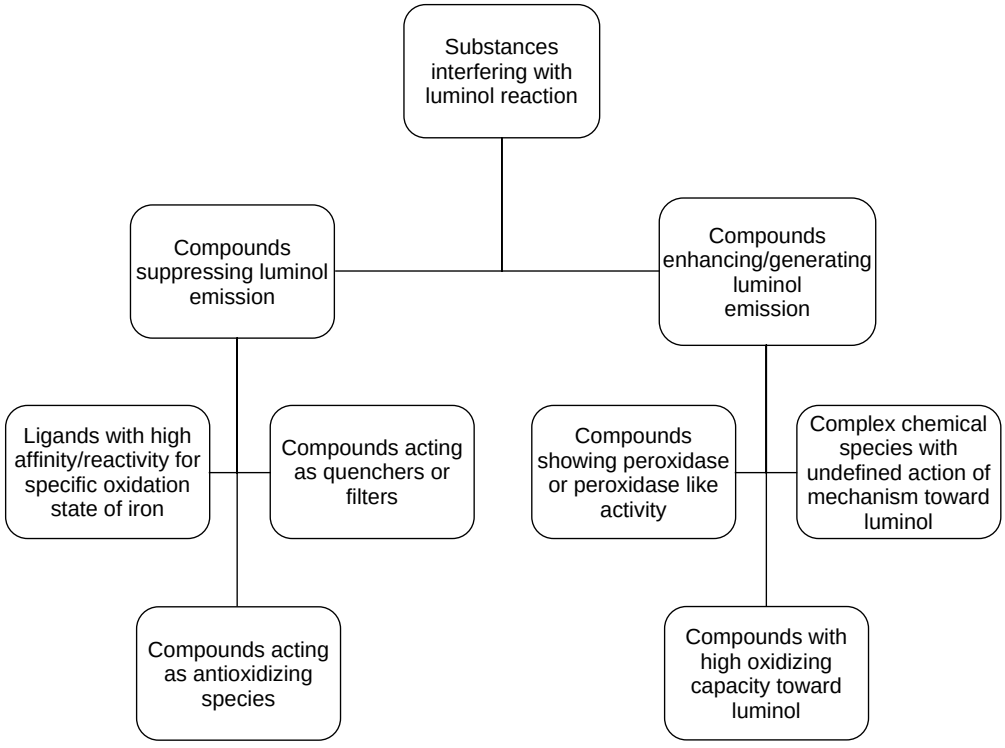

Figure 7 Classification of substances interfering with luminol chemiluminescence

mechanism underlying these interferences is not yet completely understood.

Quickenden and coworkers used instrumental methods to carry out extensive surveys of the effects of interferents with the luminol reaction [64, 65]. This included comprehensive studies of the luminol chemiluminescence emission elicited by a wide range of common, potentially interfering substances such as vegetable and fruit smears, pulps and juices, and household/industrial chemicals such as cleaning agents, insecticides, glues, paints, and varnishes. Of the 250 substances examined, they identified only a small number that produced chemiluminescence comparable to that of hemoglobin, including turnips, parsnips, horseradish, commercial bleach (sodium hypochlorite), copper metal, some furniture polishes, some enamel paints, and some interior fabrics from automobiles [66].

The serious issue of the hypochlorite interference effect with the luminol test [67] was also examined by this group [63]. They observed that when a person attempts to remove bloodstains by washing the area with water or sodium hypochlorite solution, depending on the thoroughness of the clean the effect on the luminescence spectrum could range from the complete absence of emission to various combinations of blood-initiated emission and hypochlorite-initiated emission (each peaking at its separate, respective wavelength), which might be expected if the cleaning process is not complete.

Finally, the same group examined a specific kind of crime scene, namely, the interior of an automobile. This study took into consideration both the effect of potential interferences from the internal fittings of the vehicle and also the effect of high temperature within the vehicle on the efficacy of the test [68]. Attempts to wash hemoglobin from the interior of the vehicles were tested using a variety of cleaning methods. It was found that there was little interference from materials within the three automobiles tested, although some surfaces did elicit weak luminol chemiluminescence. Attempts to remove hemoglobin with water alone were not successful; however, soapy water or a proprietary car cleaner removed

a significant proportion of the hemoglobin from the tested surface (ca. 90%). The use of cleaners and soapy water produced better results than water alone because they have the ability to solvate the globin proteins more effectively. The effect of increased car interior temperature led to improved sensitivity and chemiluminescence emission intensity of the test and was hypothesized to be due to thermal conversion of hemoglobin to methemoglobin in the presence of molecular oxygen.

Interpretation of Luminol Test Results

Luminol emission pattern interpretation can involve a qualitative statement of the luminescence pattern characteristics and an evaluation of emission spectra characteristics (maximum emission wavelength and emission intensity) [64–66]. In addition, attempts can be made to inhibit or at least reduce the interferences of chemiluminescence deriving from the reaction of luminol with substances other than blood by using chemical species followed by an emission intensity measurement [2, 3]. The latter approach, however, has only been employed successfully for hypochlorite bleach-induced chemiluminescence.

Generally visual examination is used when the luminol test is employed in a forensic situation. An experienced practitioner may distinguish the true blood-catalyzed chemiluminescence from that produced by other substances by the evaluation of parameters observable to the naked eye, such as emission intensity, duration, and spatial distribution. However, as this approach is subjective, it may lead to misinterpretation, and therefore caution should be exercised when using the test. Any confusion that may arise over a stain can usually be resolved by intelligent observation and, if necessary, by further testing [42], for example, by using a different presumptive test for blood, such as the immunochromatographic test for the confirmation of human blood presence [69].

In practice, false positives with metals are rarely a problem, as these can usually be anticipated or resolved by careful observation of the crime scene (see Figure 6). Interfering solid substances such as a metal object or surfaces that are coated homogeneously with these substances (e.g., some varnishes and paints) generally show different and distinguishable emission patterns with respect to both the spatial distribution and, often, the emission intensity of chemiluminescence. Upon reaction with metals, both emission kinetics and the intensity of chemiluminescence are rather characteristic: the emission will be intense but short. The reaction with blood will produce a less intense, longer-lasting even glow. Moreover, interfering chemiluminescence, especially from a solid object, such as a water valve, a knife, a copper pipe, floor, a carpet, or soil, will reproduce the shape and the dimension of the object. Emission patterns with blood will appear as spatters, wipes, smears, drag marks, or even footwear impressions.

The presence of hypochlorite-based bleaches on nonporous surfaces being sprayed is sometimes recognizable and can be identified by an experienced forensic practitioner, as it leads to bright flashes of chemiluminescence as opposed to the more gradual development of chemiluminescence by blood.

One operational advantage of the luminol test is the ability to highlight the presence of scattered, very small droplets of blood by the individual “sparkles” of blue chemiluminescence produced by each droplet. This makes this test easier to interpret than the other three common presumptive tests for blood (benzidine, phenolphthalein, and leuco-malachite chromogen tests) [7, 53].

Improvements to Luminol Formulations

A number of approaches to minimize luminol interferences and/or to increase the yield of the chemiluminescence emission have been described in the analytical chemistry literature. This has included the use of derivatives and analogs of luminol, a variation in the order of mixing of the reagents, the pretreatment of the substrate to be tested with chemical substances [58], and the addition to the luminol mixture preparation of chemical additives that selectively react with the putative interfering species reducing their availability for the reaction with luminol [54]. The successful use of a chemical species preventing luminol emission by interfering compounds has been reported by Kent and coworkers in their studies into reducing the effect of hypochlorite-containing bleaches [2]. Kent and coworkers found that certain strongly basic amines, such as 1,2-diaminothane, could inhibit the chemiluminescence due to hypochlorite under the alkaline conditions typical of forensic luminol tests (Grodsky’s or Weber’s formulations) [2]. A major disadvantage to this approach to reduce hypochlorite effect

on luminol emission was the toxicity of the amines involved. In a follow-up study, King and Miskelly confirmed the above results but they also found that the far less toxic amino acid glycine was nearly as effective [3].

In the above studies it was also noted that if the bloodstain could be left in air for a period of 1 to 2 days, the hypochlorite would decompose and thus no longer interfere with a standard luminol treatment. This effect has also been reported by Creamer *et al.* in 2005 [63], who found that the interference effect by bleach decreased if the area to be sprayed were left for several days allowing the bloodstains to thoroughly dry, as the hypochlorite decomposes, thus dissipating its effect on luminol emission.

Recently, a commercially available patented luminol-based formulation called Bluestar Forensic (ROC Import Group, Monte Carlo, Monaco) has become available and has been evaluated against traditional luminol preparations [4, 5]. From examination of the material safety data sheets available at the supplier's website (http://www.bluestar-forensic.com), the key differences in the formulation are the use of urea peroxide as an oxidant and sodium hydroxide to provide the basic conditions required for the reaction. These papers concluded that Bluestar Forensic provided the convenience of preparation (easy to mix in the field), that the chemiluminescence was sufficiently intense and long-lasting so that it could be visualized in the presence of some ambient light, and that the emission intensity was still reasonable when a bloodstain was resprayed. A recent comparison of luminol and Bluestar Forensic however found that while Bluestar Forensic gave good sensitivity, it showed poor specificity [6].

Acknowledgment

This article is substantially based on the authors' earlier review [8]. The authors would like to express their gratitude to Steve Gutowski from the Victoria Police Forensic Services Centre in Macleod, Victoria, Australia, to Donatella Pietraforte from the Cellular Biology and Neuroscience Department of the Superior Institute of Health in Rome, Italy, to Ron Nichols from the Department of Justice-Forensic Science Laboratory of Walnut Creek in California, USA, and to Dimitri Svistunenko Gordon Miskelly, University of Auckland from the Department of Biological Sciences of the University of Essex, UK. All these persons indirectly collaborated at various levels to the earlier review providing both valuable bibliography material and suggestions, comments, and important contributions. The authors would also like to thank Lisa Swann and Renee Jelly, both at Curtin University of Technology, for reviewing the draft article.

Malingering: Forensic Evaluations

Malingering in Forensic Evaluations

The essential feature of malingering, as defined by the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*), is the "intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives such as avoiding military duty, avoiding work, obtaining financial compensation, evading criminal prosecution, or obtaining drugs . . ." [1] (p. 739). Malingering for the purposes of evading criminal prosecution or obtaining drugs are commonly seen in forensic settings and forensic mental health clinicians often face difficult decisions when evaluating and treating these individuals. In civil settings, malingering is often related to obtaining potentially large financial settlements.

In order to appropriately assess and manage malingering, clinicians must have in-depth knowledge of the following: (i) prevalence rates of malingering and how the *Diagnostic and Statistical Manual of Mental Disorders* Fourth Edition, Text Revision (*DSM-IV-R*) inadvertently encourages misdiagnosis and mismanagement of malingering-related issues, (ii) common reasons for countertransference toward malingering patients and strategies to avoid it, (iii) empirically validated measures of malingering, and (iv) clinical issues related with the evaluation of malingering.

Malingering and the DSM

Recent evidence [2–4] indicates that malingering is common in forensic settings with prevalence rates ranging from 10 to 29%. Even with the most conservative estimate of malingering, one thing is clear that forensic mental health practitioners cannot rely on the veracity of their patient's self-reports to establish diagnoses or effectively manage their patient's symptoms. Self-report distortion is especially salient in pretrial forensic evaluations where the stakes can be quite high.

For instance, individuals undergoing an evaluation of their mental status (i.e., insanity) at the time of offense, will, at times, embellish pre-existing psychopathology or fabricate mental health symptoms in

order to avoid prison sentence[5]. Likewise, competency to stand trial evaluees may feign psychopathology in an attempt to avoid trial altogether [6]. Others malinger for some reasons apart from trying to avoid prosecution. Such reasons include moving to a mental health unit where the environment is often viewed as calmer and safer [7] or to acquire psychotropic medications [8].

How clinicians view the issue of malingering can have significant influence on their treatment of bona fide patients and individuals who are feigning. Unfortunately, countertransference (see next section) often accompanies malingering and staff members frequently make assumptions about other aspects of the patient's presentation based on a malingering diagnosis. Current diagnostic nomenclature does little to disabuse professionals of this potential conflict.

The DSM [**1**] criteria indicate that malingering should be suspected if any of the following are present: (i) medicolegal context of presentation, (ii) marked discrepancy between the person's claimed stress or disability and the objective findings, (iii) lack of cooperation during the diagnostic evaluation and in complying with the diagnostic evaluation, and (iv) the presence of Antisocial Personality Disorder. In forensic settings, either one or several of these criteria are routinely present for reasons wholly unrelated to malingering. Reliance on these criteria can lead to the misclassification of patients with bona fide mental illnesses as feigning cases. In fact, exclusive reliance on DSM-IV TR criteria can result in up to 80% misclassification rate [9]. If a test for a medical disorder, such as human immunodeficiency virus (HIV), resulted in high false positive rate, the test would be discontinued forthwith.

Avoiding false positives with malingering cases must be the primary responsibility of the forensic examiner. Evaluators must be cognizant that certain evaluees are more at risk to be misdiagnosed as **malingerers**. Research has shown that bona fide patients with lower educational attainment and absence of previous mental health treatment are much more likely to be misclassified as **malingerers** [10]. Clinicians can avoid false positives by conducting comprehensive evaluations that include multiple data sources, continuing to evaluate for psychopathology or cognitive deficits in the presence of malingering, and not making facile assumptions based on incomplete data.

Malingering and Countertransference

An issue that frequently goes unchecked in malingering evaluations is the misuse and conveyance of diagnostic information. One prime example is the use of emotionally laden words by clinicians to describe a malingerer; a clear sign of countertransference [11]. I have overhead staff using terms like "liar", "fraud", or "fake" when describing an individual found to be malingering. These descriptors are clinically useless and result in untoward feelings toward the patient.

Even more distressing is that longitudinally, a malingering diagnosis can follow the patient and subsequent complaints may be dismissed as bogus and misattributed to malingering. As such, clinicians conducting forensic evaluations have an ethical responsibility to minimize harm by accurately reporting their findings [12]. When malingering is identified, discussing situational-specific aspects of the diagnosis would be the first step toward minimizing future consequences.

One way to avoid countertransference with malingering cases is through the use of explanatory models. Rogers [9, 13] introduced explanatory models as a counterperspective to the unitary perspective provided by the DSM. Rogers proposed three explanatory models: (i) criminological, (ii) adaptational, and (iii) pathogenic.

Criminological

The DSM is focused on the criminological model, which closely aligns malingering with antisocial behavior. The criminological model accounts for only a minority of malingering cases, which explains the high rate of false positives associated with the DSM criteria.

Adaptational

A prototypical analysis of the responses of forensic experts [14] reinforced that the majority of individuals who malinger in psycholegal evaluations do so as an adaptive response to adversarial circumstances. The adaptational model allows for the possibility that people facing difficult circumstances engage in deception designed to decrease the likelihood of a bad outcome (e.g., lengthy prison term).

Pathogenic

The pathogenic model posits that feigning can occur as a result of underlying psychopathology. Although

this model is infrequently used and has mainly fallen into disfavor, there is some support for this model derived from both a historical perspective and surveys of forensic practitioners [15].

Explanatory models are especially useful if clinicians consider alternative explanations for malingering. Using models to understand malingering can provide objectivity to the assessment process and eliminate emotionally laden statements regarding patients who are engaging in deception.

Measures that Detect Malingering of Psychopathology

The use of extant measures for evaluating feigning is necessary for accurate assessment. In reviewing measures used to systematically assess for the malingering of psychopathology, it is clear that clinicians have several available options. Given space constraints, I primarily focus on measures specifically designed to assess malingering, with the exception of the *Minnesota Multiphasic Personality Inventory Second Edition* (*MMPI-2*) [16]. Other multiscale inventories with malingering or response style scales such as the Personality Assessment Inventory (PAI) [17] and the Millon Clinical Multiaxial Inventory (MCMI) [18] are not discussed. It should be noted that both the PAI and MCMI-III possess significant psychometric limitations for detecting feigning, although recent research suggests that the PAI does possess utility for screening feigned presentations [3, 19].

- The Structured Interview of Reported Symptoms (SIRS), [16] is an interview designed to comprehensively assess malingering and related response styles. The SIRS is often employed as the criterion measure in feigning research due to its very strong psychometric properties and exceedingly low false positive rate [16]. Its eight primary scales focus on measuring symptom patterns consistent with malingering include rare, combinations, improbable and absurd, blatant, subtle, severity, selectivity, and reported versus observed. Rogers *et al.* [20] performed a confirmatory factor analysis (CFA) of the SIRS with a large sample of forensic referrals. The results obtained strongly support for a two-factor dimensional model: Spurious Presentation and Plausible Presentation. "Spurious Presentation" was consistent with "classic" malingering made up of atypical and rare symptoms. "Plausible Presentation" was defined by over-reporting actual symptoms of mental illness and issues related to psychological maladjustment. Considering these two factors, Spurious Presentation was focused on the overall content of the report while Plausible Presentation was focused on the magnitude of report.
- The Miller Forensic Assessment of Symptoms Test (M-FAST, [21]) is a 25-item structured interview that consists of seven scales designed to be used to screen for malingering. The M-FAST is closely modeled after the SIRS and consists of seven scales and a total score; the total score is especially effective for identifying patients who are potentially malingering and in need of a more thorough assessment [3]. The M-FAST was subjected to a CFA in order to assess if the two-factor structure found in the SIRS was applicable. Vitacco *et al.* [22] tested models of the M-FAST with 244 forensic patients and cross-validated those findings with 210 forensic patients. Results demonstrated that a single, parsimonious factor emerged that was closely aligned with the SIRS' Spurious Presentation ($r = 0.75$) and moderately related to Plausible Presentation ($r = 0.64$). The clear implication is that the M-FAST is most effective for identifying patients with atypical and rare symptoms.
- The Structured Inventory of Malingered Symptomatology [SIMS, [23]] is a 75-item true/false test composed of five scales: low intelligence, affective disorders, neurological impairment, psychosis, and amnesia. The SIMS evaluates a wide range of feigning aspects, including aspects of cognitive feigning. With the SIRS as a criterion for known-groups design, the SIMS effectively differentiated malingerers from nonmalingerers (*M* Cohen's $d = 2.25$) with excellent reliability estimates [3]. However, the use of self-report measure has inherent limitations in that aspects of interpersonal presentation are not evaluated. Given that interpersonal interactions are important in evaluating malingering, this limitation is noteworthy.
- The MMPI-2 [16] is a 567-item multiscale inventory designed to assess psychopathology. In addition to its clinical scales, the MMPI-2 contains specialized scales designed to evaluate issues related to response styles. These scales use validated strategies for assessing response styles

including (i) rare symptoms, (ii) erroneous stereotypes, (iii) symptom severity, or (iv) obvious and subtle symptoms. Rogers *et al.* completed a large meta-analysis of malingering on the MMPI-2 [24] and generally found robust effect sizes for many malingering scales. However, clinicians should be cautious in using the MMPI-2 to assess malingering for a wide range of cut scores that dramatically vary by disorder and study [24]. Research [25, 26] evaluating the Infrequency (F) and Infrequency Psychopathology [F(p)] scales with large groups of mental health and criminal-forensic patients found the presence of an underlying taxon for both scales.

Clinical Issues Related to Evaluating Malingering

A key consideration in the accurate assessment of malingering is the realization that mentally ill individuals can engage in deception. This is referred to as *partial malingering* [18], which is defined as the exaggeration of current symptomatology or reporting symptoms from a previous episode of mental illness. Partial malingering is common in forensic settings and can contribute to error when clinicians fail to recognize the presence of underlying mental disorder(s). Obtaining a thorough psychosocial history from the patient, interviewing collateral sources, and reviewing available records are useful tools in disentangling bona fide illness from feigned symptoms.

One potentially useful strategy to disentangle pathology and response styles is to employ a structured interview such as the schedule of affective disorders and schizophrenia-change version [(SADS-C), [27]]. The SADS-C provides an extensive evaluation of psychopathology [28], it has two scales (symptom combinations and symptom selectivity) that act as an effective screen for malingering [28, 29]. Ultimately, success may rely on the clinician's overall knowledge of psychopathology and response styles and the ability to integrate conflicting information regarding mental disorders and feigned presentation.

Another issue adding to the complexity of diagnosing malingering is the differentiation of malingering from factitious disorders. Similar to malingering, factitious disorders involve the intentional production of physical or psychological symptoms [1]. The key difference is the goal of factitious disorders is to assume the sick role in the absence of other incentives. Clinicians often struggle with assessing motivation and trying to determine the underlying rationale for the behavior. Differential diagnoses between malingering and factitious disorders should occur in two related steps: First, determine the occurrence of feigning using a validated instrument. If feigning is present, clinicians are then supposed to determine the underlying motivation [15, 30].

Neurocognitive Malingering

Malingering can extend into civil settings as well. Unlike forensic settings where individuals malinger to avoid trial or prison sentence, individuals often malinger in civil settings to receive monetary compensation. A prime example is personal injury litigation whereby an individual alleges that he or she received an injury of the mind or body. Given that compensation for personal injuries can be highly lucrative it is not surprising that rates of malingering in such cases have ranged from 20 to 35% [31].

Clearly the information presented earlier in this article regarding countertransference and assessment strategies remain salient; however, evaluating malingering in civil situations requires additional skill sets including assessing malingering on neuropsychological examinations (e.g., alleging brain damage). Malingering neurocognitive deficits is commonly seen when evaluating individuals in civil settings.

Cognitive Malingering

To understand cognitive malingering and know how to best diagnosis it, clinicians are advised to familiarize themselves with the criteria for malingering neurocognitive dysfunction (MND) functioning known as the *Slick criteria* [32]. The Slick criteria set forth in a seminal article [32] provided a definition of MND as "the volitional exaggeration or fabrication of cognitive dysfunction for the purpose of obtaining substantial material gain, or avoiding or escaping formal duty or responsibility. . ." (p. 552). The article allowed for gradients in MND ranging from definite to possible. These criteria are well reasonable and provide a fundamental foundation for diagnosing MND. To aid in the diagnostic process, measures specifically developed for MND are marketed and should be considered when cognitive malingering is expected.

Measures that Detect Cognitive Malingering

For the testing of MND, clinicians have many options; we focus only on few well-validated and frequently used measures due to space limitations. These measures often use chance responding for a forced-choice test and performing significantly lower than chance is indicative of poor effort and potential malingering. However, more sophisticated measures like the Validity Indicator Profile (VIP) [33] assesses for several issues relevant to MND and represent a major advancement in assessing for MND.

- Rey 15-Item Test consists of a 3×5 alphanumeric sequence that an individual is asked to reproduce. This is a simple measure that has continued to be very popular [34]; however, such popularity seems overstated and it may be best used to screen for cognitive malingering [35] as there have been reports of poor sensitivity, but good specificity. As such, this test does not appear appropriate for evaluating MND. An important consideration is not to use the test for individuals with mental retardation [35].
- Test of Memory Malingering [TOMM, [36]] is a forced-choice test, where the individual is presented with a series of pictures and later "forced" to pick which ones they previously viewed. The TOMM has shown some promise for use in forensic and civil evaluations [37, 38]; however, its cut score has been deemed to be high for some individuals with actual cognitive dysfunction and poor effort could be misinterpreted as malingering. Clinicians must differentiate reasons for poor performance, as low scores might be indicative of suboptimal effort.
- VIP [33] is a self-report test that has both verbal and nonverbal sections. The VIP has several advantages over its counterparts including three providing scores on three possibilities for poor performance: inconsistent, irrelevant, and suppressed. The latter is consistent with what would be considered MND. Over 1000 individuals were subjected to initial validation and 312 cases were cross validated [33]. The VIP has three scales, Inconsistent, Irrelevant, and Suppressed, to detect atypical performance. Notably, the Suppressed scale indicates formal malingering. The ability to differentiate among random responding, irrelevant responding, and malingering is the real strength of the VIP. The VIP has demonstrated excellent properties in evaluating cognitive malingering [39, 40].

Conclusions

Mental health practitioners are encouraged to receive specialized training to understand the complexities of malingering as fully as possible. In the context of assessing malingering, clinicians should strive for diagnostic accuracy with the following:

1. Use only reliable and valid instruments with a proven track record of successfully differentiating bona fide patients from individuals engaging in deception.
2. Untangle psychopathology and true cognitive deficits from malingering through comprehensive assessments that include an evaluation of both response styles and actual deficits. Improve diagnostic accuracy through the use of collateral sources and extensive record reviews to buttress psychological assessment findings.
3. Use explanatory models, especially the adaptational and pathogenic models, to generate an understanding of situational aspects of feigning.
4. Understand that malingering is not "all or none" and should be viewed on a continuum. A prime example is partial malingering where an individual with a bona fide illness exaggerates his or her symptoms.

Malpractice Actions against Experts

Introduction

The term "malpractice," when describing expert behavior in professional dealings with third parties, has several connotations. In its popular understanding, it may be seen as a characterization of either negligent or intentional conduct that is considered harmful, inequitable, or fraudulent.

In professional practice, the term describes conduct that may expose the person guilty of such conduct to professional criticism by his peers in terms of sanctions within professional organizations to which the expert belongs. These sanctions may result in public or private reprimands, suspension or loss of membership privileges, expulsion from professional societies, and temporary or permanent loss of credentials or certifications. This form of malpractice is discussed in the separate article of **Ethics: Codes of Conduct for Expert Witnesses**.

The connotation in which the word "malpractice" is used in this article is as a legal term used in common law jurisdictions, particularly in the United States of America, to describe unlawful conduct that exposes an expert to possibly three different consequences: (i) a civil court action for damages caused to third parties while conducting professional duties; (ii) a criminal action brought by the government to punish defined criminal conduct such as fraud, theft, obstruction of justice, contempt of court, or similar crimes; or (iii) a quasi-criminal action brought by a governmental entity to restrict or remove a license to conduct a professional practice granted by public officials.

Since legal systems differ depending upon the country or jurisdiction, an in-depth exploration of malpractice becomes impossible within the confines of this work. For that reason, the possible legal consequences of professional misconduct are described only briefly here with reference to approaches taken by American courts and in the context of civil actions brought against experts.

Expert Malpractice – a Problem of National Scope

The development of a new cause of action designed to hold expert witnesses, like forensic scientists, doctors, and lawyers, responsible for their negligent professional behavior [1] has been driven by the growing recognition that expert negligence is not uncommon [2]. High-profile incidents have revealed failures in the application of some of the most well-established scientific techniques such as fingerprint identification [3, 4], DNA testing [5], and serologic analysis [6]. Other investigations have demonstrated that pathologists faked hundreds of autopsies [7] or committed grievous errors [8] in determining cause of death.

At present, the law does little to regulate the quality of expert testimony [9]. Nontort solutions offered by the scientific and legal communities to curb expert abuses include capping expert witness fees [10]; prescreening experts; using only court-appointed experts [11]; adhering to strict ethics codes [12]; instituting peer review [13]; and establishing a

science court [14]. Additionally, it has been suggested that fraudulent experts be prosecuted [15].

The conventional wisdom long held that the principal safeguard against errant expert testimony is the opportunity for adversarial cross-examination [16]. In reality, however, most lawyers do a woefully inadequate job in cross-examining experts [17] due to a general reluctance to challenge experts in their own fields and improper trial preparation [18]. Finally, the vast majority of civil and criminal cases are settled or plea bargained prior to trial so that the expert may never be subjected to rigorous questioning during the adversary process.

To date, none of the nontort solutions offered to curb expert abuses have succeeded in accomplishing their goal. While attempts at self-regulation and court supervision may provide some deterrence, they do not compensate individuals harmed by negligent experts. This lack of effective solutions to expert negligence or intentional professional misconduct has led to the developing area of expert malpractice tort law.

The Tort of Expert Malpractice

The expert witness malpractice cause of action offers the most effective means of achieving the twin goals of compensating injured individuals and deterring future misconduct. As a result, the last two decades have seen a substantial increase in the number of tort actions against experts and their employers.

The four elements of an expert malpractice claim are (i) the existence of a duty owed to the plaintiff arising out of the relationship between the expert and the plaintiff; (ii) a negligent act or omission by the expert in breach of that duty; (iii) causation; and (iv) damages [19].

The premise of the cause of action is that, first, expert witnesses owe a duty to their clients. However, the duty does not end there. Expert witnesses also owe a duty to any foreseeable plaintiff who may be affected by the expert's conduct and who are likely to suffer damages due to a negligently rendered opinion. These duties are based upon their professional knowledge and skills and are similar to the duties owed by a doctor to a patient and a lawyer to a client. In this way, the specter of malpractice encourages experts to be careful, accurate, and compliant with "quality control" measures.

The standard of care for a forensic scientist is that of the reasonably prudent practitioner in the relevant scientific field [20]. Standards of professional practice and ethical codes help define the standard of care, and most disciplines within the forensic sciences have adopted such standards. In order to prevail, a plaintiff must prove that the expert did not adhere to the standard of a reasonably prudent expert in rendering an opinion, conducting an examination, or giving testimony. Ordinarily, an independent evaluation by a disinterested expert in the same field will be required to determine whether an expert deviated from the required standard of care.

A crucial element of the tort of malpractice is causation. Causation tests whether the defendant's actions were in fact connected to the plaintiff's injury, and whether the connection was close enough to allow compensation to the injured party. In some cases, it will be readily apparent that an expert's testimony alone "caused" the wrong. This is especially true when the expert evidence is the only determinative evidence presented in the litigation [21]. Studies have demonstrated that, despite jury instructions to the contrary, jurors give expert testimony greater weight than other evidence [22]. Thus, it is clear that financial injury to a potential plaintiff or conviction and incarceration of a potentially innocent individual who is prosecuted on the basis of an expert's opinion evidence,[a] are reasonably foreseeable consequences of expert negligence or intentional misconduct.

When a plaintiff proves that an expert has committed malpractice, the measure of damages that may be awarded include, though are not limited to (1) the difference between a full verdict of proven loss and the reduced verdict resulting from the expert's testimony; (2) the difference between a full settlement and the reduced settlement that resulted from the expert's misconduct; (3) the cost of the expert's investigation; and (4) the attorneys' fees for responding to the expert's testimony and in proving the misconduct [23].

Although traditionally experts were afforded absolute immunity in trial testimony and trial preparation, expert witness malpractice causes of action are gaining momentum [24]. Courts in New Jersey [25], Connecticut [26], Texas [27], California [28], Pennsylvania [29], Massachusetts [30], Louisiana [31], Vermont [32], and Missouri [33] are among the growing number of jurisdictions that have allowed plaintiffs to sue experts for malpractice. This trend has induced defendants to settle cases even when

the jurisdiction has yet to recognize the cause of action [34].

Despite this trend, some jurisdictions continue to adhere to a policy of absolute immunity for expert witnesses [35]. Although witness immunity is an exception to the general rules of liability, and is traditionally extremely narrow in scope, a few courts have nevertheless shielded experts from civil liability for ordinary negligence by reasoning that (i) negligent mistakes or inaccuracies do not constitute perjury, or (ii) testimony and reports provided to courts are privileged [36]. Other courts have held that the expert witness who gives opinion evidence is the court's witness, and therefore enjoys immunity against all post-trial damage claims whether sued by a party or non-party to the action [37]. Such limitations are increasingly rare, however, and no court shields erring expert witnesses from perjury charges for willful deceptions, or from damage actions where the expert's conduct involved intentional or grossly negligent conduct.

There is a compelling argument to be made against expert immunity. First, the doctrine of immunity was not created to bar a suit against a professional who negligently performs services [38]. Moreover, when an expert is accused of malpractice, the real complaint is not with the testimony provided in court, but rather with the negligently produced out-of-court work product. By testifying, the expert merely publishes his negligence to the court. Absolute immunity should not be afforded to experts, who are neither judges nor their adjuncts, but merely third party participants in litigation. And the courts, the legal profession, and the forensic disciplines recognize that the trend is firmly toward permitting claims for damages resulting from negligent expert testimony.

Concerns that the proliferation of expert malpractice suits will have a chilling effect on the supply of willing forensic experts are misplaced. While the emergence of such a cause of action may chase the habitually negligent or incompetent expert from the field, this is, of course, a salutary by-product of the legal trend. Any additional impact on the supply of experts, or in the fees charged for their services, is not so compelling as to justify a public policy against recognizing the cause of action.

Conclusion

The interests of our system of justice in expert accountability and the full and accurate development of evidence in civil and criminal litigation are not served by protecting the incompetent or dishonest expert. The justice system as a whole benefits when expert malpractice actions are permitted, and the forensic sciences should enjoy greater respect and admiration when it is known that their members are accountable for their misdeeds.

While not universally recognized in American courts, malpractice actions against experts have been permitted in more and more jurisdictions and are occurring in greater numbers. This trend is likely to continue in the foreseeable future.

End Notes

[a.] Courts have awarded plaintiffs damages for illegal confinement due to legal malpractice, rejecting the argument that estimating the value of a person's loss of liberty is speculative. Geddie v. St. Paul Fire and Marine Ins. Co., 354 So. 2d 718 (La. App. 1978); Holliday v. Jones, 264 Cal. Rptr. 448 (Cal. App. 4 Dist. 1989) (awarding damages for emotional distress as a result of wrongful incarceration due to professional malpractice); In re Investig. of W. Va. St. Police Crime Lab, 438 S.E.2d, 509 (underlying civil suit settled for the state's $1 million insurance policy limit); see also, Restatement (Third) of the Law Governing Lawyers: Liability for Professional Negligence and Breach of Fiduciary Duty § 53 cmt. (g) (2000) ("emotional distress damages are . . . ordinarily recoverable when misconduct causes a client's imprisonment").

Marks or Impressions of Manufactured Items

Introduction

Marks and impressions are regularly encountered at scenes of crime and may be produced by a vast number of objects such as tools, tires, footwear, and fabric. Marks produced by tools (*see* **Toolmarks**), tires (*see* **Tire Impressions**), and footwear are covered in separate articles. Marks left by fabrics can be encountered in a variety of situations. However, of particular interest is the fact that investigators frequently encounter glove marks when looking for fingermarks (*see* **Mass Grave Investigation**). When a gloved individual presses his or her hand on a surface, a residual mark may be left showing the pattern of the glove. This can result from dirty or greasy gloves, or even gloves that have been previously "contaminated" with body secretions or cosmetics. Negative marks can also occur from the removal of material from the surface, dust, for example. Glove marks can be two-dimensional or tri-dimensional, depending on the malleable nature, or not, of the recipient substrate.

Similar to shoe marks and tire marks, glove marks can be made of a combination of manufacturing and acquired features. The identifying power of glove marks will therefore depend on the quality of the mark (e.g., clarity) as well as the rarity of the fabric pattern and construction combined with the presence, or not, of random acquired features such as holes or wear and tear.

Glove marks may also help the investigator establish the "path" taken by an individual around the scene of crime. Furthermore, when clothing is pressed against a smooth surface, a latent mark is produced resulting in another type of fabric mark [1]. This is prevalent in motor vehicle hit and run accidents, where the examination of fabric impressions occurs

when a segment of the vehicle comes into contact with the clothing of a pedestrian [2]. These marks may help determine the path taken by an individual, as well as the sequence of events that had taken place during the course of the crime.

Detection, Collection, and Examination of Fabric Impressions

Glove Marks

In the age of forensic science awareness, criminals are using gloves as a protective measure to prevent deposition of their fingerprints at a crime scene. Both leather gloves and fabric gloves are commonly utilized. Although leather gloves contain a natural fat, both types of gloves collect grease, sweat, and dirt through everyday wear. Further, at scenes of crime where blood is involved (such as homicide), the glove may be contaminated with blood. It is the presence of these materials that allow the pattern of the glove to be marked onto a surface [3]. Glove marks may be either latent or visible. Latent marks are "invisible" and can be found by performing a grazing angle search with a light source. It is important to remember that glove marks are much more fragile than fingermarks [1].

As glove marks are formed best on smooth surfaces, the powdering method can be used to increase the contrast between the latent deposit and the background surface. Either black or white powder may be used for the development process, which should be brushed on sparingly. If the powder is brushed on vaguely and in excess, the print detail will be destroyed [1]. Any glove mark found at the crime scene should be documented and evidence photography carried out. Photographing should be done with a camera set up on a tripod, taken perpendicular to the glove print to remove distortion and eliminate perspective (*see* **Crime Scene Photography: US Perspective**). The glove print must be photographed with and without a scale [3].

If possible, the entire object on which the glove print was found should be taken back to the laboratory for direct examination and comparison. However, if this is not possible, the glove print may be lifted with a gelatin lifter similar to that used for lifting fingermarks (*see* **Toolmarks**). If the glove mark is "negative" (such that the glove removes material off the surface, dust is an example [4]), it can be simply lifted using a black gelatin lifter.

A technique involving electrostatic attraction of the marks onto a plastic lifting film may also be used. This process is especially effective for faint glove marks on a colorful background [3]. Glove marks in blood can be enhanced and developed using reagents used for the detection and enhancement of fingermark in blood, such as amido black [5] for example, which is a stain sensitive to the presence of protein.

Comparison (or test) prints can be made from the suspect's glove, usually on glass or in some cases on the same material as the glove print deposit found at the crime scene. A number of comparison prints may be produced using varying degrees of pressure. Although producing a good-quality comparison print may be difficult, powders and polish should be avoided when making the print as minute details may be lost. Instead, breathing slightly on the finger of the glove may help improve results [3].

Fabric Marks

Fabric marks can be made with items such as clothing, socks, towels, and handkerchiefs. Although not as common as glove marks, fabric marks do arise during casework. Such marks are generally left on a surface if the fabric is thin and contains residual material such as moisture or is dirty. These marks are searched for and developed in the same way as for glove marks. Evidence photography is also carried out the same way as for glove marks; however, if the fabric print is adequately large, several photos must be taken.

The scale position and the angle of lighting should be altered for each photograph so that maximum detail of the fabric mark is documented [1]. Such marks should be compared with the suspect fabric exhibit, and the similarities and differences between the seams, structure of the fabric, and other oddities examined. For cases involving clothing impressions made on areas of a vehicle in a motor accident, one way of preserving the evidence is by photographing the fabric impression that was made on the segment of the vehicle. An exemplar is produced of the clothing article of interest, which is done using the previously described method. This exemplar is then used for direct 1 : 1 comparison with the photograph of the impression found on the motor vehicle [6].

Interpretation and Evidential Significance of Fabric Impressions

Glove Marks

When used as evidence, glove marks may demonstrate manufacturing (class) characteristics that show that the mark *could* have been made from a particular glove (i.e., nonexclusion). In some instances, glove marks show enough random acquired characteristics, such as distinctive holes, for example, that allow the examiner to conclude that a particular glove *did* leave the mark found at the scene (i.e., identification). Between these two conclusions, a qualified opinion may be given, where the value of the mark will depend on its quality as well as the rarity of the fabric pattern and construction combined with the presence, or not, of random acquired features. In any case, the presence of a meaningful (or unexplainable) difference between the mark and the test print allows the examiner to conclude that the mark *could not* have been made from a particular glove (i.e. exclusion).

In general, it is more common for an identification to be made with leather gloves than cloth gloves. Cloth gloves may exhibit tears and snags, or irregularities in the weave pattern due to the manufacturing process or material used. Leather gloves may show wrinkles and crease formations, which is more likely to leave a mark with a large number of comparative features. The presence of tears and cracks due to the random process of wear and tear may allow the mark to be identified, as exactly the same pattern of imperfections cannot be found on any two different gloves [3]. The difference between a cloth glove mark and a leather glove mark is the surface pattern. Leather gloves are made of the skin of an animal, which leaves unique marks on a surface not dissimilar to those left by fingerprints (Figure 1). Naturally, the patterns found on animal skin are not homogenous and vary from animal to animal. On the contrary, cloth marks are consistent for each type, and so the individual identification is more difficult to achieve. Furthermore, both leather and cloth gloves often mold to the finger tips of the individual, allowing another point of identification for the examiner. In rare cases, partial fingerprints can also be found within or superimposed with a glove print (occurring when there is a hole in the glove), obviously increasing the evidential value of the mark [1].

It should be noted that when a glove is seized in a case it should be collected and protected appropriately, as it may be possible to detect and examine finger marks or DNA recovered from inside the glove.

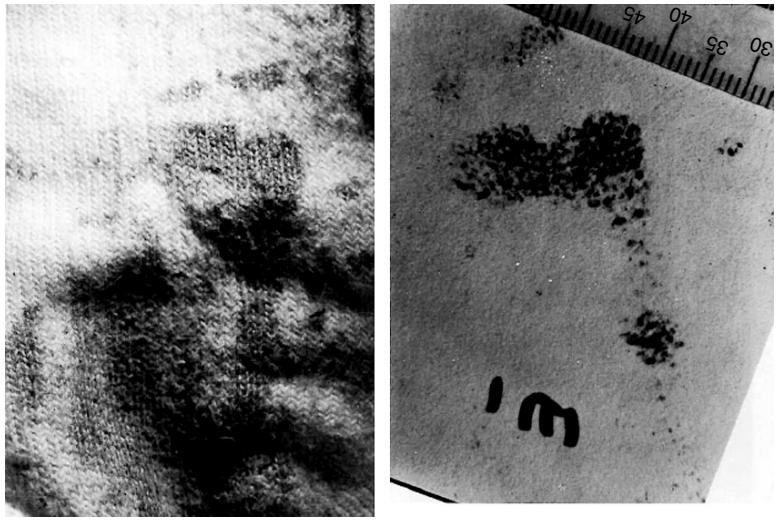

Figure 3 Comparison of the bloodstained sock and another fabric impression found at the crime scene, showing that the fabric tuft pattern on the sock was transferred onto the impression [Reproduced from Ref. 1. © Taylor and Francis Group, 2000.]

Fabric Prints

In most cases, fabric marks made by items such as towels and socks are hard to identify and individualize, reducing its evidential value. Unlike a glove mark, there is no definite boundary for the edges of the material. Comparing seam patterns or other surface patterns is difficult if the area on the item of interest that may have left the mark cannot be identified [1]. However, there has been a documented case involving the identification of fabric impressions made by a sock [2] (Figures 2, 3).

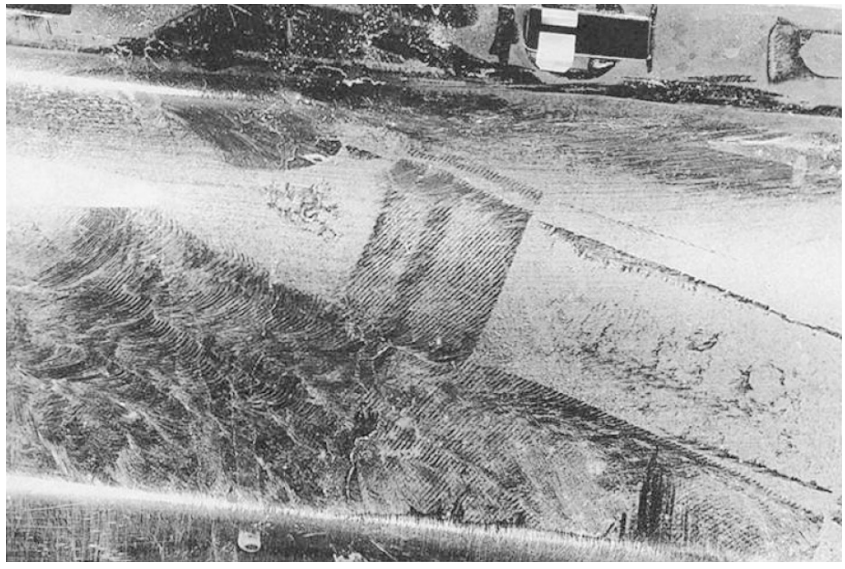

Figure 4 Impression found on the chrome bumper of a car after a motor vehicle accident involving a pedestrian [6] [Reproduced from Ref. 1. © Taylor and Francis Group, 2000.]

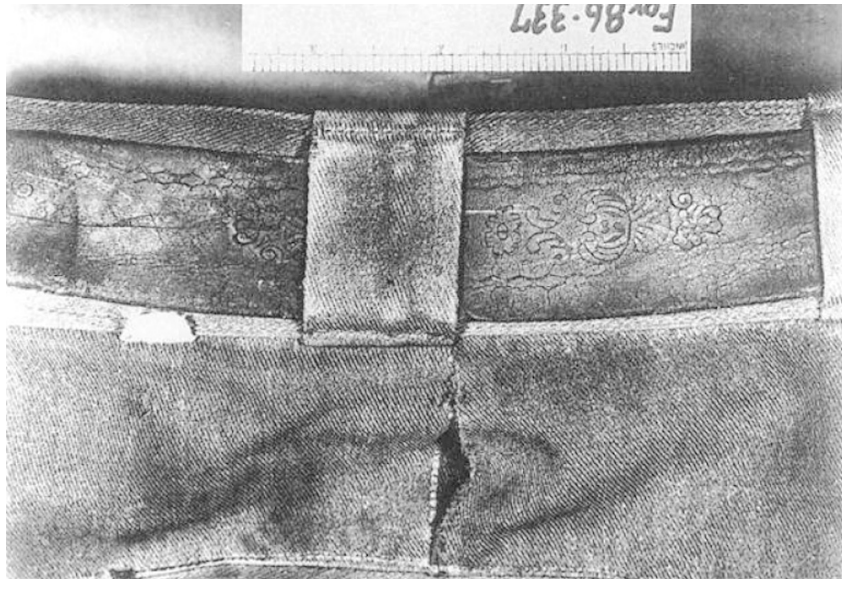

Figure 5 Pants and belt of the pedestrian, showing the pattern on the belt and the loop [6]

Fabric impressions were found at a homicide scene through the use of amido black stain (for marks in blood). After sequestering the suspect's bloodstained sock, it was discovered that the main bloodstain along with secondary bloodstains were in agreement with the impression found at the scene. Furthermore, the presence of four randomly placed raised tufts found on the sock corresponded with tuft markings found on the impression. The unique and random pattern as a result of the bloodstains and tufts was significant enough to trace the fabric impression to the suspect's socks [2].

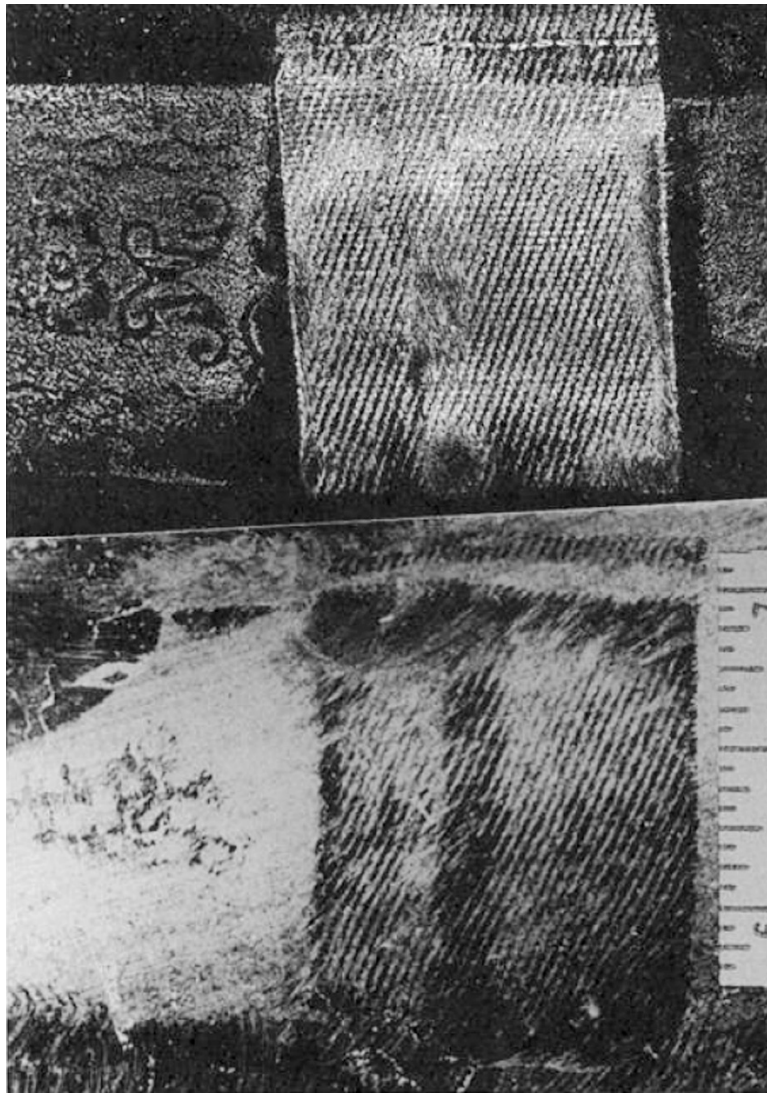

Figure 6 Juxtaposition of the belt and loop (top figure) with the corresponding region of fabric impression left on the chrome bumper (bottom figure) [6]

This example shows that the position and presence of unusual characteristics is enough to warrant an individual identification. The types of fabric impressions in such incidences as hit and run are also difficult to identify, as finding and preserving the fabric marks pressed into the vehicle is a tedious process. Although such impressions are not uncommon, it is rare to obtain evidence that permits identification of the clothing at the origin of the mark. However, an unusual case involving the individual identification of a clothing impression on a motor vehicle has been reported [6]. A pedestrian was hit by a motor vehicle, thereby causing his death. Upon examination of the chrome bumper an impression was found. The sites on the impression corresponded with the weave pattern on the pedestrian's pants and the stitching and loop hole of his belt. The combination of the size and position of the clothing items and the inscription found on the belt, which was also transferred onto the impression, was very unusual and was the basis

for the individual identification between the clothing and impression to be made [6] (Figures 4–6).

In most cases, fabric impressions provide class evidence, as it may be difficult to state that the marks had come from a given item excluding any other similar items. However, as for glove marks, the evidential value of fabric impressions will depend on the quality of the mark as well as the rarity of the fabric pattern and construction combined with the presence, or not, of random acquired features. As for glove marks, the presence of any meaningful (or unexplainable) difference between the fabric impression and the test print will allow the examiner to reach a conclusion of exclusion (i.e., the fabric impression *could not* have been made from the known fabric).

Mass Grave Investigation

Mass Grave Definition

Mass graves are defined in various ways, most revolving around the number of people in a grave and what constitutes a "mass". This has ranged from two or more bodies that physically touch each other [1] to at least six individual bodies [2, 3]. Mant's [1] definition brings in the physical component that the bodies must be physically touching each other. Haglund [4] also feels that having remains in contact with each other is what makes mass graves different from other grave types, and uses that criterion in his definition.

Other definitions include the genesis of the grave. The United Nations Rapporteur interprets a mass grave as a location where three or more victims of extrajudicial, summary, or arbitrary executions were buried, not having died in combat or armed confrontations [5]. Schmitt [6, p. 279] defines a mass grave as "one that contains the remains of more than one victim who share some common trait connected with the cause and manner of death". He further goes on to state that "criminal mass graves contain the remains of a group of individuals who share some common trait that justified their assassinations in the eyes of the perpetrators" [6, p. 279]. A basic flaw in a definition of a mass grave that includes the genesis of the inhumation is that the investigator may never know whether they are dealing with a mass grave or not, if the genesis is not known. It is likely that this would lead to the need to find another term for such a grave where the reasons for the deaths are unknown.

A simple definition of a mass grave is that it contains four or more individuals buried at or about the same time. This is consistent with the definition of a mass murder in the *Crime Classification Manual* [7, p. 12] used by the Federal Bureau of Investigation. The Manual defines a mass murder as "a homicide involving four or more victims in one location and within one event" [7, p. 12]. A mass grave definition consistent with the standard definition of mass murder is simple and logical. The differentiation between a criminal mass grave and another type should rest on the result of the investigation, depending on whether the deaths were the result of a criminal act.

Mass Grave Taphonomy

Single and mass death sites have taphonomic differences. Graves with poor drainage and multiple layers of bodies tend to trap moisture, even if only the moisture from the decomposing remains themselves. This scenario accounts for the adipocere seen in mass graves created years or decades earlier. Undisturbed soils at the bottom of the grave trap water in the softer, unconsolidated soils of the grave fill and create

conditions in which adipocere develops. This keeps the bodies in a moist environment, and they tend to saponify, as do remains under water. Thus, bodies in the center of a large body mass may be well preserved after years of burial. Where bodies are laid side by side in a single layer, the decomposition fluids leach into the soil and the bodies decompose in a manner more similar to a body in a single grave.

Thus, mass graves tend to create their own microenvironments toward preservation [4, 8]. Mant [8, p. 33] notes that in a mass grave the bodies in the center of the grave are much better preserved than in the periphery of the grave. Mant did his research after World War II, exhuming graves for the Nuremberg Tribunal. Also related to World War II were the 1943 German excavations in Poland investigating mass graves in the Katyn Forest. A professor of forensic medicine and criminology at Breslay University summarized the condition of the bodies at Katyn as follows:

> The stages of decay were found to vary in accordance with the position of the bodies in the pits. Whilst mummification had taken place on the top and at the sides of the mass of bodies, a humid process could be observed caused by the damp nearer the center Buhtz 1943 in [9, p. 142].

The German investigators attributed the preservation of the remains to the microenvironment created by the mass grave:

> In the mass graves at Katyn the murdered captives were packed so tightly together (either dead or dying) and sealed over with copious quantities of solid soil, that the putrification process was slowed considerably. For example, in the "L" shaped grave ... the initial interment was estimated to be almost 3000 bodies. These bodies were packed together so tightly that decaying and decomposing fluids of each body penetrated, imbibed, and infiltrated other dead bodies within the grave

(Official Statement Concerning the Mass Murder at Katyn 1943 as quoted in [10, p. 53]).

While it might seem contradictory to have mummified tissue, skeletonized remains, and adipocere tissue in the same grave, it happens in mass graves and is dependent on the moisture available to the remains. Moisture is essential for both decomposition and adipocere formation. In talking about mass graves excavated after World War II:

> Adipocere formation depends on the hydrolysis of fat to fatty acids, and cannot take place without an adequate supply of water. This water is derived not only from the exterior of the body but also from the interior, dehydrating the underlying tissues and organs including the muscles themselves. Thus adipocere formation retards the action of putrefactive organisms.
>
> It was found at exhumation, as would be anticipated from the above, that there was an outer layer of adipocere surrounding a layer of mummified muscle tissue. Some mummified muscle tissue was usually found incorporated in the deepest layers of adipocere [8, p. 45].

In the best of circumstances, relating the amount of adipocere formation to postmortem interval is difficult. Adipocere may appear as early as a few days following death [10, p. 101] and has been observed in burials as old as 122 years [11, p. 470]. Sledzik and Micozzi [12, p. 485] state that "presence of adipocere is an artifact of decomposition suggesting that a minimum length of time has passed since death, but it may not always be useful in determining the postmortem interval." In mass graves in particular, adipocere formation tells little about the length of the postmortem interval.

Mass Grave Investigation Strategy

The investigation of larger graves has a number of logistical challenges not seen in investigating smaller graves [2, 4, 13]. Maintaining access to the central remains for body removal, while cleaning the surrounding remains, can be a challenge. The large amounts of fill in the grave mean that the disposal of the soil removed from the grave must be carefully planned. As discussed above, a large mass of bodies creates differences in decomposition, which become more noticeable the larger the mass of the remains. Removing, as well as analyzing, remains in all stages of decomposition adds to the equipment and personnel needed, both in the field and the morgue. Other large graves may not have large body masses that create the differences in decomposition, but share the logistical challenges of a large excavation, adding to the logistical challenge. The larger the grave, the greater the range of preservation likely to be present.

Locating mass graves, like smaller graves, is often dependant on witness testimony [6]. Also, the same remote sensing technologies may apply

(*see* **Length Measurement**), given the appropriate soil and topography conditions. In addition, the size of the graves makes them more likely to show up in aerial photography [2, pp. 120–121]. Given that large numbers of individuals were buried in the area and possibly executed there, and that it might have taken a number of people, as well as vehicles and equipment, to accomplish this, there is often surface evidence of a mass grave [6].

As with any archaeological feature, the outline and size should be defined before excavation. As the overburden is removed from a large grave, the excavator should look for the edges of the grave. This may be most easily done by placing two trenches, perpendicular to each other, over the grave (called *cross-trenching*). This should give the excavator an idea of the location of the sides of the grave. If the grave fill can be differentiated from the undisturbed soil, then the outline of the grave should be traced all around the edge. It sounds like common sense, but this will help keep the excavators from placing soil removed from one part of the grave on top of another part of the grave.

If the grave was dug using heavy machinery, it is probably going to take heavy machinery to remove the overburden to the depth of the remains. This will make it harder to look for tool marks or other indications of how the grave was dug. The excavators should look for teeth marks on the side of the grave showing the teeth of the original front-end loader or backhoe bucket. There may also be traces of a ramp that the machine used to access the bottom of the grave. On the ramp, or at the bottom, may be imprints of the tires, or treads, of the machine.

In some mass graves, the bodies are laid neatly side by side in rows in a long trench. In a case such as this, where the bodies were buried in an organized manner, the bodies can be numbered at one time, documented in sequence, and lifted in sequence.

Haglund and others [13] describe a method that worked satisfactorily on graves where the bodies were dumped in a disorganized manner. The excavators worked in two teams: a documentation team, and a body removal team. Working with groups of about 10 bodies at a time, the documentation team completed the mapping, notes, and photographs of the next 10 bodies to be removed on one side of the grave. If the bodies are not laid neatly in the grave, deciding on the next bodies to be removed takes some investigation to ensure which remains are least encumbered by other remains. Bodies were not numbered until they were ready to be removed, in order to create fewer errors in numbering. It is possible to label two portions of the same body with different case numbers when the intervening portions of the remains are covered with soil or other bodies.

The body removal team then removed the remains from the grave. On fleshed remains, this sometimes entailed lifting limbs of some bodies in order to free the target remains. Skeletal remains presented more of a challenge, and portions of a single body sometimes needed to be documented and partially removed to get to the remains below. When this is done, then both the portion removed and the articulating portion left in the ground need to be carefully labeled. No more than two skeletons on each area should be partially removed, or confusion will inevitably result. At no point should personnel in the team change, if skeletons have been partially removed. The same people that partially removed one skeleton should remove the remainder of that same skeleton.

In graves where heavy machinery was used to bury the remains, it is not uncommon to find disassociated body parts. This also happens at sites where the remains were buried after they were partially decomposed. Should isolated body parts be found, they should be catalogued separately from the complete sets of remains. A "partial remains" log can be started that numbers the assemblage, gives the location, photograph numbers, and gives a brief description of the remains. Including the partial remains in the same numbering system as the complete remains is sure to lead to confusion during the examination when the partial remains are reunited with the remaining body parts.

Determining a Charge

Mass graves are (thankfully) relatively rare in domestic criminal cases. They tend to result from mass fatality incidents, either natural or cultural. Only the cultural incidents become forensic cases. The most common of these are war crimes, crimes against humanity, and genocide, and so a brief definition of each are discussed.

Genocide was defined as a crime after World War II in the 1948 Convention on the Prevention and Punishment of the Crime of Genocide. The definition

of genocide set forth in the Convention is still definitive and used in the statutes of the Rwandan and Yugoslavian tribunals as well as the Rome Statute that established the International Criminal Court (ICC). The Convention defines genocide as a crime in either peace or war:

> any of the following acts committed with intent to destroy, in whole or in part, a national, ethnical, racial, or religious group, as such: killing members of the group; causing serious bodily or mental harm to members of the group; deliberately inflicting on the group conditions of life calculated to bring about its physical destruction in whole or in part; imposing measures intended to prevent births within the group; forcibly transferring children of the group to another group

(Convention on the Prevention and Punishment of the Crime of Genocide, United Nations. December 9, 1948).

The crime of genocide requires an intent to physically destroy a certain group of people. The court also requires that the group destroyed be a national, ethnical, racial, or religious group. Political dissidents and soldiers are not groups protected by the genocide convention. The forensic investigator considering genocide as a charge must attempt to determine whether there was intent to kill the deceased and that they belonged to a specific target group.

War crimes are violations of the international laws of war, a body of law known as the *International Humanitarian Law* (*IHL*). While limitations on armed conflict date at least as far back as the Chinese warrior Sun Tzu in the sixth century BC [14], p. 374], the Hague conventions of 1899 and 1907 codified much of the humanitarian law for the Western world. The Charter of the International Military Tribunal at Nuremberg defined war crimes as "violations of the laws or customs of war, including murder, ill-treatment, or deportation of civilians in occupied territory; murder or ill-treatment of prisoners of war (POWs); killing of hostages; plunder of public or private property; wanton destruction of municipalities; and devastation not militarily necessary" [14, p. 374].

Only intentional, grave breaches of the treaties are considered war crimes. If individuals violate the treaties, but do not commit a grave breach, then they have committed an illegal act, but not a war crime. Grave breaches of the conventions are defined as willful killing, torture or inhumane treatment (including medical experiments), willfully causing great suffering or serious injury to body or health, extensive destruction and appropriation of property not justified by military necessity and carried out unlawfully and wantonly, compelling a prisoner of war or civilian to serve in the forces of the hostile power, willfully depriving a prisoner of war or protected civilian of the rights of a fair and regular trial, unlawful deportation or transfer of a protected civilian, unlawful confinement of a protected civilian, and taking of hostages [14, p. 374]. In 1977, Protocol I of the Conventions expanded the definition of grave breaches to include certain medical experimentation, making civilians and undefended localities the object or inevitable victims of attack, the perfidious use of the Red Cross or Red Crescent emblem, transfer by an occupying power of parts of its population to occupied territory, unjustifiable delays in repatriation of POWs, apartheid, attack on historic monuments, and depriving protected persons of a fair trial [14, p. 374].

A crime against humanity has come to mean anything atrocious committed on a large scale [15, p. 107]. The term originated in the preamble of the 1907 Hague Convention, which was based on existing State practices that derived from the moral values that constituted the "laws of humanity". In 1945, the Nuremberg Charter, formally the Agreement for the Prosecution and Punishment of the Major War Criminals of the European Axis and Charter of the International Military Tribunal, first defined crimes against humanity in positive international law:

> Crimes against humanity: murder, extermination, enslavement, deportation, and other inhumane acts committed against civilian populations, before or during the war; or persecutions on political, racial or religious grounds in execution of or in connection with any crime within the jurisdiction of the Tribunal, whether or not in violation of the domestic law of the country where perpetrated [15, p. 107].

The statutes for the International Criminal Tribunal for the former Yugoslavia (ICTY) and the International Criminal Tribunal for Rwanda (ICTR) added rape and torture to the list of specific crimes included in crimes against humanity. The ICC added apartheid and enforced disappearances to the list [15, p. 108]. Crimes against humanity overlap with both genocide and war crimes. However, crimes against humanity can occur in either war or peace, unlike war crimes. Unlike genocide, they do not require

the intent to "destroy in whole or in part" a specific group, but rather are part of a "widespread and systematic attack directed against any civilian population" (Rome Statute of the ICC, UN document A/Conf. 183/9, 17 July 1998, Art. 7).

The investigator, then, must show that the subjects of the attack are civilians and the incident is part of a systematic or widespread pattern, rather than an isolated incident. Widespread, according the to the ICTR court, is not defined geographically, but rather as an attack carried out against a "multiplicity of victims" [16, pp. 34, 35].

In framing a charge, the existence of the grave and the location of remains are the first indicator that a criminal act may have occurred. This proves that these people are not refugees, that they are not alive somewhere but unaccounted for, but that they are, indeed, dead. The demography of the grave also becomes of paramount importance. A grave full of adult males, dressed in military uniforms, may result from a postbattle cleanup. However, a grave full of woman and children in civilian clothing, suggests that something else occurred.

The artifacts in the grave and personnel effects are the best indicators of whether the individuals belonged to a specific target group. To decide on a charge, it may, in fact, be unnecessary to identify individuals, although international human rights groups consider the exhumation of the remains without an attempt to identify them and return the bodies to the families extremely unethical [17]. To determine a charge, what is needed is the knowledge that the bodies did or did not belong to a specific national, religious, ethnic, or military group. Clothing, identification papers, jewelry, and artifacts with the bodies are crucial in this regard.

Corroboration of Witness Testimony

In the forensic examination of a mass grave, as in any forensic investigation, witness information is of paramount importance and the forensic evidence often plays only a corroborative role. As Schmitt [6, p. 280] says, mass graves are seldom a secret. Often there are survivors to the massacre who come forward and tell their story. In the scene reconstruction of a mass grave scenario, everything, from the topography of the area to the location of materials in the grave, plays a part.

The ecological artifacts, or "ecofacts", in and near the site are important in reconstructing the events at the site. In the investigation of World War II graves in the Katyn Forest, the trees on the graves were used to help date the graves themselves [9]. So, it is helpful to be aware of the natural features of a site area and what they mean in relationship to the activities at the site.

The location of cartridge cases can be used to trace where individual shooters stood and how they moved throughout the area, through firearms identification analysis [18]. In an investigation in the village of Koreme, in the Kurdish portion of Iraq, investigators plotted each cartridge case found in an execution area, where 27 young Kurdish men had allegedly been killed by an Iraqi military execution squad. Of a total of 124 cases collected, the firing pin analysis identified a minimum of 7 individual weapons used in the execution. The weapon used was an AK-47, or similar weapon, which normally has a detachable magazine containing 30 rounds. The firearms analysis showed that one weapon fired a minimum of 37 rounds, requiring reloading during the executions [19]. Scott [19] was able to use the map of the cartridge cases to show that several weapons moved closer to the victims as they fired. At least two rounds were fired within 10 m of the victims by the same weapon that reloaded. This type of detail in scene processing and analysis is crucial in scene reconstruction and can be used as strong corroboration in witness testimony.

Summary

Definitions of mass graves include factors such as the number of bodies, whether they touch each other, and how the bodies came to be in the grave. This article suggests a definition of mass graves parallel to the definition of mass murder: mass graves are graves of four or more individuals buried at or about the same time.

Mass graves are different from single graves in the changes in how bodies decompose when in a mass and the logistical challenges in excavation. When bodies are piled up on top of each other, they decompose much differently than in a single grave, owing to accumulated water and body fluids. This variation in decomposition stage, as well as the sheer size of the graves, can make the exhumations logistically challenging.

Criminal mass graves rarely result from simple homicide, but often are a result of genocide, war crimes, or crimes against humanity. Determining a charge relies on attention to the cause and manner of death of decedents, grave demographics, artifacts, and personal effects. Attention to how the grave is dug and bodies are arranged can help to corroborate witness testimony on the sequence of events and mechanics of execution and body disposal.

Materials Science

Materials Engineering and Failure Analysis

The discipline of materials engineering and science spans the scope of the physical and chemical makeup of materials, the strength and other mechanical properties that are critical to appropriate decisions in product design, the relationships between and among materials, and finally, the analysis of actual or potential failures.

The primary forensic question in materials engineering and science is usually why a materials failure occurred. The exact reason will depend on the application, but four fundamental questions given in the following are frequently considered:

- When did the material fail in relation to a sequence of events? Did it fail and cause an event, or did it fail as a result of the event?
- Was design or manufacturing a factor?
- Was the choice of material a factor?
- Was inadequate maintenance a factor?

The materials engineer answers these questions using specific training in the relationships among material structure, properties, and processing, and their affect on material performance. The materials engineer also uses a variety of characterization techniques to determine these relationships.

The materials engineer's knowledge overlaps with other fields. The materials engineer must be familiar, for example, with civil engineering principles to establish stress states in materials under loading conditions, chemical engineering to determine the effect of environment on material properties, and mechanical engineering to understand how a particular part fits into an overall design.

In the forensic aspect, the materials engineer applies his understanding of materials to identify the root cause of material failures. The engineer is frequently called on to provide opinions in cases of product liability due to a materials failure. Typical cases include the failure of a variety of products, automobile or aircraft accidents, and industrial or residential construction defects.

When evaluating a materials failure, the materials engineer considers the relevant material properties. Depending on the material in question and the type of failure, these properties can include mechanical properties such as strength, hardness, ductility, and toughness. Component design, stress state, and the effect of manufacturing defects, if present, must also be considered.

A variety of specialized references exist to assist the materials engineer in failure analysis. These include handbooks, testing protocols, and material specifications and standards.

Failure of Materials

The Stress–Strain Curve

Failure of materials in the extreme case is the fracture or permanent deformation of the material. Failure can also be any changes from the original or specified state of the material that prevent it from performing according to specification. Failure in this case includes mechanical changes such as temporary, elastic, or permanent, plastic, deformation, or the presence of defects that affect the expected mechanical properties.

To understand the processes of deformation and fracture, one must understand the mechanical properties of materials. The specific behavior of materials differs according to the type of material, but the defining properties are essentially the same. The important mechanical properties are given as follows:

- yield strength;
- tensile strength;
- percent elongation;
- Young's modulus;
- toughness;
- ductile or brittle behavior; and
- hardness.

These mechanical properties are tabulated for most engineering materials, including metals, plastics, and ceramics, and can be found in many print and on-line references, some of which are listed in the section "Information References" that deals with various information sources. For composites, bulk properties can be derived from the properties, volume fraction, and orientation of the constituents.

All of these properties, with the exception of hardness, can be directly determined from the stress–strain diagram of the material. A typical

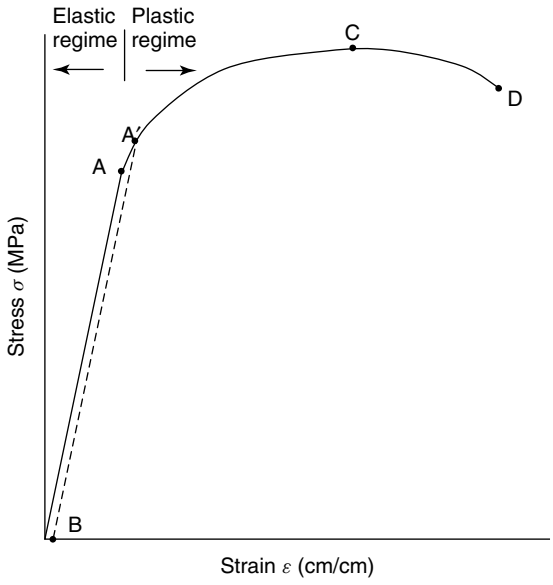

Figure 1 A typical stress–strain diagram for a metal

example of a stress–strain diagram for a metal is shown in Figure 1, and is discussed in the sections below.

The stress–strain diagram is obtained from a special type of materials characterization test called a *tensile test*. In a tensile test, an increasing load is applied to a specimen of the material being tested. As the load increases, the sample lengthens and deforms until fracture occurs. The changes in load and sample length with time are recorded, and converted into engineering stress and strain. From this data, the stress–strain diagram is created from which the mechanical properties of the material can be determined. Further details on the tensile test are provided in Section "Tensile Testing" (see Section "Materials Characterization").

Engineering Stress and Strain. Engineering stress, σ, is the amount of load, or force, per unit area applied to a material. Stress is commonly used instead of the force to remove the affect of material dimensions. For the same applied force, more deformation can be expected if the material being acted on has a smaller cross section, and less if the material has a larger cross section. The stress is defined as follows:

$$\sigma = \frac{F}{A_0} \tag{1}$$

where F is the load at any given time and A_0 is the initial cross-sectional area of the specimen. Stress is expressed in units of megapascals (MPa), or as pounds per square inch (psi), in the English system of units, where 1 MPa = 145 psi.

Engineering strain, ε, is the change in length of a material under stress, in the direction of that applied stress. It is the change in length at any time compared to the initial length, and is calculated as follows:

$$\varepsilon = \frac{l_i - l_0}{l_0} = \frac{\Delta l}{l_0} \tag{2}$$

where l_i is the length at any given time and l_0 is the initial specimen length. Strain is given in units of inches per inch (in./in.) or is stated as a percentage of the initial length ($\varepsilon \times 100\%$).

Deformation. When a load is applied to a material specimen, its dimensions will change in response. Depending on the amount of load, the deformation will be either temporary or permanent. For a small load, this deformation is temporary or elastic. Within the region of the material that is deforming elastically, inside the material itself, the bonds between atoms are being stretched. Atoms are displaced from their original positions and pulled away from each other, but no interatomic bonds are broken. In this case, when the load is removed, the bonds are no longer being stretched, and the atoms return to their equilibrium positions.

When a larger load is applied, the material will deform permanently or plastically. In this case, atoms are displaced far enough from their original positions that interatomic bonds are broken, and atoms move through the material. The movement of the atoms in response to the applied load results in permanent deformation.

These two regimes are shown on the stress–strain diagram of Figure 1. The linear region to the left of point A is the elastic region, and the nonlinear region to the right is the plastic region. As Figure 1 shows, plastic deformation only exists along with temporary elastic deformation.

The existence of the elastic and plastic deformation regimes has important implications for failure analysis. When an investigator examines a deformed component, the elastic portion of the deformation has recovered, and the actual deformation at the time of the event was greater than what is observed later.

The amount and significance of the elastic deformation can be determined from mechanical tests or from mechanical property data.

During a standard tensile test, changes in load or displacement are usually made slowly. When the load is applied rapidly, atoms have less time to move through the material. The effect is to make the material behave as if it were more brittle, in which case plastic deformation may be nonexistent.

Yield Strength. The yield strength of a material is the stress at which the material begins to deform plastically. Point A of Figure 1 is the demarcation point between elastic and plastic behavior. Below the yield stress, the material has only been elastically deformed. This elastic deformation can be compared to stretching a rubber band; if the stress is removed, the material returns to its original shape. If the yield stress at point A is exceeded, permanent deformation will occur. However, if a stress greater than the yield strength is applied and removed, recovery of the elastically deformed amount will take place; however, the plastic deformation will be permanent.

The exact point where the material behavior changes from elastic to plastic is not clear. Therefore, by convention, the yield strength is defined as the stress at a strain offset of 0.2% of the maximum measured strain before failure. As shown in Figure 1, the point on the x-axis where the strain is 0.2% of the maximum measured strain is located at point B. A line is drawn through that point, and parallel to the elastic portion of the stress–strain curve. The point, A′, where that line crosses the stress–strain curve is defined as the yield strength.

Tensile Strength. The tensile strength is the maximum tensile stress that the specimen can bear. On the stress–strain curve, this occurs at point C, the point of greatest stress on the curve. As the load is constantly increased during the tensile test, after point C, nonuniform deformation will begin to occur, along with necking of the sample, leading rapidly to fracture, at point D. In other words, if the stress at point C is reached, the material will fail completely unless the force is immediately reduced.

Percent Elongation. Percent elongation is a measure of the amount of deformation in the specimen. Specifically, it is the ratio of the change in specimen length to the initial length, and is calculated using the equation for strain (Equation 2).

Young's Modulus. Young's modulus, also called the *modulus of elasticity*, indicates how much stress can be applied to the material before permanent deformation occurs. A mechanical analogy is the deformation of a spring under tension. When a load is placed on a spring, the spring deforms in direct proportion to the load. If a load is removed, the spring returns to its original length. If the load exceeding the stiffness of the spring is applied, the spring is stretched beyond its capability to rebound, and is permanently deformed. The Young's modulus is the slope of the linear region of the curve, from zero up to the yield stress, or

$$E = \frac{\sigma_y}{\varepsilon} \tag{3}$$

where the strain is 0.02, by definition. The units of Young's modulus are megapascal.

Ductile or Brittle Behavior. The stress–strain curve can also reveal whether a material is ductile or brittle. As seen above, ductile materials, such as metals, undergo plastic deformation before failure; hence, failure occurs above the yield stress, and will result in permanent, plastic deformation of both the gross dimensions of the sample as well as the fracture surface. By contrast, with brittle materials little or no plastic deformation occurs. Typical stress–strain curves for ductile and brittle materials are shown in Figure 2.

Toughness. Toughness is a measure of the energy absorbed in the deformation until fracture of a material, and is measured as the area under the stress–strain curve. The units of toughness are joule per cubic meter.

Hardness. Hardness cannot be found directly from the stress–strain curve. It is determined by measuring the deformation resistance at the surface of the material. Several different methods are available for measuring hardness; however, all involve measuring the force required to press an indenter into a surface. Common methods are the Rockwell, Brinell, Knoop and Vickers hardness tests, and are specified by standards such as ASTM E18-05, E10-01, C730-98, and E92-82 [1].

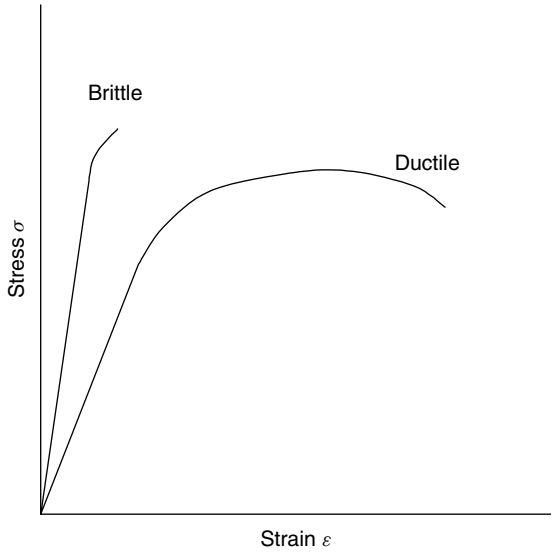

Figure 2 Typical stress–strain diagrams for a ductile and a brittle material

Hardness does correlate well with yield strength, since both yield strength and hardness measurements are taken when plastic deformation is just beginning. Tables and charts can be found in references such as the *ASM Metals Handbook* [2], which relate the yield strength of a metal to hardness.

Failure Modes

Fracture. The discussion until now has focused on ideal materials in a nominally defect-free state. Under those conditions, the material will fail when the tensile stress is exceeded. Materials in the real world can frequently contain defects or flaws, which may lower the strength of the material and lead to unexpected failure. The role of defects or flaws must be considered in failure analysis.

Defects can be material or geometric heterogeneities. Examples are inclusions, second phase particles, voids, machining marks, geometric variations, and miscellaneous surface flaws. These defects can act as stress concentrators, and by their geometry prevent the material from sustaining normal loading.

To demonstrate the effect of flaws on the strength of a material, a simple model of a flaw, a symmetrical crack, can be used. The crack is inside the material, and perpendicular to the direction of tensile loading. If the crack is small, it will be relatively stable. The size of the crack may remain constant, or it may grow slowly, depending on the applied stress, any cyclic loading, and the morphology of the material.

This crack growth is occurring by ductile fracture mechanisms, where the term ductile indicates that the material at the crack tip is deforming. If the crack grows, once it reaches a critical length with respect to the direction of the applied stress, it becomes unstable. At the point of instability, the crack will rapidly propagate through the material, resulting in a fracture. The unstable crack growth occurs by brittle fracture, with little or no plastic deformation occurring at the fracture surface.

Since materials without any bulk defects can sustain stress up to their yield strength without deforming, the yield strength would seem to be an appropriate design criterion. When defects are present, however, the material can fail below the yield strength. To account for this, during design the yield strength is usually multiplied by a safety factor. The designed safety factor varies according to the application, but may be 1.5–2 times the yield strength. A material whose yield strength is above the resulting design strength can then be selected.

Choosing a material with a yield strength exceeding the expected stress is intended to protect against failure in three different ways:

- If the maximum stress is slightly or occasionally greater than expected, the stress will still remain within the design envelope as long as a safety factor is used.
- If the yield stress of the material is slightly below the anticipated strength, perhaps due to a processing problem, impurities or internal flaws, the applied stress will remain below the actual yield stress.
- In some materials, not prone to brittle fracture, if the tensile stress is exceeded, the material will fail, catastrophically and without warning. Since yield stress is used as the design criterion, rather than the tensile stress, if the yield stress is exceeded, the part will deform, and thus may provide warning of an incipient failure.

Fatigue. Variable loads, cycling between large and small, or from tension to compression, can lead to failure at stresses below the normal design strength of the component. This is called *fatigue failure*, and is caused by the simultaneous action of cyclic stress,

tensile stress, and plastic strain. The cyclic stress starts the crack (nucleation); the tensile stress produces crack growth (propagation) until the remaining cross section of the part becomes too weak to sustain the load and quickly fails in overload.

The general features of a typical fracture surface can be seen in the photograph below (Figure 3).

The fluctuating tensile stress produces the striations shown in the figure, which are sometimes referred to as *beach marks* or *clamshell marks*. The presence of beach marks is a reliable evidence of fatigue crack propagation. However, depending on material and loading, the absence of fatigue striations does not mean that no fatigue occurred. The definitive call will depend upon the specifics of the material application and the events leading up to and following the failure, upon further examination under a high power optical microscope or scanning electron microscope (SEM) and upon fracture surface microstructure.

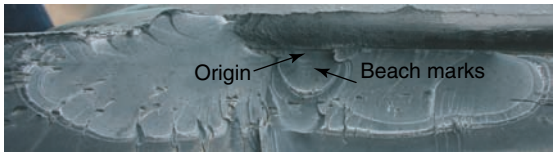

Figure 3 General features of a fatigue fracture, shown here in high-density polyethylene (HDPE). The fracture origin site can be located by tracing the center of curvature of the beach marks back to the root

In cases where cyclic loading is present, the component must be designed to accommodate cyclic loads by setting the maximum load below an endurance load defined below. The $S-N$ curve is used for this purpose, where S stands for stress and N stands for the number of cycles.

The $S-N$ curve for steel, shown in Figure 4, illustrates that, as the stress decreases, the number of cycles before failure increases. In this figure, if the stress is kept below 50% of the fracture strength, then the metal is said to have an "infinite life", or is at least able to survive more than 10 million cycles. This stress level is called the *endurance level*. The

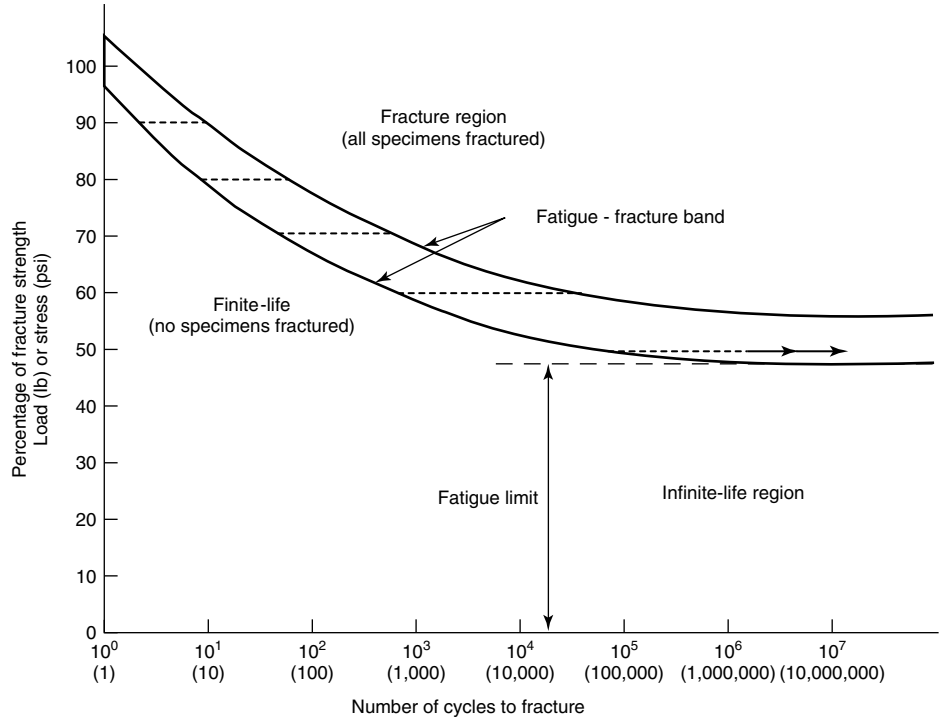

Figure 4 $S-N$ curves that typify fatigue test results for testing of medium-strength steels [Reproduced with permission from Ref. 3. © ASM International, 1986.]

American Society of Metals (ASM) Atlas of Fatigue Curves [3] may be referred to for the $S-N$ curves of particular metals.

Corrosion. Corrosion is an important mechanism of materials failure. Corrosion occurs when a metal interacts with the surrounding environment, and degrades as a result of electrochemical reaction. There are a number of specific types of corrosion; however, all follow the same basic process. Material is removed from the metal in the form of ions. This is called an *oxidizing*, or *anodic*, reaction. Ions are atoms that, in this case, have lost electrons. These lost electrons are taken up in a second reducing, or cathodic, reaction.

For corrosion to occur, three conditions described below must be present:

1. ionic pathway;
2. electrical pathway; and
3. a driving force.

The ionic pathway is generally moisture or an atmosphere with greater than 70% relative humidity. This allows the migration of the ions of corrosion.

The electrical pathway is any conducting pathway between the anode (oxidized area) and the cathode (reduced area).

The driving force may be two different metals in contact (galvanic driving force); a concentration difference such as an area of low oxygen potential on a pipe; or the difference stress in a metal part (so that the higher stress area tries to dissolve to lower its stress).

Generally, failure from corrosion is obvious in the initial inspection. To confirm corrosion and locate the root cause, it is useful to identify the required conditions listed above.

Materials Characterization

The forensic engineer or scientist specializing in materials has a variety of materials characterization techniques and protocols to use for explicitly testing or analyzing a failure. Standard testing protocols are defined by engineering and scientific organizations, such as the International Organization for Standardization (ISO) or the American Society of Testing and Materials (ASTM).

Mechanical Properties Characterization

Tensile Testing. Tensile testing methods, for example, ASTM E8, were originally developed to determine mechanical properties of metal specimens, although standard tests now exist for plastics (ASTM D638), ceramics (ISO 15490), and composites (ISO 527).

Two specimen configurations are preferred for the tensile test, one rectangular, and one cylindrical. For either configuration, the test specimen is tapered in the middle so that the cross-sectional dimensions are small compared to the length. The tapered section is called the *gauge length*. Owing to the smaller cross section in the gauge length, the stress is much higher there than anywhere else on the sample. Deformation is constrained to the gauge length, and failure will occur there, rather than where the testing fixture grips the specimen.

The sample is mounted in the tensile test instrument, held vertically by an upper and a lower grip. The lower grip is fixed, the upper on a movable crosshead. Load is applied by moving the upper crosshead upward. The specimen is elongated at a constant rate. Thus, the load and the cross-sectional area, and therefore the stress, change with time.

Internal load cells measure the applied force, from which the stress is calculated. Position sensors measure the crosshead location, from which the strain is determined. After the test is completed, the sample is removed from the fixture. In older test machines, load versus displacement is plotted continuously during the test with a pen plotter, and is then manually converted to a stress–strain curve. Modern instruments using computer control automatically generate the stress–strain curve.

Charpy Impact Test. The area under the stress–strain curve obtained in the tensile test corresponds to the toughness of the material. However, the area under the curve is dependent on the loading rate of the tensile test, which is typically very slow. The Charpy impact test, performed by ISO 179 or ASTM E23 methods, allows measurement of fracture toughness under dynamic conditions of rapid fracture.

A small rectangular sample with a cross section of 10 mm × 10 mm is machined with a center notch on one of the rectangular faces. Just as the smaller cross-sectional area of the gauge length in the tensile test specimen ensures that the fracture will occur within

that gauge length, the notch in the Charpy specimen ensures that impact fracture will occur at that notch.

The sample is placed in a test fixture consisting of a sample holder, a weighted pendulum, and a scale to measure the absorbed energy. The pendulum is raised and locked into place. On its release, the pendulum swings down and strikes the back, or unnotched, side of the specimen, breaking it.

The pendulum is almost frictionless, so without a specimen, the pendulum will swing back up to approximately the initial height. However, with a specimen in place, the pendulum swings to a lower height than it began at, as some of the kinetic energy of the pendulum is lost in breaking the specimen.

Therefore, the impact toughness measures the difference between the initial, potential, energy of the pendulum and its kinetic energy after breaking the sample. The Charpy impact energy is measured in foot-pounds.

Microstructural Characterization

Metallography. When alloying elements or impurities are present in a material, they may segregate into different regions, forming different structures or phases within the material. These structures can have a significant effect on the properties of the material. Many of these structures can be observed and identified with a microscope. If testing reveals that the mechanical properties of a material are different from the expected properties, it is frequently of interest to examine the structure of the material on a microscopic level. This examination often requires special sample preparation to reveal the microscopic features.

Originally developed to reveal the native microstructure of metals, cutting, mounting, polishing, and etching procedures exist to prepare specimens of any type of material for examination. The specimen preparation techniques are collectively grouped under the term *metallography*. The presence of flaws, such as inclusions or voids, and/or regions of differing elemental composition can frequently be identified by these methods. Preparation of a typical metal specimen is discussed below; preparation of other materials is substantially the same, although with different idiosyncratic challenges.

First, a specimen is cut to reveal a surface to examine. The typical specimen size is less than 1 inch by 1 inch. Cutting is best if done with a water- or oil-cooled cut-off wheel, to reduce any heat-induced changes. The mechanical cutting will necessarily create a zone of damage below the surface of the specimen, which will be removed later by polishing.

Once the specimen has been cut, it is encased in phenolic or an epoxy resin mixture. This hard mount will protect the sample and make polishing easier.

The mounted sample is then polished with various abrasives to remove the damaged surface zone. The polishing media starts out rough, with abrasive sandpaper of 120 or 240 grit size, and gets progressively finer, finishing with fine (0.3 μm) alumina or diamond polishing compound. In between polishing steps, the specimen surface is washed with soap and/or isopropyl alcohol and rinsed in an ultrasonic bath to remove any loose particles of the polishing media or sample fragments. It is also examined with a metallographic microscope to ensure the surface is smooth with no scratches.

Once a surface has reached the desired level of polish, chemical etching may be performed. Etching is the process of exposing a material to chemicals, such as acids, that preferentially remove materials of one phase or elemental composition with respect to other phases. This creates differences in surface height across the sample, which in turn, creates contrast during viewing with an optical microscope. Note that, owing to its different imaging technique, etching does not always produce contrast when the sample is viewed with an SEM.

Optical Microscopy. Information can frequently be gained about materials, especially fracture surfaces, from visual examination; however, it is frequently necessary to go to higher magnification to observe important features of a fracture surface or the distribution and morphology of different phases.

The typical magnification range of optical microscopy runs from 1 to 400 times the original size; 1000 times magnification is the upper limit of the magnification range for optical microscopes. When viewing fracture surfaces, which are typically rough, the depth of field, which is the ability of the microscope to keep the entire region being viewed in focus, can be a limiting factor. This is a function of the optics of the microscope, as well as of the behavior of light in general.

Electron Microscopy. When greater magnification than that provided by optical microscopy is required, an electron microscope can be used. The SEM

is a common instrument, and one that provides images that are intuitive and easy to understand. Magnification ranges from 20 to above 20 000 times the original size.

In an optical microscope, an image is created by light reflected from, or transmitted through, a specimen, the focused through a lens, and into the eye. In the SEM, the image is created by bombarding the specimen surface with electrons. A beam of these primary electrons is scanned across the surface of the specimen. The primary electrons either reflect back from the specimen surface (as backscattered electrons), or eject electrons from the atoms in the specimen (secondary electrons). A specialized detector then detects the backscattered and secondary electrons. The signal collected by the detector is converted into an electrical signal that is proportional to the detected intensity; this electrical signal is then converted to a gray scale image that is displayed on a computer monitor. Magnification occurs when the primary electron beam is scanned across a small area of the samples, and the image of the scanned surface region is displayed on a larger computer screen. This image can be displayed, printed, or saved in digital format.

Common Failure Analysis Procedures

Many features of forensic materials failure investigation are the same, despite the type(s) of materials involved. Identification of the root cause of failure is key, as careful documentation of the details of the investigation and preservation of the materials are involved. However, owing to their different mechanical behavior and failure modes, different procedures are commonly used in failure analysis of metals, ceramics, plastics, and composites. Some examples of procedures required in a forensic investigation are presented below.

- **Metals**

The fracture surface must be preserved because the fracture surface contains the information on where the failure originated and how it occurred. The fracture origin is the point from which cracking begins which may occur because of damage or a defect in that area. The fracture surface may reveal information about the time to failure, as in fast failure by overload or gradual fatigue leading to overload of the remaining metal. The fracture surface can be examined by processes such as optical microscopy or SEM but normally should not undergo any testing which is destructive in nature. For items too large to allow study of the surface without cutting, the surface can be replicated using a rubber mold material that allows the replica to be examined without destruction of the original. Collections of fracture surface photographs can be found in the ASM references discussed in Section "Information References".

- **Ceramics and Glass**

In glass, the direction of the fracture movement from the origin can be determined by observing the rib marks, also called *Wallner lines*, which are found on the fracture surface. The rib marks, which appear as concentric ridges, are almost always concave toward the origin, in the direction from which the fracture initiated. Owing to the brittle nature of glassy materials, the failure mechanisms are complex; a reference such as Failure Analysis of Brittle Materials [4] may be consulted for more details.

- **Plastics**

The fracture surface of hard plastics has failure information like a metal. Plastics, unlike a metal, may be more strongly affected by the chemical environment and temperature it is exposed to. A plastic may fracture by simple overload, fatigue, creep or stress cracking. Creep fracture occurs some time after the application of a load to the plastic. Stress cracking occurs under a comparatively small load when the plastic is exposed to a chemically active environment. In all cases, a properly preserved surface can provide information as to the cause of the failure.

- **Composites**

Depending on the type, shape, and amount of fiber reinforcement and the type and properties of the matrix containing the fibers, the properties and characteristics of composites widely varies. Composite materials where fibers, such as glass or carbon, are bonded together are found in high strength, lightweight structures such as aircraft and sport car bodies. Composites also are found in fiberglass ladders and wood siding products used in construction where wood fibers are held in place by resins. Each composite is generally unique in its creation and individual in its characteristics. The most common composite failures are due to delamination (separation) of the fiber mats because of failure of the

adhesive, or misorientation of the fiber mats due to design or manufacture.

Information References

A number of reference sources, including handbooks and textbook references, provide background and details on the materials science and engineering concepts introduced in this article. Callister's text [5] is popular for undergraduate courses in materials engineering, and provides an accessible overview of the relevant principles. Deiter [6] or Courtney [7] provide in depth information on metallurgy and failure modes of materials. For corrosion, Uhlig's text [8] is covers both corrosion mechanisms and prevention methods.

The expert will frequently consult the publications of the ASM [9]. ASM publishes a 21-volume series of handbooks, on various aspects of materials engineering and science, including but not limited to metals. Handbooks of particular interest are Volume 10 (Materials Characterization) [10], Volume 11 (Failure Analysis and Prevention) [11], Volume 13B (Corrosion: Materials) [12] and Volume 19 (Fatigue And Fracture) [13]. A selection of articles from these handbooks, specific to metals, is contained in the previously discussed Metals Handbook [2].

As previously discussed, accepted materials property testing methods are standardized by both the ASTM [1] and the ISO [14]. Descriptions of specific methods or standards are available for purchase through both organizations. For validation of methods and consistency of results, it is preferable to follow a standard method when an appropriate one is available.

Matrix: DNA

Contemporary forensic DNA identification systems utilize a panel of fluorescent dyes to identify specific fragments, alleles, or nucleotides. Commonly, four or five dyes are used simultaneously. As the excitation of a particular fluorescent dye indicates a specific forensic outcome, it is essential that the detections systems have high specificity in their ability to isolate a particular dye or color. As there is some overlap in the emission spectra of the dyes that are simultaneously utilized, there is a need to filter out the "background" color that is drawn up with each individual dye. The technique applied is referred to as *multicomponent analysis* or *color deconvolution* [1].

A set of standards is run, each of which is labeled with one of the individual dyes that are to be utilized in the test system. Computer software is then able

to analyze the fluorescence data from each dye and assess the amount of overlap contributed by the other dyes of the system. As each dye analyzed generates data for each of the other dyes, collectively, the dataset is referred to as a *matrix* or *matrix file*. Matrix files differ for different sets of dyes and different electrophoresis systems and instruments. They are also subject to slight variation if there is a change in environmental conditions (such as temperature) and they should be regenerated for different batches of polymer or polyacrylamide (if using slab-gel systems).

The application of the matrix file occurs after the raw fluorescence data has been collected; it is usually applied automatically as one of the first steps of analysis. Applying the matrix has the effect of optimizing the signal from each dye, which sharpens the image and simplifies interpretation. A common artifact associated with this aspect of profile interpretation is known as *pull-up* and it occurs when there is incomplete separation of the spectra of two or more dyes. This creates spurious peaks of different colors that are effectively drawn up under the true peak. Pull-up is most likely to occur when the sample is overloaded, or off scale.

Medical Malpractice

Introduction

Medical malpractice charges are nearly as old as medicine. Already in the Codex Hammurapi (1700 B.C.), punishment in cases of medical malpractice was described [1, 2].

The *Constitutio Criminalis Carolina* (1532 A.D.) contains a separate chapter on medical malpractice (Chapter XXIX), and in this chapter, notions such as negligence, causality, and expert evidence can be found.

From the seventeenth to the nineteenth century it was mainly experts in forensic medicine who dealt with medical malpractice in their textbooks [1–3], e.g., Paolo Zacchia (1584–1659). In his book *Quaestionum–Medico legalium cura* (1621–1635) the sentence, "Medicus errat ommitendo et commitendo" can be found, which means that damage to the patient can not only be caused by doing something wrong but also by omitting to do the right. For a long time medical malpractice was a subject that was not frankly discussed within the medical community and public. A change was caused by the U.S. report "to err is human" (1999) [4], although

Table 1 Adverse events in hospitalized patients – an international comparison[(a)]

Study and place of study	Number of investigated cases	Adverse events (%)	Potentially preventable adverse events (%)
New York	31 000	3.7	–
Colorado and Utah	14 321	2.9	58
Australia	14 179	16.6	51
London	1014	10.8	46
New Zealand	6579	12.9	63

[(a)] According to [7]

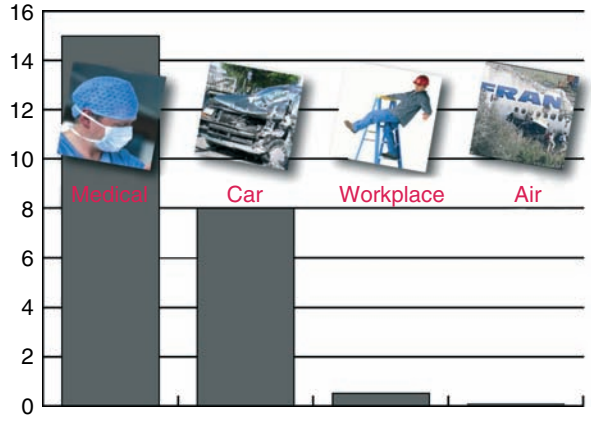

Figure 1 Incidence of annual accidental deaths in the United Kingdom (in thousands)

the message "Errare humanum est" is not new [5, 6]. But it was mainly the estimated cost caused by adverse events and medical malpractice that was surprising (Table 1). On the basis of Anglo-American studies, an estimation of adverse events in hospitalized patients in Germany was carried out. Taking into account the 16.5 million hospitalizations a year (in 2001), 31 600–83 000 deaths were estimated to be due to adverse events [7]. This would mean that more people would die as a consequence of wrong medical diagnosis or therapy than as a result of colon cancer (20 200), breast cancer (18 000), pneumonia (17 800), and traffic accidents (7700). For the United Kingdom, similar figures have been arrived at (Figure 1).

However, speaking about mishaps during medical care, adverse events, and medical malpractice requires a strict consideration of the terminology since epidemiologic research and law have different understandings of similar terms [8–12]. In the following, some aspects of medical malpractice will be addressed, which are based on international studies and also on experiences in Germany since some nationwide statistical data are available.

Definitions

Meanwhile, different institutions have proposed different definitions, e.g., the European Council, WHO, etc. [8, 9, 11–13].

Examples of definitions are given below:

An adverse event (AE) is a noxious and unintended response.

A preventable adverse event (PAE) is a noxious and unintended response that might have been prevented.

A negligent adverse event (NAE) is a noxious and unintended response due to a break of duty of care. An NAE is an equivalent of medical malpractice.

In penal law, medical malpractice is mainly defined as an AE (injury, harm) due to medical negligence. Medical negligence is defined as a preventable mistake caused by a breach of duty of care. Furthermore, there must be a causal connection between the mistake and injury, and in most jurisdictions this causal connection has to be proved without reasonable doubt.

In civil law, medical malpractice is defined as follows: "The defendant (doctor) owed duty of care to the plaintiff (patient). The doctor breaches the duty of care by failing to adhere to the standard of care expected. The standard is the quality that would be expected of a reasonable practitioner in similar circumstances. This breach of duty caused an injury to the patient." Furthermore, for epidemiologic research a definition of medical error is of importance.

Error may be error in planning or execution. An error of execution is the failure of a planned action to be completed as intended, whereas an error of planning is the use of a wrong plan to achieve an aim.

Epidemiology

Clear data on the epidemiology of medical malpractice are lacking. However, in the United States,

United Kingdom, and Australia, several studies were conducted concerning AE, PAE, and NAE but mostly only in hospitalized patients [14–36]. For ambulant medical care, hardly any data are available.

It is well known that only a small proportion of misadventures are on record, while the majority of misadventures or injuries do not become known [7, 11, 12, 37]. This fact is often illustrated by an iceberg model of accidents and errors (Figures 2 and 3).

The German Alliance of Patient Safety has carried out a systematic review of papers on the incidence of AEs, errors, etc. [33, 35]. Studies fulfilling the following criteria were included:

- original papers with data from January 1995 to December 2005;
- data collected on a well-defined reference group of patients;
- papers in which at least one of the following relevant criteria had been checked:

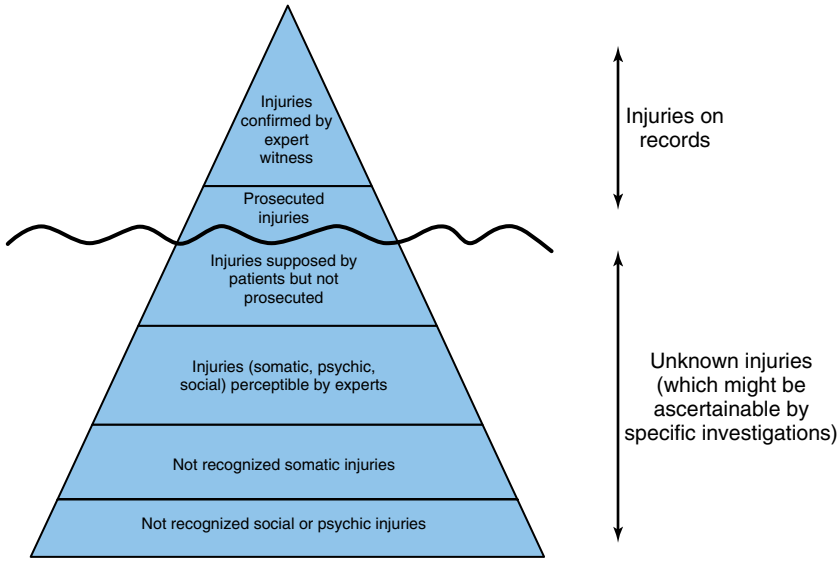

Figure 2 Types of injuries and probability of detection

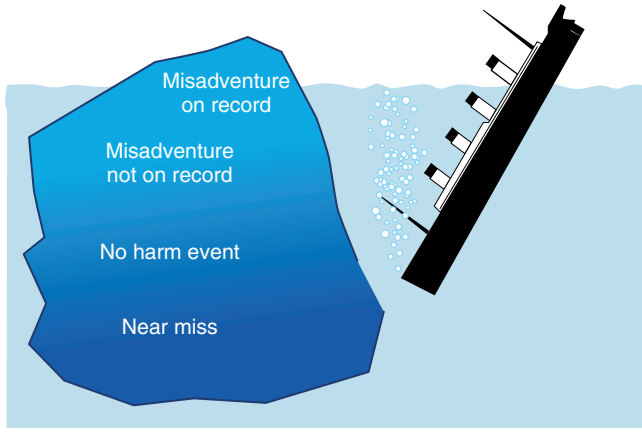

Figure 3 Iceberg model if accidents and errors

- AE
- PAE
- NAE
- errors
- near misses.

Each paper must contain a clear description of how the data were evaluated. Furthermore, clear data on factors like proportion, ratio, incidence rates must be evident. From more than 25 000 studies in PubMed and Embase, 151 studies from 25 countries with 7 686 166 patients fulfilled these criteria. The review revealed a dependency of the frequency of reported AEs, PAVs, and NAEs on the sample size: the higher the sample size, the lower the frequency. Furthermore, there was no influence of the geographic origin of the study; so the results may be more or less representative for countries with a "western" standard in health care. Among hospitalized patients, AEs can be expected in 5–10%, PAEs in 2–4%, NAEs in about 1%, and lethal outcome in about 0.1%. This would mean that on the basis of epidemiologic studies for hospitalized patients in Germany, 880 000–1 750 000 AEs, 350 000–700 000 PAEs, 175 000 NAEs, and 17 500 lethal cases would be expected. These data on the mortality due to AE and PAE were confirmed in a recent review of the German Alliance of Patient Safety [34]. According to this review, mortality due to PAE is 0.1% of all hospitalized patients. This would mean that in Germany with 17 million hospitalized patients per year, 17 000 lethal cases have to be expected. However, only a small proportion of these cases raise legal discussions. For most countries, data on the frequency of medical malpractice claims are not available. For Germany, it is estimated that only 1500–2000 cases a year are investigated by the public prosecutor [38]; these are mainly cases where death is thought to have occurred because of medical malpractice, and by a legal autopsy the cause and manner of death have to be cleared. In penal law, it is estimated that one investigation by the prosecutor is performed per 60 000 inhabitants, one piece of information of a prosecutor on 90 000 inhabitants [38]. On average, only eight cases per year are brought to a penal court, with four convictions and four stays of proceedings. For civil law, data are not available on the frequency of medical malpractice claims, but estimations speak of about 15 000 claims per year [39–41].

Every doctor is obliged to have a liability insurance. Data from the liability insurance companies are, however, not available [41, 42]. One insurance company with 108 000 insured doctors reported about 4500 incidents a year, with a settlement of cases in 30%, going to a civil court 10%, and medical malpractice confirmed at court in 4% [7].

In Germany, most claims of medical malpractice are dealt with at the arbitration committees of the medical councils. More than 30 years ago the medical councils formed these arbitration committees to make medical malpractice claims possible without applying to the courts [39, 43–50]. More than 10 000 cases per year are dealt with at the arbitration committees, and in 30% cases patient claims are confirmed.

Data of the Arbitration Committees

Since the data by the arbitration committees of the medical councils are well documented and evaluated either locally by the responsible medical chamber or nationwide by the German medical chamber, some details shall be addressed.

At the present moment, nine arbitration committees exist in Germany (Baden-Wuerttemberg, Bavaria, Hesse, Northrhine, Northern Germany, Saarland, Saxony, Westphalia, Rhineland-Palatinate). These arbitration committees have annual meetings and have recently evaluated their material nationwide (Medical Error Reporting System, MERS) [39, 43, 50]. The data of the nine arbitration committees are shown in Table 2. The largest arbitration board is that of the Northern German chambers in Hanover, and the smallest is that of Saarland. Table 2 gives details and numbers of applications per year, mode of settlement, and decisions [43].

Doctors in hospital are more often concerned with medical malpractice claims than those in private practice (Table 3). The most frequent complaints were on surgical therapy, followed by postoperative care, diagnostic imaging, informed consent, etc. (Table 4). The most frequent diagnoses resulting in malpractice claims are coxarthrosis, gonarthrosis, and fractures of lower leg and ankle (Table 5).

The bodily damages caused by medical malpractice can be classified as follows (Figure 4): no damage, minor damage, passing damage, permanent damage, and death [49]. Results concerning the severity of damages shown in Figure 4 are

Table 5 Most frequent diagnoses resulting in malpractice claims[a]

Most frequent diagnoses resulting in malpractice claims	2006
Decisions all together (total no.)	6751
Most frequent diagnoses	
Coxarthrosis (degenerative arthritis of hip joint)	225
Gonarthrosis	170
Fracture of lower leg and ankle	155
Fracture of forearm	130
Breast cancer	130
Intervertebral disk degeneration, lumbar	115
Traumatic injury of the knee	103
Deformity of toes/fingers	100
Degenerative injury of the knee	96
Femoral fracture	94

[a] Taken from [43] The table specifies the 10 most frequent diagnoses according to frequency. For all proceedings, a (correct) diagnosis (*ex post*) is referred to; for cases with more than one diagnosis, only the most important one is taken into consideration

based on the material of the arbitration committee in Northrhine [49].

The frequency of confirmed medical malpractice differs between doctors in private practice and hospital doctors as well as from discipline to discipline (Table 6). Medical malpractice is more often confirmed in doctors in private practice than in hospital doctors. Disciplines that are at special risks are general surgery, gynecology, and trauma surgery [43].

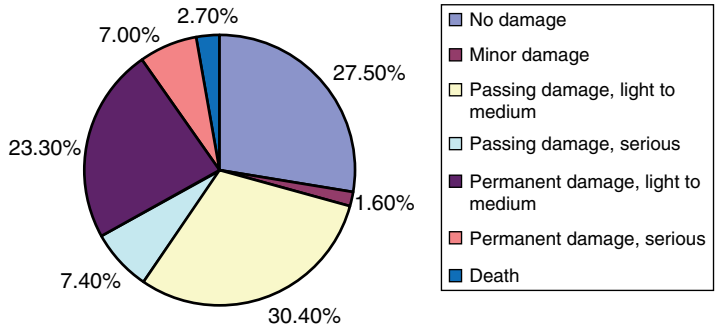

Figure 4 Bodily damage caused by medical malpractice (taken from [49]) [Reproduced with permission from Ref. 35. © Ärzteblatt, 2007.]

Medical malpractice claims have increased over the last few years (Figure 5). The error rate differs widely between the different arbitration boards (Figure 6). The arbitration board in North Rhine has the highest error rate (39%), and the board in Saarland the lowest (22%) [47].

While in Bavaria just 51 claims per 1 million residents are registered per year, other areas of Germany have many more claims per 1 million residents, e.g., North Rhine or Northern Germany [47] (Figure 7). While in Bavaria just 2 errors per 1000 physicians per year are confirmed, this rate is much higher in other German areas (Figure 8).

The probability to be charged for medical malpractice differs by the factor 3 for different regions of Germany. The probability that a medical malpractice is confirmed differs even by a factor of 6.

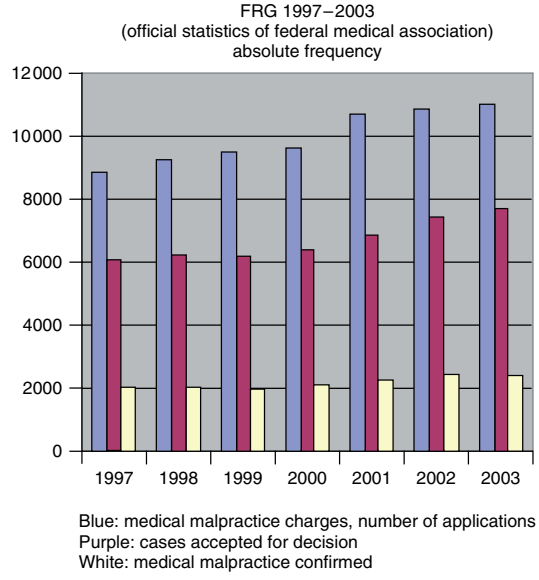

Figure 5 Medical malpractice claims, cases accepted for decision, and the number of confirmed medical malpractice over the years (from [47]) [Reproduced from Ref. 21. © Springer, 2005.]

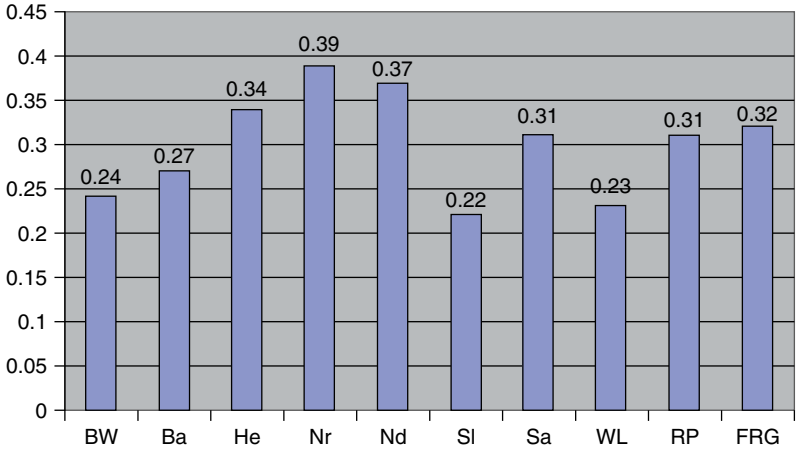
Data from the Files of Institutes of Forensic Medicine

The arbitration committees deal predominantly with living patients [48, 49]. Lethal cases are a special subgroup and the best available data source are the files of the Institutes of Forensic Medicine [51–58]. Therefore, this special subgroup shall be addressed separately, especially since death is the severest outcome of medical malpractice.

From a separate retrospective analysis of medical malpractice claims in lethal cases, it is known that the number of cases has increased in the past years [57, 58]. Concerning medical malpractice claims in lethal cases, a doubling of cases could be observed (from 300 to 600 cases a year) in the cooperating German Institutes of Forensic Medicine (Figure 9). The autopsy rate due to medical malpractice claims varied between the institutes from 2.4 to 20%. That means that in some institutes every fifth autopsy was due to medical malpractice claims. Obviously, the prosecutor has a wide range of discretionary powers.



Hospital doctors are more often confronted with medical malpractice claims than doctors in private practice.

The medical disciplines concerned are surgery followed by internal medicine, general practice

Table 6 Medical malpractice charges: Arbitration committee North Rhine[a]

and anesthesiology (Table 7). The cause of accusation was mostly conservative therapy, followed by surgical therapy, endoscopy, and intensive care (Table 8). There are different classifications of the types of mistakes, e.g. (see also Figure 10),

- medical malpractice, mistakes in information, documentation, and medication errors; and
- machine/medical product and organization.

In a separate evaluation of medical malpractice claims in lethal cases, medical malpractice charges were subdivided as follows:

1. negligence (omitting the necessary treatment)
   – insufficient diagnostics

	BW	Ba	He	Nr	Nd	Sl	Sa	WL	RP
Claims/1000 physicians	28	13	33	44	42	26	25	51	29

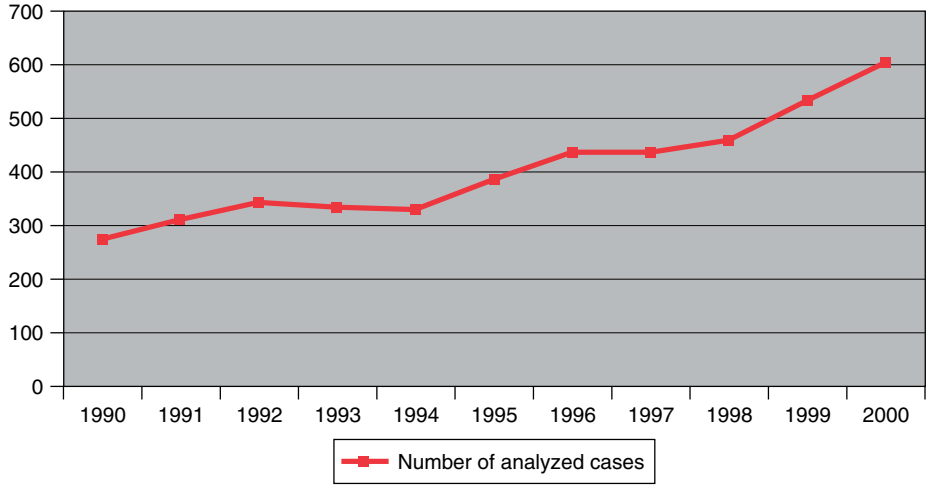

Figure 9 Number of autopsies in cases of suspected medical malpractice over the years

- delayed reaction to postoperative complications
- delayed admission to hospital and to intensive care unit

2. Complications in/or after surgery
   - intraoperative complications
   - exitus in tabula
   - complications concerning endoscopic operations
   - postoperative complications (bleeding, suture insufficiency, peritonitis)
3. Wrong treatment
   - transfusion reaction (transfusion of ABO-incompatible blood)
   - telephone diagnostics (therapeutical recommendations by telephone without visiting the patient)
   - further wrong treatment (retained instruments)
4. Mistake in care
   - insufficient prophylaxis of decubital ulcers
   - insufficient thrombosis prophylaxis

- wrong positioning during operation

5. Adverse drug event, medication errors
   - wrong drug
   - wrong dose
   - wrong application/administration
   - wrong frequency
   - disregarding drug allergy
   - misinterpretation of order given
   - illegible order.

Table 7 Medical disciplines concerned

Medical disciplines	Cases
Surgical disciplines	1272
Internal medicine	699
Practitioners	434
Anesthesiologists	156
Gynecologists and obstetricians	151
Orthopedic surgeons	126
Psychiatrists/neurologists	117
Pediatricians	86
ENT (ear, nose, and throat) specialists	72
Urologists	66
General practitioners	20

From patients and relatives, mostly the accusation is for negligence of a doctor, followed by complications within surgical therapy, wrong therapy, and medication errors (Table 9).

In nearly 40% of cases, the cause of the preliminary proceedings was the classification of the manner of death as "unclear" or "unnatural" in the death certificate (Table 10). Only in 20%, a complaint by relatives is the cause of the preliminary proceedings. Of special interest is the fact that medical malpractice is more often confirmed in doctors in private practice than in clinicians (Table 11). This is of importance since most epidemiological investigations on AE, PAE, and NAE are confined to hospitalized patients. For doctors in private practice

Table 8 Cause of accusation

Cause of accusation	
Conservative therapy	2604
Surgical therapy	1737
Endoscopy	232
Intensive care	88
Naturopathic treatment/alternative medicine	18

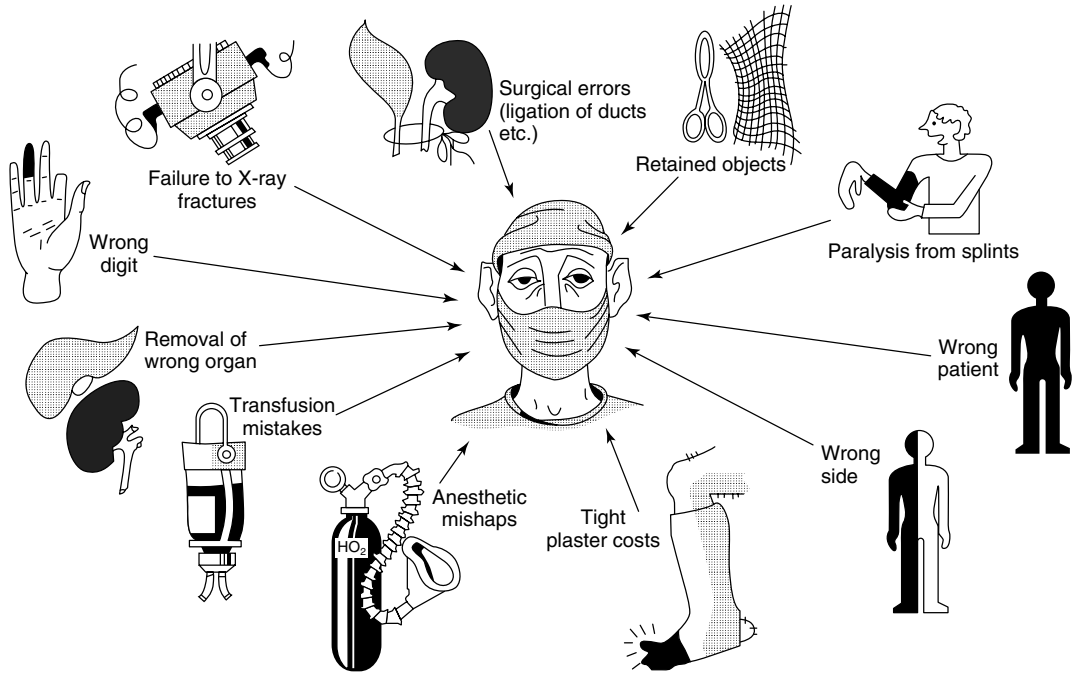

Figure 10 Types of medical malpractice (from Knight 1992)

Table 9 Classification of accusation

Type of accusation	Cases	Percentage (%)
Negligence	2158	48.5
Medication error, adverse event due to drug therapy	557	12.5
Complications within surgical therapy	1472	33.1
Wrong therapy	766	17.2
Mistake in care	320	7.2
Accusation not specified	153	3.4

Table 10 Causes of preliminary proceedings according to the analyzed documents

Cause of preliminary proceedings	Number of cases (%)
Manner of death "unclear" or "unnatural" in death certificate	1715 (38.5)
Cause of proceedings is unknown	1303 (29.3)
Complaint of offense by relatives (including friends and carers)	831 (18.7)
Complaint of a cotreating or post-treating physician	271 (6.1)
Complaint of offense by relatives as well as "manner of death unclear" or "unnatural" in the death certificate	190 (4.3)
No formal preliminary proceeding by the prosecutor, but proceeding to clear cause and manner of death	73 (1.6)
Self-complaint of the physician(s)	21 (0.5)
Complaint by the patient himself before death	18 (0.4)
Complaint by staff (especially nursing staff)	10 (0.2)
Anonymous complaint of offense	9 (0.2)
Other	9 (0.2)

and nursing staff, the rate of approved medical malpractice is 14.7 and 20.3%, respectively, much higher than for clinicians.

Table 11 Occupational group and number of approved medical malpractice and approved medical malpractice with approved causality for death

Occupational group	Number of approved medical malpractice	Approved medical malpractice with confirmed causality
Clinicians	7.8	3.5
Doctor in private practice	14.7	5.2
Nursing staff	20.3	9.3
Emergency service doctor	11.9	4.7
A group of doctors	12.6	4.0

Table 12 Distribution of malpractice charges by duration and site of treatment

Site of treatment	Treatment day 1	Treatment days 2–5	Treatment >days 5
Hospital	10	45	138
Home visit	58	8	26

Although surgery is the discipline with most accusations of medical malpractice, the rate of confirmed medical malpractice with approved causality is rather low, with 3.1%. Another difference between doctors in private practice and hospital doctors is that the interval between beginning of treatment and claim of medical malpractice is comparatively short in the case of doctors in private practice but longer in hospital doctors (Table 12). Apparently, death after short outpatient consultations place physicians at higher risk for malpractice charges.

In prospective clinical studies, medication errors make up a great part of AEs; medication errors are, however, underrepresented in other files of medical malpractice.

Adverse Drug Events

In epidemiological studies on adverse events, the most frequently seen iatrogenic injuries are nosocomial infections and adverse drug events [32, 59, 60]. However, these complications are not found in a comparable frequency in the files of the Institutes of Forensic Medicine, arbitration committees, liability

Table 13 Results of medical malpractice proceedings

	Ulsenheimer	Althoff/ Solbach 1984 (Aachen)	Mallach *et al.* 1993 (Tübingen)	Peters 2000 (Düsseldorf)[a]	Orben 2004	Bonn 2005[a]
Total	245	90	410	194 (297 accused)	601 (751 accused)	210 accused
Closing or acquittal	162 (66.1%)	80 (88.9%)	358 (87.3%)	89%	709 (94.4%)	183 (87.1%)
Sentence or settlement based on Section 153a StPO	66 (26.9%)	10 (11.1%)	52 (12.7%)	6%	42% (5.6%)	16 (7.6%)

[a] Partially the proceedings have been settled otherwise or have not yet been closed at the moment of data collection
Most preliminary proceedings are closed according to Section 170 Abs. 2 Strafprozessordnung (StPO; code of criminal procedure); that means that either no medical malpractice is evident, or the causal connection could not be proved with certainty. Only in 5–12% the doctor is either sentenced or the preliminary criminal proceeding is closed according to Section 153 a StPO (payment of an administrative fine). The higher frequency of sentences or settlement after paying an administrative fine in the material of Ulsenheimer (Table 13) is due to the fact that he, as a specialized solicitor, sees only cases that are quite severe

insurance companies, and health insurance companies [61–67].

Adverse drug reaction is a noxious and unintended response to a drug occurring at a conventional dose and used for disease in prophylaxis, diagnosis, therapy, or modification of physiological functions.

Adverse drug event is an adverse drug reaction and/or event caused by medication errors.

For instance, on the basis of a Scandinavian study [59], 50 000 lethal cases of adverse drug reactions would be expected in Germany just for hospitalizations in internal medicine; 28 000 fatal outcomes would be classified as preventable [60]. Obviously, there is a large gap between the frequency of fatalities based on epidemiological studies and those coming to the public attention. The types of medical malpractice in drug therapy are [65, 66] as follows:

- disregarding drug allergy
- mix-up of electrolyte solutions (KCl instead of NaCl)
- inadequate substitution of drug addicts
- wrong dose, especially in renal insufficiency, when antineoplastic drugs are given
- wrong administration of drugs (e.g., intrathecal administration of Vincristin when simultaneously different chemotherapeutics are given).

The typical patients in fatal adverse drug events are old, multidiseased patients using multiple drugs already on arrival at the hospital, very often receiving an additional four or more drugs during hospitalization. These patients have very frequently combined severe cardiac and pulmonary diseases.

Outcome of Medical Malpractice Claims

Not only are clear epidemiological data on the international frequency of medical malpractice claims missing from the literature but data on the outcome of such claims are also absent. For Germany, cases dealt with at the arbitration committees are well documented, and the success rate for medical malpractice claims is about 30% (see also Table 2 and Figures 5–8). In penal law, most preliminary criminal proceedings are closed according to Section 170 code of criminal procedure (i.e., that fault was either ruled out or could not be proved). Thus, there is either no medical malpractice, or the causal connection between medical malpractice and fatal outcome could not be proved with the necessary certainty [38, 68–71] (Table 12).

Conclusions

AEs in medical malpractice have gained importance because of their frequency as well as the socioeconomic costs and public and political attention. Organizations such as the Council of Europe or World

Health Organization have published recommendations on management of patient safety and prevention of AEs in health care [8, 13].

According to recent surveys of the German Alliance of Patient Safety among hospitalized patients, AEs can be expected in 5–10% of patients, PAEs in 2–4%, NAEs in 1%, and lethal outcome in about 0.1% [33–35].

Medical malpractice claims dealt with at the German arbitration committees are successful for the patient in one-third of the cases. The files of the Institutes of Forensic Medicine are indispensable for the epidemiology of AEs and improvement of patient safety for several reasons [58]:

First, the most dramatic cases are perhaps seen in forensic medicine – death due to medical malpractice[5, 6];
Second, since most studies on adverse events focus on hospitalized patients, the files of the forensic institutes cover the ambulant sector of health care as well.

Forensic pathologists can also contribute to an increase in patient safety since malpractice claims can provide a rich source of data concerning a small number of serious events [72]. A thorough evaluation of serious incidents, although less sophisticated than a root cause analysis, produces far more information than a usual hospital reporting system. Identification and evaluation of errors as well as reporting of errors may also contribute to the prevention of errors. This, among other medical disciplines, is also a task of forensic medicine [13].

Memory: Reconstructive

Memories Are Not Fixed

When we try to remember the past, we do not replay an event like a video camera might do. Memories are also not like books stored on a shelf, only to be opened and read the same each time. Rather we "reconstruct" what happened, sometimes by drawing inferences about what happened, or piecing together information that seems plausible. This is why memory is referred to as *reconstructive* in nature. Reconstruction is the process by which people build a memory of a past event at the time they are trying to remember it.

Sir Frederic C. Bartlett was one of the first researchers to champion the reconstructive nature of memory, as is described in his classic 1932 book *Remembering* [1]. To demonstrate how memory was a reconstructive process he had subjects read an unusual story and then asked them to recall it from memory at varying intervals that ranged from minutes to hours or even years. Sometimes he asked people to tell the story to another person, who told it to another and so on. Bartlett found that the story was often not well remembered, and that people made systematic errors when they tried to recall it or tell it to someone else. For example, they tried to make the story more coherent than it really was, and they often added details that were not part of the original story. He also found that as subjects reconstructed the story from memory, accurate recall was the exception rather than the rule.

Bartlett's experiments challenged the belief that memories were stored as static unchanging traces in the brain and that recall meant merely reexciting, or stimulating, these traces. The act of remembering is the end result of a complex process that begins when information is first presented and is stored in the mind. That complex process involves a number of stages that are fundamental to how memory works.

How Memory Works

There are three essential stages in the memory process: acquisition, retention, and retrieval [2]. Acquisition is the first stage: when an individual first experiences an event, devotes attention to it, and

encodes it into memory. Retention is the second stage and it refers to the passage of time that occurs between the original event and recollection of the event. The final stage of the process is retrieval, when the individual tries to remember the event (or reconstruct it). Errors can enter memory at any or all of these three stages.

During the acquisition stage, errors can be introduced when details of the event are not properly encoded and stored in long-term memory. In order to recall an event, an individual must first devote attention to it. When a person distorts information at the acquisition stage, the errors are sometimes called *constructive* errors. With poor lighting or long distances or a minimal chance to view the material, errors are more likely to occur.

Errors can also occur during the retention stage of memory. The length of time that passes between the initial encoding of an event and the recall of that event affects how much detail will be recalled. In 1885, Ebbinghaus conducted classic experiments documenting how recall deteriorates over time [3]. Using only himself as a subject, Ebbinghaus memorized lists of non-sense syllables and tested his recall over time. He found that forgetting occurs rapidly at first and then becomes more gradual as time goes on; these results were then plotted onto his now famous "forgetting curve".

The passage of time weakens our memory for an event and makes us more susceptible to errors. One way that errors can be introduced is through the acquisition of misleading information, a phenomenon known as the *misinformation effect* [4]. In studies of the misinformation effect, subjects witness a complex event such as a car accident and half are subsequently provided with misleading information about the event. In one study that used a car accident as the target event, participants in the misinformation group were given the suggestion that the traffic sign seen in the event was a yield sign instead of the stop sign that was actually seen. When later asked to provide a description of the initial event, participants who received the misleading information were less accurate than those who had not been exposed to any misinformation. These participants incorrectly claimed that they had seen a yield sign. The longer the time interval between witnessing the event and the introduction of the misinformation, the more memory for the initial event was impaired.

At the retrieval stage, memory for the target event can be altered by the way that questions are worded [2]. Even the change of a single word can affect memory for an event. In one study, participants were shown a short film of a car crash and then were given a questionnaire about the events that they had just seen. When participants were asked, "Did you see the broken headlight"?, significantly more of the participants reported that they had seen the broken headlight, a detail that was not in the film, than when participants were asked, "Did you see a broken headlight"? The change from "a" to "the" makes a significant difference because the use of the word "the" suggests that the item exists.

In another study on the influence of question wording, participants watched an automobile accident and then were asked about the speed of the cars involved in the accident. A question like "How fast were the cars going when they smashed into each other"? led to higher estimates of speed than the question "How fast were the cars going when they hit each other"? Moreover, the "smashed" question led people to be more likely to claim that they saw broken glass in the accident, a detail that did not occur. It is also important to note that once an individual recalls an event in a particular way, this is the new construction of the event.

These errors reveal something about the reconstructive nature of memory. When people hear the word "smashed", it is commensurate with a severe accident, one that occurred at higher speeds, and thus they infer that the speed was higher. Moreover, since broken glass is often associated with severe accidents they may infer that it occurred and think, in this case wrongly, that they saw it.

Another line of work that shows the reconstructive nature of memory is work on "pragmatic inference" [5]. A pragmatic inference is an assertion that leads people to believe that they experienced something that was not actually experienced. When people were presented with a statement like "The karate champion hit the cement block", they will often remember hearing "The karate champion broke the cement block". This is not a logical inference; the champ could have hit the block but not broken it. However, many people will draw the inference and misremember what they heard.

People also can come to remember autobiographical events that never happened. These wholly fabricated incidents are known as *rich false memories* [4].

In one study, the relatives of subjects created scenarios and implanted false memories of being lost for an extended time in a shopping mall and being rescued by an elderly person, at the age of six. This procedure for planting false memories has come to be known as the *lost-in-the-mall* technique. Using strong suggestion, people have been led to remember falsely that they were lost as a child, that they were attacked by an animal, or that they nearly drowned and had to be rescued by a lifeguard.

Rich false memories can also be planted through the use of other techniques such as guided imagination, suggestive dream interpretation, hypnosis, and the use of doctored photographs. These techniques have produced false memories in approximately 30% of the people who receive the suggestion. One criticism of the memory implantation studies is that the participants may be recalling actual memories, not false ones. In order to counter this criticism, researchers have successfully demonstrated that people can also be given impossible memories like meeting Bugs Bunny at Disneyland.

Source monitoring errors also highlight the reconstructive nature of memory. Source monitoring errors refer to the phenomenon of recalling someone or something but forgetting the source of the original object of recall [6]. For example, you may recognize a face but be unable to remember where you first encountered the person. In most cases, this failure to recall the source of the original memory does not have major implications, but for those accused of criminal acts, the consequences can be quite serious. In one known case, a psychologist was accused of rape based on the victim's detailed recollection of her attacker [3]. He was later cleared when it was discovered that he was on live television at the time, which the victim was watching during her attack. She recalled his face clearly but had misattributed the source.

Errors of source attribution can also occur when we are attempting to create something wholly our own. *Cryptomnesia* refers to the act of unknowingly attributing the work of someone else to oneself [3]. Without meaning to, people occasionally plagiarize other works or adopt the memories of other people as their own. Carl Jung reported on this phenomenon in the early 1900s noting that Friedrich Nietzsche had taken part of a story written by the German physician and poet Kerner. In a more recent case, Kaavya Viswanathan, a Harvard sophomore and author, claimed that her plagiarism from two novels by Megan McCafferty was entirely unconscious and unintentional.

On occasion, we sometimes unintentionally adopt the memories of siblings or close others. Common memories that have been adopted from someone else are for achievements or suffered misfortunes. We recall these events as happening to us, and are genuinely surprised when we discover that these memories are not ours. The memories that we are least likely to appropriate are those pertaining to wrongdoing, perhaps because of our self-serving biases. The adoption of another person's memory is not an intentional act but rather, it reflects the reconstructive nature of memory and how errors can insert themselves in our recollections. Knowing that these errors can occur unintentionally should make us less irritated and more forgiving when we observe them.

To reiterate, memories may sometimes become less clear over time, but they also change for other reasons. They are continually constructed and reconstructed, and for these reasons will often differ from genuine reality. Unfortunately, without independent objective corroboration, there is no way to assess whether a memory is accurate or not.

Applications

The courtroom is one arena where the reconstructive nature of memory is apparent. Eyewitnesses are frequently the cornerstone of the prosecution's case against a defendant, and provide compelling evidence to jurors (*see* **Eyewitness Testimony**; **Interrogative Suggestibility**; **Memory: Repressed**; **Eyewitness: Suggestibility of**). Yet eyewitness testimony is often mistaken, and such mistakes can be disastrous. Analyses of wrongful convictions, where individuals have been exonerated on the basis of DNA, have shown that the major cause is faulty eyewitness memory [7]. When a witness takes the stand and professes certainty about the defendant's guilt, it is powerful evidence. Unfortunately, confidence is not equal to accuracy and confidence can be inflated by many factors. One such factor is confirmatory feedback. When an individual is given positive feedback about the identification that they have made, they become more confident about their choice. The feedback need not even be verbal, as in a remark "Good job, you picked

the suspect". Even a nod can serve as positive feedback, and artificially inflate a witness's confidence, making them more compelling when they testify in court.

Rich false memories can also appear in the courtroom. In one case, a sheriff's deputy named Paul Ingram confessed to sexually abusing his daughters and being involved in a satanic cult that involved animal sacrifice and infanticide [8]. Ingram was highly suggestible and was imprisoned despite a lack of evidence indicating that the cult even existed. Sadly, Ingram is not the only individual who has been imprisoned or had a life destroyed by false memories. In the early 1980s, dozens of individuals were swept up in accusations of child abuse involving satanic cults. Most, but not all, of these people have been released from prison but the emotional scars of the accusations remain.

Memory is inherently a reconstructive process, one that works well in most cases but can occasionally result in errors with dire consequences. Since memory errors can have such serious consequences, it is important that we keep in mind that memory is malleable. When we seek to recall, we seek to reconstruct and errors can occur at any stage.

Memory: Repressed

Memory, Repressed

The term "repression" was popularized by Sigmund Freud in the late nineteenth century. By Freud's account, repression consisted of individuals making certain events that elicited painful or disruptive effects on the psyche inaccessible as a defense mechanism for the self. Although the term and various definitions of repression have existed for more than a century, there has been essentially no substantial proof that massive repression exists. There are, however, alternative explanations for what looks like "repression". Some individuals do not think about unpleasant experiences and are later reminded of them. This is not repression, but ordinary forgetting and remembering. Moreover, some individuals can have false memories planted in their minds as a result of suggestion, giving the appearance that an event was not being remembered (*see also* **Eyewitness: Suggestibility of**; **Hypnosis and Memory**; **Recollective Accuracy of Traumatic Memories**).

Despite the lack of verifiable proof of massive repression [1, 2], allegations of repression can have dramatic consequences. The existence of repressed and recovered memories became a fierce topic of debate due to alleged cases of childhood sexual abuse (CSA), many of which involved memories recovered by suggestive therapy techniques. A number of these cases resulted in legal battles and families being torn apart. This entry offers a brief overview and history of the repressed memory debate, legal claims and cases that resulted from the debate, and research that has attempted to examine the existence of repression.

Surge in Recovered Memories and their Effects

Media Contribution

Claims of recovered memories of CSA blossomed in the late 1980s and early 1990s. Accusations of CSA, including claims of satanic ritual abuse, peaked in the two-year period of 1991–1992. Since the early 1990s, the number of CSA accusations as a result of recovered memories has steadily declined. The media undoubtedly contributed to the surge in

repressed memories that were recovered in therapists' offices throughout North America. A notable case that was brought into the public eye as a result of the media coverage was a murder case involving George Franklin.

In 1990, George Franklin stood trial for a murder that had occurred more than 20 years earlier. Franklin was accused of murdering Susan Nason, a friend of his daughter, Eileen. Although Eileen was 8 years old at the time of her friend's murder, her testimony was key. Eileen testified that she had witnessed her father murder her friend and repressed the memory for 20 years. When her "memory" returned in the late 1980s, she contacted the police. George Franklin was found guilty of murder based solely on Eileen's testimony of her recovered memory. It was the first time that an American citizen had been tried and convicted of a murder on the basis of a recovered memory.[a]

In addition to the media coverage of trials involving recovered memories, a number of people began to write self-help books to assist victims of CSA. One of these books, *The Courage to Heal* by Ellen Bass and Laura Davis, encouraged victims to recover memories of abuse and to confront alleged molesters. There were a number of supporters of *The Courage to Heal*; however, there were also those who criticized its message. The critics contended that it caused widespread harm to many innocent people – both the alleged perpetrators, and the accusers whose lives may have been negatively affected by false accusations. Bass and Davis have no formal training in psychiatry or psychology, and some critics have argued that their book encourages the recovery of memories that may not be true. Because *The Courage to Heal* has sold over 800,000 copies, many people feel that it has contributed greatly to the surge in the number of recovered memory cases by engendering people to embrace their recovered memories, regardless of the existence of corroborative evidence of abuse.

Statute of Limitations

Another development that fueled the controversy over repressed memory concerned changes in how claims of repression were handled by the judicial system. Washington State was the first state to toll the statute of limitations for repressed memory cases. This meant that people with newly recovered memories of CSA had three years from the time of remembering to sue their parents, other relatives, or any alleged molesters. A number of other states followed Washington's example, and as a result, thousands of lawsuits were filed.

Most provisions applicable to victims of CSA fall into the categories of "minority tolling" and "delayed discovery doctrine". A tolling doctrine postpones the date from which a statutory period begins. In the case of minority tolling, a statute might run three years after the child turns 18, the legal age of majority. This delay is thought to be beneficial because some children may not feel comfortable coming forward to report abuse while still under the care of their abuser.

The delayed discovery doctrine has typically been used in cases involving medical malpractice. For example, the statute of discovery would be extended for a patient who had surgery and later realized that her abdominal pain resulted from her doctor failing to remove a sponge during a prior surgery. Thus, at the time it was determined that the sponge was causing the abdominal pain, the statute of limitations for a malpractice suit would begin to accrue. Those in support of applying the delayed discovery doctrine in recovered memory cases purport that such a medical malpractice claim is analogous to an individual who alleges recovery of CSA memories in that the source of their pain would be realized when the memories are recovered. Such an individual would have some number of years from the date they assert the memory was recovered in which to pursue legal action.

Because the statutes of limitations were tolled, a number of victims were able to sue their alleged abusers more easily. As a result, thousands of cases were brought to the courtroom. Soon there became another way in which repressed memories made their appearance in the court. People who were accused of CSA sued their accusers' therapists for planting false memories of childhood abuse that led to the original accusations. In addition, some patients who had "recovered" memories of abuse began to realize that those memories were not true. These patients retracted their claims and many of them sued their therapists. They are categorized into the group known as "Retractors".

Retractors

There have been a number of CSA accusers who have reestablished family relationships and acknowledged that their prior accusations were false. These

retractors typically blame their therapists for suggesting to them that they were victims of CSA and for encouraging memory recovery through questionable therapeutic techniques such as guided imagery, "truth serums" (sometimes termed *Amytal interviews*), and hypnosis.

In 1997, a landmark case ensued in which a retractor sued her therapist who helped her "recover" memories of CSA. Ms. Burgus, a patient of Dr. Braun's, originally sought treatment for postpartum depression, but was diagnosed as having multiple personalities. Dr. Braun believed that her symptoms resulted from sexual and ritual abuse including cannibalism and torture. He purported that this abuse was the cause of her forming multiple personalities. Even though Ms. Burgus had no recollection of the sexual and ritual abuse, Dr. Braun encouraged her to try and remember these instances of abuse through hypnosis. Ms. Burgus eventually realized that these allegations were not true. She retracted her previous abuse accusations and sued her former therapists, including Dr. Braun and the hospital. The lawsuit was settled for 10.6 million dollars.

False Memory Syndrome

Although therapy helps a number of people, it can have detrimental effects in cases involving recovered memories. This is particularly true in situations where there is no history of sexual abuse. For example, when a daughter accuses her father of child abuse, the family can be devastated. Often it forces other family members to choose sides; this has caused some families to become torn apart as a result of "recovered" memories (for the landmark legal case in this area see *Ramona v. Ramona*, No. 61898, California Superior Court, Napa County, 1994; reported in Johnston, Moira (1997) *Spectral Evidence*. Boston: Houghton Mifflin).

In addition to causing strain on family life, patients may develop new symptoms unrelated to the primary concern for which the patient sought therapy in the first place. These symptoms include false beliefs and memories of having been abused, a syndrome now referred to as *False Memory Syndrome*. This syndrome is characterized by flashbacks, which include detailed memories, and even hallucinations and delusions of the abuse. Thus, the patient believes that she has specific recollections of abuse that may not have occurred.

Families and professionals who saw the need to prevent the spread of False Memory Syndrome formed an organization in 1992 called the False Memory Syndrome Foundation (FMSF). The FMSF also supports the reconciliation of families who were torn apart by claims of repressed and recovered CSA.

Research in the Field

Like the topic itself, research in the field of repressed and recovered memories has been controversial. There are several different methodologies that have been used to study such alleged memories. The most common types of studies are retrospective, prospective, and case histories. Retrospective studies rely on the self-report of alleged abuse years after the actual event was said to have happened. Prospective studies use later self-reports of alleged abuse, but attempt to corroborate the abuse through various channels such as police reports or social worker reports. Lastly, case histories rely on data collected from an individual's personal experience. In general, most of the data has been collected from women who were alleged victims of CSA.

In one example of a retrospective study, researchers Briere and Conte [3] asked participants, who were recruited by their therapists, if there was ever a time in which they failed to remember their first instance of abuse. Those who reported forgetting the abuse at some point reported that the abuse occurred at a very young age compared to the reported age of the participants who claimed continuous memories of abuse. Overall, more than half of the participants reported that there was some point in time that they did not remember the abuse. However, from this study, it is problematic to conclude that repression exists. Not specifically remembering an event does not necessarily constitute massive repression. In fact, this lack of remembering can easily be accounted for by ordinary forgetting. Because of this, the results of this particular study cannot be satisfactorily interpreted, nor can they be considered adequate proof that memories can be repressed.

Another researcher, Melchert [4], conducted a retrospective study to clarify the confusing findings of earlier studies. In a nonclinical sample of individuals, of those reporting physical, emotional and/or sexual abuse, around half reported that they did not have

continuous memories of the abuse. Many participants in this study who claimed to not remember being abused later reported that they either consciously avoided thinking about the abuse, could have remembered the abuse if they had been reminded, or did not realize that the abusive acts against them were in fact abuse until a later time.

Another strategy for examining "repression" involves the use of a prospective design. Here, there is documentation made by an agency or individual (e.g., social worker) at the time of or shortly after the alleged CSA occurred. Some time after the abuse has been reported, individuals are contacted to determine what they remember about their prior claims of abuse.

In a prospective study conducted by Williams [5], women were contacted 17 years after CSA had been reported to authorities. Of these participants, 38% failed to recall the previously reported abuse to the interviewer. Thus, some consider this study to be a prime example of evidence that memories of CSA may be repressed. However, critics assert that participants may have remembered the abuse, but may have not wanted to discuss such an uncomfortable event with the interviewer. Additionally, in this study the younger the participant was at the time of the reported abuse, the less likely they were to remember the incident. This difference in remembering due to age could be explained by childhood amnesia, which is discussed later in this entry. More recently, in another prospective study conducted by Goodman and colleagues [6], only 8% of participants who had previously reported abuse failed to report remembering the abuse at the later interview. Even the rather low percentage could be the result of unwillingness to tell rather than inability to remember.

Another method for examining repression is with individual case histories. Some mental health professionals report on a patient who they claim had a repressed and recovered memory. The case of "Jane Doe" is a famous case history within the field of repressed and recovered memories [7, 8]. In the mid-1980s Jane Doe's parents filed for divorce and engaged in a vicious battle over custodial rights of Jane. As a result of this custody dispute, Jane, who was 6 years old at the time, was psychologically evaluated. A psychiatrist supported the abuse accusation, and Jane's father obtained custody while Jane's mother lost the rights of visitation.

In 1995, when Jane Doe was 17 years old, the same psychiatrist videotaped Jane again. At first Jane failed to remember being abused by her mother and then, during the same videotaped session, she appeared to spontaneously recover memories of the abuse. The psychiatrist asserted that this particular case was solid evidence of traumatic amnesia and recovery of memory. Following this claim, some critics who questioned the validity of this case history investigated other facts surrounding the reported abuse of Jane to determine whether this case offered conclusive evidence for repression. These investigators discovered that Jane had discussed the alleged abuse on many occasions between the first and second video tapings, thus undermining any claim of repression. Additionally, documented facts were brought to light that suggested that Jane may have not been abused by her mother at all.

Alternative Explanations for Repression

There are a number of possible sources from where richly detailed memory reports may come. The reports of victims who have claimed to recover memories could reflect true memories that have simply been forgotten by normal memory processes. The "recovery" of these memories may have been triggered by a retrieval cue. Another explanation is that the memories could reflect lies. Finally, it is possible that these memories are the result of therapists' suggestions and other activities in group therapy sessions that planted false beliefs.

True Memories

Instances where individuals claim to have recovered memories may actually entail ordinary forgetting and remembering. For example, an individual may remember an event that occurred at a much later date that they had not thought of in a long time. This true memory may be brought to mind by a trigger in the environment, such as a particular setting. However, this would be a case of ordinary forgetting and not repression and recovery of a memory. Additionally, failing to think about an event such as sexual abuse for any given amount of time does not necessarily mean that the memory for the event was repressed. In any given case in which a person reports recovering a memory, the statement could be an accurate reflection

of the individual's experience; however, it may be an instance of ordinary forgetting.

False Memories

It can be difficult to discriminate true memories from false ones; however, there are a few situations where we can say with near certainty that the reported recovered memory is false. For example, some people have claimed that they remembered abuse inflicted upon them before they were two years old. There have even been people who claim to have recovered memories of abuse that occurred when they were six months old. As adults we do not have concrete and reliable episodic memories for events that occurred in the first couple years of our lives. This phenomenon is known as "childhood amnesia". Therefore, it can be concluded that these very early "memories" are almost certainly false.

For those individuals whose recovered memories cannot be explained by childhood amnesia, research on suggestibility and the malleability of memory may explain their situations. Researchers have shown that humans are rather susceptible to forming false memories. In addition, a number of individuals believe those memories to be true and even embellish upon the details of those false memories. In research where rich false memories have been planted, a significant minority of subjects have been led through suggestion to believe that they had experiences like being lost in a shopping mall [9] or being attacked by a vicious animal [10]. These studies have shown that people are even susceptible to embracing false memories as their own. Once planted, the individual can report the false event with a great deal of detail, confidence, and emotion.

Conclusion

After decades of research in the field, there is little, if any, substantial evidence that massive repression exists. Moreover, there are other possible explanations for what might look like the recovery of a repressed memory. These include ordinary forgetting or being subjected to suggestible circumstances. Given the massive evidence that has been gathered on the malleability of memory, it should not be surprising that at least some individuals who purport they have recovered memories of past abuse may have actually formed false memories.

End Notes

Mental Health Courts

Introduction

In a perfect world we should not need mental health courts, let alone a literature about them. But we do. Realistically, in a less than perfect world we should perhaps aspire to see mental health courts as part of our future but not as the full "answer to the problem" as they are currently seen. "The problem" is that over the past 15–20 years the criminal courts have had to contend with ever-increasing numbers of mentally disordered individuals coming through the courthouse doors. This article describes the basics of mental health courts, how they operate, and examines how and why these courts have become an integral part of both the criminal justice and mental healthcare systems.

Background

The provision of mental healthcare services in most Western European and North American communities has witnessed a steady decline over the past number of decades. Beginning with the deinstitutionalization movement occurring in the later half of the twentieth century, adequate mental healthcare services became increasingly scarce. The reality today is no different; mental healthcare systems are generally underfunded and overexpended. There has been a movement toward community-based treatment of major mental illness, which in many instances appears to be insufficient. Despite what was promised, the money saved with the closure of hospitals has typically not been reinvested in community treatment. At the same time, while it is acknowledged that community-based mental healthcare is an important component of the mental healthcare system, it cannot address the needs of many of the more seriously afflicted individuals.

It goes without saying that decreasing mental healthcare services does not lessen the needs of those

members of our society who rely on such services. For these individuals closed doors and long-wait lists have offered little. Regrettably, those unable to receive adequate services often find themselves attracting the attention of the criminal justice system, leaving that system to "sort out the mess".

The effects of our emancipated mental healthcare system are varied; however, a site where it has had a particularly acute impact has been the criminal justice system. Being the social safety net of last resort, the criminal justice system has swelled with mentally disordered accused and has struggled to meet the rising demands placed upon it. In some jurisdictions, mentally disordered accused entering the criminal justice system has increased at a rate in excess of 10% per year over the past dozen years [1].

Unfortunately, the criminal justice system has become the surrogate mental healthcare provider in most societies. A *criminalization* of mental illness has occurred: a shifting of responsibility onto the criminal justice system for the provision of basic mental healthcare services.

Understandably, the criminal justice system has not delivered. The criminal justice system was neither designed nor intended to address society's responsibility to the mentally disordered individual. Even a basic familiarity with the traditional criminal justice system will reveal that it is no substitute. Undoubtedly, it is worse. Accused with mental disorders languish in detention centers and correctional facilities. They often fail to receive much needed treatment, typically feel alienated and marginalized, and generally have a difficult time regaining normal functioning once entwined in the system. The regression in treatment and rehabilitation, along with an overreliance on warehousing the mentally ill in penal settings, is a deplorable anachronism that harkens back to before the development of asylum care. Ironically, we presently find ourselves where we were situated 200 years ago trying to get the mentally ill out of the prisons and criminal justice system. We have come full circle.

Mental Health Courts: A Response

Mental health courts are a response to this reality. Recognizing the criminalization process that has occurred, these courts have sought to reverse the misplaced responsibility for the provision of mental healthcare services. These courts have various objectives, which include the targeting of accused with mental disorders, and have as their mandate one or more of the following objectives:

1. "diversion" of accused who have been charged with minor to moderately serious criminal offenses and offering them an alternative;
2. expediting the pretrial processes of assessing fitness to stand trial;
3. treatment of operative mental disorders; and
4. a slowing of the so-called revolving door.

Through successful participation in a treatment program overseen by a mental health court team, some accused can avoid conviction and sentence, as they are "diverted" back into the civil mental healthcare system. This model is based upon the earlier established drug courts. The court "intervenes" at a discrete point in time along the criminal justice continuum. Some jurisdictions have included diversion as a component of their mental health court but have attempted to also intervene at multiple postarrest junctures and to a much larger population of mentally disordered accused.

Mental Health Courts – A Broadly Defined Category

Despite sharing similar objectives, there are many models that claim the label of a "mental health court". Accordingly, when considering these courts it is important to gain an appreciation for the scope of what is being referred to. Different courts have different (or multiple) entry points in the criminal prosecution process, different entrance requirements, objectives, and outcomes. Nevertheless, very generally speaking, mental health courts are all attempting a rehabilitative response to what would otherwise have been criminally sanctioned behavior. The general philosophy driving this approach is quite simple – the traditional response to aberrant behavior where it is substantially the product of mental disorder is both ineffective and inappropriate.

Therapeutic Jurisprudence

In beginning to appreciate mental health courts, it is necessary to understand the principles of therapeutic jurisprudence (*see* **Therapeutic Jurisprudence**). It

is a theory which holds that the law should be administered and applied in a way that incorporates therapeutic goals. It advocates use the justice system in a manner which addresses the underlying factors that may lead an individual to come into contact with the law. It is a vehicle to obtaining a better societal response to proscribed behaviors.

This novel approach to criminal justice has particular relevance to mentally disordered accused in today's society.

We know that many mentally disordered accused often "end up" in the criminal justice system. Often they are charged with minor and nonviolent offenses. Many times the factors that place these accused in the justice system could more effectively be addressed in ways other than imposing traditional criminal justice sanctions. It is this normative foundation that explains why mental health courts often focus on treatment of mental health systems, housing, substance addictions, job training, and other matters in preference to such traditional options as jail, fines, and probation.

Restorative Justice

The creation of mental health courts also resonates with the principles and ideological foundation of the restorative justice movement. Restorative justice is a view of justice that centers on repairing the harm and relational disruption caused by criminal behavior. One of restorative justice's key tenets is to foster the involvement of all stakeholders, including the community, to restore victims and offenders to intact, contributing members of society. Mental health courts play a key role in this restorative process by rerouting accused to both treatment and a place in the community, and by enlisting the community to provide care and supervision for an afflicted individual deserving of both compassion and intervention. Given the frequency with which family and others close to a mentally disordered accused become his or her victims, a therapeutic outcome is more likely to reflect victims' wishes that offenders be dealt with in a compassionate, humane, and ultimately more socially protective way, notwithstanding their having been victimized by the accused.

The First Mental Health Courts

The first mental health courts began as grass root initiatives in the mid-1990s. Early versions, as mentioned above, found inspiration from the success of drug courts – an emerging brand of court dedicated to accused with substance addictions. On a very basic level, drug courts operate by offering accused an option: avoid serving a sentence for a drug-related offense by completing a drug-treatment program.

As judicial initiatives, drug courts were quickly lauded as helping to break addiction cycles. By adopting principles of therapeutic jurisprudence and focusing upon addiction as opposed to crime, these courts were assisting the participants avoid subsequent drug offenses. The success of the treatment model espoused by drug courts spawned a parallel idea for accused with mental disorders.

Like drug courts, the first mental health courts in the United States found promise in offering treatment instead of punishment. Their ability to effectively remove individuals from the criminal justice system through the provision of services demonstrated an important reality: for many accused, minor offenses may more accurately represent an inability to control or manage their mental health symptoms as opposed to deliberate criminality.

The increasing appeal of specialty courts and a growing awareness that the traditional criminal justice system was failing individuals with mental disorders have combined to legitimize the emergence of mental health courts. And come they have. The onset has been remarkable; despite only appearing within the past decade or so, they now number in excess of 200 within North America alone. Beyond the courts that currently exist, numerous jurisdictions are actively pursuing implementation.

The first known program in Canada that addressed the issue of mentally disordered accused in the criminal justice system appears to have been in Toronto, Ontario, Canada. The "Diversion of Mentally Disordered Accused" became a program that was officially part of the Crown Policy Manual in 1994. This program is most like the programs referred to as "mental health courts" in the United States. In addition to this program, a mental health court has been created to deal with a broader range of issues. Diversion is just one option in the court's range of options and therapeutic armamentarium. The mental health court operating in Toronto houses a diversion program but intervenes at various other postarrest junctures to assist all mentally disordered accused, regardless of the offense charged, whether or not "diversion" will ultimately become an option.

The Operation of a Mental Health Court

Understanding the operation of a mental health court requires an appreciation of both the mental health court team and the eligibility of accused for program participation.

While the "nuts and bolts" of mental health courts will vary, integral to the functioning of a mental health court is a multidisciplinary team approach. Judges and lawyers are supplemented by any number of psychiatrists, psychologists, case workers, and social workers who collaborate on how the particular needs of the accused can effectively be met. The various disciplines represented in these teams form a concentrated resource which facilitates the court's operation.

Each court maintains a formal or informal policy outlining the type of accused eligible for the court. Typically, participation in the "diversion" component of a mental health court is reserved for individuals with mental disorders charged with minor to moderately serious offenses. Nevertheless, certain courts also provide services that do not involve eligibility requirements. As an example, the Toronto mental health court addresses the pretrial issues of fitness to stand trial and treatment of underlying mental disorder for all accused, regardless of the seriousness of the offense. As well, the court may order assessments to determine the issue of criminal responsibility. On a voluntary basis it will also entertain resolutions and bail hearings.

In most mental health courts in the United States, eligible and consenting accused are given a choice: participate in a treatment program and have your criminal charges stayed, dropped, or reduced, or proceed in the regular stream. The treatment program is strictly voluntary, and accused are most often able to opt out at any time. The approach in Canada has been somewhat different. The primary focus is with respect to assessing fitness to stand trial and providing treatment. The accused's participation in this aspect of the court's operation is not voluntary. Thereafter, once fit to stand trial, whether the accused elects to remain with the court for a bail hearing, participate in "diversion", or resolve the matter with a guilty plea is the accused's option.

Accused who elect to participate in the mental health court will typically be required to comply with an individually tailored treatment program designed by the mental health court team.[a] The benefit of a multidisciplinary team is that treatment can take a variety of forms and is not limited to medication, but can include psychological therapies, educational training, occupational training, housing and access to social services, budgetary counseling, etc.

As previously noted, a primary goal of mental health courts is to reconnect and reintegrate individuals in need of treatment to the appropriate services. In this way, mental health courts form bridges to various services within the community. Assisting individuals manage their mental disorders through the provision of mental health and social services reduces the likelihood of subsequent offenses, and in this way mental health courts also seek to curb the disproportionately high rate of recidivism in this segment of the population. With a reduction in recidivism, the courts also make communities safer places to live. There are now studies that support the previously intuitive projection that mental health courts do, indeed, reduce recidivism rates [2].

That the behaviors that resulted in the accused's appearance before the court were not contrived by him or her to be criminal in nature in the usual sense, and more likely reflect one or more mental disorders, is a foundational premise of a mental health court. All of the court's personnel are inevitably guided by the premise that, but for the accused's mental disorder or condition (and attendant socioeconomic decline), he or she would not likely have become involved in the conduct before the court. The corollary to this premise is that no professional or worker from either the legal or mental health arenas should become involved in a mental health court unless he or she is philosophically oriented to a therapeutic outcome, and this is so notwithstanding public protection considerations.

Mental health courts consequently do not share the hard-hitting adversarial atmosphere associated with most criminal courts; actually, mental health courts hardly feel like courts at all. An informal atmosphere aimed at putting the participants at ease and fostering an environment conducive to discussion is a feature common to all mental health courts.

General Observations and Caveats

The recent emergence of mental health courts has transformed the criminal justice landscape for mentally disordered accused. While traditionally one general criminal court served any type of offender, today

mental health courts represent one of many specialized "problem-solving" courts in existence to serve specific types of offenders with special needs, including drug courts, domestic violence courts, aboriginal courts, and prostitution courts. The speed with which mental health courts have emerged cannot be understated. A mere 10 years ago none was reported to be in existence, while today well over 200 mental health courts exist in North America alone.

It can be stated that mental health courts have emerged out of frustration and an abhorrence of the realities faced by mentally disordered accused. Lengthy delays for fitness assessments, a cast of courtroom players untrained and/or unfamiliar with the realities of mental illness, and a prison system more prone to exacerbate than to manage, only begin to enumerate the list. These courts are often held to be direct commentaries on the failure of the traditional justice system to meet the needs of mentally disordered accused.

The mental health court movement in North America appears to be proceeding on the assumption that these courts represent the answer. In the United States, a congressional commitment to the funding of an additional 100 mental health courts in 2001 evidences this belief. Currently in Canada there exists a strong impetus in many provinces to create these courts.

Yet, it is ironic that if one were to design the optimal mental healthcare delivery system it is unlikely that too many professionals would conclude that judges, courts, and the criminal justice system at large are the best vehicle. Judges and lawyers as mental health service brokers? Unfortunately, our systems, both the mental health and criminal justice system, are the product of evolution rather than design. They have evolved like any other complex organism. Unable to turn back the clock, the question remains: what of mental health courts? The unfortunate reality is that mentally disordered accused are in ever-increasing numbers dropped at the courthouse door.

It is accepted that there will continue to be a need for mental health courts in the criminal justice system – but hopefully the need will be reduced in the context of our ultimate solution. Even if overhauls of the mental healthcare system reduce the numbers of mentally disordered accused coming in to the criminal justice system as they are presently recognized, it is clear that the courts should endeavor to respond more appropriately to this population. Mental health courts may be the mechanism for that better response within the criminal justice system.

The question to ask then is how to proceed; how, and what, should we learn from the short existence of mental health courts? A distillation of the accumulating literature [3] permits a listing of the features of mental health courts which should be avoided, those which we should strive to include, and general observations regarding mental health court's role in the justice system.

Mental health courts did not emerge in a vacuum. They represent an evolutionary response to an escalating need to deal more effectively with the growing numbers of mentally ill entering the criminal justice system. Their existence is a reflection of decades of erosion of the civil mental healthcare system's ability to completely fulfill its role and a testament to the expression "necessity is the mother of invention."

Mental health courts are an example of the justice system's ability to respond to a societal problem in a nontraditional, yet more effective, manner. The traditional punishment-based response of the criminal justice system to individuals who are in need of correction has failed both society and the mentally disordered accused and is, in fact, counterproductive. As an example of therapeutic jurisprudence, mental health courts attempt to get at the underlying root causes of undesirable behavior. They are an example of therapeutic jurisprudence in action.

Mental health courts should have no "entrance ticket" other than a willingness on the part of the accused to attempt change. It is inappropriate to require an accused entering a diversion program to enter a guilty plea or to accept criminal responsibility. It is antithetical to both the goal of "decriminalization" and the notion that the accused we are diverting are being diverted because their otherwise criminal activity is more reasonably seen as the product of their mental disorder. To dangle the prospect of leniency in front of the mentally disordered accused and promise that lenient outcome only if he pleads guilty completely undermines the voluntariness of the plea.

Participation in a diversion program should be voluntary. Setting aside the philosophical debate as to what is truly voluntary, an accused should be permitted to enter or leave a diversion program at will. It is well established that motivation is the lynchpin for change. It is equally well established that it is rather pointless to waste rehabilitative time,

resources, and effort on an individual who is not a willing participant.

Noncompliance with a diversion program should not attract criminal sanctions. For the reasons noted above, there is little point in *forcing* an accused to comply with a treatment regime. Noncompliance should, first of all, be visited with further reassurance and support. Perhaps alternative therapeutic courses should be considered. Relapse is a normal, expected feature of rehabilitation. It should not attract penalties. If after all supportive options have been exhausted the accused is showing no interest in participating, they should be permitted to withdraw and return to the regular prosecutory stream. A mentally disordered accused should not be punished for attempting a therapeutic avenue, but failing.

A second reason for not including criminal sanctions as a response to noncompliance is that it is inconsistent with the principal objective of decriminalizing the mentally disordered accused.

Upon completion of the diversion program the accused should avoid a criminal conviction. The objective is to "divert" the accused out of the criminal justice system. Therefore, once society's intervention has been successfully complied with, the accused should be rewarded with the avoidance of a criminal conviction. Again, this is consistent with the primary objective of decriminalizing the mentally disordered individual.

Diversion programs should, as much as possible, divert the accused back in to the civil mental healthcare system. In order to avoid a two-tier mental healthcare system with one perceived to be superior, it is seen as preferable to rely upon one universal system. Diversion programs constitute another entry portal, but the resources should not be dependent upon outstanding criminal charges. It should not be one system for the "bad" and one system for the "good". Such a system may actually serve to increase the arrest rates of mentally disordered individuals if the police believe that the only or best way to secure treatment for the individual is to introduce him to the criminal justice system.

The duration of a diversion program should be a function of clinical improvement rather than participation for a fixed period of time. If the objective of the diversion program is to reintegrate the accused back in to society once sufficiently stable, it does not seem logical to connect completion or "success" to a time line. The duration of time spent in the diversion program should naturally vary from individual to individual.

Counsel should be mandatory for all accused entering a diversion program. Given the problematic considerations of "capacity" to consent to assessment and treatment and the general issues of voluntariness, to some extent the court can take comfort when the accused is represented by counsel. For vulnerable accused, such as mentally disordered accused, the assignment of counsel is a layer of protection and comfort that should be included as a matter of routine.

The expectations of the diversion program should be explicitly stated. Of course, if an accused is to be a voluntary participant, it is imperative that the accused understand precisely what it is that he is agreeing to participate in. A very good practice adopted by some courts is the creation of a "contract" wherein the particulars of the diversion plan are clearly articulated and agreed to. This may serve a useful purpose in refreshing all party's memories as to what was agreed. Again, the agreement can be modified, as necessary, in that most rehabilitative programs are to a large extent a matter of trial and error. In addition to assisting the mentally disordered accused, clearly defined goals and objectives can provide focus for the service providers within the court.

Any jurisdiction contemplating a diversion program or mental health court should not see that as a singular or unidimensional response to the problem of mentally disordered individuals coming in to the criminal justice system. The need for a mental health court should often be seen as symptomatic of a "sick" civil mental healthcare system. A full review and overhaul of the civil mental healthcare system will also reduce the extent to which the mental health court will be relied upon as a principal delivery vehicle. It makes little sense to divert an accused back to a civil system that was not adequate in the first place. As well, it is apparent that precharge diversion and the identification of high-risk individuals may be preferable to postarrest diversion. Accordingly, mental health courts comprise only one response within a range of solutions. Optimally, these courts should simply form one part of a larger strategy; it is inappropriate to view mental health courts as a panacea to the range of problems that have given rise to the existence of these courts.

Every diversion program or mental health court should strive to include a plan for evaluation. A confluence of factors and barriers has served to

frustrate research into the functioning and efficacy of mental health courts. To counter this reality, it is important for mental health courts to be diligent in data collection and to collect data ranging from the volume of accused coming through the system to recidivism rates. Monitoring a program in a systematic way will provide useful information as to which components are efficacious and which ones are not.

A court-based diversion plan should incorporate as many community "partners" as possible. The success of a diversion program will inevitably be, in part, determined by how robustly the community is supporting the plan. In many ways the effectiveness of a mental health court can be predicted by the strength of the essential services found in the community. By having both forensic and nonforensic programs and community agencies in the diversion scheme, mental health courts will provide for a better transfer of the accused out of the criminal justice system and back in to the community.

All professionals participating in the diversion program or mental health court should receive specialized training. Training is an important aspect of a mental health court to ensure that participants are approaching the task of diversion from the same perspective, and having the same objectives ensures that the team will function more consistently. As an example, it is not uncommon for different factions within a mental health court to view "success" differently, such that the accused will be confronted with a confusing and frustrating set of expectations. Again, consistency and effectiveness require all mental health court staff to be fully apprised and "on the same page".

Trained judges, lawyers and prosecutors, clinicians, and other court personnel, are on the forefront of a new and challenging area of service provision and study. They are often in the best position to understand the complex relationship between mental disorder and criminality, and the plight of the mentally ill in the criminal justice system. Their knowledge and experience provides them with an opportunity to play a unique educative role within their own community, or other communities looking to put a mental health court in place.

Families and friends of the accused should be included in the diversion process to the greatest extent possible. Where possible, and where appropriate, mental health courts should strive to enlist the support of friends and family so that the accused will experience a consistently supportive environment within which he may progress. Individuals close to the accused can also be recruited as "therapists" and sources of information with respect to progress as well as relapse.

Upon completion of a diversion program a continuation of treatment and support in the community must be guaranteed. It is pointless to invest in a court-based diversion program only to have all the supports put in place withdrawn upon completion. Involvement with a mental health court should not lead to a dead end but hopefully should represent a bridge to the recipient of essential services on a going-forward basis. Again, this points to the desirability of having one universal mental healthcare system that supports all mentally disordered individuals regardless of whether they are presently before the courts.

Mental health courts should intervene at multiple junctures. It is submitted that a comprehensive mental health court should assist the accused at multiple junctures, not just "diversion". This view strikes as both obvious and inevitable in light of the various mental health concerns that often arise at any point from the inception to conclusion of a criminal prosecution. Commencing at the point of arrest, a specialty court can assist the mentally disordered accused with bail hearings, the assessment of fitness, treatment orders, keep-fit orders, uncomplicated criminal responsibility matters, disposition hearings, guilty pleas, and sentencing as well as the business of diversion. While diversions are typically focused on "outcomes", the mentally disordered accused has unique concerns at many junctures in the prosecution process which can be addressed by a mental health court.

End Notes

[a.] At the same time, some jurisdictions have a fixed 'program' of a fixed duration in which all candidates enroll. It is the author's view that individually fashioned regimens adjusted to the individual's particular needs are more likely to be successful.

Mental Retardation

Over the years, there have existed many definitions of mental retardation, each of which has been revised based on the new knowledge and/or the changing perceptions of scholars in the field (see Reference [1] for an overview). At present, there exist three primary definitions that have been put forth by the following organizations: (i) American Association on Intellectual and Developmental Disabilities (AAIDD, formerly the American Association on Mental Retardation (AAMR)), (ii) the American Psychiatric Association (APA), and (iii) the World Health Organization (WHO). There are similarities among the three definitions, but there are also differences that can result in different ways of portraying the disorder. In the following paragraphs, the reader is provided a glimpse into the construct of mental retardation as put forth by each organization; for a more comprehensive description, the reader is encouraged to consult the primary sources (see below for details) and current authoritative texts, such as Jacobson *et al.* [2] and Switzky and Greenspan [3].

American Association on Intellectual and Developmental Disabilities (AAIDD)

According to the AAIDD [4], mental retardation is defined as "disability characterized by significant limitations both in the intellectual functioning and in adaptive behavior as expressed in conceptual, social, and practical adaptive skills. This disability originates before the age of 18" (p. 8). The AAIDD does not identify any one measure of intelligence as necessary for diagnostic purposes, nor does it require the use of a particular measure of adaptive behavior. Instead, the organization states that the measures must be standardized using the general population and be appropriate for their intended use [1].

As noted in the manual, the following five assumptions are essential to the application of this definition.

1. Limitations in present functioning must be considered within the context of community environments typical of the individual's age peers and culture.
2. Valid assessment considers cultural and linguistic diversity as well as differences in communication, sensory, motor, and behavioral factors.
3. Within an individual, limitations often coexist with strengths.
4. An important purpose of describing limitations is to develop a profile of needed supports.
5. With appropriate personalized supports over a sustained period, the life functioning of the person with mental retardation generally will improve (p. 8).

American Psychiatric Association (APA)

Similar to the definition put forth by the AAIDD, in the Diagnostic and Statistical Manual, fourth edition, text revision (DSM-IV-TR) the APA conceptualizes mental retardation as a disability that is characterized by deficits in both the intellectual functioning and adaptive behavior that are manifest before the age of 18. Specifically, the diagnosis of mental retardation is made if all of the following criteria are met [5].

1. Significantly subaverage intellectual functioning; an intelligence quotient (IQ) of approximately 70 or below on an individually administered IQ test (for infants, a clinical judgment of significantly subaverage intellectual functioning).
2. Concurrent deficits or impairments in present adaptive functioning (i.e., the person's effectiveness in meeting the standards expected for his or her age by his or her cultural group) in at least two of the following areas: communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, and health and safety.
3. The onset is before the age 18 ([5]; p. 49).

A feature of the diagnosis that was dropped by the AAIDD but maintained by the APA is severity of impairment. Specifically, according to the APA, mental retardation falls along a continuum of severity. The four levels of severity identified by the APA are based on the measured IQ: (i) mild, (ii) moderate, (iii) severe, and (iv) profound. The diagnosis of mental retardation, severity unspecified may be applied when there is strong evidence to support the diagnosis, but the individual cannot be tested using a standardized measure of intelligence.

International Classification of Diseases (ICD; 10th Edition)

Unlike the definitions put forth by the AAIDD and the APA, the WHO provides only a description of the disorder and not the means by which to diagnose it [6]. As noted in the International Classification of Diseases (ICD)-10, mental retardation is

> . . . a condition of arrested or incomplete development of the mind, which is especially characterized by impairment of skills manifested during the developmental period, skills which contribute to the overall level of intelligence, i.e., cognitive, language, motor, and social abilities. Retardation can occur with or without any other mental or physical condition.
>
> Degrees of mental retardation are conventionally estimated by standardized intelligence tests. These can be supplemented by scales assessing social adaptation in a given environment. These measures provide an approximate indication of the degree of mental retardation. The diagnosis will also depend on the overall assessment of intellectual functioning by a skilled diagnostician.
>
> Intellectual abilities and social adaptation may change over time, and, however, poor, may improve as a result of training and rehabilitation. Diagnosis

should be based on the current levels of functioning (p. 369–370).

Similar to APA, ICD-10 describes mental retardation as a condition that falls along a continuum from mild to profound mental retardation based on the IQ score. Again, the ICD-10 does not provide specific information regarding how to diagnose the condition but instead provides a method by which mental retardation can be classified and traced via medical databases.

It is important to note that some experts in the field of mental retardation disagree with the way it is currently defined. For example, according to Greenspan and Switzky [7], "Mental retardation (MR) is an invented bureaucratic category, currently undergoing radical rethinking and likely renaming, that includes many biological-based brain disorders, but is itself determined through functional criteria (e.g., IQ below a certain level) that are purely arbitrary" (p. 19). Given the ever-changing models and definitions of intellectual disabilities, it is critical that individuals interested in mental retardation stay abreast of advancements in the field.

Etiology

Like many disorders, mental retardation does not have a single identifiable etiological factor. As described in the 2002 AAMR manual, the etiology of mental retardation is conceptualized as multifactorial and is composed of four broad categories of risk factors: (i) biomedical, (ii) social, (iii) behavioral, and (iv) educational. These four factors do not function in isolation, but instead are thought to interact across the life of the individual and across generations [4]. In fact, in each category there exist many distinct factors that can cause deficits in intellectual functioning. For instance, chromosomal disorders (e.g., Down syndrome), maternal illness, birth injury, and traumatic brain injury are all factors found in the biomedical domain. In the social domain are risk factors such as poverty, domestic violence, lack of adequate stimulation, and institutionalization. Maternal drug and alcohol use, parental smoking, parental rejection of the caretaking role, and social deprivation are examples of behavioral risk factors. Finally, parental intellectual ability, lack of preparation for parenthood, inadequate education services, and inadequate family support have been identified as educational risk factors.

In their review of epidemiological studies on the etiology of mental retardation, McLaren and Bryson [8] found that as many as 50% of the population of individuals diagnosed with mental retardation had more than one causal risk factor. It is important to note that the presence of any one risk factor, or perhaps even a combination of many risk factors, does not mean that an individual has mental retardation. The diagnosis of mental retardation requires observable impairments in functional abilities, regardless of etiology, and in about half of the cases of mental retardation, the etiology is not known [9]. It is important to be aware that the absence of an identifiable risk factor or etiology does not mean that an individual does not have mental retardation.

Assessment of Mental Retardation

The Intelligence Quotient. As is clear from the definitions of mental retardation, an individual's level of intellectual functioning must be established before a diagnosis can be made. To do this, an individual must be administered a standardized measure of intellectual functioning that provides an IQ. Although there are many tests of intelligence, the most commonly used, individually administered, and well-standardized tests are the *Wechsler Adult Intelligence Scale – Fourth Edition* [10] the *Wechsler Intelligence Scale for Children – Fourth Edition* [11], and the *Stanford-Binet Intelligence Scales – Fifth Edition* (SB5) [1]. For diagnostic purposes, the most important index of functional ability is the overall, or Full Scale, IQ.

The AAIDD and APA both require an IQ of approximately 70 or below for a diagnosis of mental retardation. A score of 70 places an individual approximately two standard deviations below the mean of the general population at the time the test was developed.[a] When accounting for standard error of measurement, this cutoff score may be as high as 75.

Adaptive Functioning. As previously noted, in addition to the IQ criterion, a diagnosis of mental retardation requires concomitant deficits in adaptive behavior. In brief, adaptive behaviors are everyday skills, such as walking, talking, grooming, cooking, cleaning, and participating in school or work. These abilities are learned over time in the context of one's home and community, and they represent

skills that are necessary to function within that context. It is important to emphasize that adaptive behaviors develop over the course of time and with experience, and thus individuals are evaluated against their same age peers. To measure adaptive skills, adaptive behavior scales have been developed and normed on individuals with and without intellectual disabilities. These scales require that an informant, typically a parent, teacher, or other individual who is very familiar with the individual's daily level of functioning, rate the person of interest on a variety of skills. For instance, the informant may rate the extent to which the individual follows directions or balances a checkbook along a continuum ranging from "Never Does or Can't Do" to "Always Does or Can Do Without Assistance".

For the diagnosis of mental retardation, the AAIDD definition requires that "significant limitations in adaptive behavior should be established through the use of standardized test measures normed on the general population, including people with disabilities and people without disabilities. On these standardized measures, significant limitations in adaptive behavior are operationally defined as performance that is at least two standard deviations below the mean on either (a) one of the following three types of adaptive behavior: conceptual, social, or practical, or (b) an overall score on a standardized measure of conceptual, social, and practical skills" ([4], p. 14). Like the AAIDD, the APA [5] recommends the use of standardized measures in the assessment of adaptive behavior. That said, it is well recognized that in some instances quantitative analysis of functional abilities is either inappropriate or does not provide enough information to make a determination. In addition to standardized, quantitative measures, both the AAIDD and the APA state that the final determination of mental retardation requires the use of multiple sources of information and clinical judgment.

There exist numerous scales of adaptive behavior that can be used for the purposes of diagnosis, classification, and planning for supports; no single measure is best for all the three. Examples of adaptive functioning scales commonly used in the assessment of mental retardation include the Scales of Independent Behavior – Revised Full Scale (SIB-R) [12], the *Adaptive Behavior Assessment System – Second Edition* (*ABAS-II*) [13], and the *Vineland Adaptive Behavior Scales – Second Edition* (*VABS-II*) [14]. It is important to note that, regardless of the measure chosen, the utility of the information obtained is limited by the quality of the information provided by the rater [4, 15].

Mental Retardation and Everyday Life

As previously mentioned, mental retardation is characterized by problems in everyday life or adaptive functioning and the extent of these difficulties varies with the severity of retardation. Difficulties in adaptive functioning may be evident in social, conceptual, and/or practical areas [4]. There exist many misconceptions about how to conceptualize adaptive behavior for diagnostic purposes. First, some believe that adaptive behavior is measured by estimates of abilities or potential, but it is the individual's actual performance that is important. Second, adaptive behavior is typical behavior that reflects an individual's ability to function on a day-to-day basis. It is not measured by isolated successes or failures. Third, adaptive behavior is performance in one's community, not in restricted settings, such as prison or therapeutic treatment programs. Fourth, the definition of mental retardation does not require that a cause of impairment be identified; diagnosis is determined by the presence of significant deficits in intellectual functioning and concomitant deficits in adaptive behavior that are evident before the age of 18.

As previously noted, there are hundreds of identified causes of mental retardation, but the cause for any individual is often not known. This is particularly true for individuals with IQs in the 60s who usually do not have a medical syndrome that is known and do not have an obviously different appearance or manner. For instance, people with mild mental retardation have significant limitations in achieving independence, but they have fewer difficulties and require less support or assistance than people with more severe levels of retardation.

With regard to support, it is typical for individuals with mild mental retardation to receive informal help from family members or neighbors, rather than from provider agencies, and it is quite likely that they have, or have had, gainful employment in jobs that require limited decision making or judgment. In most instances, individuals with mild mental retardation require support from others to manage money and make major life decisions. Few people

in this category require a legal guardian, and many marry and have meaningful social relationships. In fact, it is common for these individuals to be active participants in their communities, and as a result, they are vulnerable to exploitation by others. Further, it is more common for people with mild or perhaps moderate mental retardation to be engaged in criminal activity, than it is for those with more severe levels of impairment.

As the degree of mental retardation becomes more severe, the need for formal supports from an agency, such as a local mental health center or other provider, becomes greater. People with moderate or severe mental retardation are more likely to require supervision for most, if not all, of their day. As a result of this greater supervision and less personal freedom, they are less likely to be exploited in the community or to become involved in criminal activity. Nevertheless, these individuals are subject to exploitation, often by care providers. For instance, men may be exploited for their labor, or women may be exploited for sexual favors.

In contrast to individuals with mild mental retardation, individuals with more severe degrees of impairment are likely to have an identifiable medical or environmental cause for their retardation (e.g., Down syndrome and/or fetal alcohol syndrome) and to need specialized medical care. These individuals are also more likely to have serious behavior problems that require professional services. Problems of aggression, self-injury, self-stimulation, property destruction, and other disruptive behavior can limit individuals' opportunities for integrated community living. These problem behaviors are sometimes associated with mental illnesses that coexist with mental retardation [16].

Services and Supports

The services and supports available today are more varied and individualized than in the past; the following are just a few examples. The federal Individuals with Disabilities Education Improvement Act (IDEIA) of 2004, Public Law 108–446, mandates individualized services from birth to the age of 22. The Early Intervention Program for Infants and Toddlers with Disabilities (Part C) under IDEIA serves children from birth to the age of two. The IDEIA also mandates services and describes procedures for services during the school years through age 22. Students are provided an Individualized Education Program (IEP) and a transition plan to smooth the path from school to community living and work. Children and adults in the United States identified with mental retardation are eligible for Medicaid [17], which provides medical and a wide variety of other lifetime services.

In adulthood, many people with mild mental retardation are not identified by any service agency and, thus, receive only informal supports from family, neighbors, and employers. This is not surprising as these individuals show fewer deficits and demonstrate a higher level of skill in some of the more obvious areas of functioning (e.g., work, leisure, and social relationships). It is important to note that the majority of individuals with mental retardation, at all levels of functioning, reside with their parents or other family members throughout their lives. Residential care is typically reserved for more impaired individuals.

The most significant trend in services in recent years has been away from uniform programs that are designed to serve large numbers of people with disabilities and toward individualized services that reflect the desires and abilities of each person. People who receive formal services from a public or private provider agency typically participate in a person-centered planning process. The result is a written, person-centered plan (PCP) that describes the services and supports best suited to that individual. The plan typically includes residential, work, and personal living considerations for the individual, and it is reviewed and revised regularly. PCPs are characterized by emphasis on living in the most integrated setting that is appropriate to the person and honoring the choices of the person with regard to residence, work, social supports, health care, community participation, recreation, and other personal preferences.

Personal planning commonly occurs in the area of residential care. Over the past few decades, the emphasis has moved from "housing" individuals with mental retardation in large institutions, toward providing them with opportunities for more independent living with individualized services in smaller settings [18]. In keeping with one's PCP, the most appropriate residential option is chosen from a range that includes small group homes, supported apartments, semi-independent living, and home ownership. All of these models of residential services require trained staff members who provide individualized supports.

A significant challenge to fulfilling the ideal of individualized residential living is the need for direct support personnel who can provide varied individualized services, often around the clock.

With regard to employment, state vocational rehabilitation agencies assist people in obtaining competitive or supported employment. These services begin in adolescence with planning for transition from school to work. People with mild mental retardation typically have basic functional academic skills and do not have physical disabilities that would limit their work opportunities. These individuals often thrive in jobs that do not require abstract thinking or decision making. They may, however, require more supervision than the average worker, and they may require support in managing their money.

Individuals with moderate or severe mental retardation are often good candidates for supported employment. In this model, the worker has assistance in learning and in performing the job for as long as needed. In some instances, the assistant or job coach can be faded out as the worker becomes more independent. In other instances, the job coach may be needed permanently. As the severity of mental retardation increases, the individual is more likely to have significant motor limitations (e.g., cerebral palsy), significant health problems (e.g., seizure disorder), or significant communication problems that interfere with work and require more assistance and/or shorter work hours. Regardless of severity of disability, the trend in employment services in recent years has been toward competitive or supported employment in real community jobs and away from sheltered workshops and other work in isolated and separate settings.

The use of community services provides a final example of how individual planning or person-centered planning can be implemented for the betterment of the individual. Services and supports in a PCP may come from "natural supports", such as family members or neighbors, or from formal provider agencies. Medicaid largely dictates the rules for services for such agencies in the United States, and the sources of funding are typically a mix of Medicaid, state, and local government, private payers, and charity. The PCP is intended to support the greatest degree of personal independence that the person wishes and can achieve. This goal may be difficult to achieve, because many adults with mental retardation are socially isolated. Their natural support network is limited to their families and paid service providers. To expand the individual's social network, the PCP describes strategies to increase the individual's participation in meaningful activities each day. Adults with mental retardation have typically led very sedentary lifestyles, and the result has been prevalent obesity and associated health problems. The PCP is designed to prevent such problems through a healthy and active lifestyle that includes access to health care and emphasis on personal choice.

In summary, the construct of mental retardation is ever evolving. At the time of writing, the 11th edition of the AAIDD manual is underway and is likely to recommend changes in methods of assessment, methods of prevention, and the identification and implementation of needed supports. Though there is a new DSM under construction, it is unlikely that the two agencies will come together to create one conceptualization of mental retardation. Historically, the DSM has followed in the footsteps of AAIDD, and based on the timeline,[b] it is likely that the fifth version of the DSM will closely mirror AAIDD's 2002 conceptualization.

End Notes

[a.] In recent years it has been shown that IQ scores for the general population, as measured by the Wechsler scales, have been increasing by 0.3 points per year. This phenomenon has been termed the *Flynn effect* and has resulted in much debate regarding the accuracy of IQ scores over time and how best to interpret scores obtained on tests with outdated norms. The interested reader may want to refer to the following publications for a more detailed description of the phenomenon and the controversy surrounding it [19].

[b.] DSM-V is expected to be commercially available in 2011.

KAREN L. SALEKIN AND J. GREGORY OLLEY

Mental Retardation: Death Penalty

In 2002, the US Supreme Court held in a 6–3 decision in the landmark case of *Atkins v. Virginia* [1] that the execution of offenders with mental retardation violates the Eighth Amendment's prohibition against cruel and unusual punishments. The Court reversed its 5–4 decision 13 years earlier in *Penry v. Lynaugh* [2], which held that the Eighth Amendment's ban on cruel and unusual punishments did not categorically prohibit the execution of offenders with mental retardation.

The Court's holding in *Atkins* was based on several stems of reasoning, including public policy justifications in support of capital punishment and the extent to which they apply to individuals who have mental retardation [3]. The Court found that a "national consensus" had developed against the execution of individuals with mental retardation based on the fact that (i) many state legislatures had previously voted "overwhelmingly" in favor of the prohibition, (ii) there was a "complete absence" of states that had reinstated the death penalty for offenders with mental retardation, and (iii) the practice of executing offenders with mental retardation was uncommon, even in those states that allowed such executions.

In the 13 years between the *Penry* and *Atkins* decisions, only five states (i.e., Alabama, Louisiana, South Carolina, Texas, and Virginia) had carried out executions of offenders who were suspected to have mental retardation [1, 4], which was documented to be as many as 44 individuals [5]. The Court remarked that it was not the number of states that prohibited the practice that was significant, but it was the "consistency of the direction of change" that the Court found to be "powerful evidence that today our society views mentally retarded offenders as categorically less culpable than the average criminal". The Court also

considered opposition to such executions expressed by religious and professional organizations, disapproval by the world community, and polling data that showed a "widespread consensus" among Americans who were against such executions.

Citing the scientific literature extant at the time [6, 7], the Court noted that although those with mental retardation may be competent to stand trial and know the wrongfulness of their criminal acts, because of their impairments, "they have diminished capacities to understand and process information, to communicate, to abstract from mistakes and learn from experience, to engage in logical reasoning, to control impulses, and to understand reactions of others". Drawing on other research findings in the field [8, 9], the Court also noted that individuals with mental retardation "often act on impulse rather than pursuant to a premeditated plan, and that in group settings they are followers rather than leaders". The Court concluded that the deficiencies of those with mental retardation "do not warrant an exemption from criminal sanctions, but do diminish their personal culpability".

The Court also considered how the underlying justifications of the death penalty – retribution and deterrence – apply to offenders with mental retardation [3]. The Court reasoned that "the lesser culpability of the mentally retarded offender surely does not merit that form of retribution". Similarly, the Court recognized that because of their cognitive and behavioral impairments that render them less morally culpable, those with mental retardation are also less likely able to "process the information of the possibility of execution as a penalty and, as a result, control their conduct based upon that information." As such, the Court further noted, "Nor will exempting the mentally retarded from execution lessen the death penalty's deterrent effect with respect to offenders who are not mentally retarded."

Finally, the Court expressed concern that as a group, defendants with mental retardation "face a special risk of wrongful execution," not only because they may confess to crimes they did not commit [9] but also because of their lesser ability to provide defense counsel with meaningful assistance, their tendency to serve as poor witnesses, and their demeanor, which may create an erroneous impression that they lack remorse for their crimes.

Following the *Atkins* decision, courts in death penalty jurisdictions have begun to call upon mental health professionals to evaluate offenders in capital murder cases to assist the trier of fact in making a determination of mental retardation. Mental health professionals may be requested to render an expert opinion about mental retardation in so-called "*Atkins* hearings" at different stages of legal proceedings, which may occur pretrial, at the sentencing phase, or during postconviction appeals. However, the assessment of mental retardation in death penalty cases presents many challenges for forensic experts. In addition, the results of informal surveys of psychologists' professional practices in *Atkins* cases suggest great variability in the assessment methods used to diagnose mental retardation [10, 11].

A comprehensive review of the assessment of mental retardation in death penalty cases is beyond the scope of this chapter. The focus here is to (i) provide an overview of death penalty statutes on mental retardation in the United States, (ii) describe the contemporary definitions of mental retardation, (iii) discuss the diagnosis of mental retardation in death penalty cases, and (iv) review the available research on malingered mental retardation.

Death Penalty Statutes on Mental Retardation

Currently, there are 37 states, in addition to the federal government and the US military, which have the death penalty [12] (*see also* **Death Penalty and Age**). The 13 states that do not have the death penalty are Alaska, Hawaii, Iowa, Maine, Massachusetts, Michigan, Minnesota, New York, North Dakota, Rhode Island, Vermont, West Virginia, and Wisconsin. The District of Columbia also does not have the death penalty. At the time of *Penry*, only two states, Georgia and Maryland, had enacted laws that prohibited the execution of individuals with mental retardation. In the 13 years between *Penry* and *Atkins*, 16 other states enacted statutes barring such executions [1, 12]. The 18 states that had statutes that barred execution of those with mental retardation at the time of *Atkins* were Arizona, Arkansas, Colorado, Connecticut, Florida, Georgia, Indiana, Kansas, Kentucky, Maryland, Missouri, Nebraska, New Mexico, New York (except for murder by a prisoner), North Carolina, South Dakota, Tennessee, and Washington [12]. In 1988, when the Congress enacted legislation reinstating the federal death penalty, it excluded the execution of those with mental retardation [3].

After the *Atkins* ruling, eight more death penalty states revised their statutes to provide definitions of mental retardation. The states are California, Delaware, Idaho, Illinois, Louisiana, Nevada, Utah, and Virginia [12]. Because the *Atkins* Court provided little guidance to the states on how to develop rules to determine which offenders have mental retardation, there is significant variability across these pre- and post-*Atkins* state statutes. Twelve death penalty states apparently have yet to develop statutes for determining mental retardation in *Atkins* cases: Alabama, Mississippi, Montana, New Hampshire, New Jersey, Ohio, Oregon, Oklahoma, Pennsylvania, South Carolina, Texas, and Wyoming. Although some of these states have statutes that define mental retardation for the purpose of civil commitment and/or guardianship, it is unclear how these statutes may apply in *Atkins* cases. Other states, such as Mississippi, have adopted the *Atkins* decision in case law [13].

Definitions of Mental Retardation

Mental retardation has been defined by professional organizations in the field (*see also* **Mental Retardation**). The American Association on Intellectual and Developmental Disabilities (AAIDD) (formerly the American Association on Mental Retardation (AAMR)) has published four major versions of its definition since 1961. The 2002 version is the most recent. The American Psychiatric Association (APA) has also published four major versions of its *Diagnostic and Statistical Manual of Mental Disorders*. The 2000 version (*DSM-IV-TR*) [14] is the most recent.

Many state legislatures enacted statutes based on the 1983 American Association on Mental Deficiency (former name for AAMR) definition of mental retardation [3]: "Mental retardation refers to significantly subaverage general intellectual functioning existing concurrently with deficits in adaptive behavior and manifested during the developmental period" [15]. In 1992, the AAMR revised its definition with an emphasis on refining the adaptive functioning component of the previous version:

> Mental retardation refers to substantial limitations in present functioning. It is characterized by significantly subaverage intellectual functioning, existing concurrently with related limitations in two or more of the following applicable adaptive skill areas: communication, self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure, and work. Mental retardation manifests before age 18 [16].

The 1992 AAMR definition was one of the definitions cited in *Atkins* and was adopted by several state legislatures in the 1990s [3]. However, it has been criticized for lacking empirical research support and theoretical grounding [17]. The APA's current definition in the *DSM-IV-TR* [14] contains language similar to the 1992 AAMR definition and also was one of the definitions cited in *Atkins*. The AAMR revised its definition in 2002 [18] and this version also focuses on describing adaptive functioning: "Mental retardation is a disability characterized by significant limitations both in intellectual functioning and in adaptive behavior as expressed in conceptual, social, and practical adaptive skills. This disability originates before age 18." Ellis [3] has suggested that the 2002 AAMR definition is most appropriate, because it contains the three essential components of all definitions cited in the *Atkins* decision. The 2002 AAMR definition also has been described as being more consistent with contemporary thinking and research on the assessment of adaptive behavior [19].

Diagnosis of Mental Retardation in Death Penalty Cases

Regardless of which definition is used to diagnose mental retardation, it is essential that the assessment methods used are consistent with the standards of professional practice [3, 20], particularly in capital murder cases, because there is no other assessment in which the stakes are higher. Because the population of individuals with mental retardation consists mostly of those who function in the mild range of impairment [14] and their impairments are often not immediately observable, accurate diagnosis for this subpopulation is difficult [19]. Some commentators [21, 22] have suggested that misdiagnosis may stem from a lack of understanding of the definition of mental retardation and failure to properly assess each diagnostic criterion.

Despite differences across the definitions of mental retardation, all have three common clinical components: (i) significant deficits in intellectual functioning; (ii) related deficits in adaptive functioning; and (iii) manifestation of deficits during the developmental period.

Intellectual Functioning

Current definitions of mental retardation require that an individual demonstrate significant limitations in intellectual functioning as measured by standardized psychometric instruments [14, 18]. This is operationally defined in the *DSM-IV-TR* [14] definition as an intelligence quotient (IQ) score of ~70 or below, or two standard deviations below the statistical mean. Because of the measurement error associated with intelligence test scores (±5 points), it is possible to diagnose mental retardation based on an IQ score of 75 or below [14].

There are three individually administered intelligence tests that are generally accepted measures of mental retardation for adults. They are the *Wechsler Adult Intelligence Scale – Fourth Edition* (*WAIS-IV*) [23]; the *Stanford-Binet Intelligence Scale – Fifth Edition* (*SB-5*) [24]; and the *Kaufman Adolescent and Adult Intelligence Test* (*KAAIT*) [25]. Group-administered intelligence tests, such as the *Revised Beta* [26], have been widely used as screening tests in correctional facilities [21, 27]. However, only global measures of intelligence are appropriate for diagnosing mental retardation [19] and are considered by many practitioners as the "gold standard" in assessments of mental retardation in death penalty cases [10].

The interpretation of IQ scores depends heavily upon the examiner's clinical judgment. Factors related to the examinee's behavior during the testing process, such as fatigue, effort, motivation, and attempts to malinger intellectual deficits can threaten the validity of scores. In addition, practice effects can be caused by repeated administrations of the same intelligence test in a short period. This problem may occur frequently in *Atkins* proceedings in which multiple experts administer the same intelligence test to offenders within a relatively brief timeframe. It is not uncommon to find differences in an individual's IQ scores over time. Such differences in IQ scores may occur on multiple administrations of the same test, scores on different editions of the same test, and scores on different tests [27].

Comparisons of IQ scores also can be misleading because of the "Flynn effect", which means there is a tendency for IQ scores to increase in the general population over time [28–30]. Thus, an individual's IQ may be artificially increased as a function of when the intelligence test was administered. The Flynn effect has become a topic of much debate, particularly with regard to the practice of adjusting individual IQ scores in capital cases. Some authors [31–34] have advocated modifying individual test scores to correct for the Flynn effect. Others [35] have argued that such modification of individual IQ scores is not an accepted professional practice. Harcourt Assessment, the publisher of the Wechsler tests, does not endorse the recommendation to modify *WAIS-III* scores to account for the Flynn effect [36].

Adaptive Functioning

The *adaptive behavior prong of the diagnosis of mental retardation* suggests that intellectual deficits are accompanied by real-world disabling effects on an individual's functioning [3]. Adaptive behavior has been described as the most problematic part of the definition of mental retardation [19] and may also be the least understood [37]. Some psychologists and legal professionals tend to view adaptive behavior only in terms of practical daily living skills. However, for those who function in the mild range of mental retardation, deficits are more likely to exist in the areas of social and conceptual skills [19].

Several standardized instruments have been developed to assess adaptive behavior, such as the *Vineland Adaptive Behavior Scales II* (*VABS II*) [38], *Adaptive Behavior Assessment System – Second Edition* (*ABAS-II*) [39], and the *Scales of Independent Behavior – Revised* (*SIB-R*) [40], each of which has been normed on the general population including those with intellectual disabilities. Although these instruments are commonly used in the field, they have been criticized for inadequately assessing the constructs of gullibility and naiveté, which are common characteristics of individuals with mental retardation [41]. Some experts occasionally use the *Street Survival Skills Questionnaire* (*SSSQ*) [42] in death penalty cases to assess defendants' adaptive functioning [10]. The *SSSQ* has been criticized [19] as an inappropriate measure of adaptive deficits because it is a test of knowledge, rather than performance, and it emphasizes practical skills and not conceptual or social skills.

Most adaptive behavior scales are intended to measure an individual's current functioning in the community. This creates methodological problems for assessments of adaptive functioning with incarcerated populations, particularly those who have been on

death row for many years. In such cases, the examiner must perform a retrospective assessment of adaptive functioning. However, concerns exist regarding the validity of retrospective assessments of adaptive behavior [43]. Some authors [44] have called for the development of a "penologically normed" instrument to assess adaptive functioning for incarcerated populations. To date, there is no such instrument available, and information about an inmate's prison behavior normed on other inmates would not contribute to a valid diagnosis of mental retardation. Because there is no perfect method to retrospectively assess adaptive behavior, experts must rely on a mixture of imperfect information and clinical judgment [19].

Age of Onset

The "third" component of all definitions of mental retardation requires that the disability be manifested during the developmental period [14, 18]. Many states have defined this as prior to age 18, although some states have extended the age to 22 [3, 12]. This prong of the definition distinguishes mental retardation from other disabilities that may occur later in life, such as traumatic brain injury and dementia, and it also helps to identify defendants in death penalty cases who may attempt to feign mental retardation [3, 45].

Malingered Mental Retardation

In his dissenting opinion in *Atkins* [1], Justice Scalia expressed concern about the possibility that individuals can "readily feign" mental retardation. This issue also has been raised in Mississippi case law, which has explicitly addressed the need for assessments of malingering in *Atkins* claims. In *Foster v. State* [46], the Mississippi Supreme Court required the use of the *Minnesota Multiphasic Personality Inventory-2* (*MMPI-2*) [47] to assess malingering in *Atkins* cases. However, the *MMPI-2* was designed to identify malingered mental illness, not mental retardation. It also has been criticized as an invalid measure of malingering for those with mental retardation because of its required eighth grade reading level [48]. Nevertheless, great pressure has been placed upon psychologists to assess malingering in *Atkins* cases (*see also* **Malingering: Forensic Evaluations**).

Malingered Cognitive Deficits

Few studies have investigated the validity of malingering measures for those with mental retardation. The studies that are available have produced mixed results. In a study by Hurley and Deal [49] using a sample of individuals with IQ scores between 50 and 78, subjects were administered four measures of malingering, which included one that assesses feigned psychiatric disorders, the *Structured Interview of Reported Symptoms* (*SIRS*) [50], and three measures of malingered memory: the *Test of Memory Malingering* (*TOMM*) [51], the *Rey 15-Item Memory Test* [52], and the *Rey Dot Counting Test* (*RDCT*) [53]. The findings did not support the use of three of the four measures with a population with mental retardation. The authors recommended that one (*RDCT*) undergo further evaluation for its effectiveness as a screening measure. On the other hand, a study by Simon [54] with a sample of 21 adjudicated forensic inpatients with comorbid Axis I disorders and mental retardation supported the use of the *TOMM* [51] for assessing malingering with individuals with mental retardation.

Goldberg and Miller [55] administered the *Rey-15 Item Memory Test* [52] to individuals with severe psychiatric disorders and those with mental retardation. Although the cut scores worked well for the psychiatric patients, they were ineffective for those with mental retardation. Similarly, Hayes *et al.* [56] administered three measures of malingering, including the *Rey 15 Item Memory Test* [52], the *M-Test* [57], and the *Rey Dot Counting Test* [53] to 38 subjects in a maximum-security forensic hospital who had been diagnosed with mental retardation. On the basis of the results, the researchers concluded that the battery of tests contributed nothing to the identification of malingering in defendants with mental retardation. Conversely, Schretlen and Arkowitz [58] used a combination of measures, including validity scales of the *MMPI-2* [47], two scores on the *Bender Gestalt* [59], and an experimental measure to identify individuals feigning insanity or mental retardation. The researchers found that the combination of measures accurately identified most of the subjects who feigned mental retardation.

Although several more recent studies investigating the use of effort measures with populations of persons with mental retardation have been published in the last year, these studied also have produced rather mixed results [60–62].

Malingered Adaptive Deficits

To date, only one study has investigated the susceptibility of measures of adaptive behavior to malingered responding. Doane and Salekin [63] investigated whether collateral informants could feign adaptive deficits on the *ABAS-II* [39] and the *SIB-R* [40] within the context of a death penalty case. The results indicated that both measures were susceptible to feigning by collateral informants. The *ABAS-II* was extremely vulnerable to exaggeration of deficits, and this response style was not easily detected. Subjects were not as adept at feigning mental retardation on the *SIB-R*, and the response style was easily detected.

In summary, few studies have investigated the validity of assessments of malingered mental retardation, especially malingered adaptive deficits. Similarly, most instruments designed to detect malingered cognitive deficits lack normative data for populations who have mental retardation and have not been validated for the purpose of detecting malingered mental retardation. Therefore, concerns regarding false positives exist with such instruments, because individuals with mental retardation may produce scores suggestive of malingering when they are not. Further research is needed to determine how to appropriately assess both malingered adaptive skills and feigned intellectual deficits in populations with mental retardation.

Conclusion

In light of the US Supreme Court's decision in *Atkins v. Virginia* [1], courts in death penalty jurisdictions are faced with the challenge of determining whether offenders in capital murder cases have mental retardation. Bonnie [64] observed that one of the "striking aspects" of the Court's decision in *Atkins* is that the constitutional prohibition against the execution of offenders with mental retardation is framed in the language of a "clinical diagnosis". Thus, expert opinions by mental health professionals play a critical role in the legal determination of mental retardation in *Atkins* cases, because the court's decision may depend heavily on an expert's diagnosis.

Standards that govern the admissibility of scientific evidence [65] not only require that forensic experts' methodology be generally accepted in the field, but expert opinions also must be based on knowledge, skill, experience, training, and education. However, few mental health professionals have extensive training in both forensic evaluation and mental retardation [66]. In addition, the mandates of some *Atkins* statutes defy principles of psychological assessment and can create ethical dilemmas for psychologists who serve in the role of experts in such cases [67].

In 2005, Division 33 of the American Psychological Association (Mental Retardation and Developmental Disabilities) formed an *Ad Hoc* Committee [68] to identify issues related to mental retardation and the death penalty and to clarify psychologists' role in *Atkins* proceedings. Several seminal articles have since been published that describe the controversies surrounding assessments in *Atkins* cases and provide recommendations for best practice [66, 69, 70]. Experts in the fields of forensic evaluation and mental retardation must continue working together to ensure that assessments of mental retardation in death penalty cases meet the highest standard of professional practice, as the outcome of these evaluations is literally a matter of life or death.

Mental Status: Examination

Introduction

No complex activity can be studied without good bookkeeping. Yet even the best system demands adequate judgment and individual initiative.
–Adolf Meyer "Motto" [1]

The Mental Status Examination (MSE) refers to the structured reporting of information systematically obtained by the clinician regarding an individual's mental state at the time of the interview. The MSE is usually presented as a separate section of the evaluation, distinct from the individual's biographical history or anamnesis (childhood, education, employment, relationships, and other history) and distinct from information regarding past psychiatric history, substance abuse, and history of medical illness. The MSE summarizes findings that are obtained through systematic assessment at the time of the interview. The examiner may rely upon direct observation as well as the individual's spontaneous statements, responses to inquiry regarding present symptoms and responses to specific test questions (of cognitive function, for example).

Historical Background of the Mental Status Examination

Although the format of the MSE was codified by the Swiss-American psychiatrist Adolf Meyer in 1902 [1, 2] in a privately printed pamphlet, some treatises from the nineteenth century present case reports or vignettes by describing the patient's symptomatology and findings on examination in a structured manner, using the categories that comprise the MSE as we know it today. As recently as the 1960 s, psychiatrists debated the value of the MSE, leading up to studies of the reliability of findings on different elements of the MSE. Today, in the English-speaking world, the usefulness of the MSE is accepted by consensus and it is taught as a standard part of the training of psychologists and psychiatrists.

Purposes of the Mental Status Examination

The primary purpose of performing a MSE is to aid in establishing a diagnosis of the individual's current state. This may include the determination of acute symptomatology in the context of longstanding illness as well as the assessment of the individual's risk of imminent harm to himself or others. Although the MSE is generally performed the most thoroughly by mental health professionals, the MSE is relevant in medical specialties other than psychiatry, because a patient's mental state may have bearing on the reliability of information given in the subjective account of his or her history, medical or otherwise ([3], pp. 5–6).

The aim of the MSE as recorded in a clinical treatment note or a forensic report is to communicate information to a reader. The MSE can be viewed as analogous to the physical examination, in that it provides a structured assessment of the person's present condition and a coherent, organized presentation of the data. A psychiatrist may make use of the MSE to remind herself on a future office visit of how the patient appeared the time before. A doctor on call may refer to the MSE to determine whether a patient was stable earlier in the day; he will then record his own examination along with the details of his management of the situation, so that the patient's psychiatrist will know the details of the patient's condition overnight.

In the forensic setting, a MSE conveys the evaluee's mental state at the time of the examination and thereby provides a context and support for the expert's findings in the evaluation. In an assessment of Competence to Stand Trial, for example, the recording of the defendant's present mental condition allows the expert to refer back to these elements in the writing of her opinion. In adversarial proceedings, the MSE allows the trier of fact to assess whether differences in expert opinion may be in part explained by differences in mental state at separate points in time.

Conducting the Mental Status Examination

Similarities Between the MSE in Clinical Treatment and Forensic Settings

Both types of interview require clinical skill in order to obtain the necessary information to complete an assessment. Information pertaining to the MSE is obtained in the context of a larger interview process that includes the history of past psychological symptoms, treatment, and personal history. Although clinicians view the MSE as a specific examination that takes place during a particular portion of the interview (usually after the individual's account of her history and pertinent background information) the clinician obtains data that contribute to the MSE throughout the entire face-to-face contact time with the person being evaluated. Development of rapport is important as is tact and a nonjudgmental attitude, as the interviewee may be reluctant to speak about symptoms such as hallucinations, delusions,

fears, or suicidal ideas (SI). The clinician should also be attentive to his own potential bias or his personal reactions to the individual, which may lead to avoidance of necessary exploration of the interviewee's responses to questions.

Differences Between the MSE in Clinical Treatment and Forensic Settings

Clinical treatment interviews and forensic evaluations serve different purposes, and the MSE is partly shaped by elements specific to each context. A succinct summary of the major differences between treatment interviews and forensic interviews may be found in Melton *et al.* [4] The differences most pertinent to the MSE *per se* concern the examiner's attitude and the degree of validity of the interviewee's self-report in forensic settings. These are addressed briefly below:

Confidentiality. Unlike the treatment interview, a forensic interview is likely to result in a written report to a legal entity (attorney, court, or administrative agency) responsible for deciding an issue that has required clarification by an expert. Despite the nonconfidentiality warning given at the beginning of the interview, the examiner's necessary use of clinical interviewing skills may put the evaluee at ease, leading the evaluee to have the impression that the examiner is in a helping role. This may encourage the individual to reveal information about current symptoms that he may later realize is not in his best interest. On the contrary, some evaluees are acutely aware of the nonconfidential nature of the content of the MSE and may purposefully or unintentionally misrepresent, distort or falsify their responses to the examiner's questions, or withhold information (*see* **Malingering: Forensic Evaluations**). One of the ethical challenges of forensic practice involves the task of maintaining an appropriate balance between scepticism and neutrality, on the one hand, and empathy and tact on the other.

Therapeutic Versus Medicolegal Aims. Related to the issue of malingering is the awareness on the part of both examiner and evaluee of the legal questions that form the backdrop and purpose of the interview. Unlike the treatment interview, with its emphasis on therapeutic aims and problem solving in the patient's current circumstances, the MSE in a forensic interview contributes to forming an opinion on a legal issue. Additionally, the forensic question posed to the evaluator sometimes entails an assessment of cause and effect, further changing the role of the MSE. An evaluee may believe that it is in his best interest to exaggerate symptoms reported in the MSE, because he is asserting emotional damages in a tort claim. Or an evaluee may seek to give the impression of having few if any pathological symptoms at present in order to support a claim in favor of fitness for return to work.

Categories of the Mental Status Examination

An essential feature of the MSE is its systematic nature. The clinician may observe a number of elements important in the MSE during the subjective, narrative portion of the interview, while the interviewee is giving an account of his past history and the issues leading up to the request for evaluation, either with the aim of treatment or for legal purposes. Nevertheless, the systematic organization of the MSE allows the examiner to review the major components of the individual's current mental state in a more thorough fashion, and helps to avoid the omission of questions regarding significant areas of mental functioning that would otherwise not be formally assessed.

Table 1 represents the major categories of the MSE, which are usually assessed by most clinicians in the English-speaking community. We define in broad outline the meanings of the technical terms that describe these categories, referring the reader to more comprehensive, detailed treatises which are available [3, 5].

The panoply of tests and possible questions that a clinician may use to assess elements of each of the categories described in Table 1 is wide, and each examiner has his preferences. There is no standardized set of tests and questions for performing the MSE, though, as stated above, consensus exists regarding the areas of mental functioning that should be included.

A Note on the Mini Mental State Examination

Although a number of the tests used to assess items on the cognitive portion of the MSE overlap with or

Table 1 Main categories of the mental status examination

Appearance, attitude, and behavior	This section of the report includes description of the individual's physical appearance (clothing, tattoos, or piercing), hygiene and physical movement (such as tics, visible side effects of medications, agitation, or slowness). The individual's degree of cooperation with the interview and his interaction style may also be noted.
Mood and affect	Mood refers to the person's description of her general emotional state (e.g., sad, happy, or nervous) and may be reported as a direct quote. Affect refers to the clinician's observation of the outward emotional expression, including the appearance of sadness or elation, range and variability of expression, and the appropriateness of emotions in relation to the content of the individual's speech.
Speech and language	A person's speech may be described on the basis of ease of flow, spontaneity, rate, and volume. The examiner may also comment on whether the individual is difficult to interrupt or speaks as though under pressure. Included here are comments on speech and language abnormalities, such as stuttering, slurring, or use of invented words.
Thought process and content	Thought process refers to the flow of ideas and whether the thinking is disjointed or coherent. The examiner may note whether the individual has a tendency to give answers in a circuitous manner or tends to express vaguely associated thoughts without coming back to the topic at hand. Thought content refers to the person's preoccupations, obsessions or delusions, as well as nondelusional paranoid or grandiose ideas. This section also includes the presence or absence of suicidal and homicidal ideas.
Perception	The presence or absence of perceptual abnormalities is noted here and may include hallucinations (when the individual reports a perception involving one of the five senses, in the absence of real stimuli) or illusions (when a true stimulus is misinterpreted or distorted).
Cognition	This section includes the person's level of consciousness (awake, alert, or sleepy), assessment of immediate and short-term memory, concentration and ability for abstract thinking. The individual's awareness of current events and general knowledge is also reported here.
Insight and judgment	Insight refers to the individual's understanding of his condition. The term is primarily used to describe his awareness and acceptance of having a psychiatric disorder, though it may also be used to indicate awareness of his legal situation. Judgement refers to the person's ability to use logical reasoning to respond to situations, and is often formally tested through hypothetical scenarios as well as assessed through observation of recent behavior and responses in the interview.

are identical to items on the rating scale known as the *Mini Mental State Examination* (*MMSE*), these two evaluations should not be confused. The MMSE was devised by Folstein *et al.* in 1975 [6] as a means of providing rapid and clinically feasible assessment of whether an individual may be suffering from an organic brain disorder. The MMSE is scored on a scale of a maximum of 30 points, and provides an impression as to whether further formal testing is required. It does not assess the noncognitive areas covered in the MSE. The full MMSE is not considered to be an inherent part of the MSE, though some clinicians may choose to perform it routinely in each evaluation by personal preference.

The Mental Status Examination in Medical Records

In the recording of a MSE in the medical record, the examiner usually assumes that any reader has the

same level of technical knowledge as the examiner himself. The writer often uses commonly accepted abbreviations (AH for auditory hallucinations, SI for suicidal ideas) and frequently does not write in complete sentences (Affect – constricted, inappropriate).

The level of detail included in the MSE varies according to the clinician's familiarity with the patient and according to the findings that may bear emphasis when a record is being created to communicate with other practitioners. Upon first contact in the outpatient setting, or at the time of admission, the MSE is recorded in detail. At subsequent outpatient follow-up visits or on subsequent evaluations in the hospital, an MSE may cover very briefly those portions of the examination that are unremarkable or unchanged. A change in clinical condition, or emergency coverage, on call for example, may stimulate the examiner to record greater detail. In general, the majority of clinicians comment on each of the main categories of the MSE in the record following any assessment of the patient. It is common practice to remark on the presence or absence of suicidal or homicidal ideas during the interview in making a record of each contact with the patient.

It is important to keep in mind that although mental health professionals tend to be aware that what they write in the medical record may someday appear in court, legal proceedings are not the main purpose of the medical record. An attorney should not attempt to interpret abbreviations, scrawls, and shorthand that are rife in the medical record without the assistance of a medical expert. Although this may seem obvious, the point also extends to the gathering of data, in that attorneys should not attempt to sort and select medical records, which are often obtained from multiple sources and can be voluminous, prior to forwarding the material to an expert for technical assessment. A set of documents that is as complete as possible – and as legible as possible (i.e., sufficiently dark photocopies) – is indispensable to the expert in formulating an opinion.

The Mental Status Examination in Forensic Reports

The recording of the MSE in the context of legal proceedings follows guidelines for all forensic reports: technical terms must be "translated" into language comprehensible to a lay reader remaining all the while coherent for assessment by another forensic examiner who may be called upon to comment on the findings. Because the MSE represents one of the most highly technical parts of the forensic report, the task of translation into lay language poses particular challenges. Descriptions should be sufficiently detailed so as to evoke for the reader a mental impression of the state of the individual at the time of evaluation. In the case of positive (abnormal) findings or findings that differ from prior descriptions of the person, examples are useful.

An MSE should be performed at each meeting with the evaluee, though repetition of the cognitive examination is usually unnecessary unless there are intervening factors between interviews (e.g., changes in medication, or an observed difference in performance in the interview). This MSE should be recorded for each interview date, in order to convey the consistency or lack thereof in the individual's mental state overtime. If the evaluee is seen on three occasions, the examiner should comment on the MSE on each of the three dates, briefly if there is no significant change, and at greater length if there are major differences.

The narrative description of the MSE in a forensic report should follow the same outline, including the same categories as that of the clinical MSE. This ensures that another clinical examiner, hired by the opposing side or brought into the case at a later point by the same attorney, is able to follow a predictable sequence familiar to all clinicians.

The writing of the MSE is also an occasion for the examiner to identify the evidence that will be included to support the determination of a diagnosis and opinion. The MSE is a chance for the examiner to systematically assess the evidence that is present at the time of the interview, in reference to the legal questions on which he has been asked to opine.

Is the Mental Status Examination "Objective"?

> *The river where you set your foot just now is gone – those waters giving way to this, now this.*
>
> *– Heraclitus, "Fragments"* [7]

We stated earlier that the MSE is analogous to the physical examination in other branches of medicine. However, psychiatric symptoms are in general more

apt to vary between evaluations than physical findings such as a tumor or a broken bone. More so than in general medicine, findings on the psychiatric examination may vary between examiners and at different points in time. This is relevant in legal proceedings, where discrepant expert opinions are subject to comparison and cross-examination.

In a 1961 article, Rosenzweig *et al.* presented findings from a study of the agreement between evaluators and consistency over time in findings on the MSE. They found that "while reliability (agreement) was not significantly influenced by individual bias in interpretation of concepts or by individual capacity to make observations it was significantly influenced by individual differences in interviewing technique" ([8], p. 1107). This suggests that if examiners are observing the same phenomenon, they are likely to record it in a similar manner, but that those elements of the MSE that require the examiner to elicit specific responses are susceptible to greater variation, depending upon the interviewer's focus and approach in asking questions.

Numerous factors may influence the result of the MSE, including the interviewee's degree of fatigue or willingness to be forthcoming, the examiner's interview style and technique, the setting where the interview occurs, etc. The evaluee's mental condition is subject to change over time, due to worsening or improvement of his mental illness, the effects of medication and the presence or absence of life stressors. The MSE is an assessment of present mental state and to some extent, differing expert opinions may reflect differing data at the time of evaluation. Nevertheless, as Ross and Leichner point out, "[t]he MSE is one of the tightest areas of clinical psychiatry, and its assessment is reliable both when the assesor's responses are restricted to highly discrete, operationalized items and in global, qualitative assessment" ([9], p. 111) even where the examiners' vocabulary in the description of details vary.

Conclusion

The MSE is a useful means of organizing clinical data concerning an individual's mental condition at the time of examination. The MSE refers to a particular time in the clinical interview when present state information is reviewed in a systematic manner, as well as to the written recording of this information, along with other observations obtained during face-to-face contact with the patient or forensic evaluee.

Microchemistry

Microchemistry, also known as *chemical microscopy*, was defined by Emile Chamot in elementary chemical microscopy as, "the application of the microscope to the solution of chemical problems". He also explained that microchemistry is chemistry on a small scale. The American microchemist, Benedetti-Pichler, defined microchemistry as the development, correlation, and systematization of the methods for handling small quantities of material, and for the observation of their properties. The scientific discipline of microchemistry has a rich and storied history going back to Pliny (23–79 AD), who describes an iron sulfate test. Microchemistry has been practiced for over 180 years, long before the development of instrumental methods. Microchemical tests provide a rapid and inexpensive way to obtain chemical data from microscopic size particles. Many rather simple tests have been developed to qualitatively analyze cations, anions, and functional groups. Francois-Vincent Raspail (1794–1878) is often recognized as the founder of chemical microscopy and the first true microchemist. In 1827, Raspail published results of his work on silica in Spongilla and calcium oxalate in the starch of monocotyledons. It is within this publication that he introduces the term *chemical microscopy*. Friedrich Emich (1860–1940) and Fritz Pregl (1860–1930) from the Technical University of Graz, Austria were the preeminent microchemists in Europe. The earliest complete book dealing with microchemistry was from an American, Theodore G. Wormley, The Microchemistry of Poisons, in 1867. There are many other exceptional scientists that have advanced chemical microscopy, an incomplete list of these individuals include E. Boricky, A. Streng, K. Haushofer, C. Klement, A. Renard, H. Behrens, A.C. Hutsse, C. Hinrichs, N. Schoorl, J. Donau, P.D.C. Kley, O. Tunmann, H. Molisch, C.W. Mason, L. Rosenthaler, L. Kofler, A. Kofler, F. Schneider, W. McCrone, H. Schaeffer, H. Keune, C. Fulton, E. Jungreis, Palenik, S., and J. Delly [1].

Practicing scientists working in chemistry, microanalysis, and serology can rely on many sources of literature in microchemistry. The classic texts by E.M. Chamot and C. W. Mason, Volumes 1 and 2, the Handbook of Chemical Microscopy [2] are essential. They were originally published in 1930–1931, and have gone through several editions and reprints. C. Fulton's Modern Microcrystal Test for Drugs [3] is a usefully text employed in drug identification. E. Jungreis' book, Spot Test Analysis, defines tests for clinical, environmental, forensic, and geochemical applications [4]. A large volume of periodical literature is available. There are three journals devoted to microchemistry: Mikrochemie (1923–1952), Mikrochimica Acta (1953-), and the Microchemical Journal (1957-). The Microscope (1937-) is an excellent source of literature on microchemistry, such as J. Hollifield's 2003 article, "Characterization of Squaric Acid Precipitates" [5] and T. Hopen and J. Kilbourn's article "Characterization and Identification of Water-Soluble Explosives" [6]. Many useful microchemical tests and spot tests have been developed over the years and incorporated into books, articles, and manuals in areas as diverse as paper and textile fiber analysis, explosives, drug chemistry, and food microscopy (*see* **Explosion Debris: Laboratory Analysis of**). Spot tests are color or precipitate reactions resulting from mixing an unknown and a test reagent on a ceramic or glass plate having a series of depressions (a spot plate). The fifth edition of the *Merck Index* describes over 4510 named reactions [7].

Long before the advent of instrumental chemical analysis "chemical microscopes" were employed to critically examine and identify materials in the physical world. These microscopes were based upon the petrographic microscope (used in the examination of mineralogical specimens) design first developed by Henry Fox Talbot in the 1840s. The microscope was equipped with Nicol prisms that polarized light. A circular rotating stage with a Vernier scale was employed to measure crystallographic angles. These microscopes are essentially the same type used today, referred to as *polarized light microscopes* (*PLM*), and are used in all modern forensic laboratories around the world (*see* **Microscopy: Low Power**; **Microscopy: High Power**). For most observations, a 10× objective and a 10× ocular, giving a total magnification of 100× is adequate. Occasionally, a 40× objective may be used giving a total magnification

of 400×. Scientists must have a good foundation in the basic principles of polarized light microscopy to understand what they are looking at and the terminology used to describe the crystals. Even no reactions or the formation of a precipitate but no crystals tell something about the material being tested.

Other equipment useful in microchemical testing include known chemically pure reagents, a small glass rod with a 3–4-mm smooth tip, glass or porcelain spot plates, disposable capillary pipettes, microscope slides, and spatulas [8].

Microchemical tests, also known as *microcrystal tests*, are used in both organic and inorganic characterization and identification of unknowns. E. G. C. Clarke states, in Isolation and Identification of Drugs [9], the value of crystal tests: "The microcrystal test is unsuitable as a primary method of identification of an unknown compound, as it does not lend itself to form the basis of an identification scheme. Its real value is as a means of final identification to confirm a provisional diagnosis made from chromatographic or spectrometric evidence, its extreme simplicity, the rapidity of which may be performed, and its high degree of specificity, rendering it ideal for this purpose". When properly performed, microcrystal testing is a useful tool for the analytical chemist. As with any other analytical tool it has its advantages and limitations. It is fast, requires very little sample, is often nondestructive (in that the tested material can be recovered), can distinguish among the isomers of some compounds, and, for many compounds, is highly specific. Some disadvantages are that when first starting, the analyst must test many compounds to learn what the products are and which reagents work best. Analysts must learn how to be consistent in reporting what they see, i.e., the written description of the crystals or drawings of the crystals must be reported in the same manner, there is no printout of the results (although with the advent of digital microphotography this problem can be eliminated), and some closely related compounds may give the same type of crystals.

The basic techniques of microcrystal testing and the examination of many substances encountered in forensic analysis are well documented in Volume II of Chamot and Mason. Microcrystal testing of materials requires getting the material in question to react with specific reagent(s) to obtain insight as to the composition of the material or to identify the substance. The nature of the material being examined, and, often, experience determine the method used. In inorganic microchemical analysis, ions of the material being tested need to be brought into solution. For most reactions water is used as the solvent. The solubility of the test material gives clues in identification. For example, sodium chloride rapidly dissolves in water whereas sulfur does not. Other times the solvent may need to be slightly basic or acidic. To perform a solubility test, a single particle (or a few particles) is placed on a microscope slide next to a very small drop of solvent. The solvent can be first placed on a glass rod and gently tapped to the microscope slide releasing the solvent. While using the stereobinocular microscope one of the test particles is pushed into the solvent and the solubility, if any, is recorded. If solubility is not observed, gentle heating over a small flame and quick microscopical observation reveal the status of solubility. Another direct method to observe solubility is "huffing" on a single crystal with warm breath. The heat and moisture from the mouth may be all that is needed to dissolve a particle. Chamot and Mason give three microscopical methods for the addition of reagents to test drops. Method I is the method most commonly used. The reagent and test particle are dissolved in separate drops of water on a microscope slide. They are joined together using a glass rod forming a narrow channel between the two drops. Diffusion occurs as the two drops contact each other forming precipitates and, or, characteristic crystals. Method II introduces a large crystal of the reagent to the test drop to form crystals. In method III, the reagent solution is drawn in a narrow channel across a dry film, obtained by evaporating to dryness a solution of the substance to be tested. A drop of the test solution is placed on a clean slide and a drop of the reagent is then placed near the dried material. Using a glass rod or a platinum needle, a small line of the reagent solution is pulled across the dried film being careful not to inundate the entire dried area and examine the crystals. The hanging drop method is another elegant test using sublimation to form crystals. A drop of the test solution, a portion of the dried material, or material containing the unknown substance is placed on a microscope slide, and a cut glass ring from a test tube is placed over it. A drop of another material that causes the sample to volatilize is added. A drop of the test reagent is placed on a coverslip, which is then inverted and placed over the opening (Figure 1). The volatilized material rises and reacts with the reagent. This is a good method when one has a mixture and

cannot develop identifiable crystals with any of the other methods and the compound of interest is known to volatilize.

Coupled with microcrystalline tests are spot tests (color tests), the basis of many tests by law enforcement agencies to test street drugs to determine what they may be. However, in the hands of the trained microscopist, many of these tests are very specific and provide detailed information. F. Feigl's books on inorganic and organic spot tests are some of the principle reference books useful when conducting these tests [10, 11]. The Merck Manual, fifth edition, is another good reference for finding tests for specific materials. These tests can be used to determine the presence of metals, chemical compounds (inorganic and organic), certain elements, anions, cations, materials in food products, building materials, poisons, plant material, etc. Feigl based his tests on reactions that produced a macroscopic color; however,

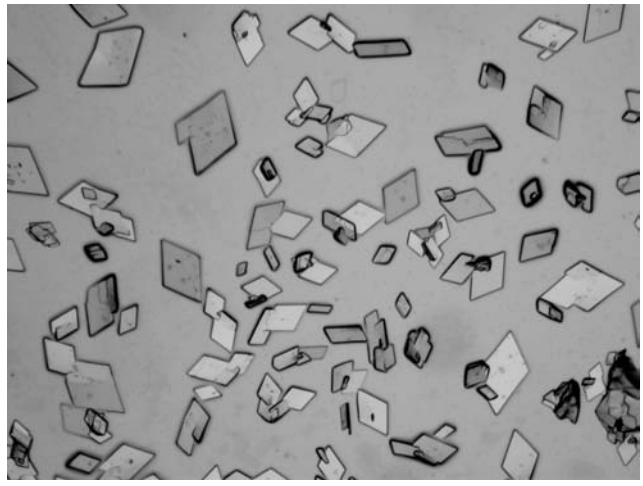

Figure 5 Yellow organic paint pigment using the sublimation cell. Original magnification 200×

Figure 6 Takayama test for the presence of blood. Original magnification 200×

when these tests are conducted on a microscale, the reactions need to be viewed using the PLM. Often the colored product forms a precipitate that may crystallize forming distinctive crystals that can be characterized.

Microchemical tests and spot tests are used by forensic scientists in a number of disciplines. Examples of some of these tests are included with photomicrographs to convey the science and art of microscopy.

In the analysis of explosive residue, microchemical tests are often used (*see* **Explosion Debris: Laboratory Analysis of**). Inorganic water-soluble explosive oxidizers can be identified by the direct addition of a particle into a small drop of water on a microscope slide. By allowing a known particle to dissolve and recrystallize, characteristic well-formed crystals of the oxidizer can be quickly identified (Figure 2). Sulfur, an ingredient in black powder, can be recrystallized from methylene chloride or chloroform and its characteristic bipyramidal crystals observed (Figure 3). Ammonium can be identified by the hanging drop method. A few grains of the test chemical such as ammonium perchlorate, are placed

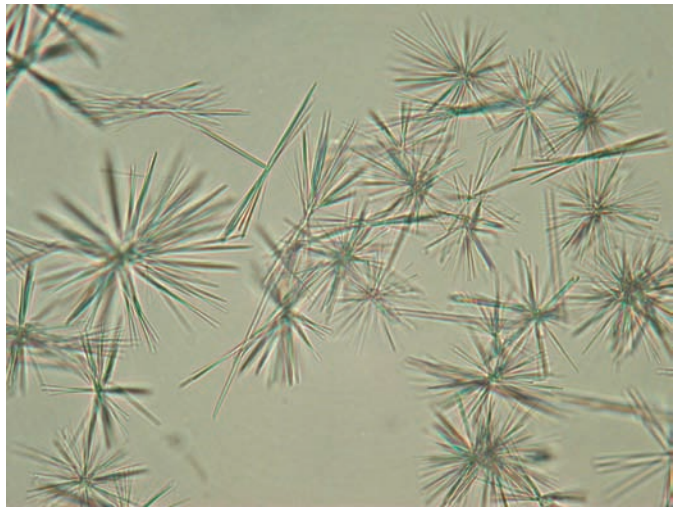

Figure 7 Colorless needles of gypsum, which formed in the presence of calcium. Original magnification 200×

Figure 8 A group of reagents used in drug chemistry

onto a microscope slide and covered with one drop of 2N sodium hydroxide. One drop of platinic chloride solution is placed on the underside of a coverslip and then placed over the glass ring. Soon isotropic octahedra indicative for the presence of ammonium, forms (Figure 4). Many organic paint pigments can be identified by placing a test particle on a microscope slide that is covered with a small cut test tube ring of glass in which a coverglass is placed on top (*see* **Paint**). The slide is placed on a hot plate and as the sample heats crystalline sublimation products form on the underside of the coverglass (Figure 5).

In the examination of microscopic flakes of material suspected to be blood, the Takayama test can be used. A portion of a suspected blood flake is placed on a microscope slide and covered with a coverslip. One or two drops of the Takayama reagent (prepared using sodium hydroxide, pyridine, glucose, and distilled water) are instilled under the coverslip. The slide is warmed for approximately 30 s on a hot

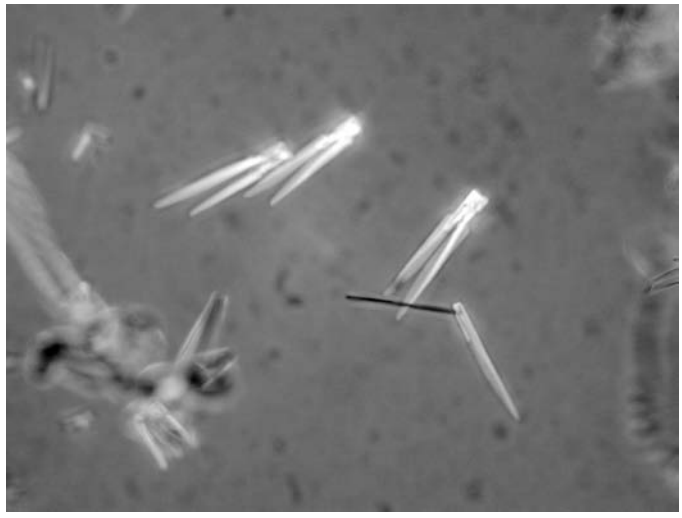

Figure 9 Gold chloride solution in phosphoric acid showing distinctive "clothe-pin" crystals indicative of methamphetamine. Original magnification 400×

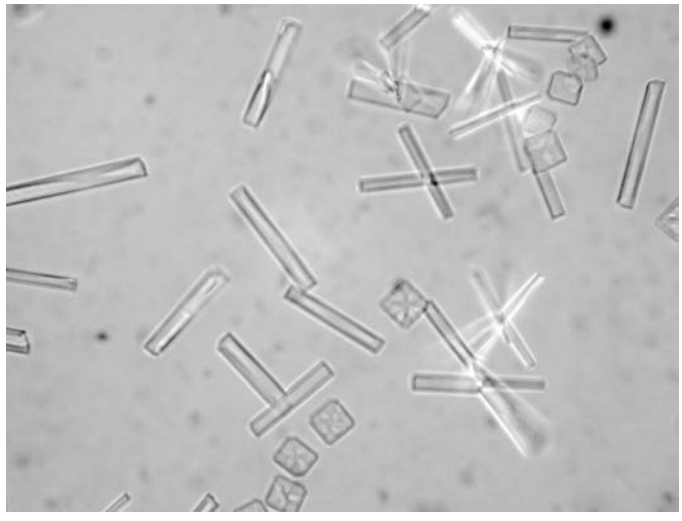

Figure 10 Gold chloride solution in phosphoric acid showing distinctive crystals indicative of dl-amphetamine. Original magnification 400×

plate. The presence of needle-shaped or rhomboid hemochromogen crystals (Figure 6) indicates a positive test for the presence of blood. This test is reported to react positive with as little as 0.001 ml of blood or 0.1 mg of hemoglobin. To test for the presence of calcium, a particle of suspected calcite ($CaCO_3$) is dissolved in a small drop of dilute hydrochloric acid. The evolution of carbon dioxide bubbles indicates CO_2 is being liberated. Using method I, a drop of dilute sulfuric acid is added. Observation along the edges yields birefringent colorless needles of gypsum ($CaSO_4 2H_2O$), which form in the presence of calcium (Figure 7). Many microchemical tests and reagents have been developed for the identification of drugs (Figure 8). Commonly used microchemical tests in drug chemistry include the use of gold

chloride in phosphoric acid to confirm the presence of methamphetamine (Figure 9) and dl-amphetamine (Figure 10).

In spite of the continuing value of microcrystalline tests, lack of training and modern tendency to rely on instrumentation results in them being used less in forensic laboratories than some years ago.

WILLIAM M. SCHNECK

Microsatellites

Prior to the 1980s, forensic genetic testing targeted polymorphic protein and blood group marker systems, for example ABO blood grouping and human leukocyte antigens (HLAs). These methods were limited by their low level of polymorphism and the relatively large amount of high-quality biological material required [1]. Also, there was limited analysis of biological material other than blood.

In 1980, Wyman and White used the restriction nuclease *Eco*RI to demonstrate variation in length between individuals at one particular noncoding locus on chromosome 14 [2]. The digested DNA was separated on a gel and detected by Southern blot analysis using a radioactive probe. This type of analysis was called *restriction fragment length polymorphism* (RFLP). This was the first example of a DNA marker that could be used to distinguish between individuals.

In 1985, Jeffreys *et al.* described a new type of polymorphic DNA marker termed *minisatellites* or *variable number tandem repeats* (VNTRs). Minisatellites are composed of sequences varying from 15 to 50 bp in length, repeated tandemly up to a total length of 20 kb [3]. It was this DNA technology that was first used in a criminal investigation (see Case study 1).

Case Study 1 This is a study of two murder investigations involving teenage girls in Leicester, England, in the mid-1980s. Owing to the case circumstances, investigators thought they were perpetrated by the same individual. Subsequently, a 17-year-old male confessed to the latter murder but denied involvement in the first. Using minisatellite technology, Professor Jeffreys was able to show that the biological materiel was left behind by the same person and that the man who had previously confessed could not be this person. A mass screen was undertaken with DNA sampled from 600 men from surrounding villages. A local baker, Colin Pitchfork, was eventually charged and convicted of the murders [4].

However, minisatellite analysis using RFLP was time consuming, difficult to interpret, and required over 50 ng of DNA.

In the 1990s, forensic DNA analysis advanced again to utilize PCR technology. PCR was originally applied forensically to HLA DQα and subsequently to minisatellites (known as *amplified fragment length polymorphisms*, *AMP FLPs*). PCR analysis of

VNTRs was quicker and required only approximately 5 ng of DNA; however, the resulting fragments of DNA were still relatively large [5].

By reducing the targeted repeat sequence, the amplified product is smaller and therefore less prone to be affected by sample degradation as many forensic samples may be. For this reason, microsatellites or short tandem repeats (STRs) amplified via the PCR became the preferred method for many forensic laboratories in the mid-1990s (*see* **Short Tandem Repeats**). STRs are lengths of DNA 2–5 nucleotides in length repeated tandemly. Their short length, variability between different individuals, and their ability to be amplified via PCR make them extremely useful as forensic DNA markers. Refer to **Short Tandem Repeats** for a more thorough discussion.

JO-ANNE BRIGHT

Microscopy: FTIR

Introduction

Infrared spectroscopy is a technique widely practiced by forensic scientists and analytical chemists in general. The principle behind the technique is to shine infrared radiation onto a specimen and record the way in which it absorbs the radiation. The way in which this is done is by using a device called an *infrared spectrometer*, which, in it simplest implementation, irradiates the specimen at any one time with only a single wavelength of light in the infrared range. After absorption at that wavelength has been measured and recorded the spectrometer moves on to another wavelength, absorbance is recorded, and so on, until the entire infrared range has been covered. In classical instruments, this requires the spectrometer to make use of a device that works like a prism, and slits that reject radiation around the wavelength being measured. A graph of the magnitude of absorbance at each wavelength is referred to as that *specimen's infrared spectrum*. In general, other types of light (or electromagnetic radiation) can be absorbed by specimens as well, for example visible light is absorbed by a number of objects, resulting in a physical manifestation we know as color. The reason why infrared radiation, in particular, is useful in an analytical chemistry sense is because its absorbance arises from the interaction between the radiation and the many different connections (or bonds) between the atoms that make up the molecules that make up the specimen. What distinguishes one type of molecule from another is the types of atoms they contain and the arrangement in which the atoms are bonded to each other. As infrared spectroscopy is very sensitive to the bonds and the atoms present in molecules, it is a very powerful technique for analyzing materials to identify the molecules that make it up. By comparison, visible light absorption is much less sensitive to the atoms and bonds present in molecules, therefore it has much less analytical power. This can be appreciated by considering, for example, three objects with exactly the same shade of red, such as an apple, paint on a car, and a piece of dyed fabric. All three objects exhibit identical visible light spectra, but as the molecules of the chemicals responsible for the color are all different, their patterns of absorption of infrared light (i.e., their infrared spectra) are all different.

The infrared absorbance experiment described earlier is conducted in the laboratory by shining a beam of infrared radiation of about 10–15 mm in diameter onto the specimen. This is not a limitation if the objective of the exercise is to analyze a drug seizure or a large sample of paint or liquid. However, a substantial amount of evidentiary material is small or microscopic. A variant of infrared

spectroscopy, which arises because there is a lower limit to the size of specimen that can be handled by standard laboratory equipment, is called *infrared microscopy* (or more correctly *infrared microspectrometry*). In infrared microspectroscopy, the infrared beam of large diameter is reduced in size to about 0.2 mm, and then caused to interact with the microscopic specimen. The infrared radiation emerging from the specimen and its vicinity is magnified and passed on to a detector. Three general types of equipment can be used for microspectroscopy: a beam condenser, which is an accessory that is attached to a standard spectrometer and makes use of its infrared beam and detector; an infrared microscope accessory, which also attaches to a standard spectrometer, but carries its own detector; and an infrared microspectrometer, which is an instrument that only operates on the microscopic domain. Beam condensers, although inexpensive, are difficult to use for trace evidence and do not produce good results for very small specimens, for this reason they are not commonly used in modern forensic laboratories. The other two accessories produce a much smaller beam at the specimen. The beam is circular, but it can be trimmed into square or rectangular shapes by curtains that can be drawn across the beam (these are referred to as a *diaphragm* or an *aperture*) before it is focused onto the specimen. This is important because fibers and many microscopic particles are not circular. Perhaps the most important feature as far as the analyst is concerned is that infrared microscope accessories and microspectrometers allow the specimen to be viewed and moved around at the focal point of the condensed infrared beam, and allow the size and orientation of diaphragms to be adjusted so that a region of interest within the specimen is analyzed, rather than the entire specimen.

In forensic science infrared microspectroscopy is used for the examination of microscopic particles of paint, rubber, explosives, and plastic, individual textile fibers, individual crystals of drugs and diluents, and individual textile fibers. Although it can be used for the examination of minerals (such as extenders in paint), it is not used for the examination of glass or metallic particles. Although there were early attempts at infrared microspectroscopy, its widespread popularity has only emerged in the last two decades owing to the widespread release of Fourier transform spectrometers. In conventional spectrometers, as described earlier, only single wavelengths of radiation are presented to the specimen at any one time. The wavelength selection process is not very efficient, with the result that only a very dim beam interacts with the specimen. If this beam is passed through a microscope to interact with a very tiny specimen, it is very difficult to measure the small levels of absorbance involved. In Fourier transform instruments, the entire range of infrared radiation is presented at high brightness to the specimen. The signal received from the specimen is a sum of all absorbances over all wavelengths over the entire infrared region, and a special mathematical procedure, called *Fourier transformation*, is used to "unscramble" the summed data into the infrared spectrum (*see* **Paint**; **Examination of Fibers and Textiles**; **Drug Analysis**).

Forensic scientists use infrared spectroscopy in two, nonexclusive general ways. Firstly, for the purposes of identification, the infrared spectrum of an unknown specimen is searched against entries on a spectral database until a "match" is found. In the case of a mixture of compounds, infrared spectroscopy is relatively straightforward in that the spectrum of the mixture is simply a direct combination or sum of the spectra of the individual components. Secondly, infrared spectroscopy is also used in a comparative sense, that is, to examine whether two pieces of material might share a common origin (for example comparison of a foreign fiber retrieved from a victim and fibers from a garment worn by a suspect). Some limitations of infrared spectroscopy are that some materials do not absorb infrared light at all (for example, common salt, metals, etc.), it is not a good technique for the detection of traces within a material (for example, explosives residues within water or soil), and sometimes it can be difficult to distinguish between members of a particular class of materials (for example, within the nylon textile fiber class, it is difficult to distinguish between nylon 6 and nylon 6, 6).

Infrared Transmission Microspectroscopy

Figure 1 depicts the important features found in an infrared microspectrometer or a microscope accessory functioning in transmission mode. The "lenses" in these devices are manufactured from paired convex and concave mirrors, because infrared radiation is absorbed by glass, and it is impractical to make

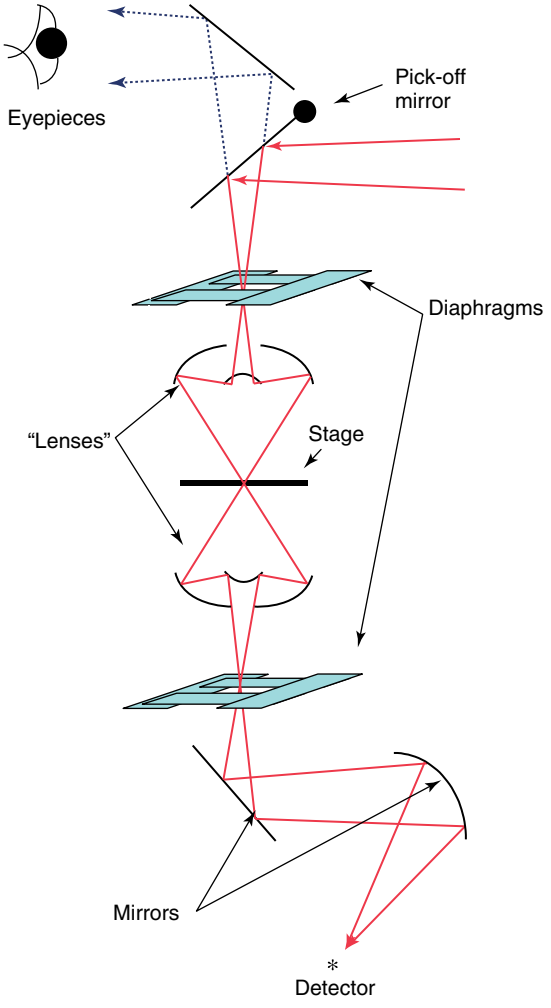

Figure 1 Schematic diagram of a typical infrared microspectrometer or infrared microscope accessory. The solid arrows and lines indicate the path for infrared radiation, while the dashed lines and arrows indicate the path for visible light to the observer once the pickoff mirror has been swung to the vertical position. Each "lens" comprises a concave mirror and a convex mirror depicted by the black lines. Not all microscopes have the diaphragm situated between the stage and the detector (termed a redundant diaphragm) [Reproduced from Ref. 3. © Taylor and Francis Group, 1999.]

lenses from material that is transparent to infrared radiation. Each diaphragm is made from four thin sheets of material opaque to infrared radiation that can be moved independently across the beam. At the center of the device is a stage upon which the specimen is mounted. X, Y, and Z controls allow the stage to be moved in three orthogonal directions in space so that the specimen can be placed into the center of the beam and brought into the focal point of the beam. The pickoff mirror can be swung into the position shown in Figure 1, which allows the infrared beam to pass through the specimen for analysis, or it can be swung vertically so that the specimen can be viewed through the eyepieces at high magnification, positioned appropriately, and a diaphragm set up. Further discussion of infrared microscopes and their application to forensic science can be found in [1–3].

Figures 2(a and b) illustrate the function of the diaphragm. Figure 2(a) depicts the situation where the diaphragm curtains are fully retracted, which results in a circular beam of maximum diameter illuminating the specimen. Obviously a substantial portion of the beam reaches the detector having not passed through the specimen. Radiation that has not passed through the specimen but reaches the detector is referred to as "stray' radiation and its intrusion into spectroscopy is not desirable. To reduce the amount of stray radiation the diaphragm can be configured as shown in Figure 2(b), where the specimen is illuminated with a small, appropriately shaped spot of radiation. Figure 3 depicts two spectra recorded from the same single polyethylene terephthalate (also know as PET or "polyests") textile fiber. The spectrum in (a) was recorded with a diaphragm established as depicted in Figure 2(a) (i.e., high stray light), while that in (b) was recorded using a diaphragm as shown in Figure 2(b) (lower stray light). The effect of stray light is that peaks do not attain their true relative heights, and this is called *photometric inaccuracy*.

Although the spectrum in Figure 3(b) is good, it is still not perfect photometrically; this arises because of the effects of a phenomenon known as *diffraction*. When any radiation is caused to pass through an opening or passes close by an opaque edge, bending of the radiation (diffraction) takes place. The amount of bending is inversely proportional to the frequency of the illuminating radiation; infrared being of a frequency lower than visible light bends more, and low frequency infrared (i.e., that recorded at the "right hand side" of spectra) bends more than high frequency infrared. As a consequence, even though the diaphragm in Figure 2(b) casts a sharp shadow on the specimen to the human eye (which operates

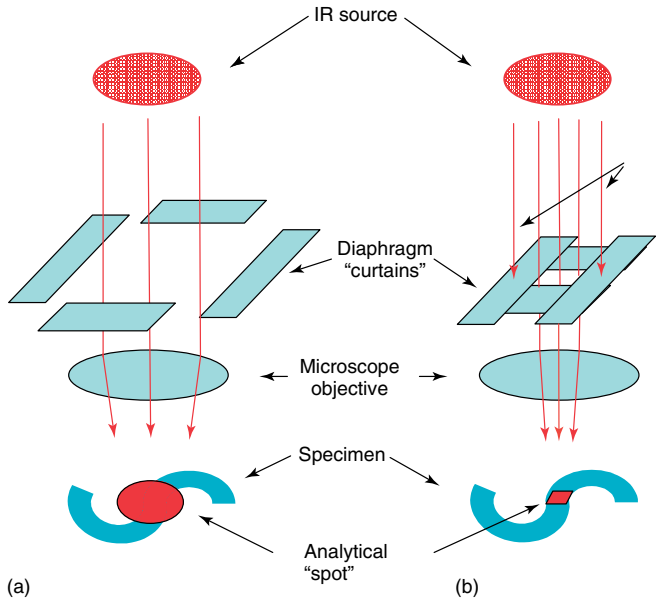

Figure 2 (a) Shows an infrared microscope with a textile fiber on the specimen stage. The curtains of the diaphragm are moved back away from the infrared beam path and as a consequence a spot of maximum size falls on to the fiber. Much of the beam does not interact with the specimen and goes on to reach the detector as stray radiation. (b) Depicts the situation where the curtains of the diaphragm are adjusted to trim off stray radiation [Reproduced from Ref.3. © Taylor and Francis Group, 1999.]

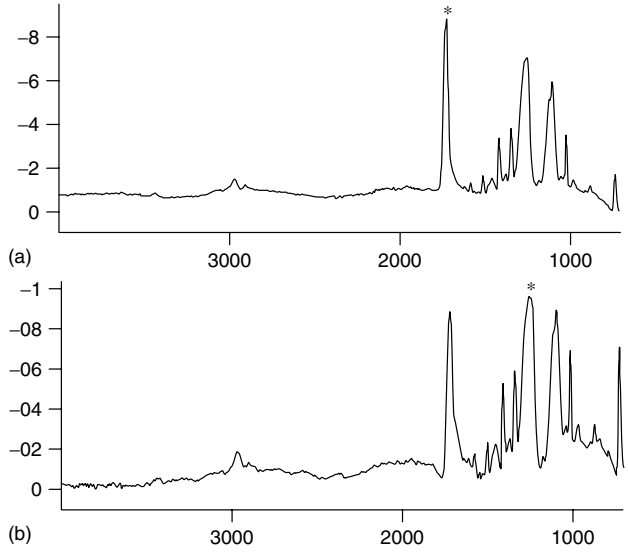

Figure 3 Spectrum (b) was collected from a single polyethyleneterephthalate textile fiber using an infrared microscope configured as shown in Figure 2(a) (i.e., with no diaphragm). Spectrum (a) was acquired from the same fiber with the microscope configured as shown in Figure 2(b). Note the differences between the two spectra with regard to the absolute absorbance values for the peaks (e.g., the two largest peaks, marked with asterisks, have values of about 0.1 and 0.8), of the two largest peaks in each spectrum (marked with an asterisk), the fact that the two maxima are at different frequencies, and the apparent "magnification" of small peaks in spectrum (b) [Reproduced with permission from reference [3], p. 189.]

using comparatively high frequency visible radiation), when infrared radiation is used to illuminate the specimen the shadow is not distinct. Figure 4 is a refinement of Figure 2(b) showing diffracted radiation and an approximation of the "shadow" of two opposite edges of the diaphragm imaged through the optics of an infrared microscope as "seen" by the specimen. Diffraction causes more stray light to reach the specimen than the size of the diaphragm would suggest. Any attempt to completely eliminate stray light is accompanied by compromises and diminishing returns. It is of course possible to reduce the size of the diaphragm to compensate for diffraction, but as indicated in Figure 4, diffraction does not stop at a certain point beyond the edge of the diaphragm, it continues indefinitely, albeit at a rapidly diminishing magnitude. For relatively large specimens (greater than about 30–40 μm in size), it is an effective tactic to configure a diaphragm to be about 5–10 μm smaller than the specimen and eliminate a large proportion of the stray light; reducing the size further reduces stray light further, but by ever diminishing returns. This is not recommended for specimens much smaller than about 30 μm as the reduction in the size of the diaphragm starts to severely attenuate the intensity of the radiation presented to the specimen, which is translated into a reduction in the signal to noise ratio of the spectral data, with the result that small peaks can disappear into the baseline. Depending upon the microscope used, a different diaphragm configuration (called *dual remote diaphragms*, as depicted in Figure 1) can be employed to improve the situation, but in any event, for very small specimens a compromise must be drawn between signal to noise ratio and rejection of stray light; it must be assumed that some residual stray light is present and its potential spectral contribution appreciated. In forensic comparisons it is a wise precaution to ensure that spectra of questioned and reference specimens are collected under conditions of equivalent stray light (i.e., specimens of approximately the same dimensions, and diaphragms of approximately the

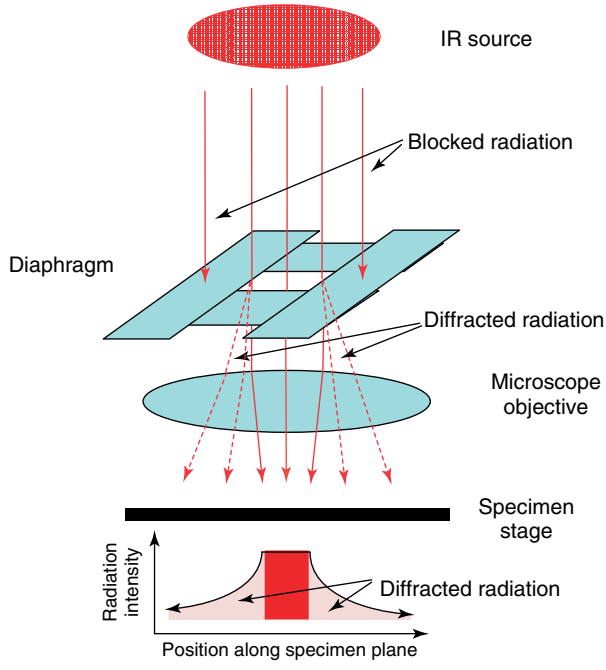

Figure 4 This diagram shows diffracted infrared radiation (dotted red arrows) that "bends" past the diaphragm established for a specimen as shown in Figure 2(b). An exaggerated approximation of the intensity of radiation across the specimen stage is depicted in the graph below. Instead of a sharp shadow (i.e., a rapid drop to zero intensity) beyond the edge of the fiber a more gradual drop to zero takes place. All the radiation that contributes to the pink zone in the graph reaches the detector as stray radiation

same dimensions). If these precautions are taken, the analyst can be certain that spectral differences between different specimens reflect a genuine compositional difference between the specimens and not spectral artifacts (i.e., these precautions guard against Type 1 errors, or false elimination of association, stray light effects are very unlikely to lead to Type 2 errors, or false association). Efforts should also be taken to minimize stray light during the recording of spectra for spectral libraries and chemometric datasets, otherwise poor matching/clustering might result.

In the case of a homogeneous specimen, such as a chip of single layer paint, the main consequence of diffraction in infrared microspectroscopy is photometric inaccuracy arising from stray light. In the case of a heterogeneous specimen, such as a cross-section of multilayer paint, the consequences of diffraction are a little more serious. Figure 5 refines the situation in Figure 4 with the diaphragm established to isolate the light gray central paint layer from adjacent dark gray and clear layers. As in Figure 4, diffracted infrared radiation strikes beyond where the diaphragm suggests it should. In this situation, however, instead of the diffracted radiation traveling through air and reaching the detector as stray radiation, it travels through adjacent paint layers and on to the detector, with the result that the acquired spectrum mostly relates to the blue layer but contains contributions from the adjacent layers. Again, with large specimens it is desirable to arrange the diaphragm well away from any interface with adjacent layers, but again it is also not an effective option with smaller specimens. For additional material relating to the effects of diffraction and stray radiation upon infrared microspectroscopy see [3–5].

For infrared transmission analysis of polymeric materials, and others that strongly absorb infrared radiation, it is desirable that the thickness of the specimen does not exceed 10–20 μm. If the specimen is much thicker than, then the possibility arises that the infrared beam at some frequencies will be completely absorbed, and this leads to photometric inaccuracies much greater than those arising from stray light and diffraction. It is usually the case that forensic specimens, even single textile fibers, exceed the desirable thickness, so it is usual in infrared transmission microspectroscopy to treat the sample in some way to make it thinner. The use of a microtome, crushing the specimen between diamond anvils, pressing or rolling it, or carefully slicing sections away using a scalpel or microknife are all effective. A collateral benefit of crushing or rolling the specimen is that it makes it wider; this allows for the usage of bigger diaphragms and therefore allows for better rejection of stray light.

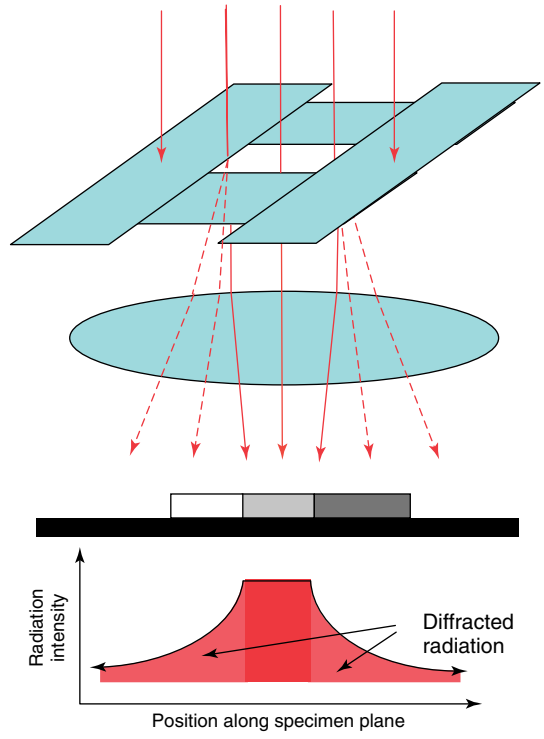

Figure 5 This diagram shows a cross section of three-layer paint placed under an infrared microscope with the diaphragm established on the interfaces between the light gray central layer and the adjacent clear and dark gray layers. As in Figure 4, the diffracted radiation and its intensity across the sample stage are depicted as dotted lines and light shading, respectively. Diffracted radiation passes through the clear and dark gray layers, carrying their spectral characteristics to the detector

Infrared Reflectance Microspectroscopy

Infrared microspectroscopy is not restricted to transmission techniques. By the use of mirrors it is possible to collect the infrared radiation reflected from the surface of the specimen and transfer it to the detector to acquire reflectance spectral data. For thin or transparent specimens, it is also possible to mount them on

a highly reflective substrate, such as aluminum foil or a gold coated glass microscope slide, and collect not only the radiation reflected from the surface of the specimen but also the radiation that has passed through the specimen, reflected off the substrate, and then traveled back through the specimen. This technique is sometimes referred to as *transflection*, as it is a mixture of transmission and reflectance spectroscopy. In this technique, the specimen thickness is effectively doubled as far as transmission is concerned, therefore it is a very useful method for very thin specimens. Reflection (and transflection) spectroscopy produces baseline artifacts (dips) that can be corrected using a mathematical function called a *Kramers–Kronig transformation*. Most spectrometer manufacturers offer software applications that perform this transformation.

Another technique of use to the forensic scientist is attenuated total reflectance (ATR) spectroscopy. In this technique, the beam from the microspectrometer is directed into a special crystal and caused to reflect internally off a face of the crystal. At the point of reflection a small proportion of the beam exists beyond the face of the crystal. This so-called evanescent wave can interact with material in contact with the surface of the crystal, and if the material absorbs in the infrared region then the reflected beam is slightly attenuated as a result. Figure 6 illustrates the essential features of ATR spectroscopy. The reflected beam is measured with and without the material in contact with the crystal and the difference between the two states yields the ATR spectrum. The distance that the evanescent wave emerges from the crystal depends upon the frequency of the incident radiation; low frequency radiation emerges further than high frequency radiation. As a result, low frequency infrared radiation interacts with a specimen placed in contact with the crystal more strongly compared to high frequency infrared radiation. Compared to a transmission spectrum of the same substance, an ATR spectrum shows an ever increasing intensification of peaks toward the right hand side of the spectrum (i.e., to the low frequency end). This means that if ATR spectra are to be compared against transmission spectra, there has to be some correction of the ATR data; this also can be done using software. The actual distance that the evanescent wave emerges from the surface of the crystal is very small (the order of microns), and therefore it only penetrates a very short distance into the specimen. Obviously ATR spectroscopy is very surface sensitive; this must be borne in mind if specimens are contaminated on their surface, weathered, or laminated. In practice, ATR microspectroscopy is very simple. Microscopes can be configured with an accessory crystal fitted to the objective, or special objectives can be purchased. The specimen is placed on a strong substrate onto the stage of the microscope, the region of the specimen to be analyzed is selected and then, using the Z control of the stage, the specimen is brought into contact with the ATR crystal. It is preferable that the microscope has some means by which the pressure brought to bear on the specimen is controlled, otherwise it is possible to damage components by using too much force, or collect poor data as a result of insufficient pressure.

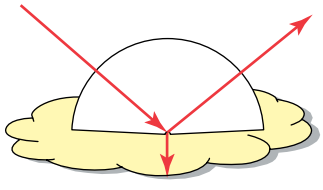

Figure 6 This diagram depicts a hemispherical attenuated total reflectance crystal of an infrared microscope pressed against a piece of paint. The infrared beam traveling from the source to the detector via the crystal is depicted by the solid arrows. At the point of reflection off the face of the crystal a small portion of the beam emerges from the face of the crystal (the evanescent wave, depicted as the small arrow) and interacts with the paint

Infrared Microspectral Imaging

Infrared microspectral imaging involves collection of many infrared spectra at many positions (called *pixels*) across the specimen The image is produced by selecting a frequency of interest (or a frequency range of interest), software then represents each pixel as a coloured spot the brightness of which is proportional to the infrared absorption at the frequency of interest at each pixel. As the image originates from the abundance and distribution of functional groups (measured by means of their characteristic infrared group frequencies) within the specimen, it illustrates the spatial distribution of chemically equivalent and chemically distinct regions in the specimen. Infrared microspectral imaging, therefore, can be very informative. As the image relates directly to

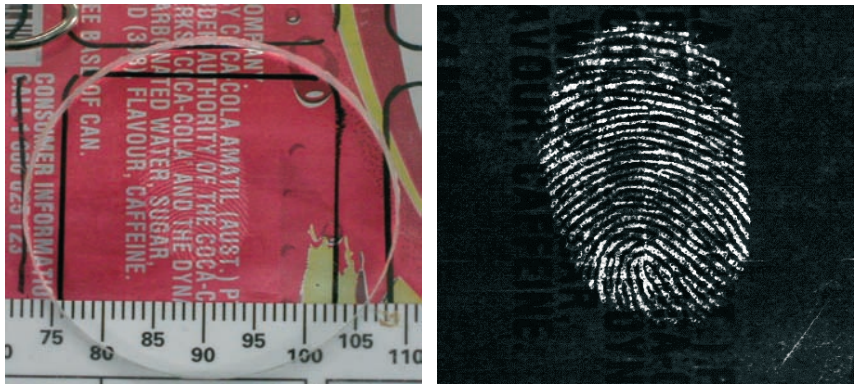

Figure 7 (a) The image was collected using visible light. It shows a fingerprint (circled) deposited on a Coke™ beverage can that has been treated with Superglue™ resin. (b) The image is a mosaic of over 1000 individual 700 μm^2 infrared images of the fingerprint displaying absorbance intensity at 1789 cm^{-1} (the C=O stretch frequency of Superglue™), Image supplied by B Reedy and M Tahtouh, Centre of Forensic Science, University of Technology Sydney, Sydney, Australia [Reproduced with permission from B Reedy and M Tahtouh, University of Technology Sydney.]

chemical information within the specimen, infrared microspectral imaging is most frequently referred to as *infrared chemical imaging*, or sometimes as *hyperspectral imaging*.

Prior to about 1995, the only way to construct chemical images was to place the specimen under an infrared microscope, establish a diaphragm delineating a certain portion of the specimen (say a 20 $\mu m \times 20\,\mu m$ area), collect a spectrum of that pixel, move the specimen 20 μm in some direction and record another pixel spectrum, and keep repeating the process until the desired area on the specimen has been analyzed. Even though this was usually accomplished with the aid of an automated microscope stage, it was a time-consuming process and low fidelity images were usually produced. In modern instruments, instead of a single detector an array of many detectors (such as 256, 1024, or 4096) arranged in a square pattern (called a *focal plane array*) is used to collect a set of spectra simultaneously from a square array of pixels (such as 256, 1024, or 4096) in the specimen. As all spectra are acquired simultaneously, focal plane array mapping is very rapid. Furthermore, images can be acquired at high spatial resolution without a requirement for apertures. If it is important to image an area larger than the field of view of the microscope then a motorized stage can be employed to move the specimen to an adjacent location and collect another data image set. Data image sets can then be displayed together to form a mosaic image of the specimen. The potential that microspectral infrared imaging offers to forensic science has been demonstrated through its successful application to fingerprint visualization [6, 7] and paint examination [8]. Figure 7 shows the greatly enhanced contrast possible with infrared microspectral imaging. The image on the left shows a fingerprint enhanced by Superglue™ fuming and photographed using visible light. The fingerprint (circled) is barely visible. The infrared image, on the right, displays the relative intensity of infrared absorbance at 1789 cm^{-1} at each pixel in a mosaic of over 1000 smaller infrared images. The infrared image has such high contrast between the background (a Coke™ beverage can) and the fingerprint because the background paint has very little absorbance at 1789 cm^{-1} while the superglue has a very strong absorbance.

Microscopy: High Power

A microscope is an instrument designed to extend man's visual capability, i.e., to make visible even the minute details that cannot be seen with the naked eye [1].

A *compound* microscope is one that provides magnification in two stages by means of an *objective* and an *eyepiece*. The term is not restricted to high magnification or high power microscopes, as low power microscopes are also compound microscopes. However, when the term *compound microscope* is used, many people think of the classical transmitted light microscope such as that shown in Figure 1. Today such an instrument can be used in a wide variety of forms, including inverted microscopes and with numerous forms of transmitted and epi-illumination allowing the observation of surface features and the ability to "see through" the specimen. In order to obtain successful outcomes, sample preparation is usually required. This can be complex and involve making thin sections (or cell preparations) and using a variety of chemical staining techniques.

It is beyond the scope of this article to explain the optical theory underlying image formation in a compound microscope. The reader is referred to [2] for the more detailed treatment of this topic. The end result is that the observer normally sees a magnified, virtual, and inverted image.

The term *high power* refers to the ability to visualize the specimen at overall magnifications of up to $1,000\times$. This is achieved with objective lens magnification of up to $100\times$ and an eyepiece magnification of generally $10\times$. The normal total magnification is not necessarily the *effective* magnification as the latter depends on the microscope being properly set up to achieve the full *resolving power* of the objective.

The RMS Dictionary defines resolving power as "the ability to make points or lines which are closely adjacent in an object distinguishable in an image. High resolving power implies that the resolved distance is small".

In order to achieve maximum resolution, the full numerical aperture (NA) of lens systems has to be achieved. Figure 2 shows the concept of NA. Briefly, if the maximum possible resolving power of an objective is to be achieved, then the maximum cone of light entering the objective must be achieved. This requires that the sub stage *condenser* is properly focused.

The highest possible NA can be achieved only with an oil immersion objective for the reasons shown in Figure 2. Maximum NA depends on the microscope being properly set up which includes correct illumination of the object. Two forms of illumination to be commonly used are called, *critical illumination* and *Köhler illumination*, where the latter is the preferred method of illumination. Assuming the microscope is correctly set up, then NA critically depends on the type and quality of objective lens. Typically, objective lenses are complex multilens systems with correction for spherical and chromatic aberrations. A typical nonresearch instrument has *achromat* lenses. These are corrected for red and blue color aberration. *Apochromatic* lenses also are corrected for blue–violet color aberration. It is also possible to correct for field curvature to provide a flat

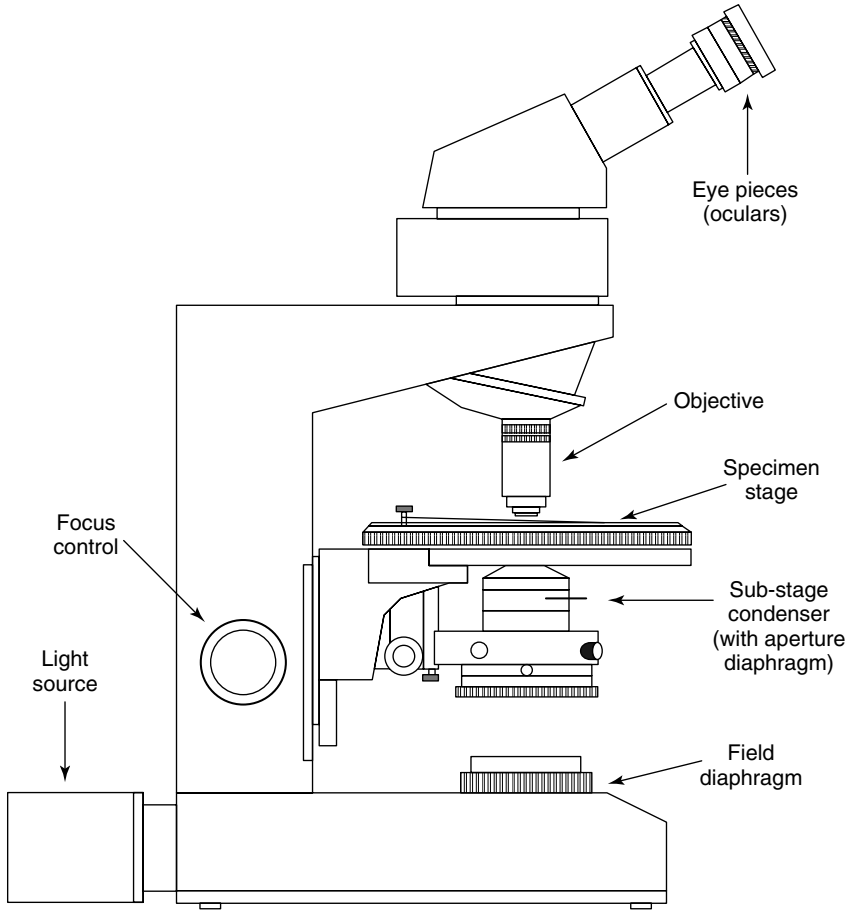

Figure 1 Main components of a modern compound microscope

field. Such lenses are called *plan*. Hence, in a high grade research compound microscope, the objectives are plan apochromat lenses with an NA in the order of 1.00 for 40× and 1.30 for 100× oil immersion. A typical achromat, dry objective at 40× would have an NA of 0.60–0.65.

The substage condenser also has a multilens system. Low cost microscopes have a two lens Abbe type condenser and higher cost microscopes have a more complex aplanatic condenser which is corrected for spherical aberration. To achieve objective NA of 1.4, a fully corrected oil immersion achromatic type condenser is required.

Finally, several types of *eyepiece* are also available. Typically today, a *compensating* eyepiece is found in which the eyepiece is designed to correct for lateral chromatic error.

Modern microscopes are designed and manufactured for ease of use and have features such as *parcentration* (ensuring that as objectives are changed the center of the visual field remains the same) and *parfocality* (ensuring focusing can be achieved as objectives are changed with a minimum of fine adjustment).

In most modern microscopes, the illuminating system is built into the base of the microscope. In low cost microscopes this is usually a precentred halogen bulb. In more expensive microscopes, a tungsten light source is common with the capability to center the light sources.

The standard set up for routine high power microscopic examination is *brightfield* microscopy in which direct light passes through the specimen, enters the objective, and illuminates the background

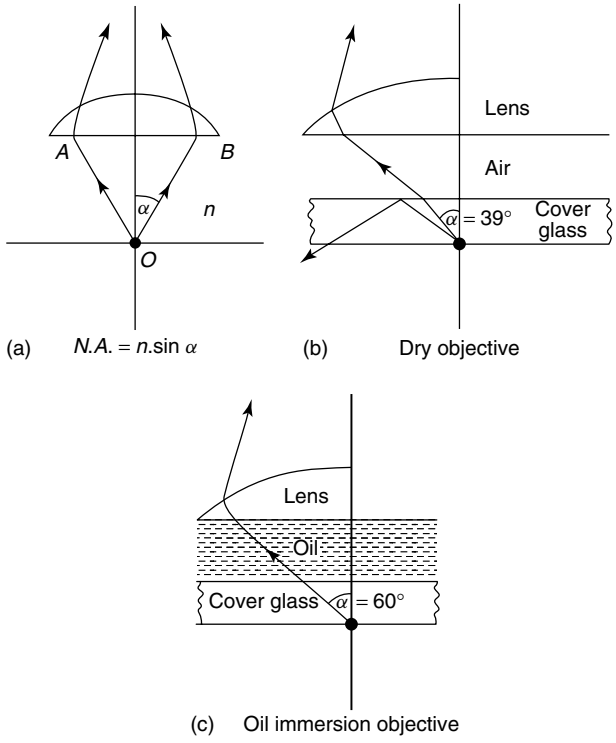

Figure 2 (a) A diagram to represent the concept of numerical aperture (NA), n is the refractive index of the medium (usually air) between the object O and the lens, α is half the angle of acceptance AOB. (b) Path of light rays in a dry objective of NA 0.95. The maximum value of α is 39° due to refraction at the air/cover glass interface. Rays with a greater obliquity are totally reflected at the surface of the cover glass. (c) Path of light rays in an oil immersion objective of NA 1.3. The value of α is now increased to 60° since there is now no air/glass interface refraction [Reproduced with permission from Edward Arnold Ltd. © 1976 [3].]

against which the image is seen. In order to visualize the image, there has to be a difference in the refractive index (RI) of the specimen and the mountant in which the specimen is placed; usually covered by a glass cover slip. For example, the measurement of the RI of glass is based on using a mountant whose RI changes as it is heated; for hair microscopy, the choice of mountant is critical if the internal structure of the hair is to be seen. For some samples, it can help to increase contrast by closing the iris diaphragm in the sub stage condenser. However, for very transparent specimens, there are a number of specialist techniques such as *dark field* microscopy and *phase contrast* microscopy, which provide images with a high degree of contrast. These techniques, especially phase contrast, are widely applied in biology but are not frequently used in routine forensic work.

Other specialist forms of microscopy include *fluorescence* microscopy and *polarizing* microscopy. Epi or incident fluorescence is commonly used in the forensic examination of fibers. Transmission fluorescence has been applied in aspects of forensic biology. It is beyond the scope of this article to describe the theory of polarizing microscopy. In brief, it makes use of the *optical* properties of some samples, (anisotropic) to "twist" polarized light. Casartelli [4] has described in simple terms how a polarized light microscope works. Although there are differing views within the forensic community as to the role of polarizing microscopy, there is no doubt that polarizing microscopy is still a valuable technique adding an analytical dimension to the microscope. The McCrone Particle Atlas [5] gives an insight into the extremely wide range of possible applications of this technique for forensic work.

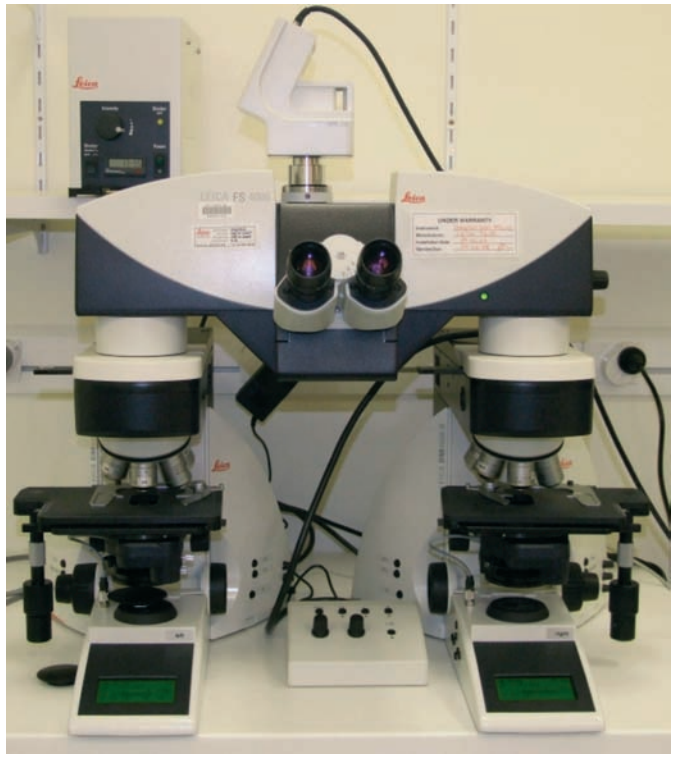

Figure 3 Comparison microscope

Finally, the forensic world makes use of comparison microscopy (see Figure 3) in which two microscope systems are linked by a system of prisms to present their images into a single binocular comparison eyepiece such that two images can be directly compared side by side. This technique is used in the forensic examination of fiber and hairs. Most of the current modern microscopes have the capability of being linked to image capture systems.

In conclusion, the compound light microscope is a versatile and indispensable piece of equipment. As a general recommendation, "simple is best". A less expensive microscope with limited options is often fit for purpose and is more preferred for routine use. This is especially the case where very little formal training is offered in basic microscopy. To achieve even close to the theoretical performance of any microscope, it must be kept clean and regularly serviced and maintained. Add to this an understanding of the basic theory of image formation, and how to use a microscope, and there is no reason why anyone cannot make effective use of microscopy.

Microscopy: Light Microscopes

Introduction

This article is intended to cover the fundamentals of light microscopy. A microscopical examination may be the only instrumental technique needed to identify a piece of evidence, provide direction for further analysis, or compliment other instrumental techniques.

The microscope is used in many forensic disciplines including firearms identification, serological examinations, drug chemistry, and trace evidence. It is in the discipline of trace evidence where the light microscope has found its greatest use in the characterization, identification, and comparison of particulate material. The trace evidence analyst may encounter limitless types of particulate matter including fibers, hairs, paint, explosives, pollen, soil, glass, and tape. The use of the light microscope provides valuable information in the examination of trace particulate and its exclusion in any examination would be inconceivable.

Stereomicroscopy

Stereomicroscopes, sometimes referred to as *dissecting microscopes*, are microscopes that produce a magnified image of a specimen that is upright, laterally correct and with a perception of depth – exactly the way the eye sees in normal vision. The stereomicroscope is of particular importance in forensic examinations because the 3-D image, the extended depth of field, and long working distance facilitate inspection, sorting, preparation, and dissection of evidence. In many cases, these instruments can also provide enough information to identify the sample.

Design

In normal vision or when using a stereomicroscope, the brain combines two off-axis images to generate one image that is not only two dimensional but also has the perception of depth. There are two types of stereomicroscopes produced today – the *Greenough* design and the *Common Main Objective* design.

Greenough Stereomicroscope. The Greenough stereomicroscope dates from the later part of the nineteenth century and uses two completely independent optical axes that are set approximately 14° apart (Figure 1). Because the left and right optical paths must maintain critical alignment throughout the entire optical path, it is impossible for the user to insert and remove accessory items such as coaxial illuminators, epi-fluorescence or add a port for documentation. However, it is possible to produce highly corrected optics, including apochromatic lenses, at relatively low cost. Many laboratory-grade stereomicroscopes are Greenough instruments and are quite adequate for examinations and sorting of evidence.

Common Main Objective Stereomicroscope. The common main objective (CMO) stereomicroscope features two parallel optical axes (one for each eye) from the eyepieces down through the main body. At the common main objective, each optical path turns inward to view the specimen at slightly different angles (Figure 2). This type of microscope also produces a stereoscopic 3-D image, but with an important advantage over the Greenough design.

Figure 1 A modern day Greenough stereomicroscope

Figure 2 A modern day common main objective stereomicroscope

Since the optical paths are parallel, the image in a CMO instrument that is above the main body and below the observation tube is projected at infinity. Thus, the CMO stereomicroscope can accommodate a wide range of accessories, which can be easily inserted and removed by the user. These accessories include multiple photo/video ports, coaxial illuminators, and epi-fluorescence illuminators, often in combinations. Additionally, the observation tube that contains the eyepieces can be easily interchanged to accept other special purpose observation tubes that have eyepieces set at unique angles, eyepiece tubes that tilt for ergonomic advantages, or eyepiece tubes with long extensions to increase the distance of the observer from the specimen.

Magnification and Resolution

The total magnification of a stereomicroscope is a function of the eyepiece magnification, the main objective (if a CMO instrument) or the supplementary objective (if a Greenough instrument), the magnification factor of any intermediate accessory, and the magnification setting of the main body of the microscope. It is possible with some CMO stereomicroscopes to extend the total visual magnification to nearly 1000X, although the resolving power of any stereomicroscope is limited primarily to the numerical aperture of the main objective, which is at most approximately 0.2 and yields a maximum useful visual magnification of about 200X. Refer to the section "Brightfield" for a more detailed discussion on magnification, numerical aperture, and resolution.

Accessories

The accessories for CMO stereomicroscopes are extensive and allow these instruments to examine the internal structures of evidence in transmitted light and their surface details in incident light. Illumination sources include fiber optic bundles and ringlights as well as fixed and adjustable LED sources. Components for polarization, darkfield, epi-fluorescence, and digital documentation may be added to expand the functionality. Stereomicroscopes may be used with compact incident light stands for the examination of small pieces of evidence or they may be attached to elaborate heavy-duty stands for the detailed inspection of clothing or other large objects such as an automobile.

Limitations of the Stereomicroscope

Because the image projected through either side of a stereomicroscope is not perpendicular to the specimen plane, the left and right edges of a flat sample are out of focus when the center is in sharp focus. This is generally not a noticeable problem at lower magnifications and when the instrument is used for observation of samples that have a significant amount of surface relief. However, when the stereomicroscope is used for video discussion or documentation, only one side of the stereo image is diverted to the camera. Since either side is off-axis, accommodations must be made for this nonperpendicular view. With CMO instruments, the major manufacturers offer carriers that shift the position of one side of the microscope over the center of the main objective. The view obtained with this uniaxial instrument is perpendicular to the specimen plane and uses the center portion of the main objective which offers more optical correction than the lens periphery. This uniaxial position also provides the most accuracy when an eyepiece micrometer or computer software is used for measuring.

Brightfield Microscopy

A brightfield (biological) microscope with ordinary (unpolarized) illumination can be utilized to characterize, identify, and compare many types of particles encountered by the trace evidence microscopist. Although we see later that a polarized light microscope will give additional properties one can use to characterize and identify particles, unpolarized light may be employed to characterize physical features and to determine average optical properties of particles. Hairs, diatoms, and pollen grains are a few examples of particles that can be identified solely based on their physical characteristics when utilizing brightfield microscopy. Also, unpolarized light can be used to determine the refractive index (RI) and the color of particles that have a single RI (isotropic) as well as determine the average RI and the average color of particles that have more than one RI (anisotropic).

Concepts in the Design of the Light Microscope

To effectively use a microscope, a microscopist must know how to configure and adjust a microscope plus have a basic understanding of light and how it interacts with matter. The following discussion of microscopy is intended to be a simple primer that provides an introduction to light and the components of a contemporary compound microscope.

Light. The portion of the electromagnetic spectrum that the human eye detects as light is the range of wavelengths of energy from approximately 380 to 750 nm. The eye recognizes the shorter wavelengths of light as the colors violet to blue, the intermediate wavelengths as the colors green to yellow, and the longer wavelengths as the colors orange to red. Furthermore, the human eye interprets an increase in the amplitude of this wave as an increase in intensity or brightness of the light (Figure 3).

The interaction of light with matter provides specific information that can be used to characterize and identify particles during a microscopical examination. Also, the interaction of light with the components of a microscope directly affects the quality of the information revealed in the resulting magnified image. The principal interactions of light with matter which are discussed here are reflection, refraction, and dispersion.

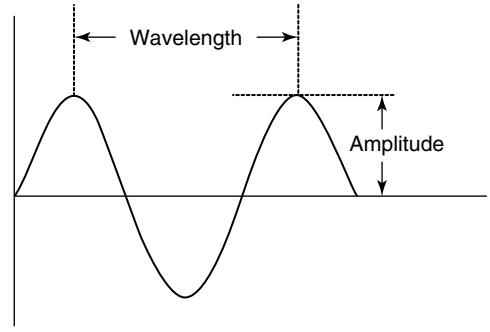

Figure 3 Diagram Figure showing wavelength and amplitude for a ray of light

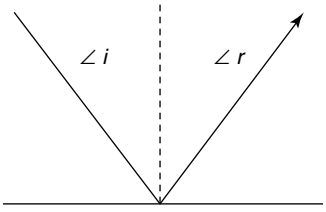

Figure 4 Specular reflection

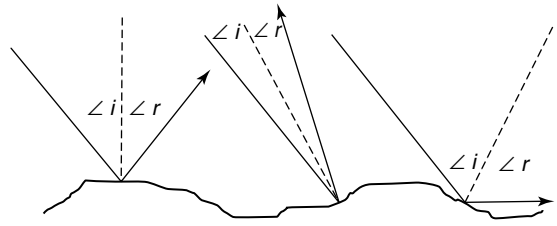

Figure 5 Diffuse reflection

Reflection. Specular reflection occurs when light strikes a smooth surface (Figure 4). The angle at which the light leaves the surface is equal to the angle at which it arrives and, therefore, the angle of reflection (r) is equal to the angle of incidence (i).

Diffuse reflection occurs when light strikes an irregular surface and the rays are reflected in different directions. Diffuse reflection still obeys the laws of reflection as the angle of reflection is still equal to the angle of incidence (Figure 5). How light is reflected off a material using incident light can provide valuable information when characterizing and comparing samples.

Refraction. Refractive index (n) is the ratio of the speed of light in a vacuum to the speed of light in a transparent medium. When light enters a medium having a different RI at any angle other than perpendicular to the surface, the light will not only change velocity but also direction. This change in direction, or bending of light, is known as *refraction*. Refraction is governed by Snell's law that states

$$n_r/n_i = \sin i/\sin r \qquad (1)$$

where n_r is the RI of the refractive medium, n_i is the RI of the incident medium, sin i is the sine of the angle of incidence, and sin r is the sine of the refraction.

Therefore, as light passes from a medium of lower to one of a higher RI, the incident ray of light will be refracted toward the normal to the interface then away from the normal to the interface as it passes from a higher to lower RI medium (Figure 6). Furthermore, as the difference between the two refractive indices increases, the amount the light ray is refracted also increases. The refraction of light as it passes through the optical components of a microscope is an essential function of the microscope lenses in the formation of a magnified image.

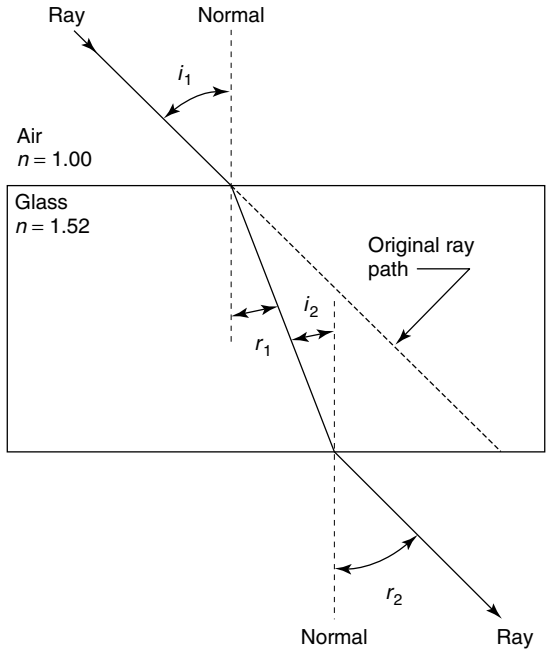

Figure 6 Refraction of light

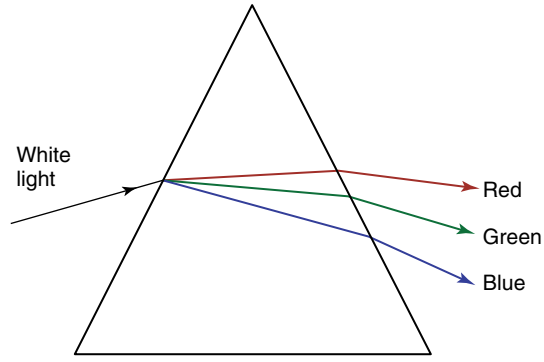

Figure 7 Dispersion of white light through a glass prism

Dispersion. Dispersion is the change in RI of a transparent substance as a function of the wavelength of light resulting in the separation of white light into its component wavelengths or colors (Figure 7). The RI is usually lower for longer wavelengths (red) and higher for shorter wavelengths (blue). The dispersion of white light as it passes through the optical elements of a microscope results in a degraded image quality and requires correction or compensation for this aberration.

Magnification. A simple magnifier helps the eye focus an object that is closer than 10 in (25 cm), which is the normal reading distance for the eye. When the object is moved closer to the eye, its visual angle is increased and the object can be focused by the eye when a positive lens is placed between the eye and the object (Figure 8). Magnification can be expressed in several ways but one simple relationship is:

$$\text{Magnification} = \text{image size}/\text{object size} \qquad (2)$$

A compound microscope uses an objective lens positioned close to the specimen to produce a magnified real image of the object. The eyepiece functions as a simple magnifier and further magnifies the real image produced by the objective. Therefore, the final magnification to the observer is the product of the objective magnification, the eyepiece magnification, and any intermediate tube factor that may be present in the microscope.

Objectives. The objective is the lens system nearest the specimen and can have a series of complex lens

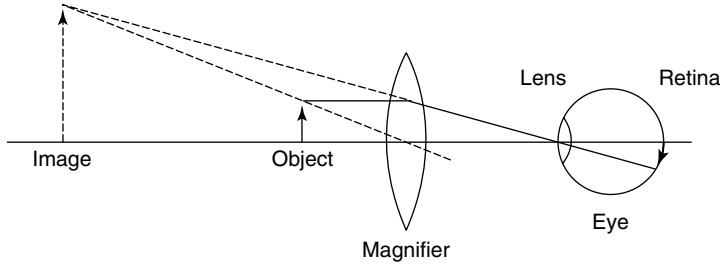

Figure 8 Diagram of simple magnification

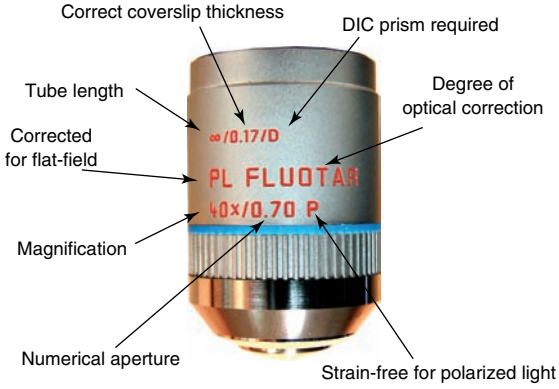

Figure 9 Objective nomenclature

elements. The objective provides the primary magnification and in part defines the resolution of the final image. Objectives are designed as having different magnifications and numerical apertures. The resolution of the microscope, which is the ability to discern fine structure or minute particles spaced closely together, is a function of the objective and the condenser. The nomenclature engraved on the body of the objective provides useful information regarding magnification, numerical aperture, and intended usage (Figure 9). For example, a 0.17 value means that the objective must be used with a coverglass of 0.17 mm thickness or the image will not be as sharp due to spherical aberration.

Eyepieces. The eyepiece provides a magnified secondary image of the primary image produced by the objective. Eyepieces having different magnifications and field-of-view indexes are available. The field-of-view index of the microscope eyepiece is the diameter in millimeters of an internal diaphragm which is used to match the level of correction of the objectives being used. Eyepieces with wide field-of-view indexes require objectives with more extensive correction for flatness of field or the periphery of the image will be out of focus. The 10X magnification eyepiece is the most widely used eyepiece and is available with a field-of-view index from 18 to 25.

Condenser. The primary function of the substage condenser in a transmitted light microscope is to concentrate and focus the light evenly across the field of view. Laboratory and research grade microscopes must be able to achieve Köhler illumination which requires an adjustable condenser. Condensers for brightfield observation techniques may span the entire magnification range from a 1.25X objective to a 100X objective and have a mechanism that permits a top condensing lens to be swung in the light path for objective magnifications of 10X and above. This dual function allows the condenser to evenly illuminate large fields at low magnification and smaller fields at higher magnification.

Special use condensers for phase contrast, polarization, darkfield, and differential interference contrast (DIC) provide the necessary components to achieve these special contrasting techniques. Since the highest numerical aperture possible with a dry condensing system is 0.90, condensers are available that allow immersion oil to be placed on the underside of the specimen slide to couple the condenser optically to the specimen allowing condenser numerical apertures up to 1.4.

Illuminators. Most microscopes today use built-in or directly coupled illumination sources, often with a power supply providing variable intensity control that is integrated into the microscope stand. The primary illumination source for transmitted light

is a low-voltage tungsten halogen bulb with high intensity wattages from 20 to 100. Light emitting diodes (LEDs) are being used in some microscopes because they produce a bright white light with an exceptionally long life.

Although a routine bench microscope may not have provisions for adjustment of the filament, the light produced is sufficient to properly illuminate the specimen and render high quality images. Research level instruments have the lamp located in an attached housing that provides for critically positioning the filament in the center of the optical axis, independently controlling a secondary image of the filament produced by a reflecting mirror behind the bulb, and precisely focusing the filament for Köhler illumination.

Numerical Aperture. As the focal length of the front element of an objective becomes shorter (closer to the object) as is required to increase the magnification of the objective, the angle of acceptance of the image forming rays (angular aperture) is increased (Figure 10). The numerical aperture is a measure of the light gathering ability of a lens system and determines the resolving power and depth of field. Generally, objectives with the shortest working distance have the highest magnification and the greatest angular apertures (AA). The numerical aperture can be calculated using the formula:

$$NA = n \sin \frac{AA}{2} \tag{3}$$

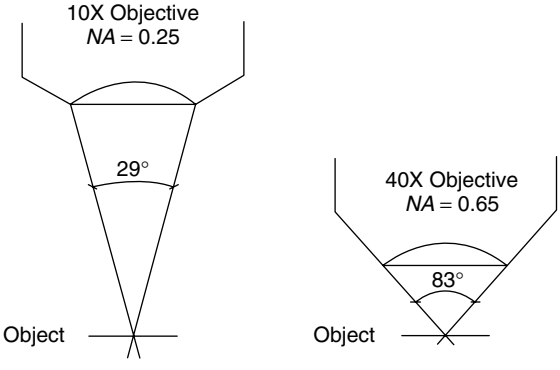

Figure 10 Diagram showing acceptance angle for two objectives having a different magnification and numerical aperture

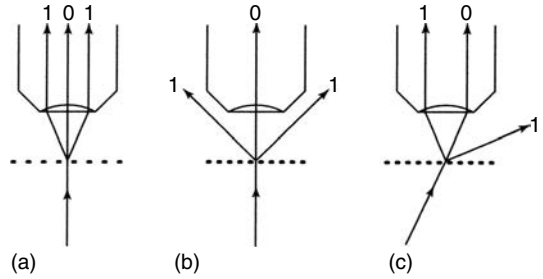

Figure 11 Diffraction of light through fine structure

where n is the RI of the space between the front element of the objective (or top element of the condenser) and the microscope slide.

Diffraction. In the late nineteenth century, Ernst Abbe demonstrated that there is a correlation among diffraction, numerical aperture, resolution, and the RI of the medium between the specimen and the front lens of the objective. A series of diffracted rays are produced when light interacts with a specimen and as the detail in the specimen becomes finer, the angle of the diffracted rays increase (Figure 11). To resolve detail in a specimen, one needs to capture the direct ray and at least one of the first-order diffracted rays. However, the image quality improves as more of the diffracted rays are captured. Also, the shorter wavelengths of light (blue) produce a smaller diffraction angle than the longer wavelengths of light (red) resulting in greater resolution for shorter wavelengths.

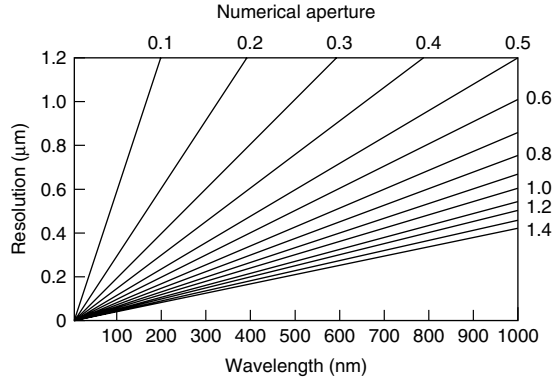

Figure 12 Diagram showing the relationship among wavelength, numerical aperture, and resolution

Resolving Power. The numerical aperture of an objective and the condenser along with the wavelength of light used to illuminate the sample determines the resolving power of the microscope. Resolving power is the ability of an optical system to make two closely spaced points (fine detail) visible as separate entities. Therefore, a resolving power of 1 μm means that two point-shaped particles at a 1 μm distance from each other will just be distinguishable as separate objects. A graph depicting the relationship among wavelength, numerical aperture, and resolving power is provided in Figure 12.

Contrast. If a magnified image is to be of value, the details of the structure of the specimen must be observable. While a microscope may be resolving the fine details of a specimen, these details are of no value unless there is sufficient contrast for the eye to detect the structure. Contrast may be enhanced by mounting the sample in a medium with a different RI, by the use of colored stains, or by simply closing down the aperture diaphragm. However, as the aperture diaphragm is closed down, the resolution significantly decreases. It is a good practice to observe specimens with the aperture diaphragm in different positions. Also, optical or illumination contrasting techniques such as darkfield, Rheinberg, phase contrast, differential interference contrast (DIC), or modulation contrast can be employed. It is the appropriate combination of resolution, contrast, and magnification that provides the microscopist with an image with sufficient detail to provide useful information.

Finite and Infinity Microscopes. The two designs for compound microscopes are finite tube length and infinity corrected tube length (Figure 13). While both systems can produce high-quality images, the infinity corrected system is now the most commonly available optical design for laboratory and research grade instruments. A microscope with infinity corrected optics allows for accessory components to be added such as incident light illuminators for opaque specimens or epi-fluorescence illumination, polarizers, and compensators without degrading the image. Many contemporary bench microscopes and all older instruments are of the finite tube length design.

Objective Aberrations. A perfect converging lens causes all of the light rays emitting from a point on one side of a lens to be converged (focused) on the

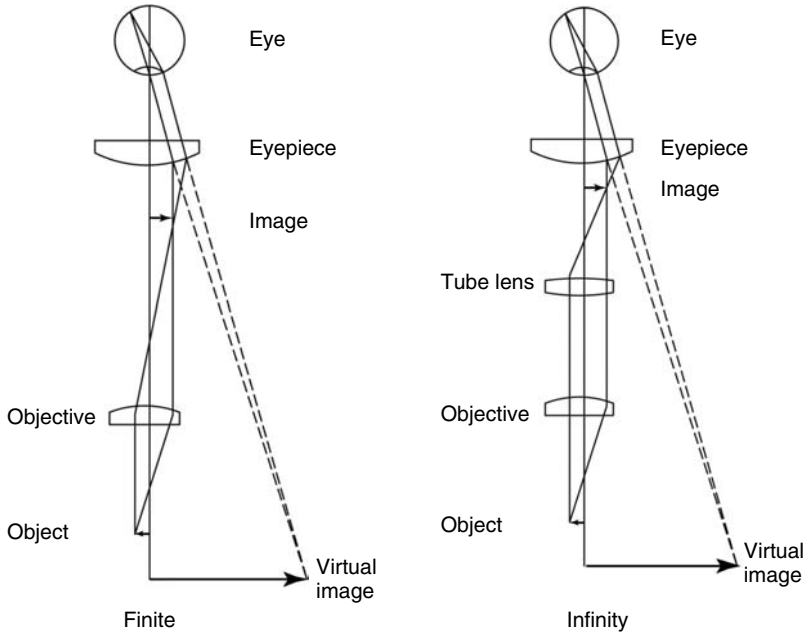

Figure 13 Ray path through a finite corrected microscope (left) and an infinity corrected microscope (right)

other side of the lens and produces an exact image of the original point. In practice, all lenses suffer from aberrations and, in fact, these imperfections impair the ability of the lens to produce that exact copy of an object. Of the six primary aberrations, spherical and chromatic affect the entire field while coma, astigmatism, curvature of field, and distortion affect the quality of the off-axis or peripheral image. To a degree, all of these aberrations can be reduced to a level at which they no longer adversely interfere with visual observation. The extent to which a microscope is corrected for these aberrations determines its performance and subsequent cost.

Particle Characterization – Unpolarized Light

Before any microscopical examination can begin, one must ensure that the microscope is properly aligned and adjusted for Köhler illumination. Depending on the microscope being utilized, the centering and focusing of the lamp filament may not be possible to obtain true Köhler illumination. This is because many manufacturers have eliminated the ability to center and focus the lamp filament and have introduced a diffuser into the light path. Once Köhler illumination is achieved, particles are characterized and identified based on the properties that are observed and measured. This is first accomplished using unpolarized light or with plane polarized light utilizing a single polar and finally with crossed (two) polars.

Sample Preparation. Samples are prepared for microscopical examination by placing them between a microscope slide and coverglass (coverslip) and using a liquid (mounting medium) of choice. The mounting medium may be a temporary medium that will evaporate away such as water or a suitable organic liquid. Xylene was commonly used in past years as a temporary medium, but its use today has been restricted in some laboratories. A stain may also be used as mounting medium. Some common stains that may be used include: Graff C stain or Selliger's stain to characterize and identify cellulose fibers; iodine solution or Betadine solution to detect starch grains and gelatinized starch particles; and malachite green in nitrobenzene to detect and identify clay particles.

A standard oil having a known RI is another mounting medium that can be used, such as Cargille refractive index liquids (Cargille Laboratories, Cedar Grove, NJ, USA). A standard oil having a RI of 1.66 is usually employed for general particle characterization and for the examination of the heavy mineral fraction (density $> 2.89\,\mathrm{g\,cc^{-1}}$) in a soil sample. A liquid having a RI = 1.550 is usually favored to characterize and identify minerals in the light fraction (density $< 2.89\,\mathrm{g\,cc^{-1}}$). Many fiber microscopists prefer a liquid having a RI = 1.525.

There are many permanent mounting media to choose from including Permount™, Meltmount™, Entellan™, and Norland Optical Adhesive™. Aroclor™ has been used in the past years as a mounting medium but is not readily available today. As can be seen, there are numerous mounting media to choose from and which mounting medium one will use greatly depends on the sample and the information one wishes to obtain from the examination.

Particle Morphology. Under examination, the first characteristic one will notice is the physical features of the particles. General terms should be used to describe particles unless one understands precise descriptions that are used in specialized fields (crystallography, wood taxonomy, mineralogy, paleontology, etc.) and can be applied correctly. Also, the microscopist will project a more visual image of the particle observed under the microscope using descriptive terms such as irregular, spherical, acicular, granular, platy, fibrous, or tabular. Also, interfacial angles between crystal faces can be measured if present.

Particle Size. The next characteristic one may determine is particle size. The size of a particle may help to distinguish between two particles that have similar morphologies such as corn starch and rice starch, the former having an average diameter twice that of latter. Also, particle size is an important consideration when comparing particles contained in two different samples.

Particle size can be either estimated or measured precisely. The particle size is estimated by comparing the particle to the diameter of the field of view. A 10X objective has a field of view of approximately 2.2 mm or 2200 μm, whereas a 40X objective has a field of view around 0.54 mm or 540 μm. Precise particle measurements can be made using a calibrated eyepiece scale, which is located in the front focal plane of the eyepiece and is therefore superimposed on the field of view. One can calibrate the eyepiece

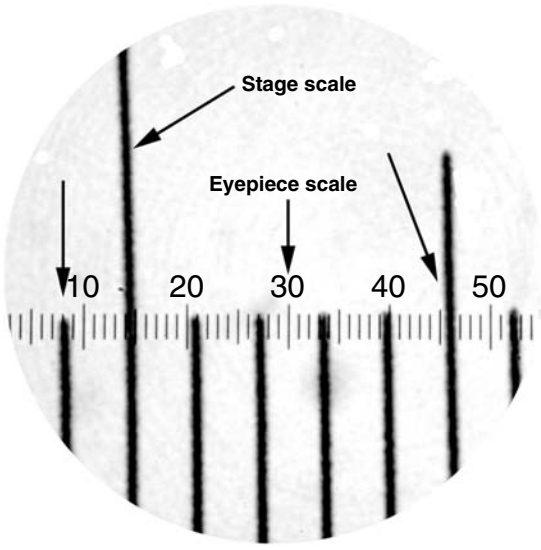

Figure 14 Image of the eyepiece scale superimposed over the stage micrometer scale

scale using a stage micrometer. For the stage micrometer shown in Figure 14, each division is equal to 10 μm. Note that 42 eyepiece divisions equals 6 stage micrometer divisions or 60 μm. Therefore, each eyepiece scale division for this objective equals 1.4 μm. Since the diameter of the field of view varies with each objective, the eyepiece scale must be calibrated for each objective so the particle size can be measured accurately using any objective.

Refractive Index. Refractive index as previously defined is the ratio of the velocity of light in a vacuum to the velocity of light passing through a transparent medium. The RI will always be greater than 1.00 and determination of the RI (or RIs) is an important aspect in the identification of transparent particles. Also, it is important to remember that the RI varies with the wavelength of light (dispersion) and it is understood that the RI value usually reported is at 589 nm (n_D) unless otherwise noted.

The degree of observed contrast (dark edges) of a particle is a measure of the RI of the particles relative to the RI of the medium. The particle contrast will increase as the difference in RI increases between the particle and the medium. If the particle has colored borders it means that the particle and medium have the same RI at some wavelength near or in the visible region of light. If the particle is "invisible" then the liquid and the particle have the same RI.

With a little practice, one can judge the difference between the RI of the particle and the RI of the liquid by the amount of contrast observed. If the contrast is low, one can estimate that the particle and the liquid have a RI difference that ranges from ±0 to 0.04. If the contrast is moderate, then the difference of the two RIs is estimated to be somewhere between ±0.04 and 0.12. If the contrast is high, the difference between the particle and liquid RIs is greater than 0.12. To "calibrate" your eye, one should estimate the amount of contrast in a consistent manner with the aperture diaphragm closed down (smallest opening).

The degree of contrast observed for a particle in a liquid does not demonstrate if the particle has a higher or lower RI than the mounting medium. Even though there are several ways to determine which has a higher RI, the Becke line technique is commonly conducted to quickly determine whether the particle or the liquid has the higher RI. The Becke line is a bright halo that is observed near the boundary of a particle which moves in and out of the particle as the particle is brought through good focus. This halo is the result of the concentration of light due to the refraction (light changing direction) at the interface of the particle and mounting medium having different refractive indices. The light will be bent toward the normal (an imaginary line perpendicular to the surface) as it enters a transparent medium of higher RI and away from the normal as it enters a medium of lower RI. As you focus above the plane of best focus (increase the distance between the objective and particle) the Becke line will move into the particle if it has a higher RI or will move into the liquid if it has a higher RI (Figure 15). The aperture diaphragm should be closed down when conducting the Becke line test and the movement of the fine focus must be slight.

Isotropic particles (noncrystalline particles and cubic crystals) have a single RI and this index will be observed whether unpolarized or plane polarized light is employed. However, anisotropic particles (crystals with more than one RI) have either two principal RIs (uniaxial) or three principal RIs (biaxial). The two principal RIs for uniaxial crystals are noted as ω and ε. For biaxial crystals, the three principal RIs are noted as α, β, and γ. Also, anisotropic fibers have two different refractive indices: RI parallel to the length ($n_{\parallel}$) and perpendicular to the length ($n_{\perp}$).

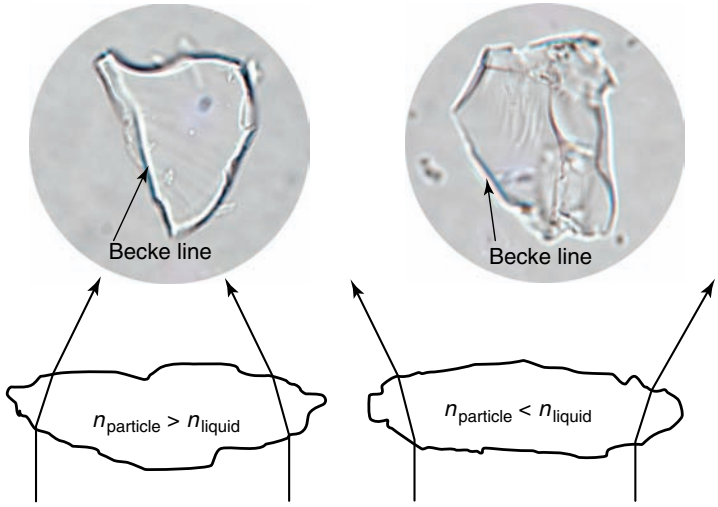

Figure 15 Ray diagram and images showing the Becke line slightly above best focus for a particle having a higher refractive index than the mounting medium (left) and for a particle having a refractive index lower than the mounting medium (right)

With unpolarized light we will observe an average RI (n_{iso}) for anisotropic particles. For most anisotropic crystals, the average RI can be calculated using the formula:

$$n_{iso} = \frac{1}{3}(2\omega + \varepsilon) \quad \text{or} \quad n_{iso} = \frac{1}{3}(\alpha + \beta + \gamma) \quad (4)$$

And for anisotropic fibers:

$$n_{iso} = \frac{1}{3}(n_{ll} + 2n_{\perp}) \quad (5)$$

One advantage of looking at the average RI (n_{iso}) of anisotropic particles is that the average RI will be observed regardless of the orientation of the particle. Determining and comparing the average RI of anisotropic particles is a useful technique when characterizing a sample containing different types of textile fibers as well as for the detection of trace components in a sample. A list of n_{iso} values for fibers is provided by Gaudette in "The Forensic Aspects of Textile Fiber Examination". If a particle/fiber of interest is found by using unpolarized light, polarized light (plane or crossed) can be quickly inserted into the light path so additional optical properties can be determined.

Dispersion Staining. Dispersion staining is a powerful technique that one can employ to find the RI relationship between transparent particles and the mounting medium. Dispersion staining colors are observed when a particle and a liquid have different dispersion curves (plot of RI with wavelength) but have a common RI. This technique is useful for the identification of particles where the RI data is known and is especially useful for the detection of a component in a "needle-in-a-haystack" type of examination.

The dispersion staining technique employs an opaque annular stop or central stop located in the back focal plane of the objective (Figure 16). This stop enhances the color that is observed at the border of the particle and liquid. The color of the particle at the border will depend on where the liquid and the particle have the same RI. Wavelengths of light at the intersection of the dispersion curves for the particle and liquid will not be deviated and will pass through the opening of the annular stop but will be blocked if employing the central stop. The other wavelengths of light will be deviated and be blocked by the annular stop but will pass through the opening of the central stop if employed. The degree of deviation of the wavelengths of light will depend on the differences in the dispersion curves of the particle and liquid. As one would expect, the dispersion staining colors become more vivid if the particle and liquid have very different dispersion curves (Figure 17).

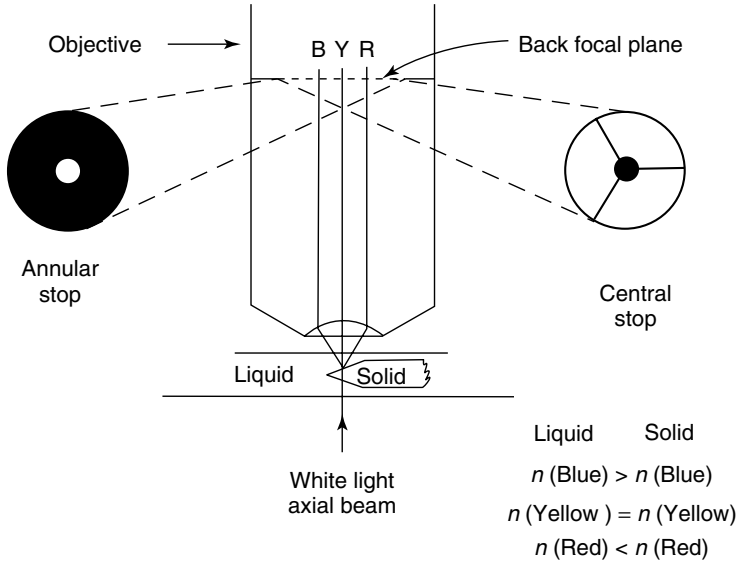

Figure 16 Diagram of the dispersion staining objective with the annular and central stop [Reproduced with permission from McCrone Research Institute.]

Table 1 Dispersion staining colors. λ_0 notes where the particle and the liquid have the same RI[(a)]

		Central stop colors	
Matching λ_0 (nm)	Annular stop colors	In focus	Becke line
<420	Blue–black	Light yellow	Faint gold + violet
430	Blue–violet	Yellow	Faint gold + violet
455	Blue	Golden yellow	Faint gold + violet
485	Blue–green	Golden–magenta	Yellow + violet
520	Green	Red–magenta	Violet + orange
560	Yellow–green	Magenta	Blue violet + red orange
595	Yellow	Blue–magenta	Blue + red
625	Orange	Blue	Blue
660	Orange–red	Blue–green	Green
>680	Brown–red	Pale blue	Pale green

[(a)]Reproduced with permission from McCrone Research Institute

The central stop method is generally preferred since the complementary dispersion staining colors are observed on a darkfield. Table 1 shows the colors observed at various matching wavelengths using the annular stop and central stop.

One can plot the dispersion curve for a particle by plotting the matching RI observed in several different liquids (Figure 18). To accomplish this, one must know the dispersion data for the liquids. This plot will provide the RI not only at n_D but also at n_F (486 nm) and n_C (656 nm), the other two refractive indices commonly listed in literature.

Alternately, one can plot a dispersion staining curve in a series of liquids and obtain the n_D value for a particle without knowing the dispersion data for the liquids. This is accomplished by plotting a horizontal line at the n_D value for the different liquids (Figure 19). However, only the RI at 589 nm (n_D) has any direct RI value to literature values. The RIs at the other wavelengths along the dispersion staining

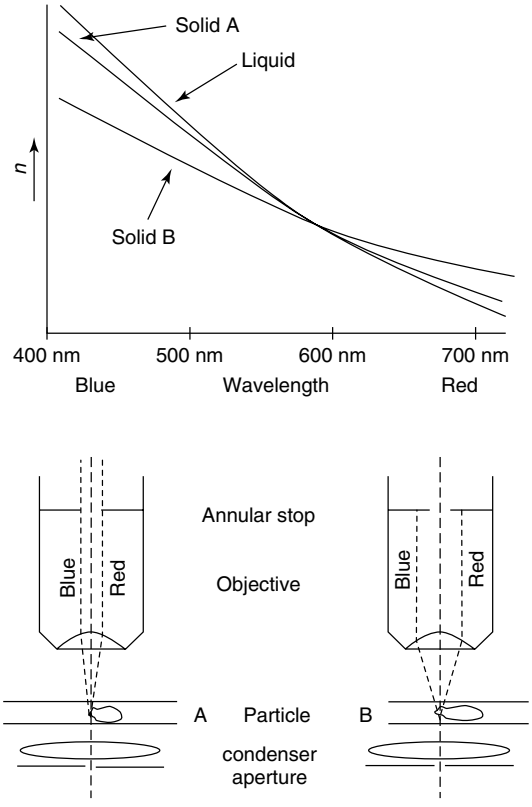

Figure 17 Ray paths through a dispersion staining objective using an annular stop corresponding to the dispersion curves for solid A and for solid B mounted in the same liquid

curve do not provide the actual RI of the particle. Therefore, to determine the actual RI for the particle at any wavelength other than n_D (589 nm), one needs to replot the dispersion staining curve using the actual known dispersion data for the liquids. In addition, dispersion curves are generally plotted with a linear wavelength scale whereas for dispersion staining curves the wavelength scale is plotted as $1/\lambda^2$. Plotting the wavelength as $1/\lambda^2$ generally provides a straighter line for the dispersion staining curve. For more information on dispersion staining, one should consult the *Polarized Light Microscopy* manual by McCrone, McCrone, and Delly.

Other Characteristics. If present, other characteristics may be noted including (but not limited to) color, transparency, and surface features. The color of the particle may be the first feature noted and can be observed with transmitted and/or reflected light. The color of a particle is the result of selective absorption of certain wavelengths of light. Only the average transmission color will be observed with unpolarized light for transparent particles with more than one RI. It can be seen later that the use of plane polarized light (single polar) will provide additional information for colored particles which have more than one RI.

Some particles may not transmit all the illuminating light and are translucent rather than transparent. This translucent characteristic may be due to optical discontinuities within the particle which scatter light through refraction and/or reflection as light travels through the particle. These optical discontinuities may be the result of different orientation of internal grain structure, impurities, or inclusions such as air bubbles. It may also be the result of surface features which are more apparent when the RI of the particle and liquid differ greatly.

The surface of the particle is another important feature used to characterize and compare particles. Transmitted light is used to observe the surface of a transparent or translucent particle by focusing on the top and bottom surfaces. However, with opaque particles, a reflected light illuminator is employed. General descriptive terms may include smooth, dimpled, fractured, rough, pitted, and nodular.

Polarized Light Microscopy

The polarized light microscope (PLM) is a powerful analytical instrument for the forensic trace analyst. The polarizing microscope can be applied to almost any type of trace evidence and will increase the number of identification characteristics one can determine for a particle under investigation. The PLM differs from a biological microscope in that it has a polarizer (polar) located in the substage condenser, an analyzer (second polar) located above the stage, a circular stage, strain free objectives, a crossline eyepiece, and a slot for inserting compensators in the body tube. The most common compensator is the full-wave (530 nm) compensator, but it is desirable to have a quarter-wave (137 nm) compensator and a variable compensator. Also, the stage and/or objectives should be centerable.

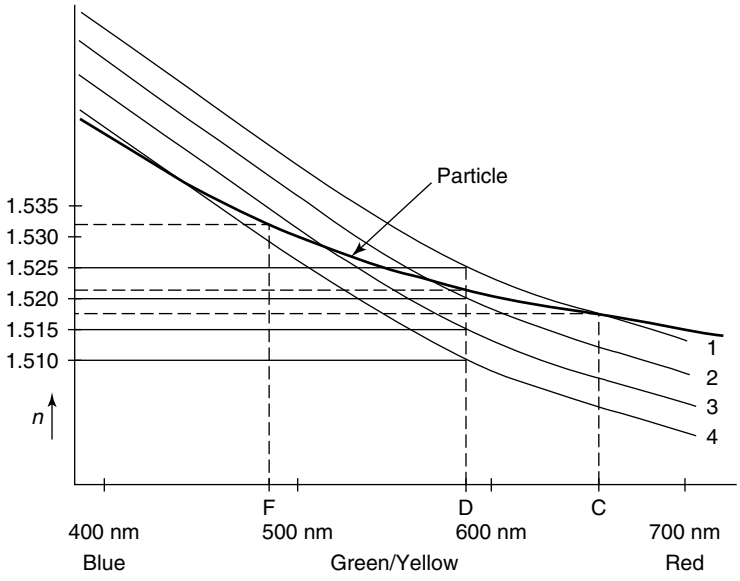

Figure 18 Dispersion curve plot for a particle mounted in four different liquids. The refractive index values are $n_F = 1.532$, $n_D = 1.522$, and $n_C = 1.517$

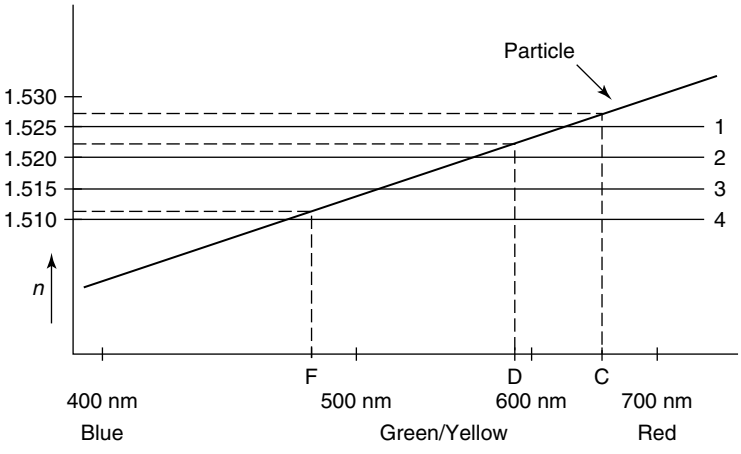

Figure 19 Dispersion staining curve for the particle in Figure 16. The dispersion staining values are $n_F = 1.511$, $n_D = 1.522$, and $n_C = 1.527$

Particle Characterization – Single Polar

As noted in the section "Brightfield", without any polarizer (polar) in the system one can observe only the average color and RI of anisotropic particles. This is because ordinary light is unpolarized and vibrates in a multitude of different directions perpendicular to the propagation direction of travel. Since optical properties will vary with the vibration of the light in an anisotropic particle, one must employ plane polarized light to observe and measure these variations.

Plane polarized light is obtained by using a polarizing filter. When unpolarized light passes through a polarizing filter, the light will exit vibrating in a single (privileged) direction perpendicular to the direction of travel (Figure 20). Now with the employment of

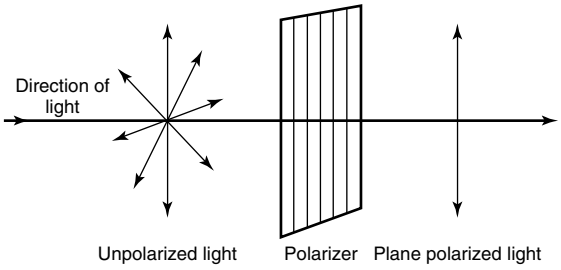

Figure 20 Unpolarized light passing through a polarizing filter resulting in plane polarized light

a single polar, one will be able to measure different optical properties of an anisotropic material as a function of the vibration direction of the light passing through the particle. Therefore, utilizing PLM will increase the number of optical properties that one can determine when characterizing and identifying particles. Before one measures the different properties of a particle, it is necessary to have a well centered stage and check the alignment of the polarizer and analyzer which are normally aligned perpendicular to each other.

Refractive Indices. With plane polarized light, more than one RI can be observed for anisotropic particles. The RIs one will observe will depend on the orientation of the particle and the alignment of the RIs with the polarizer. Fibers are discussed first since they lay flat on the microscope slide and show their two principle indices: the RI parallel ($n_{\parallel}$) to the fiber length and the RI perpendicular ($n_{\perp}$) to the fiber. When the length of the fiber is aligned parallel to the polarizer, the $n_{\parallel}$ RI will be observed (Figure 21a). If one rotates the stage and aligns the fiber perpendicular to the polarizer, than the $n_{\perp}$ will be observed (Figure 21b). If one rotates the stage so neither of the RIs coincides with the polarizer, than the light will be vectorially split between the two RIs and will be split equally when the fiber is aligned at a 45° angle to the polarizer (Figure 21c). When the fiber is aligned parallel or perpendicular to the polarizer, the respective RIs can be estimated or precisely determined using immersion methods or by employing the dispersion staining technique. Note that the polyester fiber shows higher contrast when the fiber is aligned east–west (parallel RI) and is a quick way to check that your polarizer is also aligned east–west.

Unlike fibers, which show their longitudinal view, most crystals show a randomly oriented view when mounted on a microscope slide. The optical indicatrix helps us to understand how the RI varies depending on the vibration direction of light through a crystal. The indicatrix is a 3-D model whose radii are proportional to the RI values perpendicular, or nearly so, to the direction of light and, therefore, assumes a different solid geometrical form depending on the RIs of a crystal. Thus, for an isotropic (cubic or noncrystalline) particle which has a single refractive index, all the radii would be of equal length and will result in the simplest indicatrix having the form of a sphere (Figure 22). If one would cut a section at any angle through the center of the indicatrix, a circular section would be obtained having a circumference equidistant at all points from the center of the sphere. Therefore, one would observe a single RI for light traveling perpendicular to any circular section no matter the vibration direction of the light.

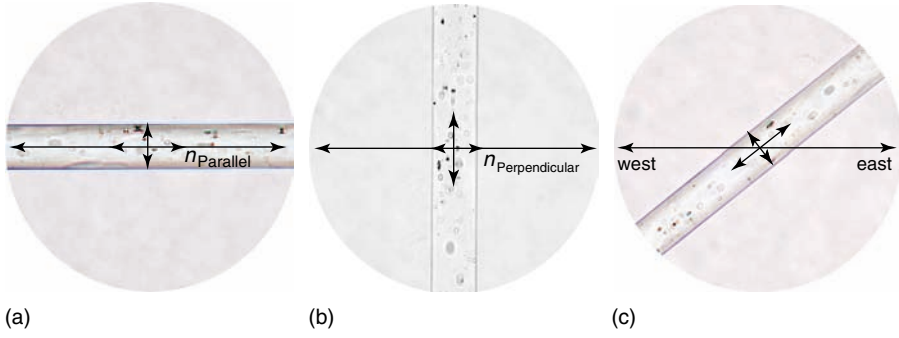

Figure 21 Three different orientations of a polyester fiber viewed with an east-west polarizer. Note the chance of contrast in the different views. The RI of mounting medium is 1.525

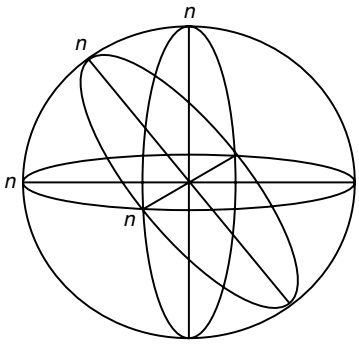

Figure 22 Isotropic indicatrix

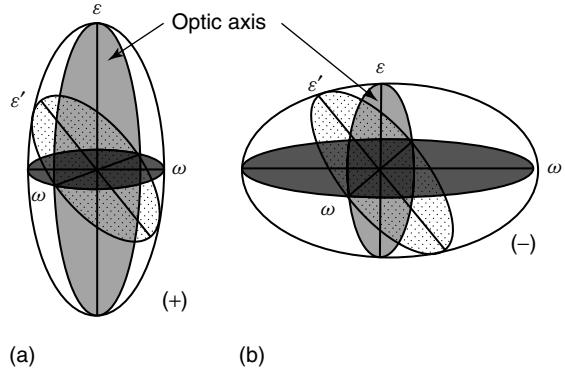

Figure 23 Uniaxial indicatrix: (a) prolate ellipse where $\varepsilon > \omega$ (positive optic sign) and (b) oblate ellipse where $\varepsilon < \omega$ (negative optic sign)

For uniaxial (tetragonal and hexagonal) crystals, the indicatrix takes on an elliptical form with the maximum and minimum magnitude of the radii equal to the two principal indices, ε and ω. If the $\varepsilon > \omega$ (+) optic sign the shape of the ellipsoid will be prolate (Figure 23a) and if $\varepsilon < \omega$ (−) optic sign the shape of the ellipsoid will be oblate (Figure 23b).

For all uniaxial crystals, the ε RI coincides with the optic axis. The optic axis is a unique axis and if one cuts a section though the center of the indicatrix perpendicular to the optic axis, a circular section (shaded dark gray) will be obtained as shown in Figure 23. Plane polarized light traveling along the optic axis will vibrate in this circular section containing only the ω RI. Therefore, a uniaxial crystal in this orientation would behave as an isotropic crystal since only the ω RI will be observed (Figure 24a) and the contrast for the crystal will remain constant with plane polarized light as you rotate the stage.

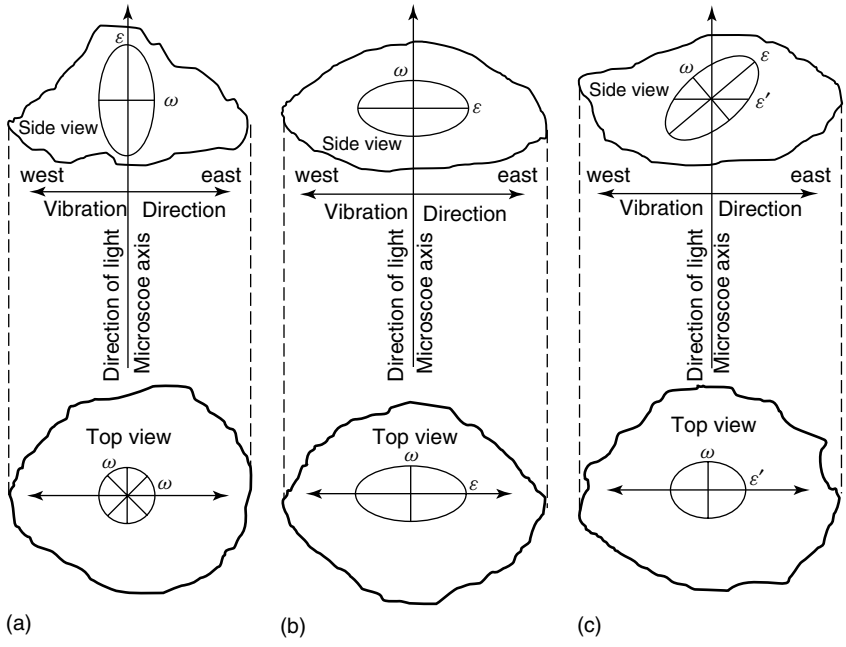

Figure 24 Three different orientations with the uniaxial indicatrix superimposed in the different views

For a section cut through the center of a uniaxial indicatrix parallel to the two principal indices, ε and ω, a principal ellipse (shaded light gray) will be obtained as seen in Figure 23. Therefore, if the propagation direction of the plane polarized light is perpendicular to this section, one will observe either the ε RI or the ω RI when one or the other is aligned parallel to the vibration direction of the polarized light (Figure 24b). If the stage is rotated so neither principal RI is parallel with the polarizer, as previously discussed, the plane polarized light will be split vectorially between the two principal RIs and equally when they are positioned at a 45° angle from the polarizer. Also, with a crystal in this orientation the contrast will change as the stage is rotated and the degree of contrast change will be dependent on the differences in the RIs between ε, ω and the mounting medium.

An ellipse will be obtained if a section (textured plane) is cut at a diagonal angle through the center of an indicatrix as shown in Figure 23. This elliptical cross section will contain the ω and ε' RIs. An ε' RI can be any multitude of RIs between ε and ω and which ε' RI will be observed is dependent on the orientation of the crystal. If the propagation direction of plane polarized light is perpendicular to an elliptical section, one will observe either the ω RI or the ε' RI when one or the other is aligned parallel to the vibration direction of the polarized light (Figure 24c). If the stage is rotated so neither RI is parallel with the polarizer, the plane polarized light will be split vectorially between the two RIs and equally when they are positioned at a 45° angle from the polarizer. Also, as mentioned above, when one rotates the stage with a crystal in this orientation the contrast will change and to what degree will depend on the differences in the RIs of ω, ε' and the mounting medium. How to easily locate the RIs for a randomly oriented crystal is discussed in the crossed polarized light section.

For biaxial (orthorhombic, monoclinic, and triclinic) crystals, the indicatrix is a triaxial ellipsoid defined by the three principal indices α, β, and γ. By definition, α is the lowest RI, γ is the highest RI, and β is the intermediate RI that lies somewhere between α and γ. As one can see in Figure 25a, light traveling parallel to γ will vibrate in the plane (shaded dark gray) containing α and β, light traveling parallel to α will vibrate in the plane (shaded gray) containing β and γ, and light traveling parallel to β will vibrate in the plane (shaded light gray) containing α and γ. In the plane (shaded light gray) containing α, the lowest RI, and γ, the highest RI, there are radii equal to β RI. Therefore, there are two sets of radii that would describe two circular planes containing only the β RI in the biaxial indicatrix (Figure 25b). Light traveling perpendicular to the two circular planes would travel along the optic axes which lie in the ellipsoid plane containing α and γ. If the β RI is closer to α RI, the crystal has a positive (+) optic sign (Figure 25c). However, if the β RI is closer to the γ RI, the crystal has a negative (−) optic sign (Figure 25d). The RIs between α and β are noted as α' and RIs between β and γ are noted as γ'.

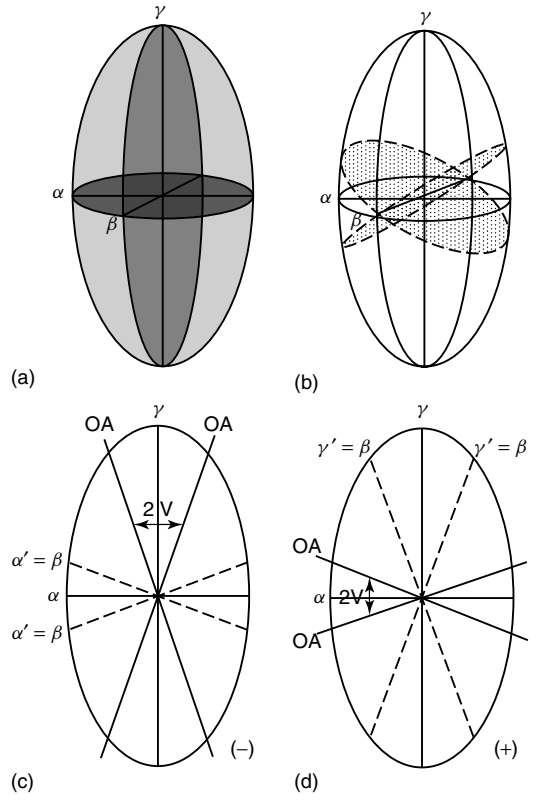

Figure 25 Biaxial Indicatrix

As with uniaxial crystals, one can superimpose the RIs within a crystal to understand and/or predict optical characteristics that one might observe during the examination of a particle (Figure 26). Again, how to easily locate the RIs for a randomly oriented crystal will be discussed in the crossed polarized section.

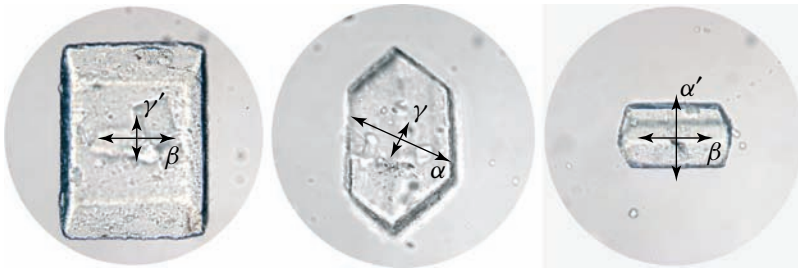

Figure 26 Three views of a sucrose crystal with the RIs superimposed in the different views

The RIs of anisotropic particles can be estimated or precisely determined using immersion methods or by employing the dispersion staining technique.

Color – Pleochroism and Dichroism. Pleochroism observed with plane polarized light provides an additional diagnostic characteristic. Pleochroism is the general term for the phenomenon of colored anisotropic particles that absorb different wavelengths of light depending on the vibration direction through the particle. Dichroism is the proper term that refers to uniaxial crystals and many dyed fibers that show two colors with plane polarized light. All colored anisotropic particles show pleochroism but at times the change in color may be too faint to detect. Colored isotropic particles and colorless particles do not show pleochroism.

Employing plane polarized light, all one needs to do to observe pleochroism/dichorism is to rotate the stage while viewing a colored anisotropic crystal or a dyed fiber which displays this effect (Figure 27). When observing pleochroism, one should note the change of color corresponding to any physical features such as a crystal face, cleavage plane, or fiber length. The strongest absorption color usually corresponds to the highest RI direction but the asbestos mineral crocidolite is an exception to this rule.

Particle Characterization – Crossed Polars

With crossed polars, one will greatly increase the number of identification characteristics that can be determined for a particle under investigation. Crossing the polars will allow one to determine the degree of birefringence, observe different types of extinction, determine the sign of elongation, and observe interference figures. As previously discussed, it is very important to insure that the polars are properly aligned with the eyepiece crosslines and the stage is well centered.

Wave Interference. Two waves having the same wavelength and traveling along the same propagation direction will interfere to produce a resultant wave having the same wavelength whose amplitude is the vector sum of the original two waves. However, it is important to understand the difference in how the resultant wave and interference colors are produced by two rays vibrating in the same plane or by two waves after vibrating in perpendicular planes.

Retardation of Waves Polarized in the Same Plane. If two waves, having the same wavelength and traveling in the same direction, are vibrating in the same plane and one wave is retarded from the other

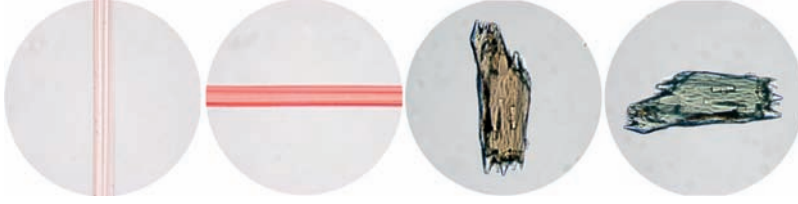

Figure 27 Dyed fiber showing dichorism (left two images) and a hyperstene crystal showing pleochroism (right two images)

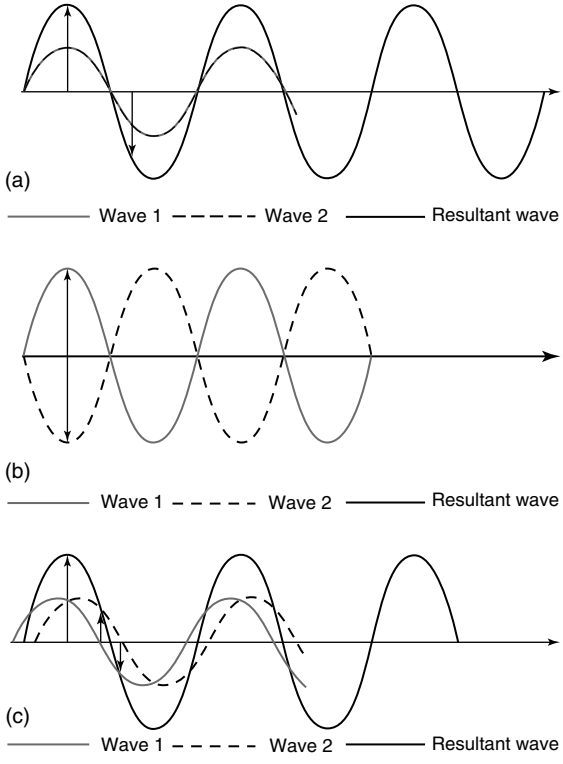

Figure 28 Interference between two waves traveling in the same plane and along the same path produce the resultant wave shown when one wave is retarded by (a) $n\lambda$, (b) $n\lambda + \lambda/2$, and (c) $n\lambda = \lambda/8$. [Illustration by David Diener]

wave resulting in a path difference 1λ, 2λ, or any $n\lambda$ (where n is an integer) the two waves will be in phase. This will result in constructive interference and the resultant wave will appear brighter since the amplitude of the resultant wave is twice the amplitude of the original rays (Figure 28a). However, if two waves, having the same wavelength and traveling in the same direction, are vibrating in the same plane and one wave is retarded from the other wave so the path difference is $\lambda/2$, $1\lambda + \lambda/2$, $2\lambda + \lambda/2$, or any $n\lambda + \lambda/2$, the two waves will destructively interfere. The resultant wave will have zero amplitude and this wavelength will be eliminated (Figure 28b). Furthermore, if two waves, having the same wavelength and traveling in the same direction, are vibrating in the same plane and one ray is retarded some distance other than $n\lambda$ or $n\lambda + \lambda/2$, the resultant wave produced will be a combination of both constructive and destructive interference (Figure 28c).

Interference Colors Produced by Two Waves Vibrating in the Same Plane. If two beams of white light interfere in the same plane as described above, some wavelengths will be eliminated while other wavelengths will be intensified. As a result, a series of colors known as *interference colors* will be produced and the resultant color will be dependent on the phase difference for the different wavelengths of light. This phenomenon produces what is commonly referred to as *thin film interference colors*, also known as *Newton's colors*. These colors are frequently seen when white light incident on a thin transparent film is reflected from the top and bottom surfaces, resulting in the reflected rays interfering with each other. Soap bubbles, a layer of oil on water, and thin deposits on a reflective substrate are a few examples that commonly show thin film interference colors.

Retardation of Waves Polarized in the Perpendicular Planes. When plane polarized light enters an anisotropic crystal which is oriented so the two indices (major or prime) are at a 45° angle from the polarizer, the wave will be resolved and vectorially split equally into two waves traveling in two mutually perpendicular planes. As a result, the slow wave (higher RI) will be retarded from the fast wave (lower RI). When both rays exit the crystal, they will continue to vibrate in perpendicular planes and will interfere with each other at the analyzer to produce a resultant wave vibrating in a single plane that is the vector sum of the two parent waves. If the two waves for a particular wavelength have a path difference of 1λ, 2λ, 3λ, or any $n\lambda$, the resultant wave will vibrate in the same plane as the original wave. The analyzer, which is a second polarizer located above the crystal whose privileged vibration direction is perpendicular to the polarizer, will block this wavelength of light (Figure 29a). However, if for a particular wavelength the two waves vibrating in two mutually perpendicular planes have a path difference of $\lambda/2$, $1\lambda + \lambda/2$, $2\lambda + \lambda/2$, or any $n\lambda + \lambda/2$, the resultant wave will vibrate in a plane particular to the polarizer vibration direction. Therefore, the analyzer will allow this wavelength of light to be transmitted through the analyzer (Figure 29b).

Furthermore, when a path difference for a particular wavelength has been separated $\lambda/4$, $1\lambda + \lambda/4$,

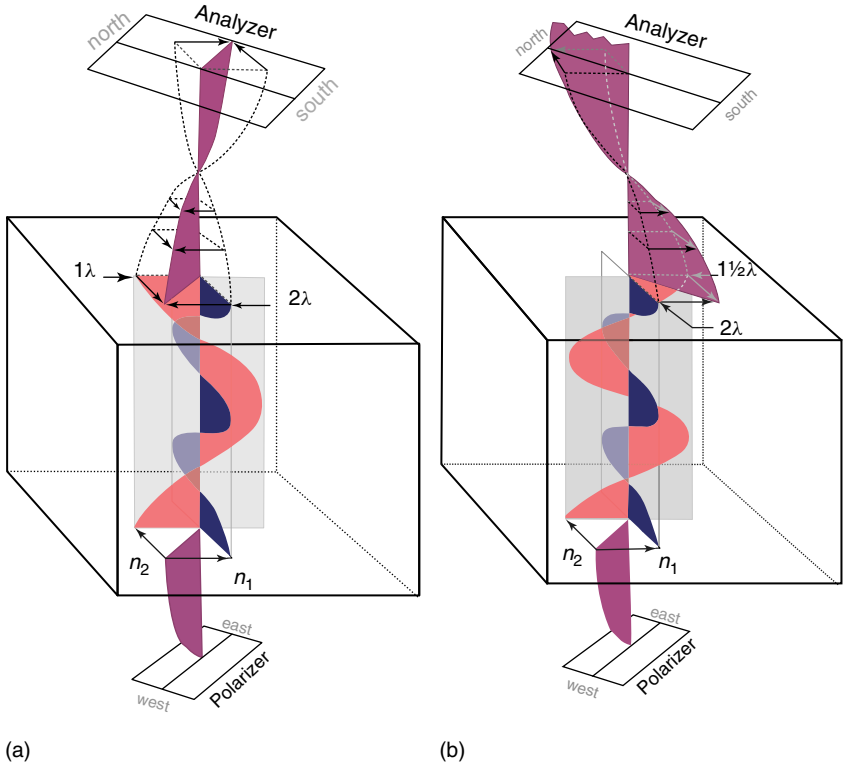

Figure 29 Interference (a) between two waves after emergence from a crystal when one wave is retarded by 1λ. Note the resultant wave is polarized in the same plane as the polarizer and would be completely be extinguished by the analyzer. Interference (b) between two waves after emergence from a crystal when one wave is retarded by 1/2λ. Note the resultant wave is polarized in the same plane as the analyzer and would be completely be transmitted by the analyzer. For illustration purposes, the waves are shown interfering before they reach the analyzer which allows for an easier understanding of the interaction of light when it reaches the analyzer. [Illustration by David Diener]

$2\lambda + \lambda/4$, or any $n\lambda + \lambda/4$, the resultant wave will vibrate in a circular, cork screw fashion and only 50% of this wavelength will be passed (transmitted) by the analyzer. And, if the path difference is any other value than $n\lambda$, $n\lambda + \lambda/2$, $n\lambda + \lambda/4$, which is normally the case, the resultant wave will vibrate in an elliptical fashion and some percentage of the resultant wave will be passed by the analyzer. The percent transmission of light by the analyzer for different phase differences is illustrated in Figure 30.

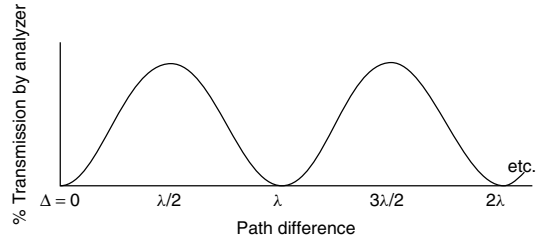

Figure 30 Percent transmission of light by the analyzer depending on the phase difference (retardation) after passage through a birefringent crystal with crossed polars

Interference Colors Produced by Two Waves Vibrating in Perpendicular Planes. If illuminated with white light, an anisotropic crystal viewed between crossed polars where the light vibrates along the two indices, a series of polarization (interference) colors will be observed as a result of unequal transmission by the analyzer of the different wavelengths of light as previously described. The interference colors of the particle will be brightest when the two indices are positioned at a 45° angle from the

vibration direction of the polarizer. These interference colors are commonly referred to as *polarization colors* or *retardation colors*.

Birefringence. Birefringence is the numerical difference of the two refractive indices ($n_2 - n_1$) for an anisotropic particle in a particular view. These indices for a crystal may be principal or prime indices and for a fiber ($n_{\parallel} - n_{\perp}$). When the birefringence value is stated in literature, it is the maximum difference between the indices of a fiber or crystal unless otherwise stated. The interference color one sees between crossed polars is due to retardation (r) of the different wavelengths of light and is the result of the relationship between birefringence (B) and thickness (T) of the material under investigation. It is very important to remember that the thickness of the material is not the linear distance measured in the plane of the preparation but the thickness along the microscope axis.

This relationship is expressed as $r = 1000BT$ and is plotted graphically in the Michel–Levy chart that was first published in 1889, and a microscopist can determine any one of the values if the other two are known (Figure 31). Referring to the Michel–Levy chart, one can see that thickness increases as you move up the left ordinate. The retardation (path difference) increases as you go to the right and the colors become paler. The birefringence for a particle can be determined by moving up the diagonal line where an observed retardation color and known thickness intersect. Glass fibers of any thickness would be black on a black field with crossed polars since glass has one RI and light travels through the particle at a single velocity. However, a 10 μm fiber showing a first-order red color would have a birefringence of 0.055

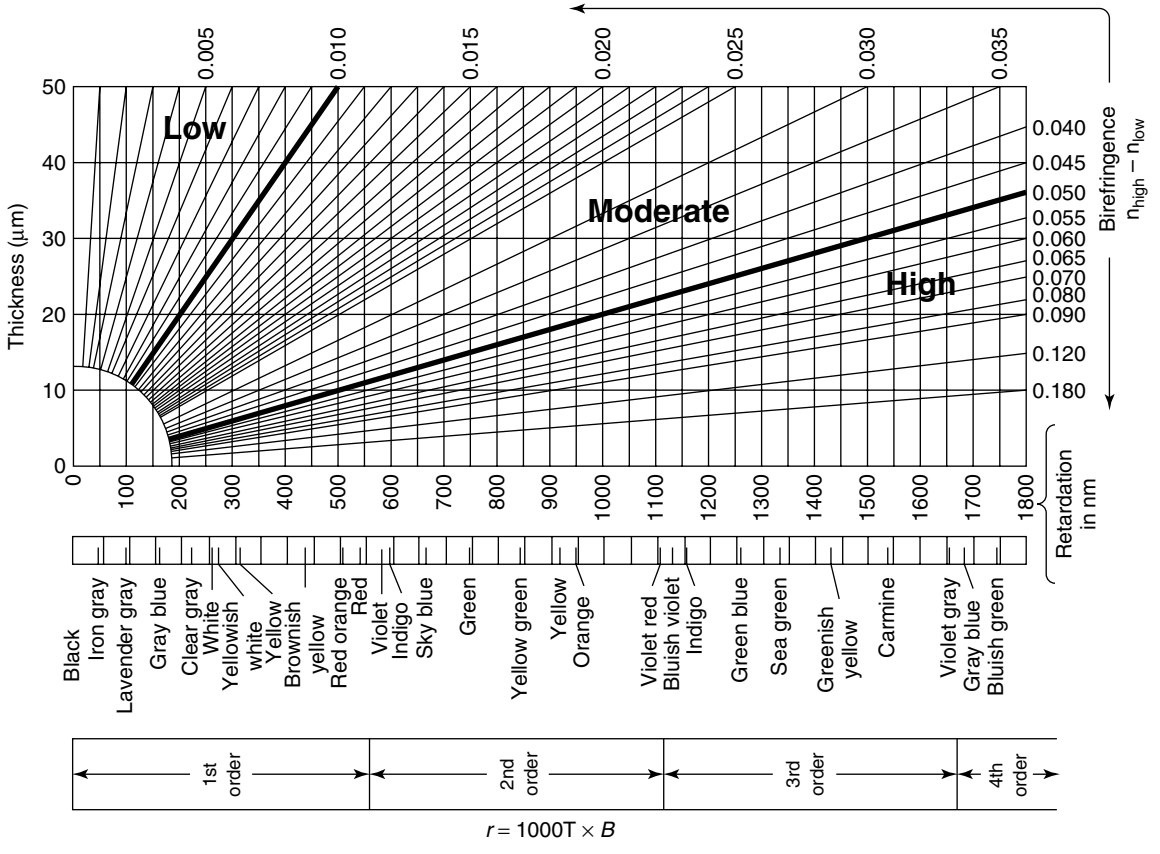

Figure 31 A black and white Michel–Lévy chart showing the relationship among retardation, thickness, and birefringence. One can obtain a color Michel–Lévy chart from most of the references listed in the bibliography

and a 10 μm fiber showing a third-order red color would have a birefringence of 0.170. Some particles will not follow the Michel–Levy series of retardation colors but will show anomalous polarization colors and when recognized it is a unique identifying characteristic.

Extinction. Particles will be brightest between crossed polars when the two indices are in a particular view. As one rotates the stage, the particle will usually go dark every 90°, a circumstance known as *extinction*. There are different types of extinction one can observe for a particle (Figure 32). Most particles will show complete or uniform extinction and may show parallel, symmetrical, or oblique extinction.

Some particles will not uniformly go to complete extinction but will show nonuniform extinction. Undulose extinction shows areas of extinction that move progressively across the particle in a fanlike motion as the stage is rotated. Polycrystalline crystals will show areas of extinction due to the random orientation of the crystals to each other.

Other particles may not show any extinction. Cotton fibers may not show good extinction due to the different orientations of the overlaying top and bottom layer of the collapsed fiber. Some particles in a particular view may show dispersion of extinction and the different "extinction" colors are dependent on the wavelength of light (Figure 33). When recognized, it is a unique identifying characteristic.

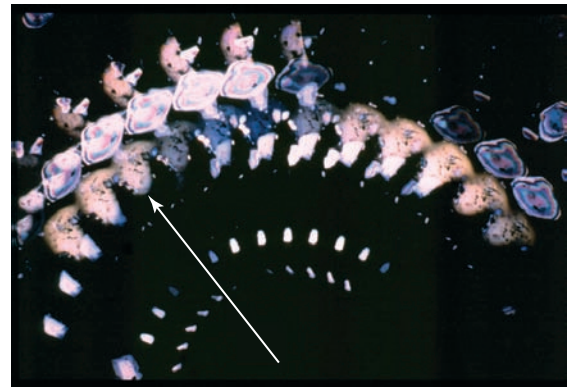

Figure 33 Photomicrograph of RDX by Dr. Walter C. McCrone with a crystal (arrow) showing dispersed extinction when viewed with crossed polars. The photomicrograph is a series of 12 exposures with the stage being rotated several degrees between each exposure. Note the crystal does not go to complete extinction but displays a series of colors from blue to purple to yellow. The RDX crystal above the crystal showing dispersed extinction has a different orientation and shows complete extinction [Reproduced with permission from McCrone Research Institute.]

Sign of Elongation. By convention, a fiber has a positive (+) sign of elongation if $n_{\parallel} > n_{\perp}$ and a negative (−) sign of elongation if $n_{\parallel} < n_{\perp}$. One can quickly determine if the fiber has a (+) or (−) sign of elongation by using a compensator. Compensators are usually marked with an arrow with a γ or Z symbol

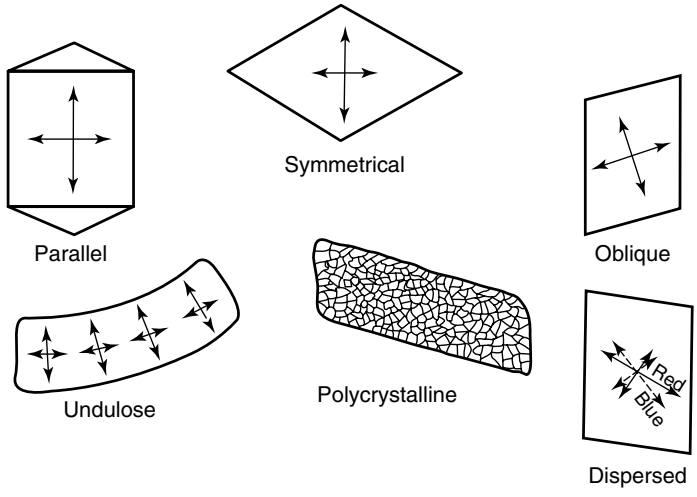

Figure 32 Different types of extinction [Reproduced with permission from McCrone Research Institute.]

to indicate the slow component (higher RI) direction. Commonly used compensators to determine the sign of elongation include the first-order red plate having a retardation of 530 nm and the quarter-wave plate having a retardation of 137 nm.

Utilizing crossed polars, the retardation colors are noted for a fiber that is aligned parallel to the slow component direction of the compensator. When a first-order red plate is inserted, the retardation will change by 530 nm and the two retardations (fiber and compensator) will be added or subtracted (lower RI from the higher RI). Addition means the two slow components are parallel and the fiber has a (+) sign of elongation (i.e., $n_{\parallel} > n_{\perp}$). Subtraction means the slow component of the fiber is perpendicular to the slow component of the compensator and the fiber has a (−) sign of elongation (i.e., $n_{\parallel} < n_{\perp}$).

For example, if a gray blue (150 nm) retardation color is observed with crossed polars for a fiber aligned parallel to the slow component of the compensator and turns blue (680 nm) when the 530 nm compensator is inserted, then the two retardations have added and the fiber has a (+) sign of elongation. However, the fiber has a negative sign of elongation if it turns yellow (380 nm). Higher-order retardation colors observed with crossed polars will appear more pale when the compensator is inserted for a fiber that has a (+) sign of elongation and brighter for a (−) sign of elongation. Wollastonite, a fibrous mineral, may show (+) or (−) sign of elongation because the β RI is parallel to the length of the fiber. When α (or α') RI is perpendicular to the length, the fiber will have a (+) sign of elongation and a (−) sign of elongation when γ (or γ') RI is perpendicular to the fiber length.

Interference Figures. An interference figure is an important diagnostic feature that is formed by rays that travel along different directions within the crystal. Interference figures are observed by examining the back focal plane of the objective using a Bertrand lens, a phase telescope, or by removing an eyepiece and inserting a pinhole eye cap. Unfortunately, most crystals have orientations that provide interference figures that are of little diagnostic value. However, if one can recognize a crystal in the orientation that will provide a useful figure, one can determine a number of optical properties such as if the crystal is uniaxial or biaxial, the location of the principal refractive indices, and the optic sign. Low retardation colors observed on highly birefringent crystals provide the best interference figures.

An objective having a numerical aperture of at least 0.65 is required to obtain an interference figure and the aperture diaphragm needs to be opened to provide a full cone of light to the objective. An example of a centered uniaxial interference figure is provided and a centered biaxial figure is provided in Figure 34. One should be aware of the value of interference figures even though a more in depth discussion is not possible here but one can investigate a number of references listed in the bibliography such as *Optical Crystallography* by F. Donald Bloss for more information.

Fusion Methods

Fusion methods many times can be included when characterizing a sample. Most of the time, a sample can be heated over an alcohol lamp and characteristic crystals that develop from the melt state can be observed. Also, a hot stage can be attached to the microscope and used to accurately determine the melting point of a particle under investigation. Many microscopists use the hot stage to distinguish between polymers like low density and high density polyethylene as well as nylon 6 and nylon 6,6.

Fusion methods can be used to characterize not only organic compounds but also some inorganic compounds. For example, ammonium nitrate has four crystal phases above room temperature: an orthorhombic crystal phase from room temperature to 32 °C, a second biaxial crystal phase from 32 to 84 °C, a tetragonal crystal phase from 84 to 125 °C, and finally a cubic crystal phase which melts at 170 °C. Using a polarized light microscope, it is truly a spectacular sight to view a sample going from room temperature to a melted state and from a melted

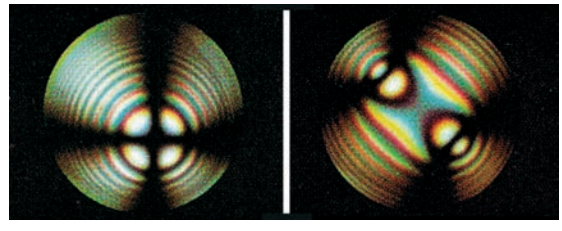

Figure 34 Interference figures: uniaxial (left) and biaxial (right) [Reproduced with permission from McCrone Research Institute.]

state back to room temperature. For more information on fusion methods one should consult the *Polarized Light Microscopy* manual by McCrone, McCrone and Delly as well as *Fusion Methods* by McCrone.

Microchemical Tests

Microchemical tests aid in the identification of particles under investigation and should not be overlooked by the forensic microscopist. These tests can be applied to both inorganic compounds (e.g., explosives) and organic compounds (e.g., drugs) and many times a microchemical test will provide more information about a particle under investigation (e.g., valence state) than other modern instrumental methods. Microchemical tests are particularly useful because they are quickly and easily conducted, their sensitivity requires only a minute amount of sample, and they are easy to perform.

Most microchemical tests are based on the formation of characteristics crystals that develop using a selected reagent and are normally carried out on a microscope slide without a coverslip using a 10X objective. An in-depth discussion on microchemical methods is not possible in this article and one should consult references such as the *Handbook of Chemical Microscopy, Volume 1 and 2*, by Chamot and Mason as well as "Microchemical Reactions in Particle Identification" by S. Palenik in the *Particle Atlas, Volume 5*, for a detailed presentation on microchemical methods.

Fluorescence Microscopy

Since the early 1980s, fluorescence microscopy has become a common analytical tool employed in the trace evidence section of many forensic laboratories. This technique is a sensitive and simple analytical tool that can be employed to characterize and compare many different types of trace evidence such as paints, cosmetics, fibers, adhesives, plastics, and mineral grains in soil samples. Fluorescence microscopy is a nondestructive method that can quickly provide information which cannot be obtained by other types of instrumentation. This article addresses only reflected or incident light (also referred to as *Epi*) fluorescence since it is the type of fluorescence microscopy used today. A simple diagram of a reflected light fluorescence microscope showing the ray paths for illuminating and imaging the specimen is provided in Figure 35.

Fluorescence

Luminescence is the term used to describe nonthermal radiation of longer wavelength (lower energy) that is emitted when energy of shorter wavelength (higher energy) is absorbed by some materials. The fluorescent material may be inorganic or organic and the emitted radiation (luminescence) is usually in the visible region of light. The energy stimulation can be ion, X-ray, electron, or photon radiation. Luminescence can also be produced by chemical reactions

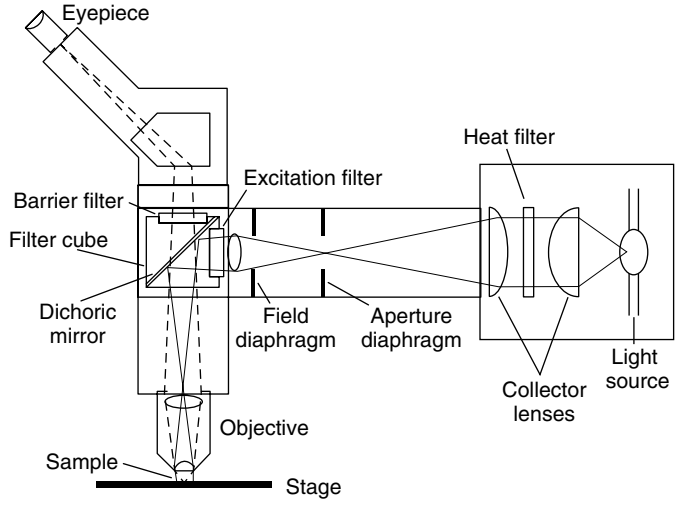

Figure 35 Schematic diagram showing the illuminating and imagining ray path through a fluorescent microscope

or by mechanical action. Depending on the type of primary excitation, different descriptive terms may be used to describe the luminescence: e.g., ionoluminescence (ion), Roentgenoluminescence (X-ray), cathodoluminescence (electron), and photoluminescence (photon).

Luminescence can be further subdivided into phosphorescence and fluorescence. Phosphorescence is generally characterized by continued luminescence after the excitation stops and fluorescence ceases instantaneously when the excitation stops. Fluorescence can also be subdivided into primary fluorescence (auto) and secondary fluorescence. Primary fluorescence is the ability to emit luminescence without any treatment or staining. Secondary fluorescence requires staining the specimen with a dye (e.g., fluorchrome). Normally, only primary fluorescence will be of interest in the examination of trace evidence.

Illuminators

There are two types of light sources used for fluorescence microscopy which are the pressure mercury lamp and the xenon lamp. The high-pressure mercury lamp produces a rather noncontinuous energy distribution with most of its energy output concentrated in several narrow bands (Figure 36). The xenon lamp produces a more continuous spectrum from the ultraviolet to the near infrared and closely resembles characteristics of visible light (Figure 37). In addition to being able to produce a more continuous energy spectrum, xenon lamps can be switched on and off without waiting for the lamp to warm-up or cool down. Various output powers are available for these

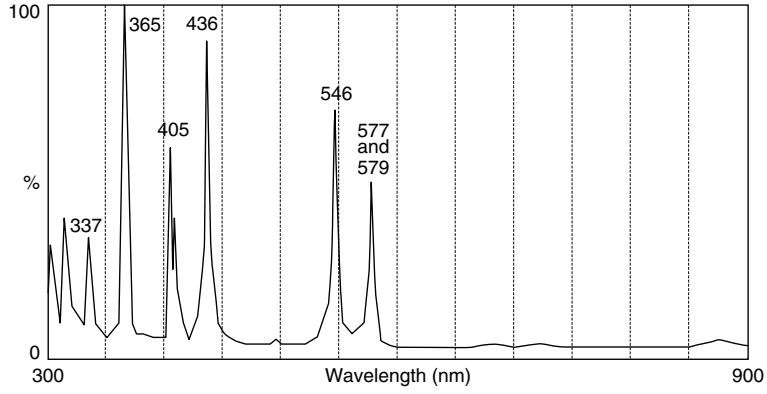

Figure 36 Spectral output for mercury lamp

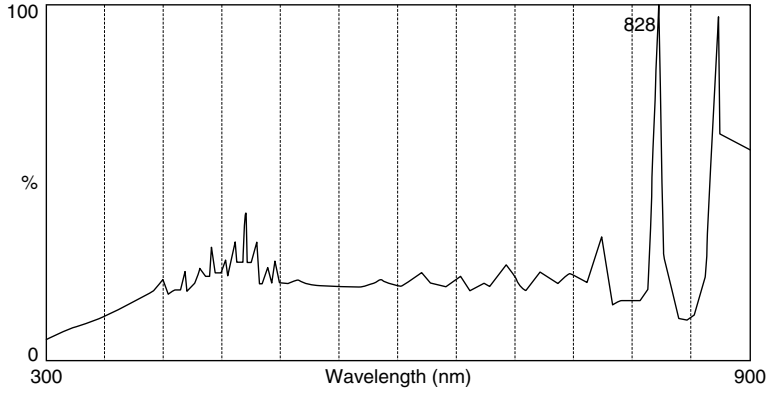

Figure 37 Spectral output for xenon lamp

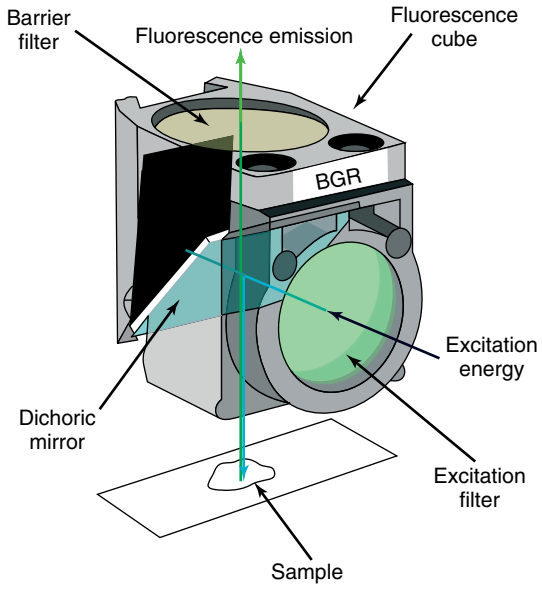

Figure 38 Cutaway view showing the components of a fluorescent filter cube

lamps, but generally 100 W mercury lamps and 75 W xenon lamps are used for the examination of trace evidence samples. Before starting any examination, one needs to ensure that the microscope has been properly aligned and adjusted so that the illumination field provides the best image quality.

Optical Cube

Besides the alignment of the microscope, the proper selection of the filters contained in the cube is an important factor in determining the intensity of the fluorescence image observed though the microscope. The optical cube or filter cube contains the excitation filter, the dichroic mirror (DM), and the barrier filter (Figure 38). Manufacturers today offer a variety of fluorescence cubes containing different filter and mirror combinations, and it is important to understand the purpose of each component of the cube. The filters and mirror in a cube allow certain wavelengths of light to be transmitted, reflected, or absorbed and the correct configuration will maximize the fluorescence intensity of the sample being examined.

Excitation Filter. The excitation or exciter filter (EX) allows shorter wavelengths of light from the

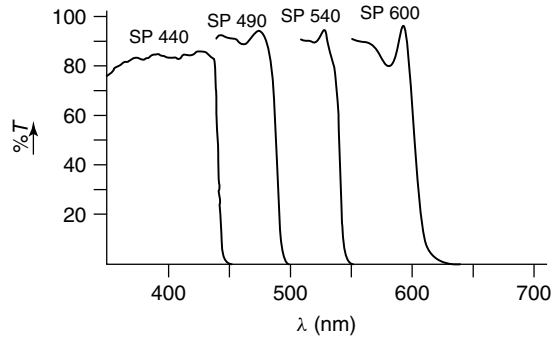

Figure 39 Typical transmission curves for several shortpass excitation filters. The nomenclature denotes the cut-off wavelength at 50% maximum transmission

illuminator to pass through while longer wavelengths are suppressed. As one would expect, the purpose of this filter is to transmit only the wavelengths of illumination that will effectively excite the specimen and eliminate longer wavelengths of light that would obscure any fluorescence from the specimen. The filter may have simple nomenclature designating the wavelength range that is passed (transmitted) such as UV or U for ultraviolet, B for blue, G for green or may have a more detailed nomenclature specifying the wavelength range that is passed by the filter. Shortpass (SP) filters that transmit shorter wavelengths yet block longer wavelengths were used in the past for the excitation filter. The nomenclature typically used for these filters denotes the cut-off wavelength that is located at 50% maximum transmission (Figure 39). Today, however, bandpass (BP) filters, or bandpass interference filters (BPIF) are utilized almost exclusively for the excitation filter. BP filters typically have a nomenclature which denotes the center wavelength of the transmission and may note the bandwidth at half of the maximum transmission (Figure 40). BP filters can further be designated as wideband or narrowband filters. As suggested by S. Palenik in "Microscopical Examination of Fibers", wideband filters would be a better choice for the forensic microscopist since they are considering a wide range of materials that may fluoresce over a broad range of wavelengths.

Dichroic Mirror. The shorter wavelengths of excitation illumination will be reflected toward the specimen by the DM, also referred to as the *chromatic beam splitter* (BS). The DM is positioned at a 45°

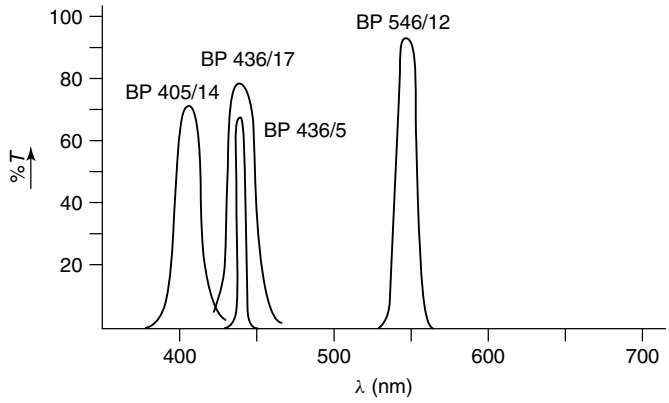

Figure 40 Typical transmission curves for several bandpass excitation filters. The nomenclature denotes the center wavelength of transmission and the bandwidth at 50% maximum transmission

in the optical light path. At the same time, the unwanted longer wavelengths of light will be transmitted through the DM and absorbed on the interior black coated surface of the cube. Once the excitation wavelength reaches the specimen, the emitted fluorescent wavelengths from the sample and some of the unabsorbed excitation wavelength(s) of light will be reflected back toward the DM. The longer fluorescent wavelengths will be transmitted through the DM toward the eyepiece and the unabsorbed and unwanted excitation wavelengths will be reflected back to the lamp. This unique ability of the DM to reflect the shorter wavelengths and pass longer wavelengths is accomplished with the use of a thin-film interference coated piece of glass. Current DMs can pass and reflect light with 90% efficiency. The typical nomenclature for a DM will denote the wavelength (located at 50% maximum transmission) at which shorter wavelengths will be reflected by the mirror and longer wavelengths will be passed (Figure 41).

Barrier Filter. The last filter in the cube is the barrier (BA) or emitter (EM) filter. Since the wavelength ranges transmitted for the excitation filter and the DM may slightly overlap, the barrier filter is needed to block any harmful ultraviolet excitation light and effectively transmit only the fluorescence emitted by the sample. A barrier filter can be either a longpass (LP) filter or BP filter. Longpass filters allow wavelengths longer than their cut-on point to be transmitted and the nomenclature for these filters denotes the cut-on wavelength that is located at 50% maximum transmission (Figure 42).

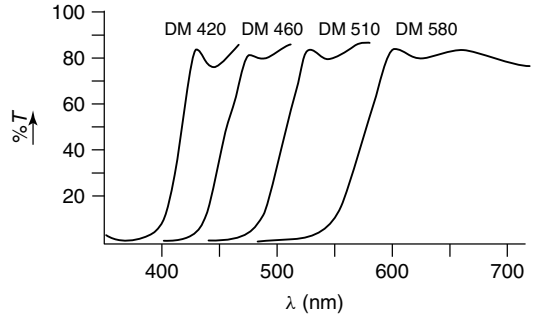

Figure 41 Typical transmission curves for several dichroic mirrors. The nomenclature denotes the cut-on wavelength at 50% maximum transmission

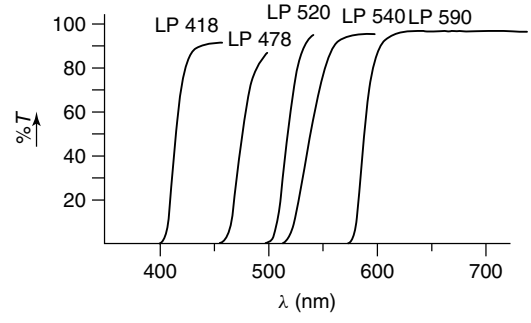

Figure 42 Typical transmission curves for several barrier filters. The nomenclature denotes the cut-on wavelength at 50% maximum transmission

A simple ray diagram showing the function of each component in a filter is provided in Figure 43

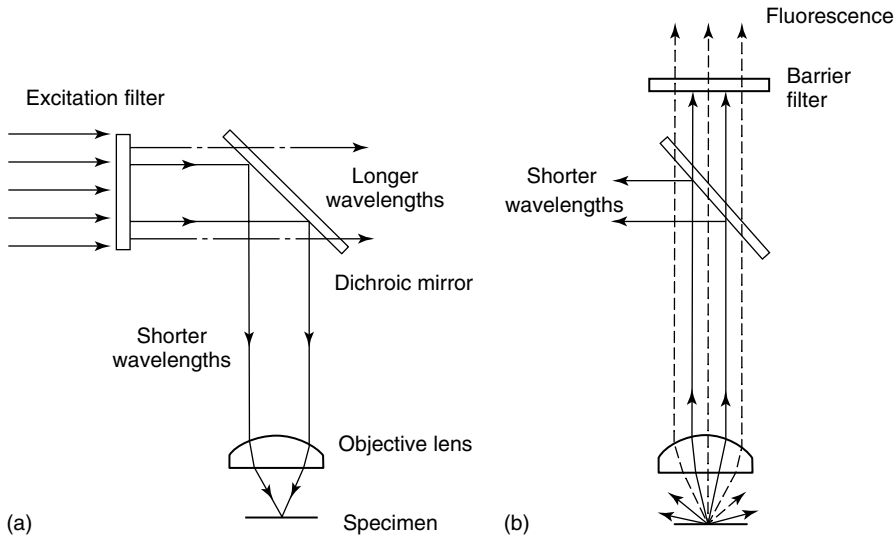

Figure 43 Schematic diagram showing the function for the different components of a fluorescence filter cube. Excitation rays (a) and fluorescence emission (b)

and an example of a typical transmission curve for a filter cube is provided in Figure 44.

Cathodoluminescence

Furthermore, it is worth noting that the use of cathodoluminescence (CL) microscopy is gaining popularity in forensic laboratories. As mentioned at the beginning of this section, cathodoluminescence is the fluorescence (luminescence) obtained by excitation of the sample using electrons instead of photons. Accessories for the scanning election microscope (SEM) can be obtained to observe cathodoluminescence or one can outfit a light microscope with a small vacuum specimen chamber containing a cold-cathode electron gun. An example of a paint sample observed utilizing reflected visible light, fluorescence, and cathodoluminescence is provided in Figure 45. For more information on cathodoluminescence, one may consult "Applications of Cathodoluminescence in Forensic Science" by S. Palenik and J. Buscaglia in *Forensic Analysis on the Cutting Edge: New Methods for Trace Evidence Analysis*.

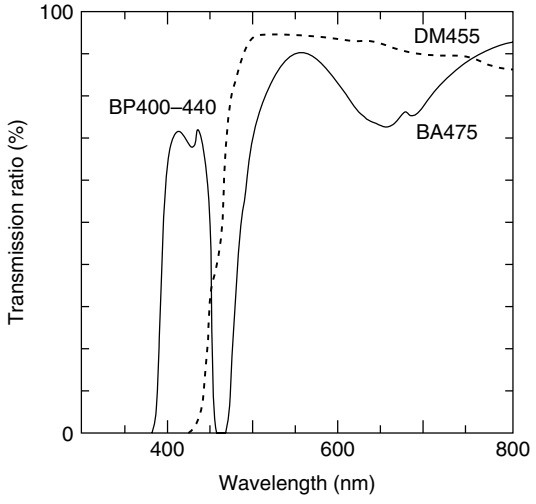

Figure 44 Transmission curves for a typical fluorescence filter cube

Comparison Microscopy

Comparison microscopes are used extensively in a forensic laboratory to compare pieces of evidence to a known specimen. Although comparison microscopes are employed in the examination of bullets, cartridge cases, or toolmarks, this type of examination is also used to compare trace evidence such as hairs, fibers, paint chips, and other types of particles that may

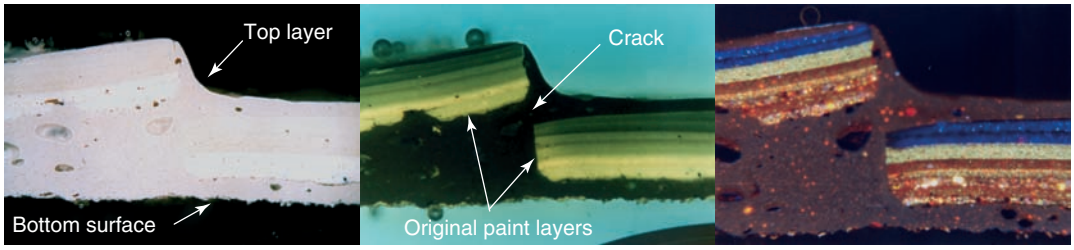

Figure 45 Embedded cross section of a multilayered white paint sample from an old building. The last application of white paint flowed through the crack in the paint and migrated under the older layers of paint. Images (from left to right) are reflected (ordinary) light, fluorescence, and cathodoluminescence

become separated from a source and accidentally left at the scene of a crime.

Design

The most critical part of a comparison microscope is the optical bridge that connects the optical paths of two side-by-side microscope systems. This bridge consists of multiple prisms arranged in such a manner to allow the magnified images from the left and right sides to be viewed simultaneously with a fine "hair-line" split between the two fields of view. Depending on the complexity of the instrument, the prisms can be adjusted either mechanically or by motors so that the hair-line is moved horizontally in the field of view to expose more or less of one side of the image or to superimpose the left and right images over each other.

The comparison microscope used for firearms, toolmarks and documents is configured for low visual magnifications from 2X to 120X and uses incident (reflected) illumination. A system used for trace evidence comparisons uses two compound microscopes usually equipped for intermediate visual magnifications from 40X to 600X and with brightfield and polarized transmitted illumination (Figure 46). Microscopes for fiber comparisons are now often supplied with epi-fluorescence components for comparison of known and questioned materials at selected excitation and emission wavelengths.

Figure 46 Modern trace evidence comparison microscope

Acknowledgment

The authors would like to thank Ms Natasha Neel with the Bureau of Alcohol, Tobacco, Firearms, and Explosives and Mr Christopher Taylor with the US Army Criminal Investigation Laboratory who reviewed many versions of this article and provided a number of valuable suggestions. A special thanks to Mr Stephen Garten with the Bureau of Alcohol, Tobacco, Firearms, and Explosives who helped prepare figures, compile references, and review various versions of this document. Also, the authors dedicate this article to the late Dr Walter C. McCrone, our mentor and good friend, who encouraged and helped many forensic microscopists worldwide.

Microscopy: Low Power

Microscope is an instrument designed to extend man's visual capability, i.e., to make visible even the minute details that can not be seen with the naked eye [1].

On the basis of the early pioneering study on microscopy in the sixteenth century, the first real microscope was made in the seventeenth century by Antony van Leeuwenhoek. Nonetheless, Leeuwenhoek, using this simple microscope, which was little more than a magnifying glass, discovered bacteria and spermatozoa and he built 400 microscopes in his lifetime! From this "single lens" microscope evolved the *compound microscope*, which simply means more than one lens so that the image magnified by one lens can be magnified by another. Today the term *microscope* is generally used to refer to a compound microscope, where the lens closer to the object being viewed is the *objective* lens while that closer to the eye of the observer is the *eyepiece*. Despite the apparent complexity of research level microscopes, they are in essence simple. They are also probably the most poorly understood and badly used of all laboratory instruments. The stereo microscope is a compound microscope. A typical high-quality stereo microscope is shown in Figure 1. In fact it comprises two compound microscopes, which are aligned side-by-side at the correct visual angle to provide a true stereoscopic image. Most stereo microscopes in laboratories today have a common main objective, and as the "workings" of the microscope are housed in a single body, it is not obvious that there are two optical systems present. Older Greenough type systems had two completely separate optical systems. Not all low-magnification binocular (two eyepieces) microscopes are stereo microscopes. Low-cost, low-magnification microscopes for students often have a single objective and image forming system, with a beam splitter delivering an image to both eyepieces. These microscopes do not produce a stereo image.

Current stereo microscopes have many attractive properties:

- they have a long working distance (the distance between the specimen and the objective lens);
- an upright nonreversed image (i.e., the image is seen in the same direction as it sits on the stage, facilitating sample movement and magnification);
- the image has a genuine three dimensional feel;
- little sample preparation usually required;
- various types of illumination can be used including transmitted light and overhead or incident light of several types (ring light, angled reflected light);
- large field of view; and
- can be attached to an arm enabling the examination of larger objects.

Modern instruments can also be set up for polarizing and fluorescence applications.

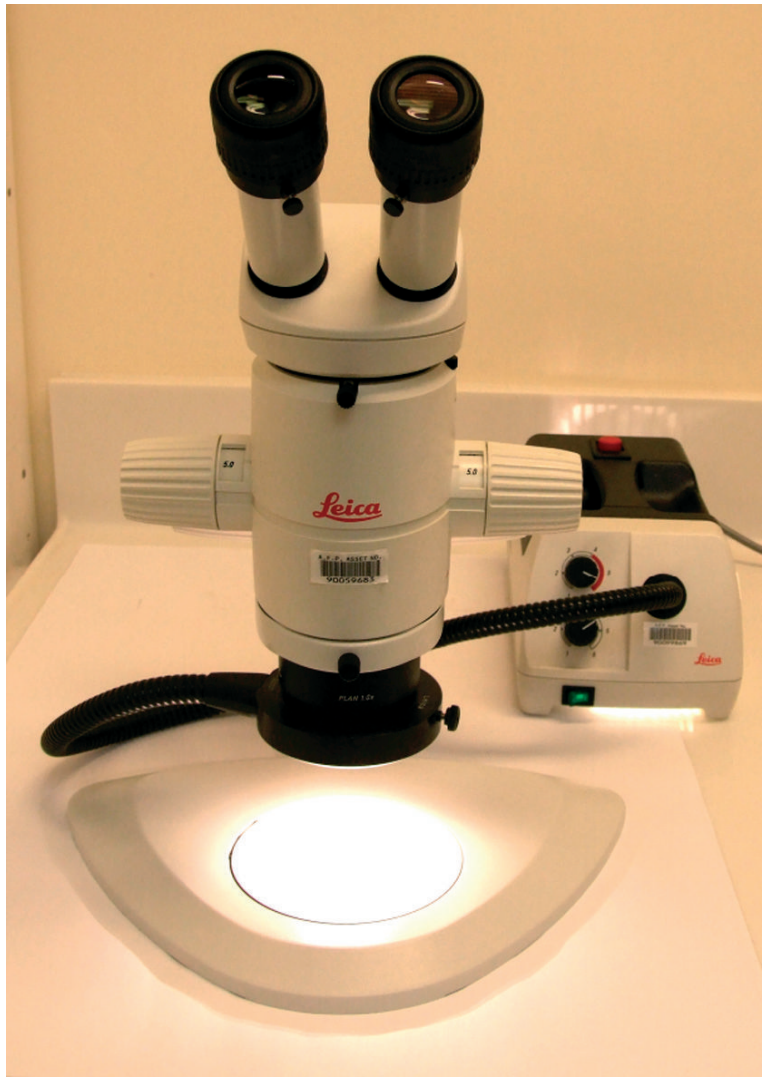

Figure 1 Stereo microscope

The useful magnification range is typically between 2.5× and a maximum of 100×. More expensive instruments often have a zoom capability.

The stereo microscope can be considered to be an extension of the human eye allowing the observer to see more details. In forensic work, stereo microscopes are mainly used to investigate the microscopic details of large objects, such as clothing, down to small fibers, soil, plant material, glass, paint, and other possible physical evidence contained in recovered debris.

There are probably no areas of forensic endeavor where low-power microscopy does not have a role to play.

With most new instruments, video or still digital cameras can be attached enabling the examiner to record images for inclusion in case notes or in case reports.

Training in the use of low-power microscopes is strongly recommended if they are to be used to their full potential. However, even a relatively inexperienced individual can make reasonably effective use

of simple low-power microscopes. This is not the case with high-power microscopes.

Microscopy: Scanning Electron Microscopy

Introduction

The invention of the electron microscope gave rise to the discovery of infinite entities, so far invisible, by optical microscopes. The use of electrons made it possible to overcome the optical limits of light. Nowadays, electron microscopy is a well-established technique and is widely used for forensic science purposes. With resolution in the nanometer and Angstrom range, electron microscopy and scanning probe microscopy are two of the most powerful microscopy techniques available today.

According to the imaging mechanism, the family of electron microscopes consists of the transmission electron microscope (TEM), the scanning transmission microscope (STEM), the scanning electron microscope (SEM), and the environmental SEM (ESEM). The Nobel prize-winning TEM was first developed, followed by the SEMs [1, 2]. The TEMs, TEM as well as STEM, are less in use for forensic observations because of the limitation of specimen thickness ($<1\,\mu$m thick).

The first SEMs were constructed in the 1930s and 1940s and have since then been constantly developed into very high-resolution instruments and this development lead to the invention of the ESEM, which allowed the observation of specimens that were, until then, impossible to submit to a classical SEM because of its high-vacuum environment.

The SEM is a very versatile instrument for the visualization of very small objects, the study of surface morphology, thanks to its resolution and excellent depth of field as well as its spectroscopic possibilities (Figure 1a, b). Like optical microscopes, the SEM measures only the X and Y dimensions of a sample, contrary to scanning probe microscopes (SPMs) that measure the Z dimension as well.

The SEM operates with an electron beam that interacts with the sample and generates several signals that are detected and processed to form the image [3]. Given that the electrons interact with the molecules of air, the electron beam has to be produced and travel in a vacuum, avoid trajectory deviations.

SEM: Functioning and Image Mechanisms

SEMs consist of five main parts: the electron source, the electron column with a series of electromagnetic lenses, the sample chamber, the signal processing part constituted of several detectors, the signal processing devices, and the image visualization devices such as a monitor (Figure 2). An elaborated pumping system is attached to the microscope, keeping the microscope and its parts under vacuum (ranging from 10^{-4} to about 10^{-10} Torr).

Electron Source

The electron beam can be generated by either a thermoionic source or a field emission (FE) source. The first kind produces electrons when heated and the second type generates electrons when an intense electric field is applied to it. These sources are part of an assembly – the electron gun. The two different systems cannot be interchanged. However, the choice of the source influences the performance of the SEM, i.e., the quality of its electron beam as well as its probe size. The FE source produces a monochromatic beam (small electron energy spread), where thermoionic sources have a greater electron

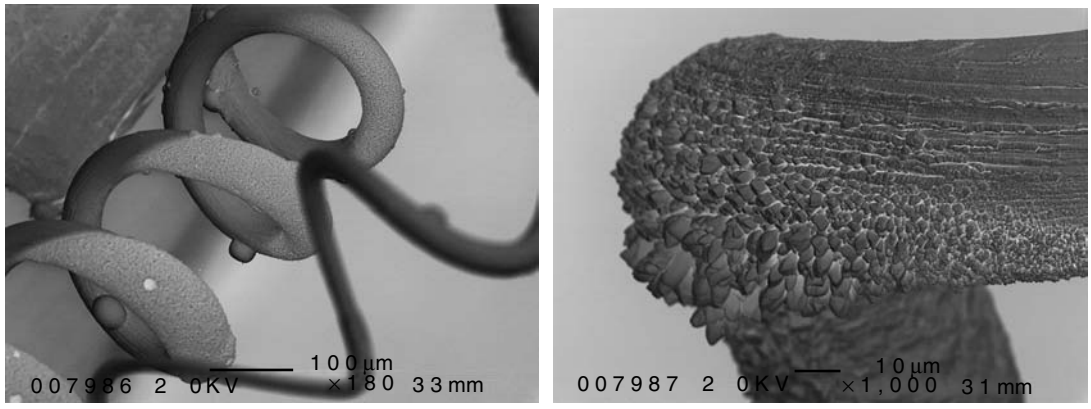

Figure 1 The high depth of field and high resolution allow having a sharp general view (a) or detail view (b) of a filament of a broken car light bulb

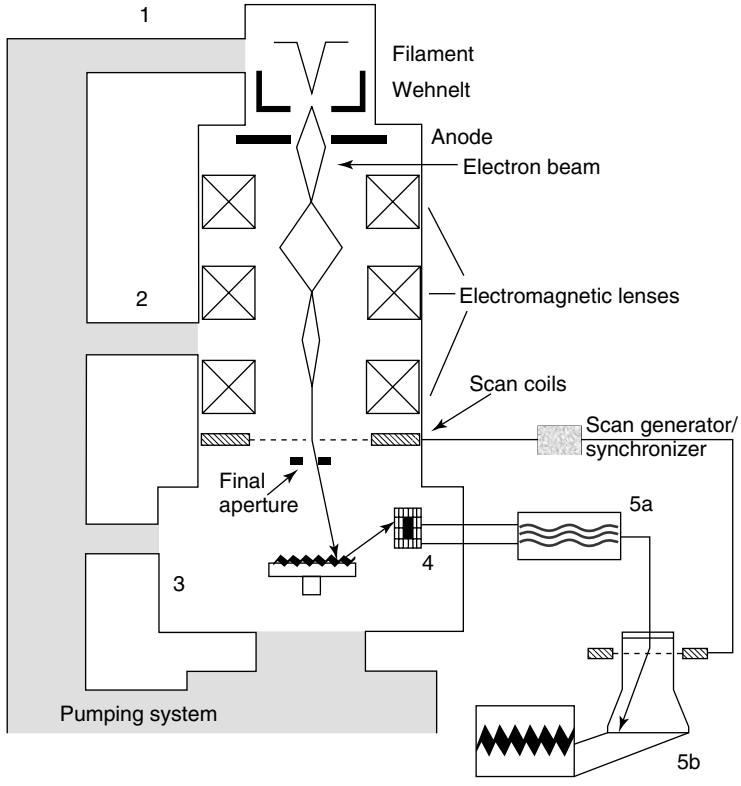

Figure 2 Schema of a conventional SEM: 1. Electron source (thermoionic gun); 2. electron column; 3. sample chamber; 4. detectors; 5a. Signal processing devices (e.g., photomultiplier, amplifier, etc.); and 5b. visualization system (monitor and computer)

energy range. The gun operates under vacuum is common to both the systems (10^{-4}–10^{-9} Torr).

The function of the electron gun, independent of the type, is to focus the electrons coming off the source and to direct this beam into the electron column and finally to the sample. To achieve this, the electron source is incorporated into a gun assembly, which acts as a lens to focus the emitted electrons. The assembly basically consists of a cathode and an anode. However, the design of the gun is different for thermoionic sources and field emission sources.

Thermoionic Gun. This gun consists of three elements: the electron emitting material (commonly called *filament*), the Wehnelt, and the anode (Figure 3).

These three parts form the so-called triode where the filament is the cathode. The Wehnelt has a potential that is more negative – the bias voltage – than the cathode itself. The bias voltage is variable and is used for controlling the emission of electrons from the filament. A high bias voltage restricts the emission to a small area, thereby reducing the total emitted current. A low bias voltage increases the size of the emitting area on the filament and thus the total emission current. The Wehnelt creates a negative field that makes the emitted electron converge to a point called a crossover situated between the Wehnelt and the anode (Figure 3). This crossover determines the size of the final probe diameter and thereby the resolution of the microscope. The Wehnelt acts as a simple electrostatic lens – the first lens in the microscope. The crossover is determined by the type of filament, the electric field between the cathode and the anode, and the exit angles of the electrons from the filament. The heating current and the Wehnelt bias voltage have to be set in order to operate at saturation condition (i.e., the smallest beam diameter with an even bright spot).

The filament in a thermoionic gun has to be either of a high-melting point material or with a low work function (i.e., necessary energy for the electrons to escape). In practice, tungsten with its high melting temperature (3660 K) and rare-earth boride crystal such as lanthanum hexaboride (LaB_6) or cerium hexaboride (CeB_6) are used. The tungsten filament has either a hairpin shape or is pointed, to minimize the emitting area. Tungsten filaments are heated directly, where rare-earth boride crystals are indirectly heated by a bonding material surrounding the crystal, such as carbon or rhenium. This type of filament can be used in standard tungsten SEM if the vacuum system is upgraded. Tungsten filaments need a vacuum of around 10^{-4} Torr where boride crystals require a higher vacuum (around 10^{-6}–10^{-7} Torr).

Field Emission Gun. FE guns are much simpler than thermoionic ones. They consist of a cathode and two anodes (Figure 4).

A very fine tungsten tip with a radius of <100 nm constitutes the cathode. This sharp tip is submitted to a strong electric field (>10^{-7} V/cm) that lowers the work function barrier sufficiently for electrons to tunnel out of the tungsten. This electric field is

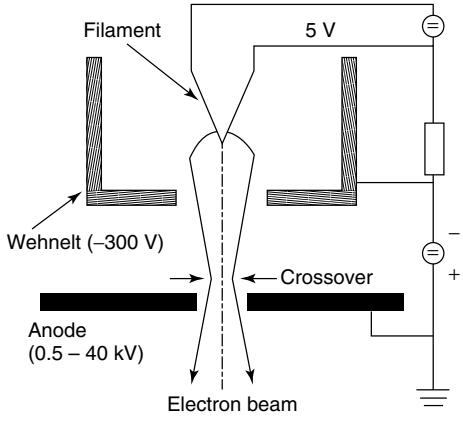

Figure 3 Schema of a thermoionic gun with a hair-pin-shaped filament

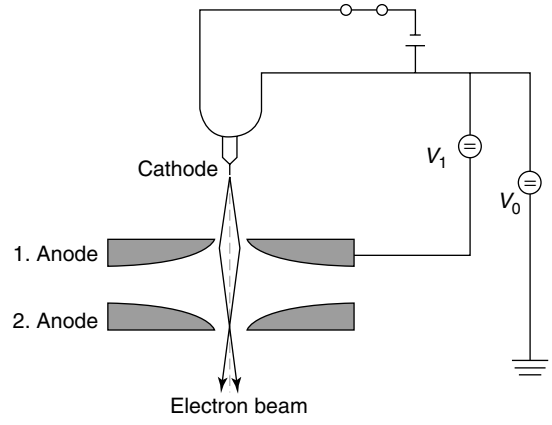

Figure 4 Schema of a cold field emission gun (V_0, acceleration bias; V_1, extraction bias)

Table 1 Comparison of the resolution in function of the electron gun system:

kV	Tungsten (nm)	LaB_6 (nm)	Field emission	
			CFE (nm)	TFE (nm)
0.5	80	50	15	
1.0	40	25	5	15
30.0	4	3	1.5	2

(CFE: cold field emission; TFE: thermal field emission). The spatial resolution depends on the type of electron gun, the electron-optical system and the extent to which the material interacts with the electron beam. The values are indicative and depend on the instrument

achieved by the first anode. The work of the second anode is to accelerate the electrons to 100 kV or more. The combined fields of the anodes act like a more refined electrostatic lens to produce a crossover. The second anode controls the effective probe size and position. In this system, the tungsten is operated at ambient temperature and that is why the process is called a *cold field emission*. This requires a high vacuum of about 10^{-9} Torr, preventing the tungsten tip from rapid surface contamination. The vacuum can be lowered when heating the tip. The thermal energy assists in the electron emission and the surface contaminations are not the same. For such *thermal field emission*, the tungsten tip is coated of zirconia (ZrO_2), which lowers the work function of the tungsten and therefore enhances the electron emission. This makes it possible to use a broader tip than for the cold FE. This type is called *Schottky* emitters.

Electron Column

Once the electron beam has left the electron gun, it is guided to the sample by a series of electromagnetic lenses. The lenses direct and condense the electron beam to its final size of about 2–80 nm (depending on the acceleration voltage). The electron beam is divergent after passing through the anode plate and must be collimated by condenser lenses and apertures into a relatively parallel stream. This is achieved by electromagnetic lenses. In fact, the lenses beyond the electron gun demagnify the image of the crossover in the electron gun. Electrons can be directed and focused by electrostatic fields (e.g., electron gun) or magnetic fields. Most electron microscopes are equipped with electromagnetic lenses because of their lower inherent aberrations. The resolution of a SEM is a function of the final electron beam diameter and the acceleration voltage and, as a consequence, of the type of electron gun. The resolution of a FE-SEM is better than that of a thermoionic gun SEM (Table 1). The limit of resolution is reached when the current within the electron probe is insufficient to produce a usable signal. Given the small size of the probe beam, the depth of field is high compared to a conventional light microscope (hundreds of times more).

Lenses. The lenses in electron microscopes are electromagnetic lenses (except the gun lens in the FE gun that is an electrostatic lens). A magnetic lens consists of a coil of copper wires inside the iron pole pieces. A current through the coils creates a magnetic field (force lines are symbolized by the circles in Figure 5) in the bore of the pole pieces. Where the circuit is interrupted (the gap), the magnetic field goes out into the vacuum and creates the lens field that is used for focusing the electron beam.

The rotationally symmetric magnetic field is inhomogeneous, i.e., it is weak in the center of the gap and becomes stronger close to the bore. Therefore, electrons close to the center are less strongly deflected than those passing the lens far from the axis. The overall effect is that a beam of parallel electrons is focused into a spot (so-called *crossover*). An electron passing through this field perpendicular to these field lines moves in a curved trajectory because there is a force on the electron created by the electron's movement in the magnetic field. It results in a helical trajectory and a rotation of the image. The focal length of the lens is controlled by the current in the lens coil. The focal length decreases as the current increases (the electrons are more deviated) or the acceleration voltage decreases.

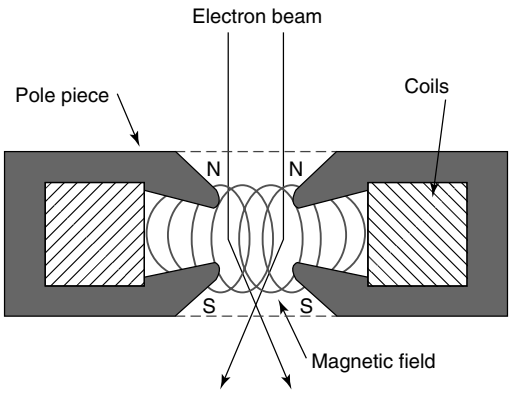

Figure 5 Schema of an electromagnetic lens (cross section)

The SEMs employ one or several condenser lenses to demagnify the diameter of the electron beam. The final lens in the column is the objective lens. Its role is to focus the image by controlling the movement of the probe crossover along the optical axis (Z-axis) of the column. The design of this lens generally incorporates space for the scanning coils, the stigmator (for correction of astigmatic lens defaults), and the beam-limiting aperture. This lens either includes the specimen (i.e., the specimen is placed inside the lens) or not (i.e., the specimen is placed outside the lens, in the case of large specimens).

Scanning Devices. In a SEM, the electron beam is not stationary on the specimen but moves in a raster on the specimen surface. The electron probe scans across the specimen in two perpendicular (X and Y) directions.

The deflection system is integrated in the last lens, the objective lens, or is situated just above it (Figure 2). The scanning coils, mounted in sets of two above another, create magnetic fields (positive and negative). The electrons in the beam will be attracted by the positive field and repelled by the other, leading to a deflection toward the positive coil. The beam moves over the specimen surface line by line in an X, Y raster covering a rectangular area. The raster is generated by the line and frame generators that feed the scan coils with the appropriate current leading to magnetic fields of different strength according to the scan size. The scan process is continuous and once one sequence is finished, a new frame is immediately started.

The output of the two scan generators is also applied to the deflection coils of a display device, typically a TV-type cathode-ray tube (CRT) on which the SEM image will appear. Since the electron beams in the SEM column and in the CRT are scanning in synchronism, for every point on the specimen (within the raster-scanned area) there is a corresponding point on the display screen. In a modern SEM, the scan signals are generated digitally by computer. The image is acquired pixel by pixel.

The signal which modulates the image brightness can be derived from any property of the specimen which is caused by (or changes in response to) electron bombardment (cf. below "image mechanism").

Magnification Process. It is convenient here to consider the magnification process. Unlike light microscopes or TEMs, the magnification is not achieved by means of lenses but is the ratio of the linear size of the viewing screen to the linear size of the raster on the specimen. The image on the screen has a fixed size given by the display screen and is bigger than the raster area on the specimen; the magnification (M) is

$$\mathrm{M} = \frac{\text{Scan distance* in the image}}{\text{Scan distance* on the specimen}}$$

(* length of the scanned line)

Magnification is therefore controlled by the current supplied to the X, Y scanning coils, and not by objective lens power. The magnification of a SEM ranges from $10\times$ or less to $1\,200\,000\times$ or more (depending on the SEM type and the operation mode, i.e., high, low, or environmental vacuum) (Figure 6).

Sample Chamber

Unlike the sample stage of a conventional optical microscope, the sample chamber in a SEM is a confined space and cannot be directly operated by hands. The chamber is constructed in order to be directed by the means of devices allowing moving, tilting (range of -5 to $\pm 70^{\circ}$), and rotating the specimen. This requires a very fine tuned mechanical system that provides small and continuous motions (mm to $<0.01\,\mu\mathrm{m}$) in the X, Y, and Z directions as well as

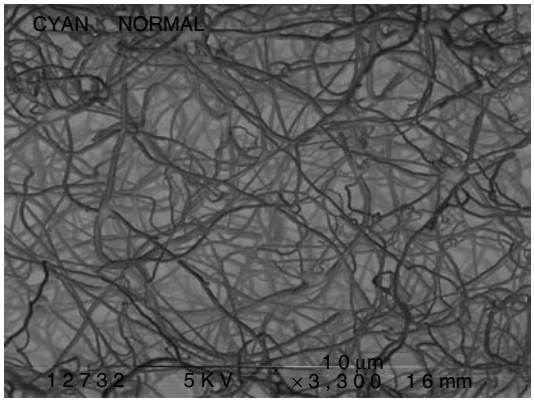

Figure 6 Cyanoacrylate deposit on a fingerprint ridge

an almost absolute stability of the object. The eucentric goniometer stage is nowadays fully motorized. The size of the chamber determines the size of the specimen. In general, forensic SEMs have a rather big chamber (up to around 400 mm left to right) in which a big object can fit and be moved (moving area up to about 150 mm × 150 mm for X/Y movements and up to 65 mm for Z movements). Standard SEMs have a rather small chamber, allowing movements of 10 mm × 10 mm. If the sample to submit has bigger dimensions, the area of interest has to be cut out (modification of the evidence). Small objects are normally mounted on specimen holders of different shapes and sizes (often with diameters of around 12 mm) according the type of stage. The chamber is constructed in order to withstand the necessary vacuum for the electron beam (high vacuum around 10^{-4} Torr or more). It also hosts all devices necessary for the caption and processing of the output signals.

Electron Interaction and Image Mechanisms

The incident electron beam will generate several reactions once it penetrates the specimen surface. The beam strikes the specimen point by point. Several interactions occur, providing the signals that form the image or give material information about the specimen. The incident electrons interact both elastically and inelastically with the specimen, forming the limiting interaction volume from which the various types of radiation emerge, including backscattered, secondary and absorbed electrons, characteristic and Bremsstrahlung X-rays,

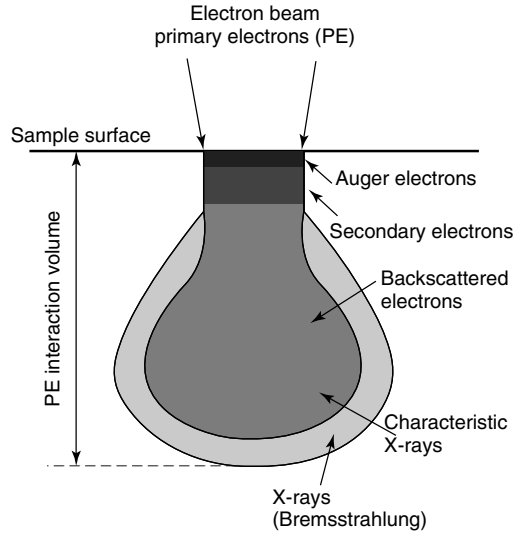

Figure 7 The interaction volume depends on several parameters (acceleration voltage, atomic number of the sample elements, and the sample density)

and in some materials, cathodoluminescence radiation (emission of photons), and Auger electrons (Figure 7).

By measuring the magnitudes of these signals with suitable detectors, a determination of certain properties of the specimen (topography, composition, crystallography, electrical conductivity, etc.) can be made at the single location where the electron beam strikes. All interactions occur together but can be selected individually by using the appropriate detector. Not all detectors are usually present on a single instrument. The size, depth, and shape of the interaction volume depend on the density of the material being investigated and the beam velocity (acceleration voltage) (Figure 8). The interaction volume takes a shape between a pear or teardrop and a hemisphere. The resulting signals are either electrons or photons. The first category is primarily used for the image and the second category of signals is mainly taken for spectroscopic information.

Imaging Signals. Secondary electrons (SEs) are the most common signal used for investigations of surface morphology. They are produced as a result of interactions, i.e., inelastic scatter between primary electrons (incident beam electrons) and the weakly bound electrons in the conduction band of the sample.

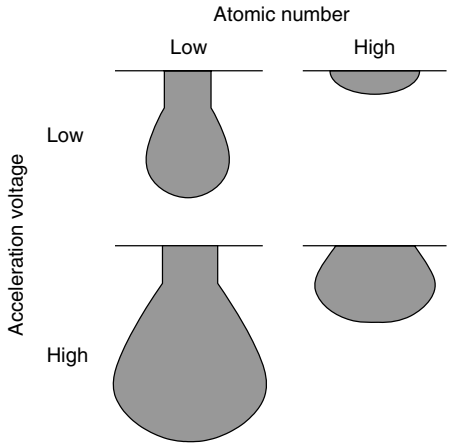

Figure 8 Influence of the acceleration voltage of the primary electrons in function of the atomic number of the sample elements

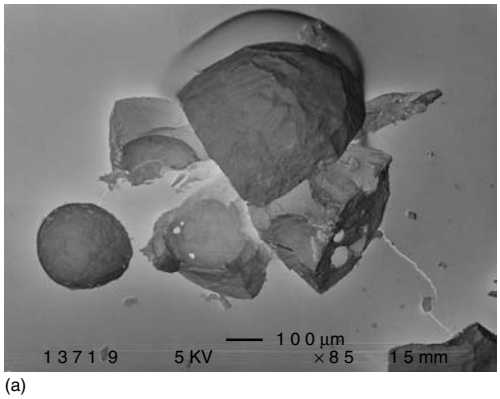
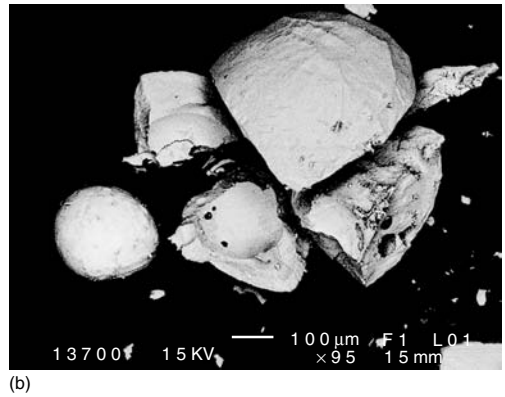
These electrons are knocked out of their orbitals and, if sufficient near the sample surface, escape as SEs. The SEs are low-energy electrons (<50 eV) and only those formed near the sample surface (within a few nanometers) have enough energy to escape and to be detected (Figure 7). The energy is obtained when they collide with a primary electron.



The other phenomenon that occurs is the elastic scatter between the primary electrons and the atoms of the sample. The electrons are diffracted by the atomic fields within the specimen and backscatter out of the sample surface. Because their trajectory changes they might travel out of the specimen. The backscattered electrons (BSEs) have energy of up to that of the primary electrons and are emitted from approximately the top 40% of the area of the teardrop or hemisphere (Figure 7). The BSE come from deeper regions in the specimen and because of the diffraction (spread of the electron beam) within the specimen material the image resolution is inferior.

An SE reproduces the morphology of the surface, whereas the BSE creates shadows (topography information) because of the straight trajectory and atomic number contrast (composition information) (Figure 9a, b).



BSE are often used in analytical SEM along with the spectra made from the characteristic X-rays. Because the intensity of the BSE signal is strongly related to the atomic number (Z) of the specimen, BSE images can provide information about the distribution of different elements in the sample as well as the crystallographic structure of the specimen.

The caption of both the signals (SE and BSE) can be achieved by one or two separate detectors. The most commonly used detector is the *Everhart–Thornley electron detector*, which is sensitive to both the signals [4]. It consists of a scintillator, a light pipe, and a photomultiplier tube. This type of detector is not very efficient for BSE signals. That is why often a second dedicated detector is installed for the caption of only the high-energy BSE. Scintillator backscatter detectors, solid-state diode detectors (semiconductors), or channel plate detectors can be fitted.

The amplified electrical signal output is displayed as a two-dimensional intensity distribution on an analogue cathode ray tube (monitor), or subjected

(a)

(b)

Figure 9 Comparison between a SE and a BSE image: the surface details of soldering particles in SE mode (a) disappear in BSE mode (b)

to analogue-to-digital conversion and displayed and saved as a digital image. The brightness of the signal depends on the number of SE and/or BSE electrons reaching the detector.

Spectroscopic Signals: X-Rays, Auger Electrons, and Light. The other signals (characteristic X-rays, cathodoluminescence radiation, and Auger electrons) that occur when bombarding a material with an electron beam are used less for imaging purposes than they are for analytical needs.

The most frequently used analytical method in association with the SEM is an X-ray spectrometer. X-rays are emitted when the electron beam removes an inner shell electron from the sample, causing a higher energy electron to fill the shell and release energy in form of photons (X-ray) or Auger electrons. These X-rays are characteristic of the difference in energy between the two shells and of the atomic structure of the element from which they are emitted. Therefore, these X-rays are characteristic for each element and are used to identify the composition and measure the abundance of elements in the sample (Figure 7). The emitted X-rays are detected and processed by two methods by using two characteristics associated with light (wave and energy quantum). The same applies to X-rays. They can be detected either by their wavelength or by their energy. The latter technique, energy dispersive X-ray spectroscopy (EDX), is most commonly associated to the SEM. In the case of the detection of the X-ray energy, the photons are detected by a semiconductor (silicon doped with lithium) that converts the energy of the X-ray into a proportional electrical charge. This analogue impulsion is amplified, digitalized, and then treated in a multiple channel analyzer. Each impulsion is attributed according to its charge to a predefined channel. The information is accumulated in a histogram and displayed on a monitor. The simultaneous counting of all the photons in the range of 0–20 keV allows to acquire in one step a spectrum of all elements, within limits, of a sample (Figure 11b). This gives a quick overview of a sample composition. However, the accuracy of EDX spectrum is affected by several limitations. The qualitative analysis does not include all the elements from the periodic table. It is restricted from boron ($Z = 5$) to uranium ($Z = 92$). Another limitation is given by its lack of specificity, with respect to the oxidation state of complex anions. Quantitative analysis is compromised by secondary fluorescence (higher energy X-rays excite the emission of X-rays of lower energy in a sample) causing the emission of more X-rays of an element than really present and overlapping peaks. A semi-quantitative analysis is more appropriate for this type of X-ray analysis, contrary to the wavelength dispersive X-ray spectroscopy (WDX).

This method allows the measuring of the wavelength of the emitted X-ray from the sample. X-ray diffraction is a powerful tool to study both the X-ray spectra and the arrangement of atoms in crystals. The X-ray wavelength is determined by irradiating a known single crystal at a precise angle. The single crystal diffracts the photons in accordance to the Bragg's law and is collected by a detector (proportional counter or scintillation counter). The crystal is positioned in equal distance to the specimen and to the detector. The crystal with known spacing is chosen. These planes reflect different wavelengths at different angles. The detector can discriminate one angle from another and attribute the corresponding wavelength. Only one element at the time can be determined. WDX counts only the X-rays of a single wavelength, not producing a broad spectrum of wavelengths or energies. Several crystals are necessary to cover the whole range of X-rays. This generally means that the element must be known to find a crystal capable of diffracting it properly. Although this technique is more sensitive than the EDX, it is less applicable in forensic science, because the sample composition has to be known and its surface has to be plane and polished, parameters that are encountered only rarely among forensic samples.

Although SEM-EDX has few restrictions, it is a very versatile and efficient technique for elemental analysis. The combination of high magnification and the possibility to analyze the target is very useful, especially in forensic science.

The next two spectroscopic techniques are encountered less in forensic applications, but they can be associated with the SEM. Instead of X-ray emission, the excess energy is transferred to a third electron from a further outer shell, prompting its ejection. This ejected species is called an *Auger electron* (Figure 7), and the method for its analysis is known as *Auger electron spectroscopy* (*AES*). The Auger electron has a specific characteristic energy that depends on the type of atom and the chemical environment in which the atom was located. Auger spectrometry is a widely used surface analysis technique.

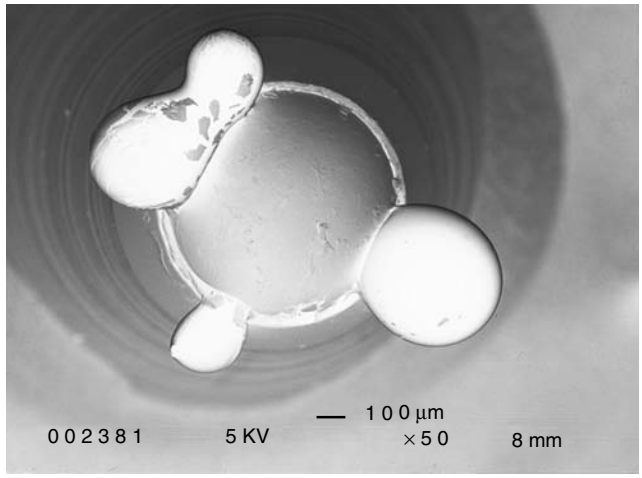


Figure 10 The influence of a high vacuum on a wet sample: the ink contained in the ink reservoir is pressed out of the ball housing and forms the drops around the tip of a ballpoint pen

Inelastic scatter can generate the emission of light (UV–visible–IR), the so-called *cathodoluminescence*. This phenomenon occurs when an electron is promoted from the valence band into the conduction band, leaving behind a hole. When an electron and a hole recombine, it is possible for a photon to be emitted. It happens for materials with a band gap structure and is useful for the characterization of semiconductors, insulators, certain minerals, glasses, and biological specimens. The radiation is detected with an appropriate photomultiplier for the photon-energy range of interest.

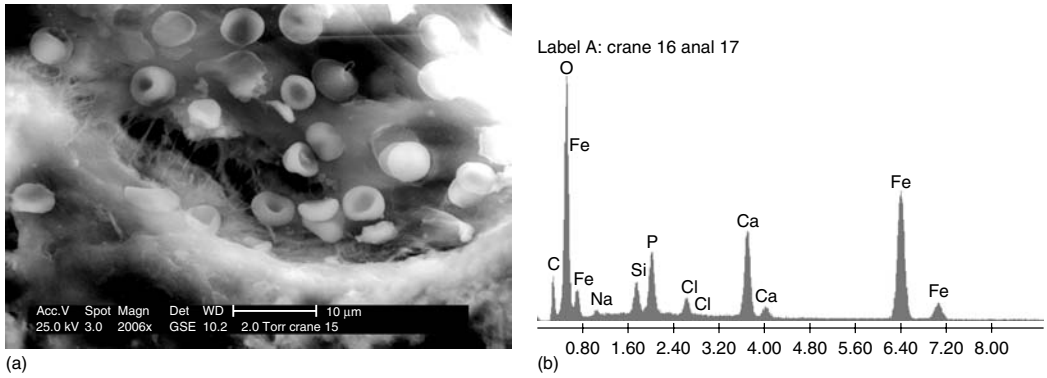
Sample Preparation

As mentioned above, classical SEMs operate in a vacuum environment and with an electron beam. This has a dramatic influence on a sample that cannot withstand the pressure of about 10^{-4} Torr or more (e.g., hydrated, oily, and out gassing samples) and/or is not conductive (Figure 10).

The chamber size might also have its influence and need a resizing of the sample, which might be a handicap for forensic investigations (disruption of the sample integrity). The problem of non-conductivity can be overcome by applying a conductive coat to the sample. Non-oxidation metals such as gold, platinum, palladium, and carbon are used. They are conductive and chemically stable (no oxidation) and inert. The metals are deposited on the sample by low-vacuum sputter coating or by high vacuum evaporation (carbon). The coat is some nanometers thick. Carbon coating is appropriate if the sample has not only to be visualized but also to be analyzed (carbon is not detected by EDX). The coating prevents the accumulation of static electric charge on the specimen during electron irradiation. Another reason for coating, even when there is more than enough conductivity, is to increase signal and improve contrast and resolution. For hydrated samples, they have to be dried or frozen before being submitted to the chamber vacuum, which may modify its morphology. If coating, drying, or freezing is required, then the SEM observation has to be done at the end of an observation sequence. Optical characteristics are altered by the coat. To overcome both the problems (vacuum incompatibility and insulating surface) without modifying the sample, one has to use a low-voltage beam of the FE-SEM and/or an ESEM. The latter even allows visualizing the samples in a nearly atmospheric pressure.

Environmental SEM

The ESEM has been invented with the aim to develop a SEM that accepts virtually any specimen regardless of composition and provides a high-resolution SE image (Figure 11a). The ESEM unites all this requirements. Commercial ESEMs have been introduced in the late 1980s and early 1990s. Ten years of research



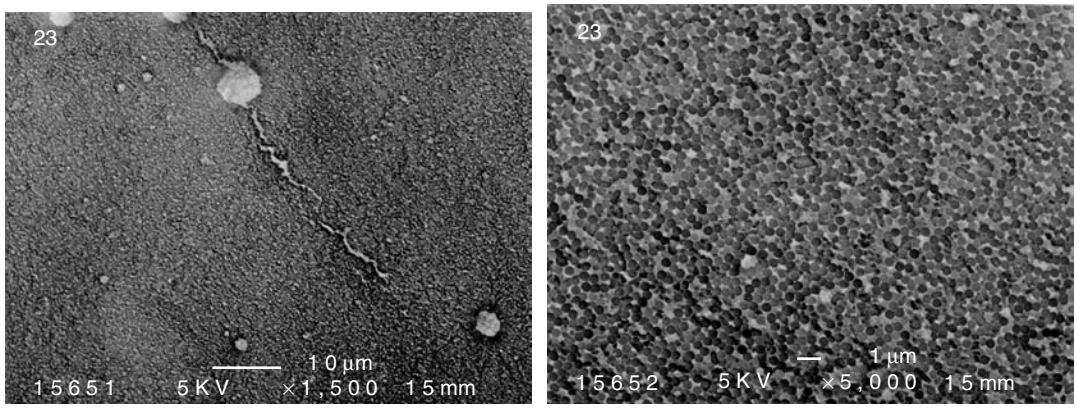


Figure 11 ESEM image (a) of hemoglobin cells around a crane fracture and their EDX analysis (b)

and development were necessary for the creation of such an instrument as well as for the discovery of a new signal detection method [5]. Although the ESEM has partially the same setup as the conventional SEM, the main problem was to find a solution allowing the use of an electron beam in a high-pressure ambience without contaminating the electron gun chamber and the electron column and ultimately to still detect the emitted signals (SE, BSE, X-rays, etc.). The problem of keeping the upper parts (gun and electron column) of the SEM in high vacuum is overcome through the use of a differential pumping technique. A series of chambers at increasing pressure along the beam path are linked by small apertures. Dedicated pumps at each stage maintain the required pressure gradient and stop contaminants from reaching the clean upper column. The sample chamber can then be maintained at a relatively high pressure (10–20 Torr) while the electron optical column is differentially pumped to keep the vacuum adequately high at the electron gun. Several stages of differential pumping system are built in the final aperture lens. The pressure is regulated by the flow of gas (inert gas and/or water vapor). The high-pressure region around the sample in the ESEM neutralizes charge and provides an amplification of the SE signal. Positively charged ions generated by the beam interactions with the gas help to neutralize the negative charge on the specimen surface. The pressure of gas in the chamber can be controlled, and the type of gas used can be varied according to the need. The detectors of the emitted signals are different from those described for the conventional SEM. The conventional SE detector (Everhart–Thornley detector) cannot be used in the presence of gas because of an electrical discharge (arcing) caused by the kilovolt bias associated with this detector. In lieu of this, an environmental secondary detector (ESD) is used [6]. It takes advantage of the ionization behavior of the low-pressure gases found in the specimen environment. Gas ionization is induced by a moderate electric field, forcing collision between highly mobile SEs and neutral gas molecules. It results in a multiplication of the secondary signal and at the same time the positive ions neutralize the electrical charges at the specimen surface.

For the backscattered electron, the conventional BSE detection means have been adapted to operate in the gaseous conditions of the ESEM. The characteristic elemental X-rays also produced in the ESEM can be detected by the same detectors used in the conventional SEM (Figure 11a, b).

Modern ESEMs have a "three-in-one" concept. Three different vacuum modes (high, low, and environmental vacuum) can be chosen with one instrument according to the specimen vacuum sensitivity. They are equipped with the conventional detectors (when working in high vacuum; 10^{-4} Torr and more an Everhart–Thornley for SE, solid state for BSE) as well as the dedicated environmental detectors as described for low vacuum. These instruments still have an excellent resolution range (3.5 nm at 30 kV in all vacuum modes, <15 nm in low-vacuum mode at 3 kV).

The possibility to work in a vacuum of about 20 Torr makes it possible to add some optional devices such as a Peltier cooled stage (−20 to +50 °C), a heating stage (for temperatures up to 1500 °C) and

(a) (b)

Figure 12 Aspect of a gel pen ink stroke (a) and (b) under different magnifications

a cryo transfer system (for *in situ* investigations) for the observation of sample behavior under temperature changes.

Forensic Utility of SEMs

With the commercialization of ESEM, there is no limit to its use in forensic science. The ESEM has demonstrated its near universal applicability, combining the high resolution and depth of field of the SEM with the flexibility and ease of the light microscope. Whenever something small has to be studied, the SEM is certainly the microscope to choose [7]. The only limit is that optical properties and characteristics cannot be studied, as well as the aspect of the sample in transparency. In case of a non-pigmented water-based ink stroke leaving no deposit on the paper (when the ink is completely absorbed by the fibers), it cannot be seen by SEM. This limits the application for line crossing problems [8]. See also the relevant article about intersecting lines in this encyclopedia.

The magnification range from macro to micro allows zooming in and out of details of the sample, with an extreme ease and with a resolution and depth of field never obtained by the conventional light microscopes (Figure 12a, b).

The additional spectroscopic tools make the SEM a powerful analytical instrument, allowing a target compositional analysis. The area of interest can be selected and analyzed. This makes the technique essential for gunshot residues (GSRs), because of its capability to analyze discrete particles in the sample. The analysis is nowadays fully automated and the position of each analyzed particle is recorded. This makes the localization and verification of each analyzed particle very convenient. An advantage is that the particles are directly taken from the support (e.g., suspect) by the SEM holder equipped with a carbon-coated adhesive. No further sample preparation is required prior to the SEM/EDX analysis. This minimizes the risk to lose particles while handling.

The elements constituting the GSR can originate from the primer, the bullet, a coating or jacket on the bullet, cartridge components, and previous residues in the barrel. The characteristic particles for Sinoxid primers contain the metal elements lead, barium, antimony, and calcium [9, 10]. The heavy metal particles in a lead-free primer (e.g., Sintox™ ammunition commercialized by Dynamit Nobel AG) are replaced by the elements titanium and zinc [10, 11]. Particles from the bullet are composed of copper, zinc, nickel, mild steel, and lead (in metallic form).

The samples usually contain many other particles that are of no particular interest (contaminations from the support); the particles of interest have to be "selected" before being analyzed. This is done by the backscattered detector, which is calibrated in relation to the Z (atomic number) and not to the video intensity. The particles are detected based on their average atomic number falling within a predefined Z range in relation to primer compositions, which tend to have particles with intrinsically high average Z. Therefore, searching for "bright particles only"

is eliminated. The older systems are based on this method, which of course lacks selectivity. The GSR particles are 0.5–10 μm in size (usually 0.5–2 μm). Therefore, the automated search and analysis of a sample, i.e., a defined area on the sample holder surface, take quite some time but is much faster and reliable than a manual search of primer residue particles.

In case of a positive result (i.e., particles containing the above-mentioned elements in combination), its interpretation is not evident. The combinations Pb/Sb/Ba and Sb/Ba are considered to be characteristic for Sinoxid primer residues [12]. However, other sources might produce particles with same combinations [13–15]. In view of these findings, the morphological aspect of the found particles becomes important and might allow to support stronger the hypothesis of GSR particles than particles generated from another source than a firearm. GSR particles have a spherical morphology. Not to forget also the memory effect when firing different ammunitions from the same firearm that might produce mixed compositions of GSR particles [10, 11, 16]. More details about GSR can be found as a separate specific contribution in this encyclopedia.

The combined abilities of the SEM to resolve fine structures and determine their elemental composition are an indispensable aid in the examination of small items of trace evidence. There is no doubt that the SEM is extremely useful and the list of its forensic applications is endless. However, the only inconvenience of the technique is still its price.

Mini-STRs

Disclaimer: The opinions and assertions contained herein are solely those of the authors and are not to be construed as official or as views of the US Department of Defense, the US Department of the Army, or the Armed Forces Institute of Pathology.

For well over a decade, short tandem repeat (STR) markers have played an important role in advancing the field of forensic DNA typing (*see* **Short Tandem Repeats**). In the United States, there are two commercial companies that produce multiplex STR kits used by forensic laboratories: Applied Biosystems (Foster City, CA) and Promega Corporation (Madison, WI). Each company has produced a "megaplex" autosomal STR kit containing 16 markers: the 13 Combined DNA Index System (CODIS) loci [1, 2]. 2 markers specific to each company's kit, and the amelogenin marker for sex determination. Both 16-plex kits have amplicon sizes ranging from 100 to 450 base pairs (bp). The availability of commercial kits has helped to standardize the STR markers used by the forensic community.

The conventional STR kits perform well when an optimal quantity (approximately 1 ng) of high-quality DNA is used, exhibiting peak height balance both within loci (heterozygous alleles) and between each marker. However, biological evidence at crime scenes is often exposed to the elements and/or microbial agents that may cause DNA to degrade. Inhibitor molecules, such as heme in blood or humic acid in soil, can also copurify with DNA and prohibit the generation of a full STR profile. Degradation and inhibition may result in amplification failure especially of high-molecular weight loci, resulting in a "partial profile" in which only a subset of the core 13 CODIS loci are obtained (*see* **DNA: Degraded Samples**). The loss of multiple forensic markers as a result of degradation and inhibition reduces the overall statistical significance of any observed match. If a biological sample is too highly degraded for STR analysis, the forensic scientist may have to turn to mitochondrial DNA (mtDNA), which can be expensive and time consuming to test, and may result in limited information, especially for common mtDNA haplotypes (*see* **Mitochondrial DNA: Profiling**).

One strategy to recover the genetic information lost due to DNA degradation would be to reduce the size of the PCR (Polymerase Chain Reaction amplicons for the "larger" loci. By designing PCR primers to bind closer to the core tandem repeat (Figure 1), it is possible to create a smaller PCR product, a "mini-STR", while still retaining the core repeat information. The reduced-size PCR amplicon then has a greater chance (relative to conventional STR primers) of generating a profile when genetic material is degraded.

Emergence of Mini-STRs as a Forensic Tool

During the mid-1990s, Dr John Butler (presently at the National Institute of Standards and Technology, NIST) and his colleagues at GeneTrace Systems developed a system to rapidly genotype STR profiles using matrix-assisted laser desorption/ionization time-of-flight (MALDI/TOF) mass spectrometry. The rapid detection of multiple unlabeled PCR products using MALDI/TOF represented a significant reduction in sample processing and analysis time as compared to standard STR profiling. One limitation of the MALDI/TOF technology, however, was related to the size of PCR fragment analyzed; amplicons larger than 140 bp were difficult to resolve with the method. To make the commonly used forensic STR

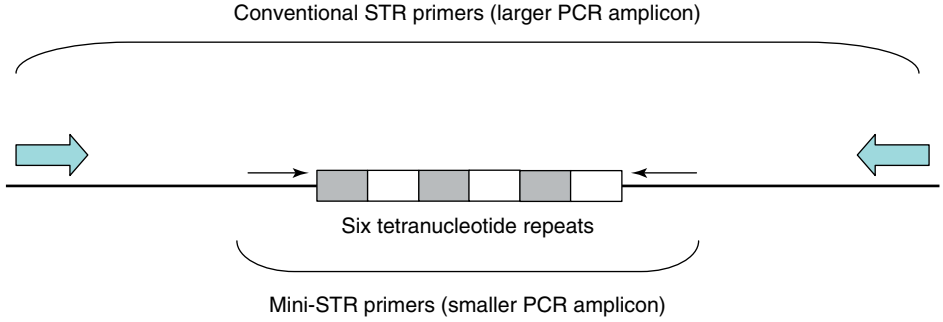

Figure 1 An example of a mini-STR compared to conventional STR primers. The mini-STR primers are adjacent to the six nucleotide repeats producing a smaller PCR product compared to the conventional STR primers

markers more amenable to MALDI/TOF detection, Butler and colleagues redesigned the primers to create smaller amplicons. Significantly, Butler and colleagues noted in their 1998 publication that these reduced-size amplicons could be utilized to increase the recovery of STR profiles from degraded samples [3, 4].

A few years later, laboratories began publishing information on reduced-size PCR amplicons for (mostly CODIS) loci [5–8]. These early studies demonstrated the forensic potential of mini-STRs, sometimes with very significant results. For example, Hellmann *et al.* [5] reduced the amplicon size of the TPOX locus by 160 bp to test telogen hairs. This group was able to recover the correct genotype over 77% of the time compared to only about 18% of the time with conventional primers – a fourfold improvement.

Additional advances in mini-STR research and application also came as a result of the terrorist attack on the World Trade Center (WTC) towers on September 11, 2001. Shortly after the attacks, the New York Office of the Chief Medical Examiner (NY-OCME) was charged with the task of identifying the nearly 3000 victims of the disaster. Knowing that many of the samples recovered from the crime scene would be highly degraded and of poor quality, the NY-OCME investigated new technologies, such as single nucleotide polymorphism (SNP) typing and reduced-size STR amplicons, to increase the success rate on the compromised samples. Through work at NIST and a private laboratory (the Bode Technology Group) all of the core CODIS markers were redesigned as mini-STRs [9]. Protocols were developed and validated at NIST [9], and samples from the disaster were tested at the Bode Technology Group [10]. Mini-STRs proved to be valuable for the identification efforts: nearly 20% of the 850 DNA-only identifications from the WTC disaster were made using mini-STRs [11].

Following the success of mini-STRs in recovering genetic information from CODIS loci, additional research into other markers of forensic interest has included autosomal loci unlinked to the CODIS markers [12]. Additional markers not linked to the CODIS loci can be useful for resolving complex paternity cases such as incest. A set of X-chromosome mini-STRs [13] have been developed for select forensic scenarios where linked X-STR markers can provide additional discrimination relative to autosomal loci. Finally, Y-chromosome mini-STRs [14] have been developed to amplify male-specific loci (*see* **Y-Chromosome Short Tandem Repeats**).

In 2007, the first commercial mini-STR kit, AmpFℓSTR® MiniFiler™ (Applied Biosystems), became available to the forensic community. A 9-plex, MiniFiler™ includes amelogenin and eight of the largest loci from the AmpFℓSTR® Identifiler® and SGM Plus® (Applied Biosystems) STR typing kits. The MiniFiler™ amplicon sizes generally range up to 250 bp (290 bp for the extended FGA locus alleles), and represent an approximate 30–200 bp size reduction as compared to the Identifiler® and SGM Plus® amplicons for the included loci. In addition to the reduced-size amplicons, the MiniFiler™ amplification protocol, which increases (relative to other AmpFℓSTR® kits) the number of thermal cycles to 30, and proprietary amplification buffer, which already contains the DNA polymerase, are kit optimizations designed to overcome inhibition and recover loci from compromised samples. MiniFiler™ is thus intended for use as a supplement to other megaplex STR kits when an insufficient number of loci are recovered, or as a stand-alone kit when extremely limited sample quantities would prevent multiple attempts to develop a genetic profile [15].

A second commercial mini-STR kit, PowerPlex® S5 (Promega Corporation), is also now available to forensic practitioners. Like MiniFiler™, the S5 kit utilizes small amplicons (under 260 bp) and a proprietary amplification buffer optimized to overcome inhibition. In contrast to MiniFiler™, however, PowerPlex® S5 includes only four loci in addition to amelogenin. Rather than as a means to recover additional loci when large-amplicon loci fail, the S5 kit is marketed as a reliable, lower-cost exclusionary tool for criminal casework and population screening.

Challenges to Mini-STR Development

With the availability of commercially available mini-STR kits, many forensic laboratories can now take advantage of using these markers on casework samples without the need to produce "in-house" multiplexes that must pass high quality control standards for use in forensic casework. However, challenges remain to the development and use of both in-house

and commercial mini-STR kits. These include repeat size limitations, limited multiplex real estate, and the potential for profile discordance as a result of primer design.

Some of the current CODIS loci are difficult to develop as true mini-STRs because of the size of the repeat region. For example, the FGA locus has a rather large allele spread – ranging from 17 to 33 repeats (and up to 51 repeats among the extended alleles). A large allele spread is advantageous for a high-diversity marker, but successful amplification of a 50 tetranucleotide repeat (200 bp) along with an additional 40–50 bp for the flanking primer sequence (240–250 bp total amplicon) in a highly degraded sample is unlikely. Ideally, mini-STR multiplexes would be composed of markers with amplicons sizes no larger than 150 bp.

However optimal from a profile recovery standpoint, the restriction of mini-STRs to amplicons sizes less than 150 bp greatly limits the number of markers that can be tested in a four or five fluorescent dye system. To overcome the limited multiplex real estate, a few multiplexes, with each dye channel containing 1–2 mini-STR markers, could be constructed for use in tandem. However, a disadvantage to typing with multiple assays is the consumption of additional, often limited, DNA template. This could be especially problematic when typing samples under "low copy number" conditions where multiple replicates are required for data analysis and interpretation [16, 17] (*see* **Low Copy Number DNA**). Although a greater number of fluorescent dyes could be used to increase the number of loci amplified in a single reaction, this is not at present a viable option because of capillary electrophoresis (CE) detection limitations.

Alternately, nonnucleotide linker molecules that shift the electrophoretic mobility of the amplified product could be used to construct a mini-STR multiplex with more than 1–2 markers per dye channel. For example, suppose that two mini-STR loci, A and B, have the amplicon size ranges 72–112 and 96–136 bp, respectively. In constructing a multiplex, it would be necessary to position these two loci in separate dye channels since there is potential for overlap between the higher molecular weight alleles of locus A and the lower molecular weight alleles of locus B. Using non-nucleotide linkers equivalent to approximately 2.5 bp [18], the addition of 10 such linkers between the primer and the fluorescent dye for locus B would shift the apparent size of the amplicon by +25 bp. As a result, locus B would migrate at 121–161 bp and provide enough separation to be included in the same dye channel as locus A. Although non-nucleotide linker molecules can increase the electrophoretic separation between overlapping loci as described, there is a limit to the number of linkers that can be added to a primer and still result in consistently high-quality data.

Primer design presents an additional challenge to the development of mini-STRs from standard STR loci. A necessity for the creation of reduced-size STR amplicons is a clean sequence region flanking the repeat motif. Not all of the industry-standard STR markers have clean flanking regions, which can make the design of mini-STRs a challenge, and may result in nonconcordant alleles when typing the same loci with different STR multiplexes. For example, the CODIS marker D7S820 has a polyT stretch found 13 nucleotide bases downstream of the core tetranucleotide repeat. Designing a primer adjacent to the repeat and avoiding the polyT repeat would potentially miss a number of microvariants created by the addition (X.1) or subtraction (X.3) of thymidine nucleotides in this region. In other words, if a sample tested with a conventional kit typed as a 15.1 allele, a mini-STR designed to avoid this polyT region (through placement of an amplification primer between the core repeat and the T-stretch) would result in a 15 allele.

There are several additional ways in which newly designed STR primers may result in allele discordance with standard STR typing kits. For example, suppose that at some STR locus an individual is genotyped as 4, 5 using a commercial kit. We shall focus only on the chromosome possessing the "5" allele (Figure 2, bottom allele). Interestingly, this particular allele has six core repeats. but between the core repeat and the forward primer of the commercial kit is a 4 bp deletion on the chromosome. The net effect of this deletion (equivalent to a single tetranucleotide repeat) is that the commercial kit scores this allele as having five repeats (Figure 2A; the sample types as a 4, 5). If the newly designed mini-STR primer is designed to hybridize between the commercial kit primer and the 4 bp deletion, then both genotypes will be concordant (Figure 2B; the sample types as a 4, 5). If, however, the mini-STR primer binding site includes the 4 bp deletion region, it is possible that little or no hybridization will occur. This would be especially true if the 3′ end of the

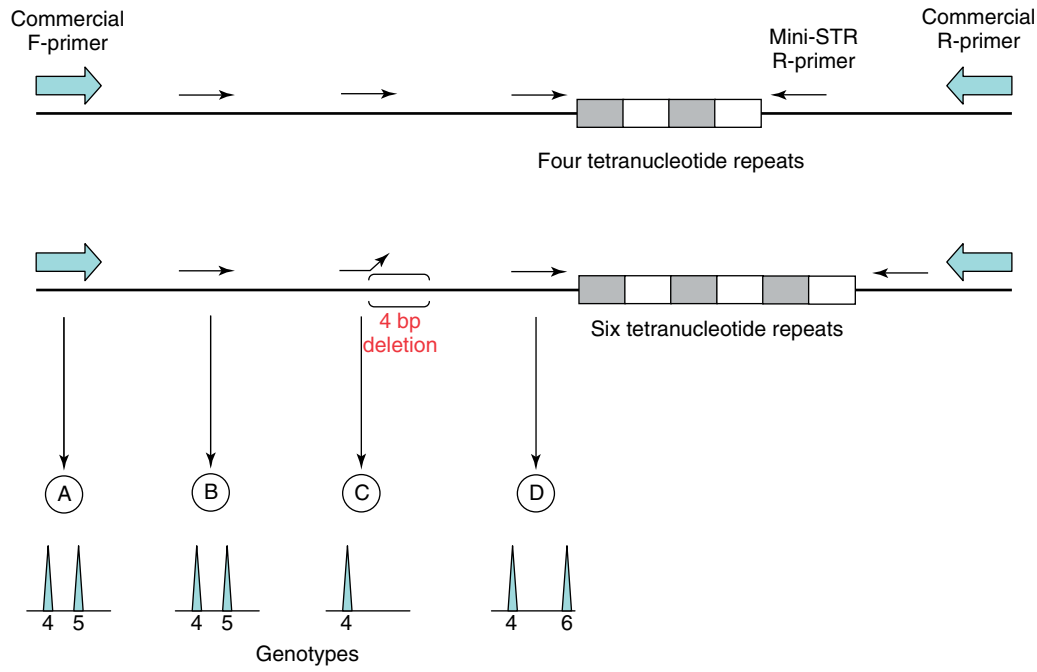

Figure 2 An example of discordance among mini-STR primers compared to a commercial kit. The top chromosome has four tetranucleotide repeats and the bottom chromosome has six tetranucleotide repeats. In the flanking region of the forward primer, there is a 4 bp deletion. Amplification using the commercial STR primers (A) results in a genotype of 4, 5 the deletion effectively "subtracts" one of the core repeats. (B) The mini-STR primer binding site is also outside of the 4 bp deletion region, and produce a 4, 5 genotype. (C) The 3′ end of the mini-STR primer produces no PCR product from the bottom chromosome resulting in a "null allele" genotype of 4, 4 and be discordant with the conventional kit. (D) The mini-STR primer is adjacent to the core repeat and is well within the 4 bp deletion, the genotype will be 4, 6 and be discordant with the conventional kit

mini-STR primer did not match the target sequence on the chromosome. If a "null allele" were to result due to the primer binding site mutation (Figure 2C; the sample types as 4, 4), the mini-STR genotype will be discordant with the kit genotype. Finally, if the mini-STR primer is adjacent to the core repeat and thus well within the 4 bp deletion, the genotype resulting from the mini-STR amplification will be 4, 6 (Figure 2D) and again discordant with the conventional kit.

Because of the mutations that result in insertions, deletions, and SNPs in the flanking regions of forensic STRs, laboratories should always test any new mini-STR primer set against the conventional kit on a set of population samples to assure concordance between the two systems. In most cases discordance is not a major issue since typically only one allele of the total 26 CODIS alleles would be affected. That is, a moderate stringency database search would still identify a profile typed with the conventional kit when compared to the mini-STR-generated profile with a single allele difference.

Conclusions

Mini-STRs have already proven effective for the recovery of genetic information from highly compromised samples, such as those encountered in mass disasters (*see* **Disaster Victim Identification**). Beyond the increased power of discrimination offered by the recovery of more genetic loci, mini-STRs have also proven valuable for the sorting and reassociation of highly commingled remains [17] from mass graves according to the International Commission on Missing Persons [19]. The European forensic community has recently recommended that current forensic loci should be reduced in size as much as possible and

that new mini-STRs be incorporated into the next generation STR multiplexes to increase the number of shared Interpol loci [20, 21]. In the future, mini-STRs may play an important role in the analysis of forensic evidence normally reserved for mtDNA analysis, such as skeletal remains [22] and shed telogen hairs [23]. The potential utility of mini-STRs is high and their frequency of use in forensic casework is likely to increase as both new and familiar autosomal, X-chromosome, and Y-chromosome loci are designed with reduced-size amplicons.

Missing Persons and Paternity: DNA

Introduction

Matching DNA profiles have proved to be of great value in forensic science when they link a person to evidence associated with a crime. The chance of a coincidental match between the profiles of two different people is so small that matches are rightly regarded as strong evidence. This has led to the increasing use of searches for a particular profile in databases of profiles previously obtained by law enforcement agencies. These forensic applications make little appeal to an essential nature of DNA profiles – genetic markers are heritable, meaning that a parent passes on one copy of his or her marker genes to a child. This leads to the similarity of profiles between related individuals and the application of DNA profiling to parentage disputes and missing person searches. The strength of the evidence from matching or partially matching profiles depends in large degree on the degree of relatedness of the people whose DNA is examined and calculations can be complex. There is simplification, however, in the situation where the people are not inbred and where their population can be regarded as being in a state of evolutionary equilibrium. These simplifications are described in this article.

The calculations described here are all within the framework of likelihood ratios of the probabilities of an observed set of DNA profiles under alternative hypotheses about the relatedness of the people whose DNA has been examined.

Measures of Inbreeding and Relatedness

The use of DNA profiles in parentage and missing persons situations rests on the comparisons of profiles from people who may be related. The greater the degree of relatedness, the more likely it is that profiles will be similar but it is necessary to be able to quantify such statements. Are father and son more related than are two brothers? How can profiles from two men be used to favor the explanation that they are brothers over the claim they are unrelated? Such questions require a means for attaching numbers to the degree of relatedness, and these numbers refer to the chance that alleles, the components of DNA profiles, are identical by descent.

People are related when they have ancestors in common and this means that relatives may share genes – the genes that descended from those ancestors. Two copies, or alleles, of the same genetic marker that have descended from the same ancestral allele are said to be identical by descent (ibd). Two individuals that have ibd alleles are said to be related, and individuals that receive ibd alleles from their parents are said to be inbred. In the classical theory of population genetics, there is an implied reference population: ibd alleles are copies of the same allele in the reference population and their histories further back in time are not considered. The probability that an allele taken at random from one individual is ibd

to an allele taken at random from another individual is the coancestry coefficient θ of those two individuals. The inbreeding coefficient F of a child has the same value as the coancestry θ of its parents.

There is a simple "path-counting" method for determining coancestry coefficients. For individuals X and Y, the number of individuals in the path linking them through their common ancestor(s) A is written as α. This number includes the individuals themselves. If F_A is the inbreeding coefficient of the ancestor, generally zero, the coancestry coefficient is given by $\theta_X = \sum_A (0.5)^\alpha (1 + F_A)$. For people related on only the maternal or paternal side of their family, there is likely to be only one ancestor A and the simplest example is that of parent Y and child X. Their common ancestor is Y and their coancestry is $(0.5)^2 = 0.25$. If Z is one of the parents of Y, then the grandparent (Z)–grandchild (X) coancestry is $(0.5)^3 = 0.125$, and so on. The two paths linking full-sibs X and Y through their parents G and H are XGY and XHY so $\theta_{XY} = (0.5)^3 + (0.5)^3 = 0.25$.

The equality of the coancestries for parent–child and full-sib pairs suggest that a more detailed quantification of relatedness is needed, and the first step is to use the number of pairs of alleles two relatives have that are ibd. There can be zero, one, or two such pairs depending on whether the individuals are unrelated, unilineal relatives (e.g., parent–child) or bilinear relatives (e.g., full-sibs). This description requires that an individual's two alleles are not themselves ibd. Calculating the probabilities k_0, k_1, k_2 that two individuals have 0, 1, 2 ibd pairs is fairly straightforward. If X has alleles a, b and Y has alleles c, d then it is necessary to ask how many of the four pairs ac, ad, bc, bd are ibd. If c is the allele that is copied by parent Y to transmit to child X, then it must be that either a or b is ibd to c. There are no other ibd relationships and $k_0 = 0, k_1 = 1, k_2 = 0$. If a, c are the alleles that full-sibs have received from parent G and b, d are the alleles they receive from parent H, then each of these pairs has equal chances of being copies of the same or different parental alleles and so being ibd or not. This leads to $k_0 = 0.25, k_1 = 0.50, k_2 = 0.25$. The coancestry coefficient θ is a summary of the three k coefficients: $\theta = k_1/4 + k_2/2$. Values of these measures are shown in Table 1 for some common relatives. Note that they all refer to the unobservable property of identity by descent. It is the expected values for those degrees of relatedness that are shown in the table.

Table 1 Identity by descent measures for noninbred relatives

Relationship	k_2	k_1	k_0	θ
Identical twins	1	0	0	$\frac{1}{2}$
Full sibs	$\frac{1}{4}$	$\frac{1}{2}$	$\frac{1}{4}$	$\frac{1}{4}$
Parent/child	0	1	0	$\frac{1}{4}$
Half-sibs	0	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{8}$
First cousins	0	$\frac{1}{4}$	$\frac{3}{4}$	$\frac{1}{16}$
Unrelated	0	0	1	0

The k-coefficients are sufficient for describing the relatedness for noninbred individuals. There is a more elaborate set of 15 coefficients for the situation with inbreeding when any two or three of four of the alleles carried by two people may be ibd. These coefficients were discussed in a review by Weir *et al.* [1]. For a random-mating population and genetic markers that have reached a state of equilibrium between the opposing evolutionary force of genetic drift that reduces genetic variation and the force of mutation that increases variation, all 15 of these more complicated ibd measures can be expressed in terms of the quantity θ. This θ is the probability that any two alleles in a population are ibd and it refers to the effect of past evolutionary events rather than immediate family membership. The probability that any three alleles are ibd is $2\theta^2/(1 + \theta)$ and the chance that any four alleles are ibd is $6\theta^2/[(1 + \theta)(1 + 2\theta)]$. The probability that two pairs of alleles are ibd (whether or not all four are ibd) is $\theta^2(1 + 5\theta)/[(1 + \theta)(1 + 2\theta)]$. These results were all derived by Evett and Weir [2].

Frequencies of sets of alleles

Setting up a set of identity measures was the first step in allowing observed DNA profiles to be used to make inferences about relatedness of the people represented by those profiles. Identity measures describe the relationship and they can also be used to express how likely it is that two people with a specified degree of relatedness have particular profiles. In other words, if the relationship is known, then the profile

types can be predicted. Some results from statistical theory can then be used to reverse the argument: if the profiles are known, what can be inferred about the relatedness?

Identity by descent cannot be observed, but the ibd probabilities allow the probabilities of sets of alleles to be expressed as functions of allele frequencies. Without any inbreeding or relatedness, the probability P_{ii} that an individual is homozygous for allele A_i is given by the Hardy–Weinberg result $P_{ii} = p_i^2$ where p_i is the frequency of the allele. The genotype frequency P_{ij} for heterozygote A_iA_j is $P_{ij} = 2p_ip_j$, $j \neq i$.

For individuals with inbreeding level F, these Hardy–Weinberg frequencies are modified to $P_{ii} = p_i^2 + Fp_i(1-p_i)$ and $P_{ij} = 2(1-F)p_ip_j$. Of more importance in the present context are the probabilities that two related individuals have specified genotype frequencies. The probability that two noninbred members of the same family are both homozygous A_iA_i has to take into account that they may share zero, one, or two pairs of alleles ibd. This means that their four copies of allele A_i may represent four, three, or two independent (non-ibd) alleles. The required probability is

$$\Pr(A_iA_i, A_iA_i) = k_0p_i^4 + k_1p_i^3 + k_2p_i^2 \qquad (1)$$

and the complete set of probabilities is shown in Table 2.

To take into account the evolutionary relatedness quantified by the parameter θ, there is a very convenient result first described in the forensic context by Balding and Nichols [3]. The probability that an allele is of type A when n_A of the previous n alleles examined were of that type is $[n_A\theta + (1-\theta)p_A]/[1+(n-1)\theta]$ and this can be called the *Dirichlet sampling formula*. For the first allele examined, the probability is just p_A. The probability an allele is A, given that an A has already been seen, is $[\theta + (1-\theta)p_A]$ so the chance they are both A is $p_A[\theta + (1-\theta)p_A] = p_A^2 + \theta p_A(1-p_A)$. The "background" or "evolutionary" relatedness produces the same effect as an inbreeding coefficient of $F = \theta$.

Table 2 Genotype-pair probabilities for noninbred relatives (different subscripts denote different alleles)

Genotype pair	Probability
A_iA_i, A_iA_i	$k_2p_i^2 + k_1p_i^3 + k_0p_i^4$
A_iA_i, A_jA_j	$k_0p_i^2p_j^2$
A_iA_i, A_iA_j	$k_1p_i^2p_j + 2k_0p_i^3p_j$
A_iA_i, A_jA_k	$2k_0p_i^2p_jp_k$
A_iA_j, A_iA_j	$2k_2p_ip_j + k_1p_ip_j(p_i+p_j) + 4k_0p_i^2p_j^2$
A_iA_j, A_iA_k	$k_1p_ip_jp_k + 4k_0p_i^2p_jp_k$
A_iA_j, A_kA_l	$4k_0p_ip_jp_kp_l$

The probability that an allele is A, given that the previous two alleles were A, is $[2\theta + (1-\theta)p_A]/(1+\theta)$ and this is of immediate use in paternity testing: it is the probability that a random man provides paternal allele A, given that the alleged father is homozygous for the allele (but see Table 4).

As one further example, the probability that an allele is A, given that the previous three alleles examined were also A, is $[3\theta + (1-\theta)p_A]/(1+2\theta)$. In the forensic context where a crime stain, left by the perpetrator, is of type AA this leads to the probability that a suspect is also of type AA:

$$\Pr(AA|AA) = \Pr(A|AAA)\Pr(A|AA) = \frac{[3\theta + (1-\theta)p_A][2\theta + (1-\theta)p_A]}{(1+\theta)(1+2\theta)} \qquad (2)$$

Note the use of the conditional probability symbol |.

The results just described for relatives, meaning familial relationships among people in the same family or evolutionary relatedness among people in the same population, are employed in the likelihood ratios for comparing alternative hypotheses about sets of observed DNA profiles. Whether the context is in the forensic situation involving a suspect and a crime stain, or the parentage situation of a child and an alleged father, or the missing person situation involving a stain or some remains and the relatives of the missing person, there is the evidence E of two or more DNA profiles and there are alternative hypotheses H that specify the relationship(s) among the sources of those profiles. One hypothesis, H_p, may be identity in the forensic case, father–child in the parentage case, and sibships in the missing person case. An alternative, H_d, may be unrelatedness in each case. The strength of the evidence is expressed as a likelihood ratio $\mathrm{LR} = \Pr(E|H_p)/\Pr(E|H_d)$.

The identity measures and expressions for joint genotypic probabilities also allow another type of calculation that has recently arisen in studies of databases [4]. When all profiles in a database are

compared to all other profiles, there are often quite striking degrees of similarity observed. It is helpful to be able to predict the degree of such similarity, taking into account familial and evolutionary relatedness, in order to determine whether or not the observed similarities indicate any unusual features of the database. To date, the observations have been consistent with expectations [4], and these expectations are now described.

The probability P_2 that two profiles match is [4]

$$\begin{aligned} P_2 &= \sum_i \Pr(A_iA_i,\, A_iA_i) + \sum_i \sum_{j\neq i} \Pr(A_iA_j,\, A_iA_j) \\ &= \sum_i \Pr(A_iA_iA_iA_i) + 2\sum_i \sum_{j\neq i} \Pr(A_iA_iA_jA_j) \\ &= \frac{1}{D}[6\theta^3 + \theta^2(1-\theta)(2+9S_2) + \\ &\quad 2\theta(1-\theta)^2(2S_2+S_3) + (1-\theta)^3(2S_2^2 - S_4)] \end{aligned} \tag{3}$$

The first line specifies the genotypes, the second shows the corresponding sets of alleles, and the third shows the value from the Dirichlet assumption. Random mating is assumed for the second line. The third line employs the notation $S_k = \sum_i p_i^k, k = 2, 3, 4$ and $D = (1+\theta)(1+2\theta)$. Partial matches occur when two individuals share one allele at a locus, rather than the two required for a match. The probability that two individuals partially match is

$$\begin{aligned} P_1 &= 2\sum_i \sum_{j\neq i} \Pr(A_iA_i,\, A_iA_j) \\ &\quad + \sum_i \sum_{j\neq i} \sum_{k\neq i,j} \Pr(A_iA_j,\, A_iA_k) \\ &= 4\sum_i \sum_{j\neq i} \Pr(A_iA_iA_iA_j) \\ &\quad + 4\sum_i \sum_{j\neq i} \sum_{k\neq i,j} \Pr(A_iA_iA_jA_k) \\ &= \frac{1}{D}[8\theta^2(1-\theta)(1-S_2) + 4\theta(1-\theta)^2(1-S_3) \\ &\quad + 4(1-\theta)^3(S_2 - S_3 - S_2^2 + S_4)] \end{aligned} \tag{4}$$

with the same meaning for the three rows as for P_2. Finally, for two individuals to mismatch, i.e., have no alleles in common,

$$\begin{aligned} P_0 &= \sum_i \sum_{j\neq i} \Pr(A_iA_i,\, A_jA_j) \\ &\quad + 2\sum_i \sum_{j\neq i} \sum_{k\neq i,j} \Pr(A_iA_i,\, A_jA_k) \\ &\quad + \sum_i \sum_{j\neq i} \sum_{k\neq i,j} \sum_{l\neq i,j,k} \Pr(A_iA_j,\, A_kA_l) \\ &= \sum_i \sum_{j\neq i} \Pr(A_iA_iA_jA_j) \\ &\quad + 2\sum_i \sum_{j\neq i} \sum_{k\neq i,j} \Pr(A_iA_iA_jA_k) \\ &\quad + \sum_i \sum_{j\neq i} \sum_{k\neq i,j} \sum_{l\neq i,j,k} \Pr(A_iA_jA_kA_l) \\ &= \frac{1}{D}[\theta^2(1-\theta)(1-S_2) \\ &\quad + 2\theta(1-\theta)^2(1-2S_2+S_3) \\ &\quad + (1-\theta)^3(1-4S_2+4S_3+2S_2^2-3S_4)] \end{aligned} \tag{5}$$

If, in addition to membership in the same population, two individuals have family relatedness described by k_0, k_1, k_2:

$$\begin{aligned} &\Pr(\text{Match}) = k_2 + k_1[\theta + (1-\theta)S_2] + k_0P_2 \\ &\Pr(\text{Partial Match}) = k_1(1-\theta)(1-S_2) + k_0P_1 \\ &\Pr(\text{Mismatch}) = k_0P_0 \end{aligned} \tag{6}$$

It is important to stress that these matching probabilities P_0, P_1, P_2 do not refer to specific profiles. They represent similarities over all profile types and so they apply to studies of databases rather than to specific parentage or missing person situations.

Parentage Testing

The usual situation in paternity disputes is that mother, child, and alleged father are genotyped. The alleged father is declared "not excluded" if he carries an allele that is inferred to be the child's paternal allele and the strength of the evidence against him is quantified as the paternity index *PI*. The two simplest explanations for the genetic evidence E are

H_p: the alleged father is the father.
H_d: the alleged father is not the father.

and the paternity index is

$$PI = \frac{\Pr(E|H_p)}{\Pr(E|H_d)} \tag{7}$$

If there is a prior probability π_0 of paternity, the posterior probability π should be changed to Bayes' theorem:

$$\frac{\pi}{1-\pi} = PI \times \frac{\pi_0}{1-\pi_0} \tag{8}$$

The PI can be expressed in terms of probability of genotype G_C of child, conditional on genotypes G_M, G_{AF} of mother, and alleged father:

$$\begin{aligned} PI &= \frac{\Pr(G_C|G_M, G_{AF}, H_p)\Pr(G_M, G_{AF}|H_p)}{\Pr(G_C|G_M, G_{AF}, H_d)\Pr(G_M, G_{AF}|H_d)} \\ &= \frac{\Pr(G_C|G_M, G_{AF}, H_p)}{\Pr(G_C|G_M, G_{AF}, H_d)} \end{aligned} \tag{9}$$

since the adult probabilities do not depend on the hypotheses. Provided the mother and alleged father are not related, so that the child's maternal and paternal alleles A_M and A_P are independent, it is more convenient to work with the alleles than the child's genotype. Noting that A_M depends only on the mother's genotype:

$$\begin{aligned} PI &= \frac{\Pr(A_M A_P|G_M, G_{AF}, H_p)}{\Pr(A_M A_P|G_M, G_{AF}, H_d)} \\ &= \frac{\Pr(A_M|G_M, H_p)\Pr(A_P|A_M, G_M, G_{AF}, H_p)}{\Pr(A_M|G_M, H_d)\Pr(A_P|G_M, G_{AF}, H_d)} \\ &= \frac{\Pr(A_P|A_M, G_M, G_{AF}, H_p)}{\Pr(A_P|G_M, G_{AF}, H_d)} \end{aligned} \tag{10}$$

because $\Pr(A_M|G_M)$ does not depend on H.

Suppose first that familial or evolutionary relatedness is not considered. Under explanation H_p, the alleged father has provided the paternal allele, of type A_i say, and the probability of the allele is 1.0 or 0.5, depending on whether he is homozygous or heterozygous for that allele. Under explanation H_d some other man, the true father TF, has provided the paternal allele and the probability of this unknown man providing the paternal allele is just the population allele frequency p_i. The PI is $1/p_i$ or $1/(2p_i)$ for homozygous A_iA_i or heterozygous A_iA_j alleged fathers.

Alleged father related to true father

There are situations, including those of incest, where the alternative hypotheses involve relatives. There may be reason to suspect that either the alleged father or his brother is the true father of a child. The two hypotheses become

H_p: the alleged father is the father.
H_d: the alleged father is related to the father.

and then it is necessary to determine the probability of the paternal allele, given that it came from a relative of the alleged father. Provided there is no inbreeding, the calculations follow from the joint probabilities for relatives given in Table 2 and are shown in Table 3. These lead to the probabilities of paternal allele A_i under H_d that it came from a relative, and the PI values are $1/[2\theta_{AT} + (1-2\theta_{AT})p_i]$ for homozygous alleged fathers and $1/\{2[\theta_{AT} + (1-2\theta_{AT})p_i]\}$ for heterozygous alleged fathers. The quantity θ_{AT} is the coancestry of alleged and (under H_d) true fathers.

It is also possible to construct a likelihood ratio for a different pair of alternative explanations for situations when the alleged father is either deceased or

Table 3 Paternity index calculations when H_d is that alleged father is related to the father. (The paternal allele is A_i and A_j, A_k are any other distinct alleles.)

Alleged father	$\Pr(A_i\|H_p)$	Relative	Pr(Relative|Alleged father)	$\Pr(A_i\|H_d)$
A_iA_i	1.0	A_iA_i	$(k_0p_i^4 + k_1p_i^3 + k_2p_i^2)/p_i^2$	1.0
		A_iA_j	$(2k_0p_i^3p_j + k_1p_i^2p_j)/p_i^2$	0.5
A_iA_j	0.5	A_iA_i	$(2k_0p_i^3p_j + k_1p_i^2p_j)/(2p_ip_j)$	1.0
		A_iA_j	$[4k_0p_i^2p_j^2 + k_1p_ip_j(p_i+p_j) + 2k_2p_ip_j]/(2p_ip_j)$	0.5
		A_iA_k	$(4k_0p_i^2p_jp_k + k_1p_ip_jp_k)/(2p_ip_j)$	0.5

otherwise not available for testing but his relative can be tested. If X is the tested man, the hypotheses are

H_p: X is a relative of the father Y.
H_d: X is unrelated to the father Y.

If the degree of relatedness in H_p is specified by θ_{XY}, then the *PI*, often called the *Avuncular Index*, when the paternal allele is A_i is $[1 - 2\theta_{XY} + 2\theta_{XY}/p_i]$ when the tested man is homozygous A_iA_i, $[1 - 2\theta_{XY} + \theta_{XY}/p_i]$ when the tested man is heterozygous A_iA_j, and it is $(1 - 2\theta_{XY})$ when the tested man does not carry A_i.

Evolutionary relatedness

For populations in which there is a (low) level of relatedness of individuals because of the evolutionary history of the population, there is a need to consider the relatedness of mother, alleged father, and father. This does not affect $\Pr(A_P|G_M, G_{AF}, H_p)$ because that is determined by the genotype of the alleged father. Under H_d, however, the Dirichlet sampling formula can be used. The probability of the paternal allele depends on the four alleles already seen: those of the mother and the alleged father. The resulting *PI* values are shown in Table 4.

Table 4 Paternity Index values for a population with evolutionary relatedness. (Different subscripts denote different alleles)

G_M	G_C	A_M	A_P	G_{AF}	PI
A_iA_i	A_iA_i	A_i	A_i	A_iA_i	$\frac{1+3\theta}{4\theta+(1-\theta)p_i}$
				A_iA_j	$\frac{1+3\theta}{2[3\theta+(1-\theta)p_i]}$
	A_iA_j	A_i	A_j	A_jA_j	$\frac{1+3\theta}{2\theta+(1-\theta)p_j}$
				A_iA_j	$\frac{1+3\theta}{2[\theta+(1-\theta)p_j]}$
				A_jA_k	$\frac{1+3\theta}{2[\theta+(1-\theta)p_j]}$
A_iA_k	A_iA_i	A_i	A_i	A_iA_i	$\frac{1+3\theta}{3\theta+(1-\theta)p_i}$
				A_iA_k	$\frac{1+3\theta}{2[2\theta+(1-\theta)p_i]}$
	A_iA_j	A_i	A_j	A_jA_j	$\frac{1+3\theta}{2\theta+(1-\theta)p_j}$
				A_iA_j	$\frac{1+3\theta}{2[\theta+(1-\theta)p_j]}$
				A_jA_l	$\frac{1+3\theta}{2[\theta+(1-\theta)p_j]}$

Missing Person Calculations

Many of the issues involved in missing person calculations are the same as those for paternity disputes. Instead of a paternal allele being known, a biological sample from the missing person is available. Suppose a person is missing; the genetic evidence E consists of the genotype from a sample that has come from some person X who may be the missing person Y, together with the genotypes from the spouse M and child C of the missing person. Two explanations of the evidence are

H_p: the sample is from the missing person.
H_d: the sample is not from the missing person.

A general approach for calculating the likelihood ratio is to work with probabilities of genotypes conditional on those in the previous generation(s):

$$\begin{aligned} LR &= \frac{\Pr(E|H_p)}{\Pr(E|H_d)} \\ &= \frac{\Pr(G_C, G_M, G_X|H_p)}{\Pr(G_C, G_M, X|H_d)} \\ &= \frac{\Pr(G_C|G_M, G_X, H_p)\Pr(G_M, G_X|H_p)}{\Pr(G_C|G_M, G_X, H_d)\Pr(G_M, G_X|H_d)} \\ &= \frac{\Pr(G_C|G_M, G_X, H_p)}{\Pr(G_C|G_M, H_d)} \end{aligned} \tag{11}$$

since the genotype of the child does not depend on that of X when H_d is true (ignoring evolutionary relatedness within the population). This likelihood ratio is the same as in the paternity case where X is alleged to be the father of child C who has mother M. Similar extensions can be made to allow for X to be a relative of the missing person, or to allow for evolutionary relatedness among all members of a population.

It may be the case that people apart from the spouse and child of the missing person are typed. The general procedure is the same: the probabilities of the set of observed genotypes under two explanations are compared. Suppose the parents P, Q as well as the child C and spouse M of the missing person Y are

typed, and that a sample is available that has come from some person X thought under H_p to be Y. Under explanation H_d, the sample from X did not come from Y, and therefore the genotype of X does not depend on the genotypes of P and Q and the genotype of C does not depend on the genotype of X.

$$\begin{aligned} LR &= \frac{\Pr(E|H_p)}{\Pr(E|H_d)} \\ &= \frac{\Pr(C, M, X, P, Q|H_p)}{\Pr(C, M, X, P, Q|H_d)} \\ &= \frac{\Pr(C|M, X, P, Q, H_p)\Pr(M, X, P, Q|H_p)}{\Pr(C|M, X, P, Q, H_d)\Pr(M, X, P, Q|H_d)} \\ &= \frac{\Pr(C|M, X, H_p)\dfrac{\Pr(M, X|P, Q, H_p)}{\Pr(P, Q|H_p)}}{\Pr(C|M, P, Q, H_d)\dfrac{\Pr(M, X|P, Q, H_d)}{\Pr(P, Q|H_d)}} \\ &= \frac{\Pr(C|M, X, H_p)\Pr(M|H_p)\Pr(X|P, Q, H_p)}{\Pr(C|M, P, Q, H_d)\Pr(M|H_d)\Pr(X|H_d)} \\ &= \frac{\Pr(C|M, X, H_p)\Pr(X|P, Q, H_p)}{\Pr(C|M, P, Q, H_d)\Pr(X|H_d)} \end{aligned} \tag{12}$$

An example is shown in Table 5.

Evolutionary relatedness can be accounted for by modifying the terms involving allele frequencies. In this case, the term $\Pr(X|H_d)$ needs to take into account the alleles already seen in P, Q, M, and C. For the example in Table 5, where $X = A_1A_3$, this probability is that of obtaining A_1 after having seen two copies of A_1 and A_2 and one copy of A_3, A_4, A_5 and A_6, and then of obtaining A_3 after having seen three copies of A_1, two copies of A_2, and one copy of A_3, A_4, A_5 and A_6. From the Dirichlet sampling formula, this probability is

$$\begin{aligned} &\Pr(A_1A_3|A_1A_1A_2A_2A_3A_4A_5A_6) \\ &= \frac{2\theta + (1-\theta)p_1}{1+8\theta}\frac{\theta + (1-\theta)p_3}{1+7\theta} \end{aligned} \tag{13}$$

Table 5 An example of a missing person calculation.

Child	G_C	A_1A_2
Sample	G_X	A_1A_3
Spouse	G_M	A_2A_4
Mother	G_P	A_1A_5
Father	G_Q	A_3A_6
$\Pr(C\|M, X, H_p)$	=	$\frac{1}{4}$
$\Pr(X\|P, Q, H_p)$	=	$\frac{1}{4}$
$\Pr(C\|M, P, Q, H_d)$	=	$\frac{1}{8}$
$\Pr(X\|H_d)$	=	$2p_1p_3$
LR	=	$\frac{1}{4p_1p_3}$

As a final example, consider the case where profiles are available from one parent P, four siblings S, the spouse M, and a child C of a missing person, as well as from a sample X that may be from that missing person. Sample profiles are shown in Table 6. Write the evidence as $E = (C, M, X, S, P)$ and the hypotheses H_p, H_d that X is or is not from the missing person. It is necessary to introduce the untyped parent Q and add over all possible genotypes for this parent that are consistent with P and S under H_d, and consistent with P, S, X under H_p. The probability of any specific genotype of Q does not depend on the hypotheses. The general procedure is still to write the probabilities for people conditional on those in the previous generations:

$$\begin{aligned} LR &= \frac{\Pr(C, M, X, S, P|H_p)}{\Pr(C, M, X, S, P|H_d)} \\ &= \frac{\sum_Q \Pr(C, M, X, S, P|Q, H_p)\Pr(Q|H_p)}{\sum_Q \Pr(C, M, X, S, P|Q, H_d)\Pr(Q|H_d)} \\ &= \frac{\sum_Q \Pr(C|M, X, S, P, Q, H_p)\dfrac{\Pr(M, X, S, P|Q, H_p)\Pr(Q)}{\Pr(M, X, S, P|Q, H_d)\Pr(Q)}}{\sum_Q \Pr(C|M, X, S, P, Q, H_d)} \\ &= \frac{\sum_Q \Pr(C|MXH_p)\dfrac{\Pr(M|H_p)}{\Pr(XSP|QH_p)}\Pr(Q)}{\sum_Q \Pr(C|MSPQH_d)\dfrac{\Pr(M|H_d)}{\Pr(X|H_d)\Pr(SP|QH_d)}\Pr(Q)} \\ &+ \frac{\sum_Q \Pr(C|MXH_p)\dfrac{\Pr(XS|PQH_p)}{\Pr(P|QH_p)}\Pr(Q)}{\sum_Q \Pr(C|MPQH_d)\dfrac{\Pr(X|H_d)}{\Pr(S|PQH_d)\Pr(P|QH_d)}\Pr(Q)} \\ &= \frac{\Pr(C|M, X, H_p)\sum_Q \Pr(X, S|P, Q, H_p)\Pr(Q)}{\Pr(X|H_d)\sum_Q \Pr(C|M, P, Q, H_d)\Pr(S|P, Q, H_d)\Pr(Q)} \end{aligned} \tag{14}$$

Table 6 An example of a missing person calculation

P	mother, with genotype A_3A_4
S	sibs, with genotypes A_2A_4, A_2A_4, A_2A_4, A_3A_4
Q	untyped father who must have genotype A_2A_3 or A_2A_4
M	spouse, with genotype A_5A_6
C	child, with genotype A_3A_5
X	sample, with genotype A_3A_3

$$\Pr(C|M, X, H_p) = 1/4$$

$$\Pr(X, S|P, Q, H_p) = \begin{cases} \dfrac{1}{1024}, & Q = A_2A_3 \\ 0, & Q = A_2A_4 \end{cases}$$

$$\Pr(X|H_d) = p_3^2$$

$$\Pr(C|M, P, Q, H_d) = \begin{cases} \dfrac{1}{2}, & Q = A_2A_3 \\ \dfrac{1}{4}, & Q = A_2A_4 \end{cases}$$

$$\Pr(S|P, Q) = \begin{cases} \dfrac{1}{256}, & Q = A_2A_3 \\ \dfrac{1}{256}, & Q = A_2A_4 \end{cases}$$

$$\Pr(Q) = \begin{cases} 2p_2p_3, & Q = A_2A_3, \\ 2p_2p_4, & Q = A_2A_4 \end{cases}$$

$$LR = \frac{(1/4) \times (1/1024) \times 2p_2p_3}{(p_3^2)[(1/2) \times (1/256)2p_2p_3 + (1/4) \times (1/256)2p_2p_4]} = \frac{1}{4p_3(2p_3 + p_4)}$$

Details for the specific profiles are shown in Table 6.

Discussion

Interpreting DNA evidence for situations involving parentage or missing person identification rests on the profile probabilities for sets of related individuals. When relatedness is a consequence of membership in the same family, there is a set of three parameters that are the probabilities two people share zero, one, or two pairs of ibd alleles. For the relatedness resulting from the shared evolutionary history of all members of a population, there is a convenient formulation in terms of a general coancestry coefficient θ. This formulation has become widely used in single-contributor forensic calculations and it should also be used in paternity calculations. The identification of remains in missing person situations can be quite complicated when many family members are typed, but the use of likelihood ratios to compare evidence probabilities under alternative hypotheses provides a general approach. The probabilities need to be written for individuals in one generation conditional on individuals in previous generations.

Relatedness coefficients allow the probabilities of DNA profiles for sets of individuals to be written out explicitly. Although increasing relatedness is expected to result in increasing profile similarity, the probability expressions in Tables 1 and 2 make it clear that even unrelated people may have very similar profiles, whereas related people may have quite dissimilar profiles. For example, unrelated people may both be homozygous A_1A_1 at a locus and full-sibs may have completely different genotypes A_1A_1, A_2A_2. It is more appropriate to compare evidence probabilities under alternative hypotheses than it is to have arbitrary rules that deny the possibility of relatedness, once some threshold level of allelic dissimilarity is reached.

Mitigation Testimony

Despite a growing consensus against the death penalty in the United States, there still exist a large number of people that believe in the use of capital punishment. Problematic to some is the holding in *Witherspoon v. Illinois* [1], which guaranteed that only those individuals that are willing to impose the death penalty be allowed to serve as jurors in capital litigation. As such, imposition of the death penalty may not be readily influenced by issues that have led to the decrease in support for the death penalty (e.g., wrongful executions, lack of deterrent value), and these individuals may be more inclined to give the death sentence than would many people in the general population.

In 1979, the United States Supreme Court (USSC) upheld the use of guided discretion in the application of the death sentence for specific crimes in a bifurcated trial; the first stage requires the jury to determine guilt or innocence, and the second to determine sentence after consideration of aggravating and mitigating circumstances (see, for example, [2–4]). In brief, aggravating circumstances are factors that define and narrow the class of defendants eligible for the death penalty (*Zant v. Stephens* [5]), and mitigating circumstances are factors that decrease a capital defendant's culpability to the level at which the death penalty is considered undeserved. In order to proceed with the option of death, the state must prove that one or more statutory aggravating factors exists.

In most states, aggravating circumstances are delineated by statute and include factors that can be separated into four categories: (i) defendant characteristics (e.g., whether the defendant was previously convicted of another capital offense or a felony involving the use or threat of violence to the person not limited to the following factors of the crime and/or the defendant); (ii) elements of the crime (e.g., the defendant knowingly created a great risk of death to many persons; the capital offense was especially heinous, atrocious, or cruel compared to other capital offenses); (iii) motive for the crime (e.g., the capital offense was committed for pecuniary gain; the capital offense was committed to disrupt or hinder the lawful exercise of any governmental function or the enforcement of laws; and (iv) victim characteristics (e.g., the murdered individual was an on-duty peace officer who was killed in the course of performing his official duties and the defendant knew, or should have known, that the victim was a peace officer; the defendant was an adult and the murdered person was an unborn child in the womb at any stage of its development) [6]. While the number of statutory aggravating circumstances varies by state, all states, however, place the burden of proof at the level of beyond a reasonable doubt.

In contrast to aggravating factors, mitigating factors are not limited to those defined by statute, but instead include "any aspect of character or record, and any circumstance of the offense that might serve as a basis for a sentence less than death" [7]. In its decision in *Wiggins v. Smith* [8] the USSC unequivocally stated that failure to investigate and present mitigating evidence during the sentencing phase of a capital trial violates the defendant's Sixth Amendment right to effective assistance of counsel. In *Wiggins*, the defense had found, but failed to present, mitigating circumstances including, but not limited to, severe neglect and physical abuse, sexual abuse, and borderline mental retardation. In the majority opinion, Justice Sandra Day O'Connor opined that "Had the jury been able to place [Wiggins's] excruciating life history on the mitigating side of the

scale, there is a reasonable probability that at least one juror would have struck a different balance" (p. 536).

Jury Decision Making in Capital Litigation

At the most basic level, the concepts of mitigating and aggravating circumstances are easily understood: a mitigating circumstance lessens a defendant's moral culpability and goes against a sentence of death, and an aggravating circumstance increases a defendant's moral culpability and may be used to support the imposition of the death sentence. Despite the apparent simplicity of the constructs, research has consistently shown that jurors' ability to apply these concepts during capital litigation is impaired (e.g., [9–13]). In their evaluation of comprehension of capital sentencing instructions in California, Haney and Lynch [14] identified significant problems in this arena. In their sample of college educated individuals, only 15% were able to provide a legally correct definition of aggravation, 12% could provide a correct definition of mitigation, and a mere 8% provided correct definitions of both terms. Perhaps the most concerning findings were that 30% of the sample provided completely incorrect definitions of mitigation and, after being read jury instructions three times, 11% of the sample was unable to provide a definition of mitigation. In 1997, Haney and Lynch [15] again evaluated the comprehension of jury instructions with respect to the value of providing jurors with explicit definitions of the constructs. The results of this study demonstrated that the inclusion of explicit definitions did nothing to improve overall comprehension.

Garvey [16] addressed an important question in capital litigation, specifically, what impact, if any, do certain factors have on jury decision making in capital cases. Using data from the Capital Jury Project (CJP)[a], Garvey found that the following factors made it more likely that a juror would impose the death penalty: (i) the murder was particularly heinous; (ii) the victim of murder was a child; (iii) the defendant lacked remorse; and (iv) the defendant was identified to be a risk for future dangerousness. Conversely, doubt regarding guilt, a defendant's youthfulness, the presence of mental retardation, and other factors that are outside of the defendant's control (e.g., mental illness) were found to be strong mitigators. Of import was that jurors assigned almost no weight to developmental factors such as child abuse or a background of extreme poverty.

Though studies on lay persons' knowledge regarding developmental risk factors have not yet been conducted, it is possible that the limited significance that jurors placed on these factors is related to lack of understanding regarding the long-term impact of negative life events. In a study that evaluated juror's perceptions of expert testimony, Sundby [17] found that most jurors held negative views about experts, and in particular defense experts. The data demonstrated the presence of three major concerns regarding defense experts, who provide mitigation testimony: (i) jurors believed that such experts lack objectivity; (ii) jurors do not believe that experts have the ability to explain human behavior; and (iii) jurors believe that experts fail to make the critical connection between the psychological principles and the defendant's behavior. Jurors clearly need more than just a recitation of traumatic life experiences and the delivery of a sad story. What jurors need is an explanation of how adverse life events impacted the development of the defendant and how such adversity can be linked to their status as a capital defendant.

Risk, Protective Factors, and Resilience: A Developmental Approach to Mitigation

The sheer magnitude of the outcome of the sentencing decision in capital litigation warrants exploration into the best method to communicate jurors. It is the opinion of this writer that presentation of a defendant's life history within the context of theories of developmental psychopathology is critical, as it provides jurors with a context to understand the defendant's life history. The rationale behind this belief lies in the fact that the capital defendant is similar to any other person in that they have a developmental history. Their developmental trajectory was influenced and shaped by numerous intervening events that either served to hinder or enhance positive growth and development.

In the field of developmental psychology, these life events have been identified under the terms *risk factors* and *protective factors*, respectively. From the developmental perspective, "maladaption is viewed as evolving through the successive adaptations of persons in their environments. It is not something a person 'has' or an ineluctable expression of an

endogenous pathogen. It is the complex result of a myriad of risk and protective factors operating overtime" [18, p. 251].

Risk factors

At the most basic level, a risk factor is a predictor that has been scientifically demonstrated to have a strong link to adverse outcomes such as delinquency, adult antisocial behavior, substance abuse, unemployment, and violence. A recent study [19] investigated the precursors to serious and chronic delinquency, as well as youth violence, and from these data were able to identify a number of risk and protective factors. Included among the many risk factors were such things as perinatal difficulties, family history of criminal behavior and substance abuse, early exposure to violence, economic deprivation, media portrayals of violence, academic failure and lack of commitment to school, and low intelligence.

It is well accepted that there is no single risk factor, or a set of risk factors, that is necessary or sufficient to produce an adverse outcome. In fact, years of research has unequivocally shown that outcomes worsen as the number of risk factors increases (*see*, for example, [20–24]). For example, longitudinal studies have shown that children and adolescents diagnosed with conduct disorder demonstrate broad-based dysfunction over multiple domains. In his review of the literature, Kazdin [25] linked seven categories of dysfunction in adulthood to a prior diagnosis of conduct disorder. Specifically, data from multiple studies have shown that these individuals are more likely to (i) experience psychiatric disturbances; (ii) engage in criminal behavior; (iii) have limited occupational success; (iv) function poorly in school; (v) have impaired marital relationships; (vi) isolate from others; and (vii) experience poor physical health. Not surprisingly, these areas of dysfunction are common among death-row inmates [26].

Protective Factors

While the lives of capital murder defendants tend to be laden with risk factors such as poverty, early exposure to illicit drugs and violence, physical abuse, and ineffective parenting [26], in even the most disadvantaged of systems, an individual is typically exposed to one or more protective factors (e.g., a teacher or coach who takes an interest in the child; an opportunity to engage in community recreation; a family member who notices danger in the home and takes the child in). For the past three decades, the importance of prevention has been recognized, and researchers and policy makers have been dedicated to finding ways to increase access to protective factors; the goal of such intervention is to foster resilience in at-risk children and adolescents (see below for a presentation of the concept of resilience).

The push toward prevention is exemplified in a study funded by the National Institute on Drug Abuse that identified protective factors that can help prevent high-risk youths from engaging in delinquent behavior and illicit substance use [27]. The authors of this study found that resistance to both illicit substance use and delinquency was directly related to the accumulation of protective factors across multiple domains of an adolescent's life. Some of the protective factors identified in the study include appropriate parental supervision, mutual connectedness between parent and child, a commitment to education by both child and parent, association with a peer group that has conventional values, parental approval of one's peer group, positive self-esteem, and child involvement in pro-social activities.

Resiliency

Perhaps the main obstacle to presenting mitigation testimony is the fact that jurors, though similar in that they have matured in response to internal and external forces, are different from capital litigants in that they have somehow succeeded (even if only marginally so) in the presence of some adversity. In the developmental psychology literature, this construct has been referred to as *resiliency* and has been used to explain how individuals that were raised in the same environment can demonstrate highly disparate life trajectories.

Resilience has been defined as a "dynamic developmental process reflecting evidence of adaptation despite significant life adversity" [28]. As previously mentioned, studies have demonstrated that the presence of any single risk factor does not cause adverse outcomes. Instead, it is the convergence of risk factors that leads to widespread dysfunction, and it is the presence of protective factors that fosters resilience (see, for example, [29, 30]).

It has become apparent that resilience in adulthood is related to a number of factors such as having

had more resources and fewer adversities early in life. Exposure to effective parenting, having had a greater number of positive relationships with adult role models, and there being a longer time between the birth of siblings have been found to buffer the negative impact of adverse life events (e.g., [31, 32]). These findings, among others, underscore the critical role of protective factors in the developmental process.

Expert Testimony on Mitigation

Searching for and understanding the role of protective factors has dual purposes in mitigation. First, like most people, the capital defendant will have had exposure to one or more protective factors over the course of their life. This may be the influence of a teacher, involvement in a coping skills program, or perhaps the presence of supportive parents. The usefulness of the identification of protective factors lies not in their presence, but in their impact on the life course of the defendant. It may be that there were opportunities for change via counseling or involvement in extracurricular activities, but that these protective factors were not powerful enough to overcome the impact of the risk factors. Second, there are cases in which protective factors are absent from the life of the defendant and this fact must be made apparent to the jury.

Furthermore, the court must be made aware that the defendant's life trajectory may have been different had someone come forward and intervened on behalf of the individual, or had their life experience included positive influences such as access to prosocial peer groups, financial stability, or a safe living environment. During the presentation of mitigation, it is important to clearly delineate what could have been done to change the defendant's life course, what was done to assist in the process of change, and what tools were readily available yet not implemented.

With respect to expert testimony on mitigation, it is imperative that the mental health practitioner is knowledgeable of the risk factors experienced by the defendant and be able to discuss the impact of these risk factors in relation to interventions that were or were not implemented. Of course, individual risk factors would need to be evaluated over the life course, and be discussed with respect to cumulative stress and the interaction among factors. While perhaps not obvious, the issue of resiliency is of great import in capital mitigation. Clearly, millions of people experience adverse life events, but it is only the rare few who engage in capital crime. In order for mitigation to be successful, the trier of fact must be convinced that the defendant's experience of similar life events was unique, and that it was the uniqueness of the defendant's response that provides an explanation for the violent behavior.

In addition to having a comprehensive understanding of developmental psychopathology, it is critical that the mental health professional is aware that juror decision making does not occur in a vacuum; instead, information is acquired, manipulated, and maintained in the context of each juror's life experience. Similar to decision making in other realms, individuals that are asked to make decisions in the legal arena are doing so, at least in part, on the basis of schemas. In other words, the knowledge that they have accumulated from previous interactions over many years has a direct influence on how jurors think and respond (e.g., [33]). As such, the strength of mitigation evidence is at least in part related to the relationship between the defendant, the crime, and the pre-existing schemata of each juror.

In situations in which jurors' schemata are based on biased or inaccurate information that are detrimental to the defendant, the power of mitigation testimony is likely to be greatly reduced. As such, mental health professionals must enter the courtroom ready to discuss stereotypes and to present information that challenges the myths that may surround the character and life history of the defendant.

Putting it all in Context: *Moore v. Parker*

The lack of understanding of the complexity of presenting mitigating circumstances was highlighted in a recent decision by the US Court of Appeals for the Sixth Circuit. In the case of *Moore v. Parker* [34], the Court affirmed the district court's denial of Moore's writ of *habeas corpus* that was based on ineffective assistance of counsel. With regard to the penalty phase, Moore brought forth the following claims: "his attorneys erred by (1) allegedly spending only about three percent of their preparation time on the penalty phase; (2) remaining unaware of ninety-five letters sent to the first court supporting

him, which could have led them to more mitigating evidence and (3) not having another psychologist examine him after the first on they selected proved to be a fraud."

In response, Judges Boggs and Cook found that the testimony of four witnesses that testified to Moore's troubled upbringing (i.e., the defendant, Moore's aunt, Moore's prison "boss", and a Reverend that had only a brief conversation with Moore) and one psychologist (not hired to conduct a mitigation evaluation) was sufficient for the purposes of mitigation.[b] Judge Boggs affirmed the lower court's ruling, at least in part, on the basis of the finding that strong mitigators were presented to the jury. Included among them were "severe abuse and neglect", "his mother stabbing his father and to his having grown up in numerous foster homes and institutions", "his mother's alcoholism and his father's abusiveness", "his abuse and neglect in foster homes and institutions," and "watching his father hitting his mother so hard that his father broke his hand in three places." Judges Boggs and Cook agreed with the district court in their view that the testimony of the psychologist "cast Moore as an easily angered, impulsive, out of control emotional leech with poor judgment" and such testimony would have been detrimental to his case.

What is pointed out in the dissent is that Moore's dangerousness was not placed in the context of his chaotic and abusive upbringing. Furthermore, Judge Martin unequivocally stated that had the jury been presented with a "graphic description of Moore's atrocious childhood" there exists a reasonable probability that the jury may have come to a different decision at sentencing.

As aptly discussed in Douglas Rau's review of *Moore v. Parker* [35], it is clear that Judges Boggs and Cook were focused on whether or not mitigation testimony would engender sympathy from the jury. In their narrow conceptualization of the goal of mitigation, the judges lost sight of the fact that sympathy does not arise solely from presentation of positive defendant attributes in the face of adversity. To the contrary, in a capital case sympathy is more likely to be engendered by the presentation of the horrible and unfathomable aspects of an individual's upbringing that help to explain how the defendant came to be the potentially dangerous, frightening, and unpredictable person that committed murder. As stated by Judge Martin, expressed mitigation specialists are "qualitatively different from lay witnesses and can translate complex information into testimony that will assist the jury in reaching its determination."

End Notes

[a.] The Capital Jury Project is an ongoing program of research on the decision making of capital jurors. The project began in 1991 by a consortium of university-based researchers and is supported with funds from the National Science Foundation.

[b.] In his dissent, Judge Martin noted that only Moore and his aunt spoke of the issue of childhood, not four witnesses as noted by Judges Boggs and Cook.

Mitochondrial DNA: Interpretation

Introduction

The general principles of interpretation of mtDNA evidence have been detailed previously [1]; we follow the same principles and nomenclature here. Any mtDNA investigation seeks to address whether or not the donor of a reference sample (K) could be the donor, or a maternal relative of the donor, of a questioned sample (Q). The sequences obtained from the samples K and Q are referred to as SK and SQ, respectively.

Despite intense interest and many attempts to detect it, paternal inheritance of human mtDNA has only been demonstrated reliably in a single instance ([2]; for a critique of studies claiming to demonstrate

paternal inheritance of mtDNA, see [3]). Therefore, for the purposes of forensic interpretation of mtDNA evidence, we assume strict maternal inheritance.

What Constitutes a Match between *K* and *Q*?

If the result of the mtDNA analysis is that *K* and *Q* have the same sequence, this observation supports the contention that these samples have a common maternal origin. If *K* and *Q* have different sequences, then the contention of a common maternal origin is not supported by the observation. However, if the difference between *K* and *Q* is slight, the interpretation is not straightforward as the mutation rate of mtDNA is an order of magnitude greater than that of nuclear DNA. Differences in mtDNA sequence can be observed both between maternal relatives (e.g., [4]) and within a single individual (e.g., [5–9]). Two main approaches to evaluating whether an "inclusion", an "exclusion", or an "inconclusive" result is reported have been adopted. The first is a simple ruleset based on the number of differences between the samples: if no differences between the samples are observed, an inclusion is reported, if one difference is observed, the result is declared inconclusive and if two or more differences are observed, an exclusion is reported [10].

In the second approach, the general framework of the likelihood ratio (LR) is applied [1, 11, 12]:

$$\frac{\text{Probability of the evidence} \mid K \text{ and } Q \text{ have the same maternal origin}}{\text{Probability of the evidence} \mid K \text{ and } Q \text{ have different maternal origins}} = \frac{\Pr(E|H_p)}{\Pr(E|H_d)} \quad (1)$$

In this approach, any uncertainty about whether or not the mtDNA samples originated from the same maternal lineage is reflected in the numerator of the LR. Thus, if the sequences match exactly, the numerator would approach 1; if the sequences differ at many positions, the numerator tends toward 0, resulting in exclusion. For sequences, which differ at a single base or a small number of bases, the numerator is intermediate, depending on the mutation rate at the particular base(s) in question, the body tissue from which *K* and *Q* originate, and the number of generations separating the donors of these samples. Data regarding the mutability of individual mtDNA bases is accumulating, with some of the most useful information coming from phylogenetic analyses, which enable distinction to be made between bases that are highly polymorphic due to recurring mutations at highly mutable sites and those that are polymorphic because an ancient mutation has reached appreciable frequency in one or more populations (e.g., [13–16]). Several large studies of heteroplasmic segregation within (e.g., [5–9]) and between (e.g., [4]) individuals provide data to inform the assessment of impact of the body tissue and that of the generational divide, respectively.

Commonly Used Methods for Assessing Evidential Strength When an Inclusion is Reported

All methods for assessing evidential strength rely on population databases to gauge how common or rare is the sequence in question. Databases are considered in detail in the section "Databases".

The Counting Method

Many practitioners rely on the "counting method" to illustrate to the court the relative strength of a mtDNA match. In this method, the number of sequences matching that of the crime scene and suspect observed in the available databases is reported, together with the size of the databases. This method has the advantage of simplicity, and relies on no population genetics assumptions. For common haplotypes, it gives a relatively good estimate of the match probability, providing the database is relevant. However, for haplotypes that have not previously been observed in the database, the practitioner must ensure that the court is not left with the impression that failure to observe a haplotype in a database of, for example, several thousand sequences, indicates that the strength of the observed match is on a par with an autosomal DNA match such as a short tandem repeat (STR) match.

Upper Bound Frequency Estimation

Some have therefore extended the approach to calculate an upper 95% confidence interval for the

frequency estimate. Following Holland and Parsons [12], this is calculated as

$$p = 1 - \alpha^{1/n} \tag{2}$$

where $\alpha = 0.05$ for a 95% confidence interval.

Confidence intervals can also be calculated for frequency estimates for haplotypes that have previously been observed. Again following [12], this is calculated as

$$p \pm \sqrt{\frac{p(1-p)}{n}} \tag{3}$$

where n is the database size.

However, this method is unlikely to give a robust estimate of the confidence interval in most instances, as the normal approximation is poor when p is small [12].

An alternative approach is to add the observations of the sequence in the case to the database, in an approach similar to that advocated by Balding and Nichols [17] for addressing sampling error. Under the assumption of innocence, the profile from the crime sample and that from the reference sample do not originate from the same individual; the calculation is therefore

$$p = \frac{(x+2)}{(n+2)} \tag{4}$$

where x is the number of observations of the sequence and n is the database size [1].

Buckleton *et al.* [11] have suggested that the correct estimator for haploid genomes should be:

$$p = \frac{(x+1)}{(n+2)} \tag{5}$$

However, we contend that the estimator is intended to provide a common sense method to ensure that the strength of evidence is not overstated, given that the sequence has been observed (twice) in the case, even if not in the reference database, so prefer to adopt the more conservative and intuitive formula as originally stated [1]. Nevertheless, when either is fed into an LR, the result converges (Tables 1 and 2).

Table 1 $SQ = SK =$ [146C, 16129A, 16189C] (quoted as differences to the revised Cambridge Reference Sequence [18]); database searches carried out using www.empop.org

Database structure method [19]	*n/a*			Not calculated as this method is for previously unobserved haplotypes only	

The Likelihood Ratio Approach

The general formulation of the LR is given in the section "What Constitutes a Match between K and Q". In adopting the LR approach, an estimate of the likelihood of the evidence conditional on K and Q having different maternal origins must come from some estimate of the frequency of the observed sequence in a relevant population. This estimate may be achieved *via* the counting method, or an extension of this method to correct for sampling error as described in the previous section.

The LR approach has the significant advantage of enabling the evidence to be considered as a whole: evaluation of whether or not K and Q match (section "What Constitutes a Match between K and Q") and evaluation of how frequently the sequences occur are weighed against each other, not considered in isolation. The usefulness of such an approach is best illustrated by examples as follows (updated from [1]):

1. *SK* and *SQ* match exactly, and there are no sequences the same or very similar to these in the database. The findings therefore support the proposition that K and Q have the same maternal origin. The counting method, a frequency estimate or a likelihood ratio (corrected for sampling error and distribution of mtDNA types in the population if necessary) could be used to assist the court in assessing the strength of support for this hypothesis.
2. *SQ* and *SK* differ by a single, frequently mutating base; neither sequence has previously been observed in the database, but there are other sequences in the database differing by a single base. The findings support the proposition that *SQ* and *SK* have a common maternal origin, but

the strength of this support is lower than that in example 1; this reduction is by a factor approximating the substitution rate, plus an additional small reduction to allow for the possibility that one of the similar sequences in the database may have the same maternal origin, albeit invoking an additional mutation.

3. *SQ* and *SK* are identical, both showing a heteroplasmic base at a site not known to be a mutation "hotspot";[a] the sequence (with either base at the heteroplasmic position) has not previously been observed in the database. The findings support the proposition that *Q* and *K* have the same maternal origin; this support is enhanced relative to that in example 1, by a factor approximating the substitution rate at the heteroplasmic base.
4. *SQ* and *SK* differ by a single base at which substitution has previously been observed, but which does not appear to be a mutation "hotspot"; *SQ* has been observed once in a database of 100 sequences, *SK* has not been observed before and there is an additional sequence in the database that differs from *SK* at a mutation "hotspot". There is significant uncertainty surrounding estimates for both the numerator and the denominator, but on balance, the *LR* is not likely to be significantly different to 1 and the result would be reported as inconclusive.
5. *SQ* and *SK* differ at a position that appears from phylogenetic and familial mutation rate estimates to be stable; *SQ* and *SK* have both been observed several times in the database. The findings support the proposition that *Q* and *K* have different maternal origins, and an exclusion is effectively reported.

Methods Not Yet Commonly Adopted

Strength of Evidence Calculation Based on Database Structure (Proportion of Singleton Haplotypes)

Brenner [19] proposed a method for calculating the evidential strength of rare Y chromosome haplotypes; this method is equally applicable to mtDNA evidential strength calculations where the crime sample has a previously unobserved haplotype

$$\Pr(T = SQ) \leq \frac{(1-\kappa)}{n} \tag{6}$$

where T is the haplotype of an innocent suspect for whom the probability of a chance match is being calculated; SQ is the crime scene profile; and K is the proportion of samples in the database that are singletons.

Hence, for example in a database where $\kappa = 80\%$,

$$\Pr(T = S) \leq \frac{1}{5n} \tag{7}$$

which in the simplest case of an exact match between crime scene profile and suspect profile results in a likelihood ratio

$$LR = \frac{1}{\Pr(T = S)} \geq 5n \tag{8}$$

Thus, as long as the crime sample is added to the database, the *LR* can be significantly greater than the size of the database. Incorporating sampling corrections and development of the method to allow for heteroplasmy and mutation have not yet been reported.

Phylogenetic Method for Calculating Match Probability

A method for evaluating match probabilities, taking into account the genealogical tree, which reflects the ancestral relationships between the sequences in a database has been reported by Wilson *et al.* [20]. This type of model can potentially take account of demographic issues such as population structure, thus avoiding the criticisms of Salas *et al.* [13], who also advocate phylogenetic approaches.

In essence, the coalescent model [21] and models for population growth and subdivision, together with mutation rate information specify the Bayesian prior distributions for the genealogical tree underlying a sample of DNA sequences. Inference about aspects of this tree is on the basis of its posterior distribution, given the observed data.

The authors used Monte Carlo Markov Chain (MCMC) algorithms for the analysis, in which the tree consisted of n (database size) $+1$ (crime scene profile) observed sequences. A new branch connecting an unobserved sequence, x, of an alternative possible culprit with an unknown mtDNA sequence with the tree *via* a new node, z, was introduced (see Figure 1; from [20]). At each iteration of the algorithm, the probability that the sequence x matches s was calculated, conditional on the location and state

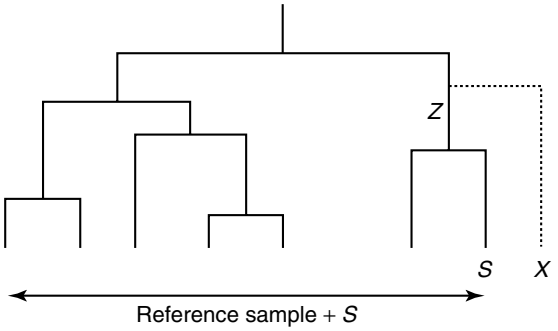

Figure 1 From [20]: Representation of the maternal genealogy of $n = 6$ individuals in an anonymous reference database, together with the suspect, s, and a further individual, x, regarded as an alternative suspect of unknown mtDNA type: the node labeled z corresponds to the most recent woman ancestral to both x and at least one of the other $n = 1$ individuals [Reproduced from Ref.16. © Elsevier, 2005.]

of the node z. The average of these conditional probabilities over 10^5 MCMC outputs approximates the match probability (P_m).

Using this algorithm under the standard coalescent (no population growth or subdivision), this match probability was calculated for the following:

1. the most common haplotype;
2. a haplotype not previously observed, but very similar to the most common haplotype; and
3. a haplotype not previously observed and very different to any observed haplotype.

from a dataset of mtDNA minisequence haplotypes in British Caucasians, Afro-Caribbeans, and Asians [22]. These match probabilities were compared with frequency estimates generated using the counting method amongst $n + 1$ observed sequences, and very similar results were obtained. Counter intuitively the match probability of the dissimilar haplotype in the Afro-Caribbean and Asian datasets was higher than that for the haplotype most similar to the most common haplotype.

The authors concluded that the counting method was usually, although not always, a conservative method. The coalescent model with growth gave similar results, but the model with population splitting was not applied. It would be a profitable area of research for mtDNA interpretation to use similar phylogenetic methods to study the effects of population substructure and establish the circumstances under which the counting method is not conservative.

Databases

Database Relevance and Availability

The availability of relevant databases is critical to the forensic interpretation of mitochondrial data. Whereas the shuffling of preexisting variants by recombination is the principal source of the discriminating power of autosomal STR multiplexes, mtDNA variation only arises through *de novo* mutation events, which are destined to remain associated with the genetic background of the progenitor molecule. Consequently the frequency of a mitochondrial haplotype cannot be predicted by simple multiplication of the relevant allele frequencies at each polymorphic site as for autosomal STRs, but must be determined by direct observation of the entire haplotype within a database.

The strength of mitochondrial evidence is heavily dependant upon the size of the database, particularly when a novel haplotype is involved; unfortunately the haploid nature of the mitochondrial genome also increases its susceptibility to genetic drift leading to higher F_{st} values and greater variation between geographically and ethnically distinct populations. This in turn necessitates the construction of databases for each subpopulation that may give rise to an evidential sample in order that the appropriate strength of evidence can be derived. Furthermore, the greater cost and complexity of sequencing combined with the difficulty of acquiring samples from the appropriate populations generally means that the available databases are often small or derive from populations that do not faithfully reflect the composition of the potential source gene pool. Many laboratories have little option but to make use of databases from areas outside of their jurisdiction. In cosmopolitan populations, where significant migration over a number of generations is the rule, it is likely that the typically general population databases available are sufficiently representative of the population from which the offender originated. Studies of mtDNA variability within and between European populations have confirmed this trend for most European cosmopolitan populations [23], although the resolution of this analysis would not detect localized differences in, for example, small village populations.

Mitochondrial sequence databases covering differing portions of the genome have been compiled for both forensic and academic purposes typically covering both HVI and HVII regions (e.g., Federal Bureau of Investigation (FBI)/Scientific Working Group on DNA Analysis Methods (SWGDAM): http://www.fbi.gov/hq/lab/fsc/backissu/april2002/miller1.htm [24] & European DNA Profiling Group (EDNAP) mtDNA Population Database (EMPOP): http://www.empop.org [25]); Mitomap: http://www.mitomap.org/ [26]) with a rapidly increasing but still limited number of whole genome sequences becoming available (http://www.genpat.uu.se/mtDB/ [27]). Although it is becoming clear that many highly informative Single Nucleotide Polymorphisms (SNPs) are located within the coding regions and much effort is being applied to detecting these in an efficient way (e.g., [28]), database size and the limited quantities of crime stain material generally confines casework sequencing to the hypervariable regions, which are most likely to discriminate between potential sources. Variant sites are typically recorded as changes from the revised Cambridge Reference Sequence [18] allowing comparisons between databases, but one should note that the span of the regions examined may not correspond precisely between data sets. Phylogenetic studies on the basis of this accumulated data have highlighted great variability in mutation rate, subsequent persistence, and distribution of variation at different bases (e.g., [13–16]). The two hypervariable regions being noncoding have fewer functional constraints and therefore can tolerate the greatest polymorphism; some sites are particularly unstable and are frequently heteroplasmic, including two poly C regions, which are inclined to slippage. Such regions are variable upon many branches of the phylogenetic tree due to recurrent mutation, while many slower mutating sites are polymorphic only in a single lineage.

Knowledge of the phylogenetic relationships between populations on the basis of their patterns of haplogroup sharing has greatly increased our understanding of the complex genetic origins of ethnic subpopulations. Many mitochondrial clades are strongly associated with geographic regions and have been used to trace the migration of humans from Africa to colonize the world. Demographic studies have highlighted several instances in which different patterns of genetic contribution are apparent for females (mtDNA) and males (Y chromosome), this being apparent in many Hispanic populations where the indigenous female contribution is very strong, but much reduced with respect to Y chromosomes, where European origins predominate but the extent to which this is apparent depends on the population being examined [29, 30].

Recent periods of mass migration, either forced or by choice, have greatly altered the mtDNA gene pool of many regions but care must be taken to ensure that databases, which appear to share similar ethnic origins, either from the continent of origin or resulting from dispersals to other parts of the globe, are indeed reliable substitutes. Similarly tribal or caste differences may exist even among indigenous people, which should be accounted for by ensuring that sampling accurately reflects the current composition of the area in question.

Database formats range from simple tables in published papers through to sophisticated online databases. The level of checking prior to publication may also vary from a single automated sequence read per sample through to duplication of sequencing using primers on both strands upon templates derived from separate duplicate extractions or polymerase chain reactions (PCRs) with witnessing of all manual stages. Online databases such as FBI/SWGDAM (http://www.fbi.gov/hq/lab/fsc/backissu/april2002/miller1.htm) and EMPOP (http://www.empop.org) are openly accessible and have been updated with additional samples or corrections as appropriate, indeed the EMPOP database includes the sequence electropherograms to aid confirmation of profile quality and accuracy [31]. Full details of the sample's geographic and ethnic origin are submitted so that its relevance to an enquiry can be fully determined. Furthermore, all potential contributors have to correctly genotype a number of quality control samples before their samples are uploaded and every haplotype is checked using the Network phylogenetic software package (http://www.fluxus-technology.com/) to screen for potential sequencing or transcription errors.

Concerns Regarding Database Quality

A series of publications have used the phylogenetic approach to highlight the likely occurrence of errors in the majority of databases (e.g., [32–34]). While genuine recurrence of mutations at hypervariable positions results in small reticulations within

phylogenetic networks in which the temporal order of mutations cannot be determined, when groups of closely spaced variants reoccur on widely separated branches of the network, this has usually provided evidence of artificial recombination resulting from errors during the transcription of data or mix-ups with tubes, which have "recombined" HVI and HVII regions from different individuals [35]. When individual slow-mutating sites show variants on widely separated branches this highlights sequences, which should be checked for accuracy but may in fact be authentic. The majority of errors are thought to occur during transcription of data to the published tables and their frequency is therefore reduced by software packages that reduce the amount of human intervention. Other potential causes include degraded samples in which contaminant DNA overwhelms an unduplicated PCR reaction, or a primer binding site polymorphism, which knocks out amplification of the authentic sequence.

Further sources of error include base shifts in tabulated data, where the positions relative to the revised cambridge reference sequence (rCRS) are incorrect; these can involve shifts of a single base, by several positions (often 10 or 100), or into an adjacent column. Phantom mutations, where unlikely transversions appear in sequences may be owing to transcription errors or problems with the sequencing chemistry, which result in hard to interpret positions [33]. Reference bias, where a change from the rCRS is overlooked and therefore goes unreported, and base mis-scoring when transversions are mis-recorded as the more common transitions also occur frequently (all discussed in detail in [32]). Virtually all of these errors could be avoided by duplication of the sequence using primers on both strands, the independent comparison of these sequences with the reference and their recording in two different formats e.g., motif and dot table, which can subsequently be compared electronically to highlight any discrepancies [31, 34].

As errors have been highlighted by these publications in widely used databases such as the SWGDAM Mitochondrial DNA Database, much effort has been made to purge these and test what effect they may have had on reports produced with the imperfect data. Budowle *et al.* [36] argue that sequencing errors have largely been eliminated owing to improved chemistries, equipment and software and the widespread adoption of duplication by forensic laboratories as outlined in International Society for Forensic Genetics (ISFG) guidelines [37]. Using up-to-date casework techniques discrepancies are exceedingly rare demonstrating that these safeguards successfully eliminate the vast majority of potential errors. They also conclude that the impact on reporting is marginal. The likely effect of any error is to create a new haplotype that does not already exist in nature, therefore assuming the error rate is low it merely reduces the true size of the database by the proportion of profiles, which contain errors. Although there is no justification for complacency and every effort should be made to rigorously control and improve the accuracy of databases used in forensics, it is unlikely that the error levels that had existed would have counteracted the conservative allowances that are made for database size.

Database Size

How large should a database be? Clearly this depends on many factors, primarily the diversity within the population. This has been modeled by Pereira *et al.* [38] using samples from a database of 549 individuals from across Portugal in comparison with 1 200 Germans from a single village [39]. While haplotype diversity peaked with samples of 300 in Portugal and 400 in the German sample, the number of haplotypes continued to rise almost linearly. The proportion of Portuguese haplotypes that were unique for HVI declined from around two-thirds when the sample size was 50 to about a third in the full database of 549, while for HVII the decline was much faster from 39.0% to 14.9% as the smaller number of polymorphic sites in this region are subject to a higher rate of recurrent mutation. When both HV regions are considered together the proportion of unique sequences remained above 50% even in the full database and modeling suggests that a sample size in excess of 1 300 would be required to reduce the proportion of novel haplotype observations below 5% among each subsequent addition of 100 samples. Given that the Portuguese population is less diverse than Central Europeans, it is clear that in most instances databases ideally need to number in the thousands before they cease to reveal a substantial number of previously unobserved haplotypes.

Worked Examples

To illustrate the practical impact of using the different interpretation methods and databases described earlier, the methods detailed have been applied to two example sequences, using two databases, both drawn from the EMPOP database: 273 Austrian Caucasians and 3830 Western Europeans. The phylogenetic method was not included, as the algorithms were developed for minisequence data, not full sequence data; computationally, full sequence data are more challenging. Additionally, for the database structure method, only 101 Austrian Caucasians were considered, as the structure of this dataset had previously been published [40].

End Notes

[a.] Hotspots are regions of the genome (usually single bases or short homopolymeric runs) that have greatly increased mutation rates to the extent that the same mutation is found in several different haplotypic backgrounds due to recurrent mutation.

Mitochondrial DNA: Profiling

Introduction

Mitochondrial deoxyribonucleic acid (mtDNA) analysis is a routine adjunct to crime scene investigation. Introduced in the early 1990s to aid with the identification of military remains, and implemented since then by the Armed Forces DNA Identification Laboratory in Rockville, Maryland, in all military conflicts [1], it was first used in criminal justice proceedings by the FBI in 1996 in *Tennessee v. Paul William Ware* [2]. In that case, a single hair located in the throat of a victim linked Ware to a homicide. MtDNA provides a valuable locus for forensic DNA typing in certain circumstances, especially for skeletal remains, shed hairs, or hair fragments, and degraded samples of all types. In general, it is used when short tandem repeat (STR) testing is not possible owing to limited or degraded nuclear DNA because mtDNA is naturally abundant and resistant to degradation [3]. MtDNA cannot be a unique identifier, as can nuclear DNA, due to its pattern of maternal inheritance, nor does it have the statistical power of a nuclear DNA match; as such, it is used as supplementary circumstantial evidence in criminal cases. MtDNA analysis has played a large role in the identification of missing persons when applied to skeletal remains.

Mitochondrial DNA Biology

Deoxyribonucleic acid (DNA) is found in two locations in all human cells except red blood cells (*see* **DNA**). Nuclear deoxyribonucleic acid (nuDNA), inherited from both parents, makes up 26 pairs of chromosomes in the nucleus. Mitochondrial deoxyribonucleic acid (mtDNA), inherited only from the mother, is located in the mitochondria, small, peanut-shaped cytoplasmic organelles that generate cellular energy. The full complement of nuDNA has about 3 billion of the four chemical bases of DNA (adenine, guanine, thymine, and cytosine, abbreviated as A, G, T, and C; also known as *nucleotides*) in a linear array within the chromosomes. Human mtDNA contains approximately 16 569 nucleotides in a small circular molecule. Whereas each cell contains two copies of nuDNA, there are hundreds to thousands of mtDNA molecules within dozens to hundreds of mitochondria per cell, depending on the particular tissue. With some exceptions, all tissues in an individual are homogeneous for the single mtDNA type, or sequence, of DNA nucleotides in that individual's mtDNA molecules.

The mtDNA types, sequences, or "profiles" present among humans have been generated by mutational changes occurring in this DNA over many generations. All living humans can be linked by their profiles into a single large tree and share a common maternal ancestor; those individuals with similar types are most closely clustered in the tree. MtDNA reflects the biogeographical ancestry of a particular maternal lineage. For example, certain types may be readily recognizable as having originated in Asia, Africa, or Europe. MtDNA is passed intact from a mother to all her children; males inherit their mother's mtDNA but do not pass it on to their children. For this reason, all maternally related individuals share the same mtDNA profile.

The natural abundance of mtDNA is the key to its forensic utility. MtDNA recovery from small or degraded biological samples is greater than nuDNA recovery owing to the high copy number (there are many mitochondria in a cell, but one nucleus) and because the molecule's small circular structure may protect it from damage by heat, humidity, acidity, and ultraviolet (UV) light. In addition, nuDNA in naturally shed hairs and hair shafts is extremely limited even when these samples are freshly collected [4].

The mtDNA molecule codes for 13 proteins, two ribosomal RNAs, and 22 transfer RNAs, and also contains a 1122 bp "non-coding" region, sometimes called *the control region* or *D-loop*, which is forensically informative [5]. The DNA sequence differs so much among individuals in two "hypervariable" sections of the control region that the likelihood of choosing two people at random with the same mtDNA sequence is very low [6]. About 8–12 nucleotide differences would be observed between two maternally unrelated individuals for the regions that are analyzed, comprised of DNA sequence about 700 bp long [7].

Candidates for forensic mtDNA typing analyses are as follows: (i) shed hairs with no follicle, tissue, or root bulb attached, (ii) hair shaft fragments, (iii) bones or teeth that have been subjected to long periods of high acidity, high temperature, or

high humidity, (iv) stain or swab material that has been unsuccessfully typed for nuDNA markers, and (v) tissue (skin, muscle, organ) that has been unsuccessfully typed for nuDNA markers. While mtDNA typing of blood, semen, and saliva crime scene stains from clothing and floors is possible, it is likely that mixtures will be obtained due to the extreme sensitivity of this form of typing in samples that, unlike hairs and bones, are difficult to clean before DNA extraction. On the other hand, degraded samples collected from near-sterile or UV radiation–exposed surfaces, such as the exterior of a vehicle, may easily provide single-source mtDNA profiles.

The Analytical Process

An mtDNA analysis begins when total genomic DNA is extracted from biological material such as a tooth, blood sample, or hair. Extraction methods, such as grinding of hair or bone or complete dissolution of proteinaceous material are designed and validated in order to optimize the yield of DNA for specific sample types. In addition, the external surfaces of samples are thoroughly cleaned via sanding with a rotary drill bit (for bones) or ultrasonic water baths (for hairs). Approximately 2 cm of a single hair is used in the average case, though success has been achieved with much less; for skeletal remains, approximately 0.1–0.5 g of bone is used [8, 9].

Following extraction, the polymerase chain reaction (PCR) is used to amplify the two hypervariable portions of the noncoding region using flanking primers. Primers are small bits of DNA that identify and hybridize to or adhere to the ends of the region one wishes to PCR amplify, therefore targeting a region for amplification. Primer pairs have been designed and manufactured to encompass virtually any region of mtDNA in humans, and may include "mini-primer pairs" that can recover the smallest fragments of DNA from a degraded sample, usually under 150 bp in length [10] (*see also* **DNA: Degraded Samples**).

Because the natural abundance of mtDNA as well as the creation of PCR product introduces many copies of mtDNA into the laboratory, care is taken to eliminate the introduction of exogenous (contaminating) DNA during both the extraction and amplification steps by methods such as the use of prepackaged sterile equipment and reagents, aerosol-resistant barrier pipette tips, gloves, masks, and lab coats, separation of pre- and post-amplification areas in the lab using dedicated reagents for each, ultraviolet irradiation of equipment, and autoclaving of tubes and reagent stocks. In forensic casework, questioned samples are processed at different times than known samples and in different laboratory rooms. Most importantly, several negative controls that would indicate the presence of contamination introduced during testing are run in parallel with all samples. Overall, contamination is more of a concern for the mtDNA laboratory than the nuclear DNA laboratory, but each laboratory determines through internal validation studies how contamination and its control, detection, and interpretation can impact casework and still result in a defensible outcome [11].

When adequate amounts of PCR product are amplified from the two hypervariable regions, as determined from either a yield gel or other detection method, sequencing reactions are performed. These chemical reactions use each PCR product as a template to create a new complementary strand of DNA in which some nucleotides are labeled with dye. The strands created at this stage are then separated according to size by an automated sequencer that uses a laser to "read" the sequence. Where possible, the sequences of both hypervariable regions (called *HV1* and *HV2*) are determined on both strands of the double-stranded DNA molecule and in overlapping PCR products, with sufficient redundancy to confirm the nucleotide sequence that characterizes that particular sample.

Two forensic analysts independently assemble the mtDNA sequence and then compare it to a standard published reference sequence called *the revised Cambridge Reference Sequence* (rCRS, [12, 13]), denoting all the nucleotide differences. The entire process is then repeated with a known sample, usually blood, saliva, or a buccal swab, collected from a known individual. The sequences from both samples, about 780 nucleotides each, are compared to determine if they match. Depending on data quality or ambiguities, portions of the analysis may be repeated.

Heteroplasmy

Heteroplasmy is defined as the presence of two or more types of mtDNA within an individual

[14]. There are two forms of heteroplasmy: length heteroplasmy and site (or sequence) heteroplasmy. The baseline state of mtDNA composition in humans, with the exception of individuals with tissue-specific mitochondrial diseases, is homoplasmy. That is, the overwhelming majority of mtDNA-containing cells within an individual contain the same 16 569 bp mtDNA molecule throughout. The exception to this dominant state of uniformity is the frequent occurrence of length heteroplasmy in certain control region strings of cytosine residues ("C-stretches"), which creates populations of mtDNA molecules in each cell that differ slightly in length. Length heteroplasmy occurs in about 50% of all individuals. Site or sequence heteroplasmy, where at a single nucleotide address there are two different DNA bases such as T and C, has been observed in approximately 1% of blood samples and 10–15% of hair samples, with other tissues such as bone believed to be intermediate with respect to frequency. Some degree of heteroplasmy exists in all individuals; precisely how detectable and abundant it is becomes the focus of the forensic DNA practitioner. Guidelines are derived from each laboratory's validation studies to allow for conservative interpretations of heteroplasmy such that false failures to exclude cannot occur when it is present.

Interpretation

The FBI's Scientific Working Group on DNA Analysis Methods (SWGDAM) Guidelines for mtDNA Nucleotide Sequence Interpretation ((http://www.fbi.gov/hq/lab/fsc/backissu/april2003/swgdammitodna.htm) state:

> The following guidelines may be used in most cases:
>
> - Exclusion
>
> If there are two or more nucleotide differences between the questioned and known samples, the samples can be excluded as originating from the same person or maternal lineage.
>
> - Inconclusive
>
> If there is one nucleotide difference between the questioned and known samples, the result will be inconclusive.
>
> - Cannot Exclude
>
> If the sequences from questioned and known samples under comparison have a common base at each position or a common length variant in the HV2 C-stretch, the samples cannot be excluded as originating from the same person or maternal lineage.

In the event of a "cannot exclude" result, the SWGDAM mtDNA database (http://www.fbi.gov/hq/lab/fsc/backissu/april2002/miller1.htm) is searched for the mitochondrial sequence that has been observed for the samples. At present, the SWGDAM database of human mtDNA sequences has around 5000 sequences available for a search of a casework sequence, but an increase to over 10 000 samples is expected within one to two years. The current convention in the event of a failure to exclude is for the analyst to report the number of times the observed sequence is present in the database in order to estimate its relative frequency in the population. A frequency statistic is calculated, and a 95 or 99% confidence interval is placed around the estimated frequency to account for the inherent uncertainty in the frequency calculation since one would never be able to type all living humans [1]. This convention of using the upper-bound frequency provides a very conservative approach to estimating how many individuals at most would be expected to have a particular type. For example, a novel type (one that has not been observed previously in the database) would be estimated to occur at most in 6 in 10 000 individuals based on the size of the database currently being used.

While around 60% of all mtDNA types appear to be rare (occurring a single time) in each of the FBI's ethnic sub-databases (individuals claiming to be African or of African origin, Asian or of Asian origin, Caucasian or of European origin, or Hispanic), there is one mtDNA sequence that is seen in around 7% of Caucasians. Interestingly, the frequency of this type has remained fairly stable as the database has grown over the last 10 years. However, almost two-thirds of the newly typed samples have novel sequences; therefore, all the mtDNA variation present in the general human population has not yet been identified. One exception to the high diversity that is present within ethnic databases has been observed: due to founder effects, mtDNA diversity in native Americans is limited, and certain types in this group are observed at high frequencies [15].

In addition to the SWGDAM database, over 20 000 human mtDNA control region sequences

have been characterized by anthropologists and forensic scientists (see the many references to human mtDNA populations that have been studied at http://www.mitomap.org/, as well as [16]). In general, the pattern observed in most populations around the world, with the exception of some populations of anthropological interest, is that most of the sequences are uncommon, and few types are present at frequencies greater than 1%. Because of this fact, it is possible to exclude greater than 99% of a population as potential contributors of a sample in most cases, except where one is dealing with a more common type. In contrast, a multilocus nuclear DNA typing profile provides vastly superior discriminatory power and statistics that permit source attribution. For this reason, mtDNA can never provide the resolution of individuality that nuDNA typing can.

As mentioned above, mtDNA is maternally inherited, so that any maternally related individuals would be expected to share the same mtDNA sequence. This fact is useful in cases where a long deceased or missing individual is not available to provide a reference sample but any living maternal relative might do so. Because of meiotic recombination and the diploid (biparental) inheritance of nuDNA, the reconstruction of a nuDNA profile from even first-degree relatives of a missing individual is rarely this straightforward. This feature has allowed some important historical mysteries to be solved, such as the identification of the remains of the assassinated Romanov family [17], the Vietnam Unknown Soldier [18], and American outlaw gunfighter Wild Bill Longley [19]. However, the maternal inheritance pattern of mtDNA might also be considered problematic. Because all individuals in a maternal lineage share the same mtDNA sequence, mtDNA cannot be considered a unique identifier. In fact, apparently unrelated individuals might share an unknown maternal relative at some distant point in the past. For this reason, it is important that judges, attorneys, and juries in criminal proceedings are educated about the maternal inheritance pattern of mtDNA.

Nonforensic Uses

While mtDNA is useful for forensic examinations, it has also been used extensively in two other major scientific realms. First, there are a number of serious inherited diseases caused by deleterious mutations in gene-coding regions of the mtDNA molecule [20]. In addition, molecular anthropologists have been using mtDNA for three decades to examine both the extent of genetic variation in humans and the relatedness of populations all over the world [21]. An mtDNA maternal inheritance pattern can reveal ancient population histories, which might include migration patterns, expansion dates, and geographic homelands. MtDNA has been recovered from several Neanderthal skeletons, and the resulting population genetics studies have allowed anthropologists to conclude that modern humans do not share a close relationship with Neanderthals in the human evolutionary tree [22]. The general methods for performing all mtDNA analyses, including forensic methods, are identical to those used in molecular biology laboratories all over the world for studying DNA from any living organism. There are several thousand published articles on mtDNA available at http://www.mitomap.org/.

Laboratory Practices

MtDNA analysis is offered by the FBI in their Quantico facility as well as in four regional laboratories. Several private commercial labs also offer testing, as do the Armed Forces DNA Identification Lab, University of North Texas Health Science Center, Office of the Chief Medical Examiner in New York, and California Department of Justice. Most, if not all, of these laboratories are guided in application of mtDNA analysis by federal Quality Assurance Standards for DNA testing and various accrediting bodies.

MtDNA matching has become an extremely valuable resource for the FBI's National Missing Person DNA Database program. Under this program, maternal relatives submit samples for typing and inclusion to the database for eventual comparison to profiles obtained from recovered skeletal remains.

Although mtDNA is still undergoing admissibility hearings in some jurisdictions, several hundred cases have been litigated in over one-half of the United States since 1996. All convictions in which mtDNA has played a role have been upheld at the appellate level (*see also* ***Frye v. United States***). For more

information on court cases and appellate decisions, see http://www.denverda.org/DNA/Mitochondrial_DNA_Legal_Decisions.htm.

A complete tutorial on mtDNA is available online at http://dna.gov/training/otc/ through the President's DNA Initiative. This course was specifically developed for officers of the court.

Mixture Interpretation: DNA

Introduction

A mixed DNA profile is obtained when two or more contributors provided biological material to an evidentiary sample that has been analyzed. Here, only routine STR analysis techniques will be considered. With a STR profile, the presence of a mixture becomes obvious when more than two alleles are detected at a given locus.

DNA mixture interpretation is a complex and contentious field. There are a number of unsettled issues in the interpretation of mixtures and current methods, while adequate, leave clear room for improvement. In this section, we will outline current methods for interpretation and also highlight those areas where further research would benefit our science.

The primary division in modern interpretation methods lies between those who seek to

1. extract from the mixed DNA profile, when feasible, a single (unmixed) profile of interest and report it using the statistical techniques used for single stain calculation (*see* **Short Tandem Repeats: Interpretation**);
2. report an exclusion probability (often termed *random man not excluded* (RMNE) or *combined power of exclusion* (CPE)); and
3. report a likelihood ratio.

Much discussion has occurred debating these points, with views often very strongly held. This is unusual as the pros and cons of each method are well known and little new information has been added to the debate in recent years.

The peak heights present in mixtures are assumed to be approximately proportional to the amount of DNA from each contributor, and there is considerable empirical evidence for this. However, the correlation is only approximate and may be affected by degradation, stutter, and stochastic effects. The larger of two contributors is termed the *major contributor* and is assumed to be the source of the largest peaks. The smaller contributor is termed the *minor*. In a three-person mixture, the contributors may be present in quantities described by the terms *major, minor*, and *trace*.

It is also possible that two contributors are present in approximately equal proportion. In such cases, the mixture may be termed a 1 : 1 mixture.

Treating the Mixture as a Single Stain

If the profile in question is a clear major minor and the major is the profile of evidential interest, then it is acceptable to interpret the mixture as if it was an unmixed stain as long as care is taken regarding a potential factor of 2. Consider the situation where the stain may be explained as mixture of the suspect as the major and an unknown minor then under the defense hypothesis two unknowns are required to explain the mixture. In such cases, the unmixed stain calculation will err in favor of the prosecution by a factor of 2. This is known as the *Whitaker effect* [1–4].

Random Man Not Excluded

A frequentist method in common use is often termed *Random Man not Excluded*. In its simplest implementation it gives the probability that a random man has both his alleles contained within the mixture. Hence, for a mixture that shows the alleles abc and d the genotypes aa, ab, ac, ad, bb, bc, bd, cc, cd, and dd are not excluded.

Formally, if the mixture has alleles $A_1 \ldots A_n$ then the exclusion probability at locus l, (PE_l) is $PE_l = 1 - \left(\sum_{i=1}^{n} p(A_i)\right)^2$ if Hardy–Weinberg equilibrium is assumed. By writing $\sum_{i=1}^{n} p(A_i) = p$, we can obtain $PE_l = 1 - p^2$. If Hardy–Weinberg equilibrium is not assumed, Budowle gives $PE_l = 1 - \left(\sum_{i=1}^{n} p(A_i)\right)^2 - \theta \sum_{i=1}^{n} p(A_i)\left(1 - \sum_{i=1}^{n} p(A_i)\right)$. We can write this as $PE_l = 1 - p^2 - \theta p(1-p)$. The use of the equivalent of NRC II recommendation 4.1 [5] leads to $PE_l = 1 - p^2 - \theta \sum_{i=1}^{n} p_i(1-p_i)$, which differs slightly. The PE across multiple loci (PE) is calculated as $PE = 1 - \prod_l (1 - PE_l)$.

The advantages of such an approach are that

1. it does not assume a number of contributors;
2. it can report a statistic for mixtures that are lower quality than reportable under an LR approach; and
3. it is easier to explain.

Extensions to this approach essentially use judgment or a set of rules to generate a list of possible

unknown genotypes. The assumptions used to generate this list may include assuming a number of contributors and a conditioning profile. Once the list of possible genotypes is generated, the combined probability of inclusion (CPI, the complement of CPE) is generated by summing the estimated probabilities of the included genotypes. RMNE is assigned as 1-CPI. Typically, the genotype probabilities are estimated using the product rule but this is not a requirement.

There is a debate at the adequacy of using RMNE as a meaningful statistics (see EFS entry by Balding). If we agree that a balanced and fair assessment of the evidence is only achieved through the use of a likelihood ratio, hence by addressing the evidence both under H_p and H_d, then RMNE statistics does not represent an appropriate expression of the weight of evidence. This is because (i) the numerator is not assessed and (ii) the proposition for the denominator implies a loose concept of a random man and the evidence is assessed without taking into account of the profile of the suspect at hand.

Likelihood Ratio-Based Approaches

The first stage in the development of a likelihood ratio for mixtures is the establishment of the two hypotheses. Even using sublevel 1 hypotheses (see EFS entry by this can be problematic and requires the use of judgment and an awareness of the case circumstances [6–11]). Issues include, but are not restricted to

- assigning a number of contributors and
- determining whether any contributors can be safely assumed to be present under both the prosecution and defense hypotheses. Contributors that are assumed to be present are termed *conditioning* contributors.

One of the more common two person mixtures is one that can be explained as containing the DNA of the suspect and the complainant. In such a case, the hypotheses may be

H_p: the DNA in the crime stain is from the suspect and the complainant and

H_d: the DNA in the crime stain is from an unknown person and the complainant.

In this case, the conditioning contributor is the complainant. The unknown person is termed *the unknown*.

If E is used to represent the DNA results obtained in the case, then the LR is $p(\mathrm{E}|H_p)$ divided by $p(\mathrm{E}|H_d)$.

Assigning the Number of Contributors

Assignment of the number of contributors is undertaken from the number of alleles observed with some attention paid to peak balances. The number of alleles per locus is an important parameter but it should not be the only criterion used [12, 13]. It is important to have an understanding of stuttering and of genetic phenomena such as trisomy, gene duplication, and somatic mutation [4]. Mixtures where an evidential profile is sufficiently low in peak height that dropout may have occurred should be treated as low-template profiles. Hence most of the discussion here will assume that dropout is not an issue (for more information on such artifacts, see EFS entry on low template DNA).

Typically, the number of contributors is assigned as the minimum number required to explain the mixed profile. Hence a profile containing at most two alleles per locus is assigned as containing one contributor unless peak balances suggest that a second contributor is present. A profile containing at most four alleles per locus is assigned as a two-person mixture. Profiles containing five or more alleles are termed *higher order mixtures*.

Interpretation of higher order mixtures can be problematic but is simplified if conditioning contributors may be assumed and if one profile is clearly a major contributor. If it cannot be simplified, it is advised to refrain from undertaking any calculation.

Once the number of contributors is assigned, the hypotheses generated and the presence of any conditioning contributors determined that the next step is to list the possible genotypes for any unknown contributors. This may be achieved either considering peak height or not.

Considering Only Qualitative Data

If no consideration is to be made of peak height, then the methods of Weir *et al.*, Fung and Hu, and Curran *et al.* return the likelihood ratio either utilizing the product rule (Weir *et al.*), NRC II recommendation

4.1 (Fung and Hu) or recommendation 4.2 (Curran *et al.*) [14–20].

Although LR computation varies in function of the propositions involved, this discussion can be pursued on the basis of a case with a two-person mixture that can be explained as containing a complainant and a suspect (H_p) or as the complainant and an unknown person (H_d). The arguments can be extended without loss of generality to other pairs of propositions. In this case, the LR is always in the form of one divided by the sum of the random match probabilities for the collection of all the possible genotypes for the unknown person. The summation under the denominator assessment implies an equally weighted contribution for each potential genotype. This is justified by the fact that the model explicitly does not take into account peak areas.

The Curran *et al.* method is embodied in the software DNAMIX II and is suitable for casework use. It does not take account of peak heights and cannot handle dropout. Since it does not utilize all the available information it has the expected performance of understating the evidence if H_p is true and overstating it if H_d is true. Recall that this is the expected performance of any method that does not utilize all the available evidence. Certain rules based on peak height may be applied to identify those situations where the approach may be nonconservative and appropriate action may then be taken. This is especially true when the peak areas would suggest that a combination of the designated contributors is not supported if the H_p is true. By default, the above methods assign a probability of 1 to the numerator of the likelihood ratio and concentrate on the estimation of the denominator. That default value may not always be supported by the data.

Beecham and Weir (in draft) have developed a method to add a sampling uncertainty consideration to the method of Curran *et al.* [14] This approach is embodied the software DNAMIX III (available at http://statgen.ncsu.edu/~gwbeecha/).

The work by Fung and Hu [19] led also to the development of dedicated software, also in case involving relatives [21] (available at http://www.hku.hk/statistics/EasyDNA/).

Considering Peak Heights

If peak heights are to be considered then the list of possible unknown genotypes is modified by eliminating those combinations that are expected to give a poor fit to the peak heights. Consider the situation where we have a conditioning profile, say the complainant, who has genotype ab. The peak heights $a = 1000, b = 2000, c = 1000$ are very unlikely if the unknown contributor is genotype ac. Hence the genotype ac is eliminated as a possibility for the unknown. This elimination process may proceed by the judgment of an experience caseworker or according to a set of rules. One set of such rules has been published [22] and is embodied in the software suite Fss-I^3. Three types of rules are typically used on the basis of (i) expected peak imbalance, (ii) expected mixing proportion between the two contributors, and (iii) expected allelic dropout. Currently, appropriate treatments have been given to two-person mixtures only. In this case, the LR is on the form of one divided by the sum of the random match probabilities for the collection of all the genotypes for the unknown person that have passed the rules.

The situation where a minor evidential profile is present in an assumed two-person mixture and dropout is possible can be handled by careful application of judgment or the rules. Typically, possibilities for the unknown are expanded to include one or two unobserved alleles. The possibility of two unobserved alleles returns a likelihood ratio of 1 for this locus and is not always conservative (see the recent case against Garside and Bates [23]). The possibility of one unobserved allele is typically handled using the $2p$ rule [24] or its subpopulation corrected variants. However, any profile where dropout is possible is really low-template DNA (LTDNA) and the LTDNA style of interpretation should be applied [25].

Once the set of possible unknown genotypes has been determined the likelihood ratio may be developed using either the product rule or one of the subpopulation correction options (see EFS entry by Balding). The approaches outlined above are commonly referred to as *binary*, because the decision on accepting or rejecting a given combination amount to assign a weight of 1 or 0 in the likelihood ratio calculation. It is not a full probabilistic approach as early advocated by Evett, Gill and Lambert [26] and continued by Perlin and Szabady [27], but it constitutes a promising step toward it. However, the use of a binary model should be undertaken having in mind a clear understanding of its limits. As mentioned for the techniques not involving peak areas, the analyst needs to make sure that the genotype of

the suspect is the best supported option (taking into account peak areas) under the numerator proposition and that all reasonable genotypes are included in the denominator [28, 29].

Standard

There has been a substantial move amongst the European Network of Forensic Science Institutes toward setting standards for interpretation of mixtures, see [28, 30].

Issues in Mixture Interpretation

Currently, there are a number of areas in DNA mixture interpretation, which are under active research. This includes methods to handle the uncertainty in the number of contributors, dealing with dropout, automation of the process, and a more effective use of the peak height information. Of particular interest is the research involving Bayesian networks that may bring intuitive ways to handle the complexity of mixture interpretation [31].

Natural Causes of Sudden Death: Noncardiac

Respiratory

Pneumonia

Prior to the discovery of antibiotics, one-third of all people who developed pneumonia subsequently died from the infection. Until the introduction of antibiotics, pneumonia was the most common cause of death in the United States and, perhaps, worldwide. Since the advent of antibiotics, the situation has changed radically.

More often than not, pneumonia-related deaths do not occur quickly. Respiratory and/or systemic symptoms and signs are often present before death occurs. Occasionally, the forensic pathologist may be confronted with cases of sudden unexpected death (SUD), which are the sequel of a fulminant course of a previously undiagnosed pneumonia.

Children represent a special population; in a series of 265 autopsies of children with SUD, the main cause was disease of the respiratory system (total 113 cases, 42.6%, included lobular pneumonia (28.3%), aspiration pneumonia (24.8%), and viral pneumonia (16.8%). The high predominance of respiratory deaths is probably explained by the relative immaturity of children's lungs, and the fact that the body's resistance is reduced [1].

Many cases of SUD in infancy can be adequately explained after performing a careful postmortem

examination (*see* **Autopsy**). Vennemann *et al.* [2] reported that, in Germany, 2910 infants died in 2004, and of these 394 babies died suddenly and unexpectedly. The authors of that report investigated a three-year population-based, case–control study, in Germany (1998–2001). A total of 455 deaths were reviewed and 51 (11.2%) were found to be unexplained. Most of these deaths were due to respiratory or generalized sepsis, and, of course, a number of different viruses and bacteria have been suggested as causative agents of sudden infant death syndrome (SIDS), though this connection has never been conclusively established.

Bacterial Pneumonia

Acute bacterial infection of the lungs is still one of the commonest causes of death, especially in the very young and very old, but often its presence is due to the existence of some other secondary to some other debilitating process. For example, bacterial pneumonia is a major cause of morbidity and mortality among transplant recipients.

The onset of bacterial pneumonia varies from sudden to gradual. The patient experiences shaking chills, high fever, sweating, shortness of breath, chest pain, and a cough that produces thick, greenish or yellow phlegm. Acute respiratory insufficiency and/or severe sepsis may cause death in these subjects [3]. And, while there are case reports describing rapid symptom progression, SUD from pneumonia is rare [4, 5].

Some evidence for respiratory tract infection is common among infants dying suddenly. For example, Lin reported that in his autopsy series of sudden infant death, 28.3% of the decedents had lobular pneumonia [1]. Epidemiologic evidence indicates that SIDS is associated with *Bordetella pertussis* infection. Nicoll and Gardner [6] examined postperinatal infant deaths resulting from respiratory causes and SIDS. All these cases occurred in England and Wales between 1968 and 1984; they estimated an excess mortality rate for undiagnosed pertussis of 460–700 deaths. Similarly, Cherry calculated 362 excess infant deaths caused by pertussis [7]. Data from Sweden and Norway indicate a direct correlation between the incidence of pertussis and the occurrence of SIDS [8]. In another study, Heininger *et al.* [9] enrolled 254 infants with SUDs; an autopsy diagnosis of SIDS was made in 76% of the infants. In the remaining subjects, causes of death were respiratory or other infections (14%), congenital anomalies or organ failures (4%), aspiration (2%), or accidents or traumatic events (4%). During a standardized autopsy, nasopharyngeal specimens and tracheal specimens were obtained for polymerase chain reaction (PCR) assays to detect B pertussis. PCR results were positive for B pertussis for 12 case subjects (5.1%) (all with SIDS or respiratory infections).

Generally, bronchopneumonia and pneumonia are characterized by widespread patchy areas of inflammation that begin as a widely dispersed bronchitis and bronchiolitis; focal areas of pneumonia then develop in the centers of the acini. The consolidated areas are generally larger and more numerous in the lower lobes where they may be several millimeters across. Small beads of yellow mucous can often be expressed from the bronchioles on the cut surface of the lung. In severe cases, patches of consolidation may become confluent. Once the bacteria reach the alveoli they elicit an acute inflammation, with copious exudation of fluid and migration of neutrophils into the alveoli [10]. In lobar pneumonia (as in the case of pneumococcal infection), the changes are uniform throughout the affected lobe.

Viral Pneumonia

Half of all cases of pneumonia are believed to be caused by viruses. More viruses are being identified as the cause of respiratory infection, and though most attack the upper respiratory tract, some produce pneumonia, especially in children. Most cases of viral pneumonia are mild and get better without treatment, but some cases are more serious and require hospitalization. People at risk for more serious viral pneumonia typically have impaired immune systems such as people with HIV, transplant patients, young children (especially those with heart defects), the elderly, and those that immunocompromised for whatever reason.

Viral pneumonia is caused by several different viruses, including influenza, parainfluenza, adenovirus, rhinovirus, herpes simplex virus, respiratory syncytial virus, hantavirus, and cytomegalovirus. The initial symptoms of viral pneumonia are the same as influenza symptoms: fever, dry cough, headache, muscle pain, and weakness. Increasing breathlessness may also occur; fever may be present. Viral pneumonia may be complicated by an invasion of bacteria,

with all the typical symptoms of bacterial pneumonia. Sometimes the clinical course is quite uneventful and viral infection only recognized with the occurrence of SUD.

Cases of fatal varicella pneumonia have been described in adult patients [11–13]. Fatal influenza infection can be caused by influenza pneumonia alone, by respiratory complications caused by bacterial superinfection [14], or by extrapulmonary influenza-associated manifestations such as myocarditis or encephalopathy. Complication rates of influenza infection, as well as for all the other virus infections, are highest in immunosuppressed patients, diabetics or individuals with other severe metabolic illnesses, and people older than 65 years. Case reports of fatal, sudden death due to influenza pneumonia have been described in the literature [14, 15].

Many viral infections may result in life-threatening complications in healthy children and many cases of a SUD of children due to viral pneumonia have been reported [16–20].

It can become difficult to unequivocally diagnose the underlying disease, especially if incipient stages and/or general infections are involved. Interstitial pneumonia, as caused by viruses, is defined histologically, but in its early stages the changes can be nonspecific; detection of the virus would therefore be required to verify the diagnosis [21, 22]. In viral pneumonia, the lungs appear bulky, and may be hyperemic (overfilled with blood). Bloodstained, frothy fluid oozes freely from the cut surface. Areas of hemorrhage are present and may be extensive. The mucosa of the bronchial tree is very hyperemic. The histological pattern is characterized by interstitial pneumonitis, with extensive alveolar collapse, and filling of remaining alveoli with fluid and desquamated epithelial cells. Alveolar epithelial damage is common in viral pneumonia; it causes the formation of hyaline membranes [10].

Mycoplasma Pneumonia

The vast spectrum of diseases caused by *Mycoplasma pneumoniae* includes pharyngitis, sinusitis, tracheobronchitis, pneumonia, myocarditis, pancreatitis, hepatitis, arthritis, and meningoencephalitis. Such infections are generally benign and often run a subclinical course; it is estimated that less than 5% of the cases of mycoplasma pneumonia are severe enough to require admission to a hospital. A very small number of fatal sudden mycoplasma pneumonia cases have been reported [23, 24].

Mycoplasma pneumonia generally produces widespread bronchiolitis and interstitial pneumonia similar to that caused by many respiratory viruses. The bronchiolitis sometimes progresses to epithelial ulceration. Lymphocytic infiltration of the walls of alveolar ducts and alveoli characterizes the interstitial pneumonia while edema fluid, red blood cells, and macrophages are found in many groups of alveoli and some alveoli may contain hyaline membranes [10].

Acute Interstitial Pneumonitis

A particular form of interstitial pneumonia is acute interstitial pneumonitis (AIP), a fulminant disease culminating in acute respiratory failure and often death. First described by Hamman and Rich [25], AIP is a life-threatening respiratory disease of unknown cause that occurs in patients of both genders equally; generally, it occurs in previously healthy people with no significant medical history. Patients report a prodromal (before main symptoms) illness lasting several days with fever, nonproductive cough, malaise, followed by the acute onset of progressive shortness of breath, which rapidly evolves to respiratory failure. Other signs and symptoms that may be present include cyanosis, crackles, wheezing, hemoptysis, diaphoresis, and hypotension [26, 27]. The radiological and histological patterns are those of acute respiratory distress syndrome (ARDS); however, AIP differs from ARDS because, in the former, there is an absence of known inciting events and multiorgan failure does not occur. While mortality in all patients with ARDS has decreased over the years, there have been no analogous reports of an improvement in survival rates for patients with AIP; in every reported series, the hospital mortality has been >50% [28].

We have previously reported a fatal case of AIP in a 15-year-old boy with sudden death [29]. The postmortem diagnosis was made on the basis of the convergence of clinical onset and course, anatomical, pathological, and radiological findings, as well as the exclusion of each known cause of ARDS, in particular infections, confirmed by negative results of microbiological analysis, and of immunohistochemical and laboratory tests for the detection of more common respiratory virus.

The exact pathogenesis of AIP remains a mystery; thus, the diagnosis of AIP remains a diagnosis of exclusion. The differential diagnosis includes infectious pneumonia, ARDS, drug-induced lung disease, acute pancreatitis, congestive heart failure (CHF), connective-tissue disease, and other acute forms of interstitial lung disease.

The histological features of AIP, as seen in open lung biopsies or autopsies, are those of diffuse alveolar damage (DAD), a nonspecific pattern of acute lung injury deriving from numerous causes, which shows both epithelial and endothelial injury. Histological lung examination generally shows the typical findings of DAD: alveolar septa mildly thickened by edema and capillary congestion, alveolar edema, hyaline membranes lining the denuded alveolar walls, hyperplastic Type 2 pneumocytes, alveolar infiltrates of polymorphonuclear neutrophilic leukocytes, pigmented macrophages, monocytes and plasma cells, and fibrin thrombi in small arteries.

Thromboembolism

Thromboembolism encompasses two interrelated conditions that are part of the same spectrum, deep venous/vein thrombosis (DVT) and pulmonary embolism (PE). Obstruction of blood flow to one or more arteries of the lung occurs when a thrombus lodged in a pulmonary vessel breaks free and travels to the lung. Almost all clinically important PEs are the result of a DVT occurring in the deep veins of the lower extremities, proximal to and including the popliteal veins. However, emboli also can originate from the pelvic veins, the inferior vena cava, and even the upper extremities. PE and thromboembolic disease represent major health problems worldwide. The diagnosis is often difficult to establish and is frequently missed. De Bakey [30] published a review after critical evaluation of more than 375 000 postmortem cases and more than 3 000 000 clinical cases of PE that had been reported around the world over the preceding half a century. He concluded that there was great confusion over true incidence of PE. Fifty years later, the true incidence of thromboembolic disease is still not known [31].

Risk factors for venous thromboembolism include patients age, surgery, trauma, hospital or nursing home confinement, active malignant neoplasm with, or without, concurrent chemotherapy, central vein catheterization or transvenous pacemaker, prior superficial vein thrombosis, varicose veins, and neurological disease with extremity paresis. Compared to residents in the community, hospitalized residents have over a 150-fold increased incidence of acute venous thromboembolism. Those hospitalized for medical illness and those hospitalized for surgery account for cases of thromboembolism in almost equal proportions. The incidence in nursing home residences independently accounts for over one-tenth of all venous thromboembolism diseases in the community. The risk among surgery patients can be further stratified on the basis of patients age, type of surgery, and the presence of active cancer. The incidence of postoperative venous thromboembolism is increased for surgery patients who are 65 years of age or older. High-risk surgical procedures include neurosurgery, major orthopedic surgery of the leg, thoracic, abdominal or pelvic surgery for malignancy, renal transplantation, and cardiovascular surgery. Active cancer accounts for almost 20% of all cases of venous thromboembolism occurring in the community. The risk appears to be higher for patients with pancreatic cancer, lymphoma, malignant brain tumors, cancer of the liver, leukemia, and colorectal and other digestive cancers. Prior superficial vein thrombosis is an independent risk factor for subsequent DVT or PE, remote from the episode of superficial thrombophlebitis. Long-haul (>6 h) air travel is associated with a slightly increased risk for venous thromboembolism. Among women, additional risk factors for venous thromboembolism include oral contraceptive use and hormone therapy, pregnancy, and the postpartum period. Other conditions associated with venous thromboembolism include heparin-induced thrombocytopenia, myeloproliferative disorders (especially polycythemia rubra vera and essential thrombocythemia), intravascular coagulation and fibrinolysis/disseminated intravascular coagulation (ICF/DIC), nephrotic syndrome, paroxysmal nocturnal hemoglobinuria, thromboangiitis obliterans (Buerger's disease), thrombotic thrombocytopenic purpura, Bechet's syndrome, systemic lupus erythematosis, inflammatory bowel disease, homocystinuria, and possibly hyperhomocysteinemia [32]. Heart failure is another well-known risk factor for thromboembolism.

The spectrum of disease produced by thromboembolism ranges from clinically unsuspected or clinically unimportant to massive embolism causing death. Untreated acute proximal DVT accounts

for clinical PE in 33–50% of patients. Mortality in untreated PE is approximately 30%: about one-third of PE cases are fatal. Data indicate that more than one half of all cases of thromboembolism remain undiagnosed. The clinical diagnosis of pulmonary thromboembolism is notoriously inaccurate, with many cases either wrongly diagnosed (overdiagnosed) or missed (underdiagnosed). Autopsy is still regarded as the diagnostic gold standard (*see* **Autopsy**). The accuracy of antemortem diagnosis of PE is within the range of just 10–30% [31]. DVT and PE are very often undiagnosed in life, especially in children dying SUDs.

The prevalence of PE at autopsy varies widely in different published autopsy series, from not less than 10% in unselected material [33]; in 20% of all hospitalized patients [34]; in 20–60% of adult autopsies [35]; in more than half of all autopsies [36]; in about 10% of adults who die suddenly in hospital [37]; approximately 3.5% of all hospital deaths [38]; 1% in the general population of hospital patients; and 30% in patients dying after severe burns, trauma, or fractures [39]. The incidence of PE at autopsy is strongly influenced by the nature of the population surveyed (age and nature of patients, i.e., surgical, oncological, gerontological), by the mode of selection for postmortem examination and, in particular, by the care with which the autopsy is performed [31].

At autopsy, gross examination will reveal embolus in the main pulmonary vascular tree; segmental or subsegmental pulmonary arteries are affected in most of the cases and are more prevalent in nonfatal pulmonary thromboembolism (PTE). On the other hand, emboli in the main arteries, as well as in arteries of the trunk and above, are more prevalent in fatal PTE. Pulmonary infarctions that appear as dark areas where the air space has become filled with blood are frequently seen. They are commonly multiple.

Thrombosis of the deep leg veins is often detected at gross examination as the source of embolism. However, the absence of thrombus from these veins does not exclude them as the site of thrombosis since dislodgement and embolization may leave no residual disease.

Amniotic Fluid Embolism

Amniotic fluid embolism (AFE) is a rare but potentially fatal complication of pregnancy with an incidence approximately between 1 in 8000 and 1 in 80 000 pregnancies. The first reported case of AFE was documented in 1926 [40]. It was first recognized as a syndrome in 1941, when two investigators described the presence of fetal mucin and squamous cells during postmortem examination of the pulmonary vasculature in women who had unexplained obstetric deaths [41]. Since then, many studies, case reports, and series have been published in an attempt to elucidate the etiology, risk factors, and pathogenesis of this obstetric complication [42].

The true incidence of AFE is not known. There are many reasons for this. Firstly, there are a number of inaccuracies in reporting the cause of maternal death. Secondly, the presentation can be variable and the number of nonfatal or subclinical episodes is unclear. Finally, in those patients who do survive or in whom no autopsy was performed, it is often quite difficult to confirm the diagnosis [43]. AFE is one of the leading causes of death during labor and the first few postpartum hours, and it remains a deadly, unpreventable, and unpredictable obstetric emergency. Recent data suggest mortality rates approach 61%. Most patients do not survive the initial course and die within five days. Of those patients who survive, neurologic impairment is common [44]. Other authors refer an associated mortality rate up to 90% [45]. The fetal mortality rate, although better than the maternal rate, is a dismal 21%. Fifty percent of the surviving neonates experience permanent neurological injury. Predisposing factors traditionally associated with AFE include placental abruption, uterine overdistention, fetal death, trauma, tumultuous or oxytocin-stimulated labor, multiparity, advanced maternal age, and rupture of membranes. However, in numerous demonstrated cases of AFE, none of these conditions or demographic characteristics were present [46].

The syndrome appears to be initiated after maternal intravascular exposure to fetal material that is contained in the amniotic fluid. Many hypotheses have been proposed to explain the pathophysiology of this condition. Clark *et al.* [47] contend that AFE more closely resembles an anaphylactic reaction to fetal debris than an embolic event, and they propose the term *anaphylactoid syndrome of pregnancy*. Recently, bradykinin, released in association with DIC, has been considered as an important contributor to the severe hypotension that is manifested with AFE [48, 49]. The literature also contains evidence that AFE may not be a true embolic event resulting from

the physical obstruction of the pulmonary vasculature. The high degree of variability in symptoms, the lack of characteristic findings on radiological exam, the absence of a dose–response effect on symptoms, and the occasional occurrence of coagulopathies are not entirely consistent with a physical block to the circulation, at least not as the main mechanism of disease. An alternative hypothesis is that fetal antigen leaking into the maternal circulation might activate the complement cascade. This rare immune response may be initiated by an obscure pathological antigen, or by common antigens presented uncommonly – in amount, timing, or frequency of entry into the maternal circulation [50, 51].

Presenting symptoms may vary; common clinical features include shortness of breath, altered mental status followed by sudden cardiovascular collapse, DIC, and maternal death.

The entry criteria in the National Registry for AFE [47] include

1. acute hypotension or cardiac arrest;
2. acute hypoxia, defined as dyspnea, cyanosis, or respiratory arrest;
3. coagulopathy, defined as laboratory evidence of intravascular consumption or fibrinolysis or severe clinical hemorrhage in the absence of other explanations;
4. onset during dilatation and evacuation, labor, cesarean delivery, or within 30 min postpartum;
5. absence of any other significant confounding condition or potential explanation for the signs and symptoms observed.

Although labor and delivery appear to be the greatest risk period [52], AFE has been reported in the second trimester and as having a delayed presentation [53], up to 36 h postpartum [54].

The diagnosis of AFE is very difficult even at autopsy (*see* **Autopsy**; **Histology**). It is a commonly held misconception that the presence of fetal debris in the pulmonary circulation is diagnostic of an amniotic fluid embolus. In fact, fetal debris can be found in the pulmonary circulation in a predominance of patients who underwent a normal labor, and AFE is only identified in 78% of those patients who meet the criteria for the diagnosis of AFE [43, 47, 55].

Some authors have suggested that AFE may be the result of anaphylactic reactions to fetal antigens, and that the major part of this clinical syndrome is the result of mast cell degranulation followed by the release of histamine, tryptase, and other mediators. It has been suggested that the identification and distribution of mast cell tryptase within the pulmonary tree is a useful criteria for the diagnosis of fatal AFE. In a previous report, Fineschi *et al.* [56] demonstrated a numerical increase of pulmonary mast cells in the subjects who died of AFE compared with that of the control groups. Many other reports add further supporting evidence to the concept of AFE as an anaphylactoid syndrome of pregnancy [57–59].

Macroscopic autopsy findings in AFE are usually insignificant; neither are macroscopic findings generally found either. Postmortem diagnosis is based on histological demonstration of amniotic fluid components (fetal squames, lanugo, and mucin) in pulmonary blood vessels that can be demonstrated by various staining methods (Alcian blue, Attwood). Evaluation of pulmonary mast cell tryptase using immunohistochemistry as well as measurement of serum tryptase level as markers of mast cell degranulation are recommended in all cases of suspected AFE-related death.

Morbid Obesity

Obesity and overweight are defined as an accumulation of excess body fat, to an extent that may impair health. A crude population measure of excess fat is the body mass index (BMI), a person's weight (in kilograms) divided by the square of his or her height (in meters). WHO defines overweight as a BMI of 25 or more, and obesity as a BMI of 30 or greater. Obesity is a complex pathological condition that affects virtually all age and socioeconomic groups and threatens to overwhelm both developed and developing countries. WHO's latest projections indicate that globally, in 2005, approximately 1.6 billion adults (age 15+) were overweight, and that at least 400 million adults were obese. WHO further projects that by 2015, approximately 2.3 billion adults will be overweight and more than 700 million will be obese. At least 20 million children under the age of 5 years were overweight globally in 2005. Contrary to conventional wisdom, the obesity epidemic is not restricted to industrialized societies; in developing countries, it is estimated that over 115 million people suffer from obesity-related problems.

Overweight and obesity lead to serious health consequences. Risk increases progressively as BMI increases. In fact, there is evidence that, on a population level, the risk of chronic disease increases progressively as average BMI increases above 21. Obesity is associated with numerous comorbidities such as cardiovascular disease (CVD), Type 2 diabetes, hypertension, certain cancers, and sleep apnea [60]. A relationship exists between BMI and all-cause mortality also in adolescence [61]. In conclusion, the mortality associated with untreated morbid obesity is significant, manyfold that of the normal population and exceeds the risk of surgical intervention [62].

Even in the absence of comorbidity, when adipose tissue accumulates in excess, a variety of adaptations/alterations in cardiac structure and function occur, as do changes in metabolism [63], Obesity may affect the heart through its influence on known risk factors such as dyslipidemia, hypertension, glucose intolerance, inflammatory markers, obstructive sleep apnea/hypoventilation, and the prothrombotic state, as well as through yet-unrecognized mechanisms. As a whole, overweight/obesity predisposes, or is at least associated with, numerous cardiac complications such as coronary heart disease (CHD), heart failure, and sudden death through its impact on the cardiovascular system (*see* **Cardiac and Natural Causes of Sudden Death**).

Obese subjects have an increased risk of arrhythmias and sudden death, even in the absence of cardiac dysfunction, and the risk of sudden cardiac death with increasing weight is seen in both genders. In the Framingham study, the annual sudden cardiac mortality rate in obese men and women was estimated to be ≈40 times higher than the rate of unexplained cardiac arrest in a matched nonobese population.

Moreover, a prolonged QT_c interval was observed in ≈30% of subjects with impaired glucose tolerance, and there is a positive association between BMI and QT_c. When visceral obesity or insulin levels increase, sympathovagal balance may be the best explanation for changes in QT_c. The clinical significance of obesity-associated QT prolongation and the mechanisms involved remain speculative. Moreover, because extremely obese patients often have a dilated cardiomyopathy, fatal arrhythmias may be the most frequent cause of death [61]. In conclusion, subjects with morbid obesity have high rates of sudden, unexpected cardiac deaths and the literature is rich in reports of cases of SUD in morbidly obese subjects [64–66].

Hematological Disorders

Hemoglobinopathies

Hemoglobinopathy is a type of genetic defect that results in abnormal structure of one of the globin chains of the hemoglobin molecule. The most common hemoglobinopathy is sickle-cell disease (SCD). In the United States today, 1 of every 650 African-Americans (0.15%), greater than 50 000 individuals, suffers from sickle-cell disease. In addition, almost 2 million patients, representing 8% of the African-American population, are affected by sickle-cell trait being heterozygous for the sickle-cell gene [67].

The most common causes of death in the sickle-cell population include infection/sepsis, acute chest syndrome (ACS) (clinical term defined by new pulmonary infiltrate on chest radiography, accompanied by fever, chest pain, and variety of respiratory symptoms, including wheezing, coughing, and tachypnea), sudden cardiac death, cerebrovascular accident, and renal failure. Among all reported causes of death in sickle-cell disease, age-specific patterns are well documented. In sickle-cell infants and children, sepsis, predominantly pneumococcal, represents a leading cause of death, followed by acute splenic sequestration. In the adult sickle-cell population, mortality is much more commonly associated with ACS, sickle-cell pain crises, and/or cardiac failure [68–70].

More than 20% of sickle-cell patients develop fatal acute or chronic pulmonary complications. The acute pulmonary sequelae, including ACS, thromboembolism, lung edema, fat/bone marrow embolism, and vaso-occlusive crisis, account for a large proportion of sudden deaths among sickle-cell patients [71, 72]. In a recent report on 306 autopsies of patients with sickle-cell disease, the most common cause of death for all sickle variants and for all age groups was infection (33–48%). The terminal infection was heralded by upper respiratory tract syndromes in 72.6% and by gastroenteritis in 13.7%. The most frequent portal of entry in children was the respiratory tract but, in adults, it was a site of severe or chronic organ injury. Other causes of death included stroke 9.8%, therapy complications 7.0%, splenic sequestration 6.6%, pulmonary emboli/thrombi 4.9%, renal failure 4.1%, pulmonary hypertension (PHT) 2.9%,

hepatic failure 0.8%, massive hemolysis/red cell aplasia 0.4%, and left ventricular failure 0.4% [73].

Sudden and unexpected death in this population is not rare [74]; Manci *et al.* reported that death was frequently sudden and unexpected (40.8%) or occurred within 24 h after presentation (28.4%), and was usually associated with acute events (63.3%) [73]. Darbari *et al.* [75] reported that leading circumstances of death in 141 autopsies of adult SCD included PHT (26.2%), renal failure (22.6%), infection (18.4%), thromboembolism (14.9%), cardiac diagnoses (12.0%), cirrhosis (11.3%), pneumonia or ACS (9.9%), bleeding (7.8%), and iron overload (7.0%); in 23.4% of cases, death was sudden.

In sickle-cell disease, sudden death frequently occurs during exertion and is characterized by rhabdomyolysis, heat stroke, and cardiac arrhythmia; this entity has been widely reported in literature where many cases of sudden death associated with sickle-cell disease or sickle-cell trait have been described in affected soldiers during military basic training, in athletes during training, and in previous healthy subjects during exertion [76–83].

Military recruits, pilots, and subjects exposed to hypoxic stress such as high altitude, and experiencing sudden cardiorespiratory collapse as a result of sickle-cell trait have been described [84].

Many hypotheses have been offered to explain the high rate of sudden death in SCD. Involvement of autonomic nervous dysfunction in sudden death has been reported in various diseases and it has been suggested that this may be the case in sickle-cell anemia as well [85]. Heat stress, dehydration, viral illness, and poor physical conditioning have all been identified as factors, which may contribute to exertional rhabdomyolysis and sudden death in SCD, suggesting a multifactorial etiology [80]. Dehydration, hypoxia, acidosis, and physical exertion are known aggravating factors for sudden death in sickle-cell trait, because that can initiate a vaso-occlusive sickle-cell crisis. Others have proposed a role for some coexisting disease such as diabetes [86].

Of particular interest to the forensic pathologist, illicit drug use, especially cocaine and morphine, both of which are recognized triggers of global hypoxic events, may lead to the sickling of red blood cells, with consequent vaso-occlusion and lung edema has been and, in fact, such a sequence has been reported as explaining a case of sudden death [87].

Only few autopsy studies of sickle-cell patients have addressed patterns of pathologic pulmonary involvement that are very often recognizable in SCD [70, 88, 89]. When pulmonary involvement is present, it is usually in the form of PHT, first detected at autopsy with various grade of changes (from reversible to irreversible), consisting in mild-to-severe medial hypertrophy and muscularization of pulmonary arterioles. The lungs from many of these individuals manifest intimal fibroelastosis of small- and medium-sized pulmonary arteries. Small muscular arteries can show dilatation and may form plexiform lesions. Cardiomegaly may be also present. In Graham's study [67], almost two-third of the cases had significant pulmonary findings at autopsy (71.4%). The most frequent postmortem pulmonary findings were pulmonary edema (47.6%), followed by thromboembolism (38.1%), fat emboli (33.3%), PHT, grades I–IV (33.3%), and microvascular vaso-occlusive thrombi (28.5%). Oppenheimer and Esterly found autopsy evidence of pulmonary thromboemboli in 66%.

In conclusion, data from literature indicate a high rate of occurrence of pulmonary findings (fat embolism, PHT, and cardiac right ventricular hypertrophy) in a large percentage of SDC patients presenting with sudden death. Histological examination may reveal widespread vaso-occlusive sickling of red blood cells in the brain, heart, liver, kidneys, adrenal glands, thyroid gland, intramyocardial coronary arteries, skeletal muscles, pancreas, testis, and spleen.

Leukemia

Leukemia is a neoplastic disease that arises in blood-forming tissue such as the bone marrow and causes large numbers of blood cells to be produced and enter the bloodstream. The leukemias form a very heterogeneous group of neoplasms, which differ both in clinical course (acute or chronic), and blood cell line that affected. Depending on these factors, patients with leukemia may have a number of symptoms, such as fevers or night sweats, frequent infections, weakness or tiredness, headache, bleeding and bruising easily, pain in the bones or joints, swelling or discomfort in the abdomen (from an enlarged spleen), swollen lymph nodes, especially in the neck or armpit, and weight loss.

SUD secondary to undiagnosed neoplasia is extremely uncommon in adults, with a reported

incidence between 0.17% [90] and 0.58% [91]. Acute leukemia, as well as bronchogenic carcinoma, gastric adenocarcinoma, and adenocarcinoma of the urinary bladder, are the most common tumors causing SUD in adults [92]. Death has been attributed to a variety of mechanisms, including hemorrhage, thromboembolism, and widespread tumor dissemination.

Cases of SUDs due to splenic rupture in subjects with undiagnosed chronic leukemia have been described [93]: acute cardiovascular failure [94], intracardiac thrombosis [95], and pulmonary complications [96].

In acute leukemia, symptoms appear rapidly and progress quickly. As in chronic leukemia, sudden death is reported both in adults and children [97], sometimes occurring after a period of complete remission of the disease [98, 99]. Sudden unexpected death due to neoplastic disease in infancy and childhood (SUDNIC) is extremely uncommon. The most common causes of SUDNIC are tumors affecting vital structures, such as the heart and brainstem, and include primary cardiac tumors, primary CNS neoplasms, and fatal CNS hemorrhage secondary to hematopoietic neoplasms [100, 101]. Other less common causes of sudden death in children with leukemia may involve intracerebral infiltration or hyperviscosity and leukostasis [101]. Whybourne *et al.* [102] reported a case in which sudden death was the first manifestation of lymphoblastic leukemia in a 16-week-old boy; at autopsy, no evidence of intracranial hemorrhage was found. Infiltration of multiple organs (myocardium, lungs, etc.) was detected. The mechanism of mortem was retraced to the diffuse infiltration of myocardium probably predisposing to arrythmias, favored also by the diffuse infiltration of the lungs leading to a condition of hypoxia. Recently, *Somers et al.* [103] reviewed a 20-year autopsy cases ($n = 4926$); 8 cases of SUDNIC were identified in which postmortem diagnoses included 2 cases of acute leukemia (1 myelogenous, 1 lymphoblastic). Finally, it has recently been recognized that some form of treatment for leukemia may, themselves, cause SUD.

In conclusion, data from literature demonstrate that infants, children, and adults may have minimal or no symptoms in the presence of leukemic disease and highlight the need for a thorough autopsy examination in all cases of SUD. Arsenic tetroxide is now often used in the treatment of acute promyelocytic leukemia, and it appears to be an effective agent. However, its use is sometimes accompanied by sudden death because arsenic disrupts the normal function of potassium channels, leading to QT prolongation and torsades des pointes [104].

Metabolic Disorders

Diabetes

Diabetes mellitus (DM) is an etiologically and clinically heterogeneous group of metabolic disorders that share the common feature of hyperglycemia. Long-term hyperglycemia produces tissue damage, which ultimately manifests itself as microvascular disease, macrovascular disease, and neuropathy. Since 1991, when the British Diabetic Association initated a study of unexplained deaths in young patients with Type 1 DM [105], evidence has correlated the so-called dead-in-bed syndrome with diabetes. What characterized this kind of death is that it occurs at night and the patients are found dead in an undisturbed bed the next morning. Patients had gone to bed in apparent good health, and subsequent autopsy consistently revealed no cause of death (of course, the study was undertaken before it was possible to screen ion channel disease postmortem, and no doubt that some of the children included in the original study did suffer from some form of inherited long QT syndrome (LQTS) syndrome. See below). Nocturnal hypoglycemia is common among Type 1 diabetic patients; however, the precise mechanism by which hypoglycemia may cause sudden death remains uncertain. The suddenness of death in these patients implicated a possible cardiac cause. Many hypotheses have been proposed to explain the "dead-in-bed syndrome": undetected autonomic neuropathy, hypoglycemia-induced disturbances in cardiac electrophysiology, and other factors are probably involved in the sudden death of young diabetic patients.

However, the definite cause of the "dead-in-bed" syndrome continues to be a subject of further speculation and investigation (Figure 1) [106].

Cardiovascular autonomic neuropathy (CAN) encompasses damage to the autonomic nerve fibers that innervate the heart and blood vessels, resulting in abnormalities in heart rate control and vascular dynamics; it has been widely studied as a risk factor for sudden death in patients with DM [107, 108].

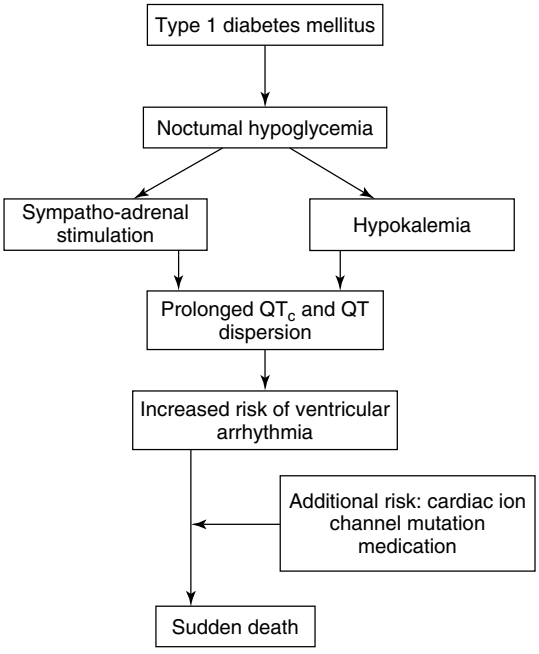

Figure 1 Hypothesis for "dead-in-bed syndrome" in Type 1 diabetes mellitus

One potential cause may be severe but asymptomatic ischemia, which can induce lethal arrhythmias. QT prolongation may also predispose individuals to life-threatening cardiac arrhythmias and sudden death. It has been shown that predisposition to arrhythmias and an association with mortality may also be related to intracardiac sympathetic imbalance [109, 110]. However, the significance of CAN as an independent cause of sudden death has been questioned recently. In the Rochester Diabetic Neuropathy Study, the investigators found that all cases of sudden death in individuals with and without diabetes had severe coronary artery disease (CAD) or left ventricular dysfunction. They suggested that although CAN could be a contributing factor, it was not a significant independent cause of sudden death. Heart failure is, however, common in individuals with diabetes; it is identified in these patients by the presence of neuropathy, even in those without evidence of CAD or left ventricular dysfunction [108]. The association of CAN in the absence of coronary disease and cardiomyopathy requires further study [111].

It is well known that DM is an independent risk for CVD: the association between diabetes and incidence of CAD is widely reported in the literature. In the United States, diabetes is referred to as the most prevalent factor placing patients at risk for coronary events [112]. Furthermore, patients with DM have increased risk for ventricular arrhythmia that is thought to be secondary to CAD or CHF. Susceptibility to dysrhythmias in diabetic hearts is a very debatable issue. Diabetes is an independent risk for cardiac arrythmias in addition to other CVDs [113, 114]. QT prolongation is associated with SUD in the diabetic populations [115]. In a large study, Mohaved *et al.* [116] founded that patients with DM have significantly higher prevalence of ventricular fibrillation independent of CAD or CHF, which, in part, may explain the higher risk of sudden death in these patients.

Furthermore, patients with DM have a hypercoagulable state that is of multifactorial origin. Many coagulation factors, such as fibrinogen, d-dimer, and von Willebrand factor may become elevated in diabetics. At the same time, there is decreased fibrinolysis along with platelet hyperaggrebility and endothelial dysfunction. Tsai *et al.* [117] founded DM as an independent risk for venous thromboembolism in a large population including both genders. Mohaved *et al.* [118] founded that DM is strongly associated with PE and PHT independent of CAD, CHF, or smoking.

In cases where diabetes is related to the occurrence of sudden death, gross necropsy examination may reveal signs of coronary plaques and coronary stenoses. The kidneys may show smaller size and granular surface. Histologically, the earliest detectable change in glomerular structure is the thickening of the basement membrane. Postmortem biochemistry of vitreous humor is a worthwhile adjunct to routine postmortem screening. Apart from the determination of glucose level in vitreous fluid, the determination of hemoglobin A1c considered as a definitive indicator of prolonged hyperglycemia has been proposed as a useful tool in postmortem diagnosis of diabetes [119].

Alcoholic Ketoacidosis

The entity of alcoholic ketoacidosis (AKA) was first described by Dillon *et al.* [120]. AKA affects chronic alcoholics and is characterized by metabolic acidosis with increased anionic gap. A typical patient with AKA has a history of chronic alcohol abuse

(*see* **Alcohol: Use, Abuse, Tolerance, and Dependency**; **Alcohol: Interaction with Other Drugs**; **Alcohol: Behavioral and Medical Effects**) and recent binge drinking, followed by the abrupt cessation of alcohol consumption. Clinical findings of AKA are very similar to those of diabetic ketoacidosis, but hyperglycemia and glycosuria are generally absent. AKA is due to the accumulation of D-β-hydroxybutyrate and acetoacetic acid. The accumulation is probably the result of various factors such as volume depletion (vomiting, decreased fluid intake) and starvation having a lipolytic effect. As the previous alcoholic intake has an inhibitory effect on fatty acid oxidation, a higher level of fatty acids will be available. When fatty acids are presented to the liver faster than they can be oxidized, it results in a surplus of acetyl–CoA. The excess of acetyl–CoA is converted into β-hydroxy-β-methyl-glutaryl-CoA, which is cleaved to form acetyl–CoA and free acetoacetic acid. Some of the acetoacetic acid is reduced to D-β-hydroxybutyrate and a small amount is decarboxylated to acetone [121].

In uncomplicated AKA, the prognosis may be good, but several complications could be present (lactic acidosis, acute pancreatitis, Wernike's encephalopathy, etc.). AKA may be a life-threatening condition and it is a significant factor in at most a small minority of alcoholic deaths [122]. Fatalities of chronic alcoholics where the cause of death could not be determined by thorough autopsy, histology and toxicology including determination of alcohol concentration are described [123]; in those cases, ketoacidosis and lactic acidosis were assumed to be the cause of death. In such cases of unexpected and unexplained deaths in chronic alcoholics, measurement of ketone bodies in vitreous humor or pericardial fluid using clinical laboratory methodologies is recommended. In particular, β-hydroxybutyric acid (β-HBA) should be considered as the diagnostic marker of choice for the postmortem determination of AKA and as the cause of death [124].

Hypoglycemia

Since the introduction of insulin into diabetes care in 1921, hypoglycemia (HoG) emerged as a very complex concern. Some medications (all insulins, all insulin secretagogs) can cause HoG. There is particular concern about the drug metformin: most experts suggest that metformin monotherapy does not cause clinically relevant HoG under usual circumstances, but it might under unusual circumstances. Such circumstances include combined therapy with metformin and insulin or insulin secretagogs (I/IS).

Many conditions make patients more sensitive to I/IS and predispose to HoG: leanness and youth, physical activity, first trimester of pregnancy and the immediate postpartum period, impaired liver function and alcoholism (depleted glycogen stores), impaired renal function (prolonged half-life insulin), counterregulatory hormone failure (adrenals, glucagon, and growth hormone), autonomous neuropathy, previous hypoglycemia, being unaware of hypoglycemia, total parental nutrition, and poor metabolic control [125].

The scientific literature quotes very different values for the incidence of mortality due to HoG, which ranges in insulin-treated diabetic patients (high-risk populations) from 2 to 4% [125].

The exact mechanism by which hypoglycemia causes sudden death remains uncertain. One explanation of HoG-related sudden death is that hypoglycemia directly causes disturbances in cardiac electrophysiology, which may provoke malignant tachydysrhythmias. There have been reports of premature ventricular contractions, atrial arrhythmias, and ischemic ECG changes during hypoglycemia [126–128]. Moreover, there is evidence that insulin-induced hypoglycemia causes an acquired form of long QT syndrome. In addition to QT_c prolongation during hypoglycemia, QT dispersion (the difference between the longest and shortest QT interval on a 12-lead ECG) increases [129, 130].

In conclusion, the sudden death of a diabetic patient treated with I/IS creates a unique diagnostic problem. A high level of suspicion based on circumstantial evidence must alert the forensic pathologists on hypoglycemia as a probable cause of death (Figure 2) [125].

Postmortem diagnosis of HoG as a cause of sudden death can be proved by testing glucose levels in blood or spinal or vitreous fluid. The measurement of the ketone body β-hydroxybutyrate (β-HBA) may also help in the investigation of cases where hypoglycemia is suspected [131].

Thyroiditis

In forensic medicine, the study of thyroid function and disease is important in cases of sudden death [132–135].

Consideration	Lower risk, less probability	Higher risk, greater probability
Age	Older	Young
Duration of diabetes	Short	Long
Control as judged by the levels of CBG, hemoglobin AIc, and fructosamine	Suboptimal	Optimal
Adjusts to late meals and activity	Yes	No
History of frequent episodes of hypoglycemia	No	Yes
History of being unaware of hypoglycemia	No	Yes
Keeps a CBG diary	Yes	No
Keeps follow-up appointments	Yes	No
Frequency of CBG testing	Frequent	Rare or never

Figure 2 Considerations for assessing risk of hypoglycemia or, if applicable, estimating the probability that hypoglycemia caused idiopathic or accidental sudden death

Cases of sudden death associated with undiagnosed chronic thyroiditis are described [136–138]. An unusual case of fatal heatstroke in a young woman discovered unconscious in a sauna has been reported in which a preexisting Hashimotos thyroiditis was revealed at autopsy [139]. Moreover, an association between lymphocytic myocarditis and lymphocytic thyroiditis in a case of sudden death involving a 40-year-old man with no known medical history has also been reported [140].

Reports in the literature also raise the possibility of thyroid disease, in particular silent (painless) thyroiditis, may be an underlying cause of SUDs. Routine microscopy of the thyroid gland is therefore advocated in cases of SUD. It has also been suggested that postmortem measures of thyroid hormones (thyroxine [T4] and triiodothyronine [T3]) and the pituitary hormone known as *thyroid-stimulating hormone* (*TSH*) may be useful diagnostic tools in cases of SUDs [141].

Anaphylaxis

Anaphylaxis was first described in the scientific literature about 100 years ago by Portier and Richet, who reported that their attempts to immunize dogs against the sting of jellyfish with actinia extract instead brought about an acute anaphylactic episode. In the extreme or classic form, anaphylaxis typically involves the cutaneous, respiratory, cardiovascular, and gastrointestinal systems, target organs all heavily populated with mast cells. Its presentation is often

more enigmatic, with variable target organ involvement and expression of symptoms.

In 1998, a Joint Task Force on Practice Parameters defined anaphylaxis as an "immediate systemic reaction caused by rapid, IgE-mediated immune release of potent mediators from tissue mast cells and peripheral basophils". Aggregation of Fc*e*RI by allergen-driven cross-linking of receptor-bound IgE activates mast cells and basophils to release mediators that induce the pathophysiologic features of the anaphylactic response. Initial sensitization occurs through a highly coordinated series of steps involving a variety of cell types and mediators, which is affected by environmental exposure and complex genetic factors. Anaphylactic reactions are distinguished from anaphylactoid reactions, which "mimic signs and symptoms of anaphylaxis, but are caused by non-IgE-mediated release of potent mediators from mast cells and basophils" [142].

The most common etiologies of anaphylactic reactions include allergic responses to food, drug (medications, biologics, and vaccines), insect sting, and latex. Also exercise (jogging, walking, tennis, dancing, etc.) can lead to typical anaphylaxis. The pathogenesis and true incidence of exercise-induced anaphylaxis remain unknown. Finally, another form of anaphylaxis consists of the so-called idiopathic anaphylaxis, whose diagnosis is one of exclusion. The exact incidence of idiopathic anaphylaxis is unknown, but several studies estimate that nearly 20% of cases of anaphylaxis are idiopathic. There are no clinically distinguishing features (although 33% of cases are nocturnal), and it may be fatal.

Anaphylaxis is an uncommon cause of sudden death. In many cases, no specific macroscopic or microscopic findings are detected at autopsy. The most common finding is nonspecific pulmonary congestion and edema, but features suggesting an allergic reaction (cutaneous erythema, urticaria, laryngeal and/or pharyngeal edema) may be present. The presence of petechial hemorrhages is another nonspecific postmortem finding as is brain swelling. Generally, histological examinations will disclose mucosal edema, inflammation with eosinophilia, epithelial sloughing in the bronchial tree, cerebral edema, and polyvisceral stasis [143, 144].

In the presence of a clinical history suggestive for anaphylaxis-related death, postmortem measurement of serum tryptase levels can be a useful diagnostic aid. Tryptase, a neutral protease, is the major protein component of mast cell secretory granules. An elevated serum tryptase level is considered to be a specific marker for systemic mast cell activation, which is a central feature of anaphylaxis. In addition to this, because this enzyme has a longer serum half-life than other chemical mediators like histamine, the measurement of serum tryptase level is reported to be useful for postmortem as well as antemortem diagnosis of anaphylaxis [145–147]. Finally, in SIDS, one possible explanation hypothesized some 40 years ago is an anaphylactic reaction to protein components such as cow's milk [148, 149]. It was suggested that sensitized infants might suffer a fatal anaphylactic reaction if recently ingested cow's milk was regurgitated and inhaled during sleep. The question is still under debate [150]. New evidence is provided for an increased degree of mast cell activation in infants whose death was classified as SIDS. The stimuli for mast cell degranulation in these infants remains unclear, but the potential for anaphylaxis to have occurred in a proportion of cases of SIDS must be considered [151–154].

Infection

Massive adrenal hemorrhage (Waterhouse–Friderichsen syndrome) is an uncommon, but usually fatal, consequence of overwhelming sepsis [155]. Despite the predominant association with meningococcal infection, there are numerous other well-recognized etiologies, including sepsis resulting from other organisms, and noninfectious causes, such as anticoagulant treatment, antiphospholipid syndrome, trauma, and spontaneously occurring or postoperative adrenal hemorrhage. Gram-negative organisms, including klebsiella, pasturella, and *Hemophilus influenzae*, have all been reported to precipitate the syndrome. There are fewer reports of Waterhouse–Friderichsen syndrome following infection with Gram-positive bacteria. The clinical picture is generally characterized by sudden onset shock, pyrexia, cyanosis, dyspnea, and purpura, with adrenal hemorrhage. Unexpected death can occur as sequel of a rapidly progressive course of a previously undiagnosed infection [156–159].

At necropsy skin rashes will be evident, as will signs of upper airway infection, bronchopneumonia, and evidence of meningitis. Hemorrhage, elsewhere, may coexist with a massive adrenal hemorrhage,

which is a more characteristic finding. Microscopic examinations generally reveal hemorrhages involving all layers of the adrenal glands with secondary cell necrosis. Measurement of serum procalcitonin concentration (PCT) may be a useful aid [160]. In fact, it is well known that in bacteremia and sepsis, PCT levels are highly elevated ($>10\,\mathrm{ng\ ml^{-1}}$ in sepsis), and therefore PCT is a well-established clinical parameter in the diagnosis of systemic infection of bacterial origin [161].

Neuropsychological Assessment

Neuropsychological assessment refers to the application of standardized psychological measurement techniques to determine the relationship between brain impairment and its cognitive and behavioral concomitants (*see also* **Head Injury: Neuropsychological Assessment**). Forensic neuropsychological assessment is the use of such techniques in responding to official or legal questions. Forensic neuropsychologists are increasingly being called upon to provide opinions in a wide range of types of legal referrals. A recent count of citations of the word "neuropsychologist" in a database of court decisions yielded a large and growing count of cases involving neuropsychological consultation. Forensic issues were recently identified as the most-researched areas in the field of neuropsychology, with recent exponential growth in the number of studies and articles referencing forensic matters, such as malingering assessment (*see* **Malingering: Forensic Evaluations**).

Choice and Credentialing of the Neuropsychological Expert

The clinical neuropsychologist is typically a clinical psychologist who is also trained in the neurosciences and clinical neurology, and who has completed appropriate postdoctoral training and experience in the field of neuropsychology. Definitions of clinical neuropsychologists have been published by Division 40 (neuropsychology) of the American Psychological Association (APA) [1] and by the National Academy of Neuropsychology [2]. These definitions define clinical neuropsychologists as being licensed psychologists with appropriate graduate training in psychology, neuropsychology, and/or the neurosciences and at least two years of supervised postdoctoral experience. The Division 40 definition includes review by one's peers as a test of these competencies, and specifically references diplomate status as the "clearest evidence" that competence as a clinical neuropsychologist is met.

The choice of a forensic neuropsychological expert should take these issues of training and credentialing into account. One should also consider the neuropsychologist's experience with the disorder in question. For example, in cases involving closed head injuries, a neuropsychologist with experience in working with head injury patients in a rehabilitation setting may be preferred. The neuropsychologist's history as a forensic expert should also be taken into account. Some attorneys may prefer to choose neuropsychologists with a substantial history of testifying in court, while others may prefer experts who have little or no track record as an expert witness. In any event, a neuropsychologist who has consistently testified in prior cases for both the plaintiff and the defense, or the prosecution and the defense in criminal matters, is a plus. Consider also the neuropsychologist's capacity for teaching or educating the court and/or jury regarding the clinical issues that are apparent in the case. Reports should be written in an accessible, straightforward style with normal language and avoidance of highly technical terms as much as possible.

Admissibility of Neuropsychological Evidence

Properly credentialed neuropsychologists are able to serve as expert witnesses in most jurisdictions (*see also* **Expert Opinion: United States**). In some states, such as North Carolina and Georgia, there has been case law limiting neuropsychologists from expressing opinions regarding the medical causation of brain injuries. In Georgia, this issue was remedied with legislation. In most states, however, courts have consistently found that neuropsychologists are qualified to render opinions regarding the causation and pathology of brain insults. The Iowa Supreme Court case decision in *Hutchison v. American Family Mutual Insurance Company* provides an outline for the use of neuropsychological testimony in court, including that neuropsychologists are qualified to diagnose the general state of the brain and the causation of brain pathology. The *Daubert v. Merrell Dow Pharmaceuticals, Inc.* (*see also* ***Daubert v. Merrell Dow Pharmaceuticals***) case sets out key principles for the admission of scientific evidence and expert testimony in courts: whether the technique can be tested (falsifiability), has the technique been published (peer review), is there an acceptable error rate, whether the techniques have gained general acceptance in the scientific field, and whether there

is a published guide or manual to govern the use of the instrument. In general, most of the widely used neuropsychological tests meet these standards; indeed, neuropsychology as a profession, because of its emphasis on empirical methods of assessment and long tradition of careful research, seems ideally suited to meet *Daubert* challenges in court.

The American Academy of Neurology [3] has produced official guidelines affirming the value of neuropsychological assessment in the practice of neurology. Professional psychological practice organizations, such as the National Academy of Neuropsychology and the American Academy of Clinical Neuropsychology, have published guidelines for performing forensic neuropsychological assessments. These guidelines are intended to describe the "most desirable and highest level of professional conduct", as opposed to other documents such as APA's *Ethical Principles of Psychologists and Code of Conduct*, which simply describe standards for competent and adequate conduct. These guidelines indicate that neuropsychologists working for a third party, such as an insurance company, attorney, or the court, must inform the examinee of the nature of the evaluation, the neuropsychologist's duty to remain objective, and the destination of the report that will be produced. The presence of a clinician–patient relationship must not be implied, but disavowed. The examination must be conducted in a manner adequate to answer the questions posed by the referral source. The measurement procedures must meet standards for psychometric accuracy, including the presence of acceptable reliability, validity, and appropriate normative standards. The potential for motivational bias must be addressed in the testing, and the report should reflect a reasoned, knowledgeable assessment of potential biasing issues in the assessment. Interpretations of test results that appear to deviate from normal levels must take into account other information as well, such as information about the patient's history, information from the direct observation of the patient, the functional abilities of the patient, and the nature of the potential neuropsychological syndromes that could account for the test findings.

The Uses and Utility of Neuropsychological Assessment

Neuropsychological assessment is often indicated when questions about cognition or brain–behavior relationships are raised during the course of a medical evaluation that are not explicable by history, mental status observations, radiological techniques, or laboratory techniques alone. The neuropsychologist is typically called upon when a complex set of symptoms and behaviors dictates in-depth measurement and observation of an individual's neurocognitive function and/or neurobehavioral characteristics. In the forensic realm, neuropsychological assessment is often sought when an allegation of brain injury or brain dysfunction is relevant to a given legal question.

The potential types of forensic referrals are many and varied. In the criminal forensic area, these include questions of trial competence in individuals with suspected neurocognitive impairment; criminal responsibility evaluations in defendants with suspected brain dysfunction or severe mental illness; evaluations to determine other criminal competencies, such as competence to waive one's Miranda rights or waive one's rights to appeal; evaluations to determine factors relevant to sentence mitigation; and evaluations to determine the appropriateness for transfer of a juvenile's case to an adult court. In the civil realm, a nonexhaustive list would include evaluations in personal injury cases in situations of alleged brain injuries, evaluations of injured employees in workers' compensation cases, alleged dementia or memory problems in disability applicants, and evaluation of civil competencies, such as evaluation of testamentary capacity or ability to manage one's affairs in the case of an allegedly demented older individual.

Neuropsychologists are often called upon to estimate whether a brain-injured individual has returned to a prior level of function, such as when confronted with the question of whether the patient can return to work. This is an issue of great interest in many medicolegal situations, relevant to the estimation of compensable impairment in workers' compensation injuries, or damage liability in personal injury cases. For example, after receiving a left frontal contusion, a professional editor may expect to encounter difficulty in tasks that tap verbal reasoning, whereas a skilled machinist might be just as debilitated from a comparable right-hemisphere lesion.

Examination of these referrals often hinges upon comparison of current test results with premorbid abilities. Premorbid function can be assessed informally by taking a careful history including prior educational achievement, occupations, daily activities, hobbies, and personal achievements. Both actuarial

and assessment techniques also exist that allow estimation of prior function. Prior intelligence can be predicted within a degree of error by mathematical regression techniques, utilizing demographic information such as educational level, occupational history, age, and region of the country. Reading ability is highly resistant to most acquired cognitive disorders, with the exception, of course, of alexia. Thus reading skill is a good marker of prior function. Other cognitive skills that can be assessed with the neuropsychological evaluation tend to remain constant, even with significant cortical insults. The most powerful techniques are those that mathematically combine both psychometric data with demographic estimation techniques (e.g., Wechsler Test of Adult Reading, Oklahoma Premorbid Intelligence Assessment).

Another important set of referral questions addresses the patient's level of residual functional capacity after recovery. Normal resumption of activities of daily living, socialization, and performance in work-like settings may not be possible depending on age, course of illness, severity of injury, and the presence of concomitant psychiatric illness. These are functional questions that may be best answered by a combination of assessment techniques, including administering formalized tests (see next section), observing the patient in demanding environments, interviewing the family, and taking a complete history of the illness.

Neuropsychological Assessment Instruments

The most recent version of a popular handbook for neuropsychologists reviews more than 160 tests which have found their way into common use among neuropsychologists Straus *et al.* [4], and these are only a small subset of the tests available commercially or in the research literature. Instead of attempting to present specific tests to the reader, categories and representative examples of neuropsychological tests will be described here, in order to convey a sense of the range and utility of neuropsychological testing.

Intelligence Tests in Neuropsychological Assessment

A comprehensive intelligence test, usually the Wechsler test appropriate to the age of the patient, often serves as the backbone of most neuropsychological evaluations. Comprehensive intelligence tests have the advantage of carefully developed norms and the fact that they tap many key neurocognitive abilities (e.g., verbal expression, processing speed, visual analytic skills). Because of the development of the standardization samples on these tests, it is also possible to account for the expected effects of such variables as educational level and ethnicity, if desired. A disadvantage is the fact that comprehensive intelligence quotient (IQ) scores and summary index scores tend to be resistant to changes caused by neurocognitive disorders. Partially, this is due to the fact that neurocognitive disorders rarely cause generalized dysfunction except in the more severe cases. Also, intelligence tests are not weighted heavily with executive function and memory tests; the tests are shown to be most sensitive to cortical dysfunction. Indeed, it is not unusual for an early to mid-stage Alzheimer's patient to be relatively debilitated due to memory loss, but score near-normal limits on most sections of the Wechsler Adult Intelligence Scale, or for a Pick's Disease (an illness involving deterioration of executive functioning and personality change due to brain degeneration) patient to exhibit grossly inappropriate behavior but to have an average or better IQ.

Folstein Mini-Mental State Examination (MMSE)

The Mini-Mental State Examination (MMSE) is a universally recognized neuropsychological test that is widely used by psychiatrists, psychologists, neurologists, and geriatric practitioners. This test taps several cognitive functions including orientation, word memory, naming, verbal comprehension, writing, and drawing. Benefits of the MMSE are the instant recognizability of the test and the fact that so many clinicians across differing disciplines can readily interpret its scores. Unfortunately, it is also short on items tapping executive function, and its memory section, as generally administered, is crude. This test is often supplanted with tests that have additional memory and executive items to allow greater sensitivity to senile dementia and a broader range of assessed functions (e.g., Modified MMSE; Dementia Rating Scale).

Halstead–Reitan Neuropsychological Test Battery

The Halstead–Reitan Neuropsychological Test Battery (HRNTB) contains many of the most commonly

used neuropsychological tests. It originated from the work of Ward Halstead, who in 1947 at the University of Chicago published his observations of several hundred case studies of patients who had frontal lobe damage. By using 10 scores, Halstead blindly distinguished patients with confirmed brain lesions from control subjects. Reitan [5], a student of Halstead, modified the battery in 1955 to identify lateralizing features of patient performances such as motor deficits expected in subtle stroke, the effect of temporal lobe epilepsy on memory, and the loss of abstraction ability associated with frontal damage. Reitan also modified the original battery to include tests that would accurately measure aphasia and variations of normal aging. An extensive norming project [6] has provided an excellent source of demographically corrected norms for the tests.

The Halstead Impairment Index is a global measure of brain dysfunction in neuropsychology backed by research and a wide degree of acceptance. Most normal subjects are able to pass 60–100% of the tests included in the Index. Patients who have moderate impairments may be within the normal range on only 30–60% of the tests, and those with severe dysfunction on less than 30%. From continued use of the battery over the decades, 3 of the original 10 scores were dropped because of questionable validity. The Index includes seven scores within the following five subtests:

1. Category Test

The Category Test is an abstract reasoning task consisting of 180 items. The patient is required to use mental flexibility and problem solving to form concepts, utilizing feedback from the examiner about the accuracy of their attempts.

2. Tactual Performance Test

The Tactual Performance Test is a test requiring the integration of multiple cognitive skills: spatial skills, spatial memory, dexterity, processing speed, and planning ability. The patient is blindfolded and placed before a board with cutouts into which blocks can be inserted. The patient is then asked to place the blocks in the cutouts, first using the dominant hand, then the nondominant hand, then both. Then the patient is asked to draw a representation of the board from memory. Since more than 40% of the brain's processing power is devoted to visual processing, removal of vision presumably cripples the efficiency with which the patient can approach the task. For the brain-injured patient, excessive time is often required to complete this task. The lateralized nature of the test allows some comparison of relative hemispheric efficiency.

3. Finger Tapping Test

Finger Tapping is a test of fine motor speed. Five consecutive 10 s trials are obtained with the dominant and nondominant index fingers, and then compared to norms. Injury to either region of motor cortex, as well as injuries affecting overall cortical efficiency, can result in degraded scores on this task.

4. Rhythm Test

The Rhythm Test originated from the Seashore Measures of Musical Talent test, in which the patient is asked to differentiate between 30 pairs of rhythmic patterns. These pairs are presented in rapid succession on a tape recorder, and the patient must distinguish whether they are the same or different.

5. Speech Sounds Perception Test

The Speech Sounds Perception Test involves 60 spoken nonsense words that are administered by audiotape. The patient is required to underline the corresponding printed response on an answer sheet, measuring verbal discrimination and sustained attention.

General Neuropsychological Deficit Scale

In addition to the seven scores provided by five index subtests, other subtests from the HRNTB are used to represent patients' performances on the General Neuropsychological Deficit Scale (GNDS). Subtests used to contribute to this scale, in addition to those in the Index, include the Lateral Dominance Examination, Grip Strength, the Sensory-Perceptual Examination, Tactile Form Recognition, the Trail Making Test Parts A and B, and the Aphasia Screening Test. The GNDS, much like the Impairment Index, provides a global impairment rating but takes into account 42 variables, thereby increasing reliability. Clinical judgment also allows the clinician to take into account variables in the interpretation of data related to the level and pattern of performance, pathognomonic signs, and laterality. In practice, though, the entire HRNTB is rarely given, with the neuropsychologist instead relying upon subtests of the battery scored with the help of the demographically corrected norms, described above.

Functions Measured in Neuropsychological Assessments

Sensorimotor Ability

Many neuropsychologists administer a partial neurological examination as part of their overall assessment. Depending on the referral questions, the sensorimotor assessment may include informal testing of olfactory function, visual fields, auditory perception, stereognosis (tactile appreciation of objects), and cerebellar function (e.g., heel-to-shin testing, alternating hand movements). As mentioned above, standardized testing of strength, motor speed (hand and foot tapping), and fine motor control are generally a component of the examination.

Attention and Concentration

After ensuring an adequate level of consciousness, assessment of attention provides fundamental information as to whether evaluation of other cognitive domains, such as intelligence, memory, or language, will be valid. Further, because the ability to focus and maintain attention is highly sensitive to many acute and ongoing conditions (e.g., alcohol withdrawal, intoxication, delirium), a stable, chronic process may be affected less than will a recent or changing one. At the most basic level, this domain measures the patient's ability to attend to incoming information without being distracted. Examples of simple attentional tasks include digit repetition or visual tapping span, requiring forward or backward sequencing of auditory or visual stimuli.

Sustained attention, known as *vigilance or continuous performance*, is another type of attention. An area of cognitive assessment which shows great promise for practitioners who work with attention deficit hyperactive disorder (ADHD) children and adults is continuous performance testing for sustained attention (e.g., Conners Continuous Performance Test and Test of Variables of Attention). Continuous performance tests are most often computer administered, and generally exist in either visual or auditory formats. In the visual modality, the child (or adult) is asked to sit before a computer screen and to respond to one type of stimulus while suppressing responses to another. The tests go on for several minutes, and the boring nature of the task tends to elicit omissions and variable response times from individuals with attentional deficits. While only limited success has been achieved with these tests as diagnostic instruments for ADHD, they are quite successful in measuring the effectiveness of psychostimulant medication on individuals known to have ADHD. As such, an assessment using these tests can allow the psychiatrist to avoid the use of costly and potentially risky psychostimulant medications among patients who are unresponsive to its effects. These tests are also widely used by neuropsychologists to assess the attentional abilities of brain-injured patients.

Learning and Memory

Compromise of memory is the most common patient complaint and referral question for neuropsychological testing. Milder memory problems, or problems with visual memory, may not be readily apparent on screening tasks such as the MMSE. Since memory is not a static or unitary process, careful assessment can help to characterize variations in performance, which can have diagnostic value. Patients who have anterograde amnesia, or faulty learning of new material or events after the onset of their disorder, have more difficulty consolidating their learning experiences into longer storage. Retrograde amnesia, or the inability to retrieve remote memories, is less prominent in organic memory loss, especially if the onset is sudden, as in head injury. However, certain chronic conditions and disease processes, such as Korsakoff's syndrome and Alzheimer's disease, may produce a more dense retrograde amnesia. Memory is often evaluated in the mental status examination by assessing orientation, current events, and recall of words or objects. Although screening is sometimes adequate to determine the presence of a gross dementia, full neuropsychological evaluation can detect whether the difficulty is with encoding, storage, or retrieval mechanisms, and whether the impairment is associated more with one modality than another (e.g., verbal or visual).

The most widely used global memory test is the Wechsler Memory Scale (WMS), now undergoing its most recent revision, which will result in the WMS–IV. These tests yield memory quotients similar to IQ scores (expected mean is 100; standard deviation is 15). It provides for evaluation of immediate memory, delayed memory, and working memory skills, in both visual and verbal modalities.

Language

Testing for aphasia is a necessary part of diagnosis and treatment planning in some developmental and learning disabilities, progressive disorders (e.g., dementia and tumor), or recovery from an acute injury such as stroke or head injury. Impairment of language on a gross level is often more noticeable because of the frequent need for clear communication. However, subtle language deficits can go undetected in informal conversation and occasionally in more formal assessment. At the very least, language screening should include tasks to measure quality of spontaneous speech, naming, comprehension, repetition, reading, writing, calculation, and left–right orientation. Naming, the most sensitive element of most underlying language disturbances, is often measured through confrontational naming tasks such as the Boston Naming Test, a 60-item test of picture identification. Well-studied aphasia screening batteries include the Boston Diagnostic Aphasia Examination and the Western Aphasia Battery. If the neuropsychological assessment confirms the presence of aphasia, a speech language pathology evaluation may be required to plan detailed treatment.

Executive Functioning

Executive functioning refers to cognition and personality skills that are integrative in nature, allowing the person to attend to salient stimuli while disregarding others, maintain situational awareness, plan, reason hypothetically, solve problems, self-monitor demands and emotional reactions; in short, executive function is composed of all meta-cognitive and emotional processes that serve to help the person adapt to the environment or reach an overarching goal. Though many of these functions are partly, if not primarily, subserved by the frontal lobes, their complex nature generally requires the entire brain working in concert for maximal success; thus the descriptive term *integrative functions* is also often used. Neuropsychological functioning under the rubric of executive tasks includes abstraction, problem solving, set generation and sequencing, ability to maintain or terminate behaviors, and ability to plan and organize. These functions are mediated by the frontal lobes. Personality characteristics having to do with judgment, social appropriateness, inhibition versus impulsivity, and motivation are also at least partially related to frontal activity. The most famous example of an organically driven personality change is that of Phineas Gage, a railroad worker in the 1880s, who sustained a traumatic injury to the frontal lobes when a tamping iron was blown through his head. This formerly docile, responsible worker became irascible, foul-mouthed, and disinhibited. As his reckless and menacing behavior continued, his coworkers described him as "no longer Gage".

Specific tasks that are frequently used to study the integrity of the frontal systems include the Wisconsin Card Sorting Test. This procedure provides an index of how well the examinee can formulate hypotheses and solve problems. Cards are matched by principles that are not stated directly, and the patient must shift cognitive sets as the rules for sorting change without forewarning. Other good measures of executive functioning include Controlled Oral Word Fluency, which requires verbal set generation (e.g., words beginning with certain letters), the Category Test (concept formation), and the Trail Making Test (measuring visual shifting and sequencing).

Visuospatial Functioning

Visuospatial functioning measures both the patient's ability to function within his or her environment with regard to recognition of objects and his or her construction and perception of spatial relations. Such abilities are important in daily activities that require the patient to recognize faces and remember geographic location and spatial orientation and in procedural learning tasks such as driving a car. Since patients with progressive neurologic disorders, such as Alzheimer's disease, and patients with right-hemisphere strokes, are particularly susceptible to deficits in this area, careful testing will be able to determine whether the patient is likely to encounter problems in getting lost or living independently. Figure copying, clock drawing, visual organization of parts to whole, facial recognition, and map orientation are samples of tasks used to assess this domain.

Malingering in Neuropsychological Assessment

The accuracy of neuropsychological assessment techniques is largely dependent upon the effort and/or truthfulness of the examinee. Malingering (*see also*

Malingering: Forensic Evaluations), or faking, neurocognitive problems is a key consideration in performing forensic neuropsychological assessments. It is estimated that approximately 30–50% of individuals undergoing forensic neuropsychological assessment intentionally underperform on cognitive testing, or otherwise seek to magnify their symptoms. Even young children have been shown in research studies to be able to successfully mislead skilled clinicians. The prospect that one out of every two or three medicolegal patients is feigning or exaggerating is a sobering one.

Patients often malinger physical disorders, pain, psychosis, posttraumatic stress disorder, severe depression, panic disorder, seizures, and memory deficits, to name a few feigned presentations. Disorders that are episodically manifested, such as panic attacks or seizures, represent a unique challenge to the clinician because of the relative lack of power of the mental status examination. In our experience, memory deficits are often feigned, presumably because it seems to many patients that loss of memory would be easy to both describe and feign on examination, though these expectations are, in fact, inaccurate.

The most powerful tool the clinician has in identifying malingered disorders is thorough knowledge of, and experience with, the disorder in question. It is a challenge for most patients to learn what symptoms to report to feign a given disorder, and an even greater challenge to convincingly produce facsimiles of symptoms upon mental status examination. For this reason, referrals to rule out malingering should preferably be sent to clinicians who are very experienced with the disorder in question. The patient suspected of feigning schizophrenia should be referred to a specialist in psychotic disorders, and the apparently head-injured patient to a clinician with extensive experience with patients who have experienced mild, moderate, and severe head injuries.

Detection of Malingered Deficits

Many patients present with malingered memory or reasoning deficits. Intellectual, neuropsychological, and other cognitive tests can be easily compromised by poor effort, and often such lack of effort is intentional. Without formal testing for malingering, low test scores or apparent dementia on mental status examination may inaccurately result in classifications of patients as demented or mentally retarded.

Cognitive malingering tests utilize several different strategies to detect feigned cognitive problems, and fortunately knowledge of these strategies does not always subvert the tests, even in clever and well-informed patients. One set of tests utilizes floor effect tests, that is, tests that appear to be difficult but, in fact, are nearly always successfully performed even by individuals with moderate cognitive impairment. The malingering patient often scores well below the expected level as compared to genuinely impaired patients, thereby allowing a probabilistic determination of malingering to be made.

Forced choice tests are another strategy, often combined with the strategy above. These tests utilize the fact that forcing the patient to choose between two dichotomous responses, one correct and the other incorrect, results in a known expected value if the patient has no ability in that area at all: 50%. If a patient scores significantly worse than he or she would by flipping a coin, then strong evidence of malingering is produced. In that circumstance, the only credible explanation is that the patient must have known the right answer, since the wrong one was so often chosen. When failed, these tests provide the strongest evidence of malingering. The technique is also adaptable to a wide variety of possibly malingered conditions, e.g., blindness, tactual imperception, and deafness. Unfortunately, very few malingers fail forced choice tests, presumably recognizing that a higher level of performance would be the norm even for a severely impaired individual.

An example of a widely used test that combines both forced choice and floor effect features is the Test of Memory Malingering (TOMM). This test is composed of 50 pictures, which are shown to the patient in repeated trials. The patient is tested by being given a dichotomous choice between each correct picture and a foil. The patient's absolute score yields a classification of likelihood of malingering. If the patient goes on to score below chance levels, a precise probability rating can be assigned demonstrating the certainty level of malingering beyond any reasonable question.

Other cognitive malingering tests utilize known principles of learning or test-taking to identify unusual patterns of test performance. For example, even individuals with severe memory impairment tend to respond with significantly more correct

answers when they are given recognition choices. Another principle is that, on average, the patient should score better on easier items than on more difficult ones, and that once a patient's level of ability has been exceeded, further answers should have no greater accuracy than chance. These and other atypical performance patterns offer the neuropsychologist further tools to identify malingering examinees.

The Minnesota Multiphasic Personality Inventory-2 (MMPI-2) is a widely used self-report personality inventory that contains a number of validity scales useful in identifying the individual malingering neuropsychological problems. These scales include the Infrequency Scale or *F* scale, the Infrequency–Psychopathology Scale or $F(p)$ scale, the Infrequency Back Scale or *Fb* scale, the *F* minus *K* Index, the sum of obvious – subtle differences, the Dissimulation-Revised Scale, and the Fake Bad Scale. These scales, and combinations thereof, have been shown to successfully identify individuals feigning psychiatric and neuropsychological dysfunction. The latter scale, the Fake Bad Scale, appears to have especial utility among persons alleging acquired physical debility and/or neurocognitive dysfunction.

Thus, the forensic neuropsychological assessment is not complete without an adequate assessment for malingering behavior. The assessment should include psychometric techniques for identifying underperformance and symptom exaggeration, as well as careful analysis of the examinee's presentation for indications of inconsistency. Such indications include notable discrepancies between test performances and observed abilities, discrepancies between claimed deficits and observed or reported functional activities, discrepancies between self-reported symptoms and known patterns of brain functioning, and discrepancies between self-reported deficiencies and symptoms reported by reliable collateral informants.

In sum, neuropsychological assessment, the application of standardized cognitive measurement techniques to brain–behavior relationships, has proved a useful and often determinative source of information in individuals with neurodevelopmental disorders and acquired brain dysfunction. Its validity and usefulness has been recognized by other disciplines and by the legal system. Neuropsychological assessment is a valuable resource, particularly in situations involving forensic questions about an individual's mental abilities, the nature/degree of neurocognitive injury, and one's neurobehavioral prognosis.

Neuropsychological Assessment: Child

Introduction

Child neuropsychological (NP) assessment involves the application of psychometric test methods in the evaluation of brain abnormalities in children. It shares

many of the same goals and principles involved in the NP assessment of adults (*see* **Neuropsychological Assessment**). However, there are many important differences. Developmentalists argue that a child should never be viewed as simply a scaled-down version of an adult. Likewise, an appropriate assessment of brain–behavior relationships in children cannot be based simply on scaled-down versions of assessment methods designed for use with adults. Not only do children differ in terms of the types of brain insult commonly experienced, they also differ with respect to the specificity of behavioral effects manifested, the pattern and course of (re)acquisition after injury, the modifying effects of ongoing developmental change, and the extent to which deficits sometimes can be "silent" until later developmental periods.

There have been a number of books devoted exclusively to the methods and unique issues involved in the NP assessment of children (e.g., [1, 2]). The focus of this article is admittedly selective and begins with a discussion of what *is* NP assessment and how it differs from other related diagnostic methods. Next, there will be an overview of different clinical applications and major test methods and approaches currently available. That will set the stage for a discussion of some key conceptual and practical issues in this area.

Contrast to Other Assessments

What defines a NP assessment and distinguishes it from simply an assessment of a child's mental abilities? In other words, how does it differ from a general psychological assessment?

Many of the standard instruments available for assessing children's abilities, such as the Wechsler Intelligence Scale for Children-Fourth Edition (WISC-IV; [3]), can be used quite effectively in evaluating a child's NP functioning. This is especially true for younger children (up to about 5 or 6 years) for whom decrements in general intelligence are often among the chief manifestations of early childhood brain injury [4]. *Sensitivity to brain dysfunction* is certainly a necessary qualification for a test to be considered a NP measure. This is an empirical issue, based on whether and to what extent performance on the test allows a valid differentiation of normal children and those suffering from one or another type of brain abnormality.

However, most tests used in a general psychological assessment were never developed from a NP perspective, nor were they designed to facilitate various types of inferences regarding a child's NP functioning. For example, different patterns of performance on the WISC-IV may be suggestive of left versus right hemispheric brain dysfunction, but the test was not constructed in a way that readily lends itself to that interpretation. Similarly, although qualitative observations during test performance on the WISC-IV may offer insights regarding a child's executive functioning, it was not designed to isolate this important area of NP functioning. Although virtually any measure of a child's abilities can be used in making NP inferences, some measures are better than others in revealing specific aspects of NP functioning. Thus, another essential feature of NP assessment is that it *facilitates the conceptualization of a child's performance in terms of brain–behavior relationships*. Sensitivity to brain damage is not enough. A test must also be constructed and validated in a manner that permits inferences regarding specific areas of NP functioning.

The NP assessment also should be based on a sufficiently broad appraisal of a child's functioning. The interest is not simply on the child's language abilities, memory, or inhibitory controls – taken separately – but instead on the child's overall performance as reflected in a *functional profile.* This is why a proper assessment typically involves a battery of tests to assure sufficient breadth and depth of coverage. This will be discussed further later on in the section dealing with current approaches to assessment.

To recap, a NP assessment of a child produces a *functional profile derived from a battery of tests sensitive to brain dysfunction and organized in a manner that facilitates inferences regarding brain–behavior relationships.*

What about distinguishing a child NP assessment from other diagnostic methods evaluating neurological abnormalities in children? Specifically, how is it different from a pediatric neurological exam (PNE)? The precise features vary across practitioners, but a PNE typically consists of a review of the child's development, clinical history and presenting complaints as well as a direct examination of areas such as station and gait, basic motor and sensory-perceptual functions, cranial nerves, and reflex integrity. The findings of the exam often are used to judge whether other neurodiagnostic methods should be pursued.

It also includes at least a brief mental status exam (assessing such things as comprehension, naming skills, immediate recall, and so forth) although this is typically rather basic and informal. The child NP assessment, by contrast, is designed to provide a far more in-depth and standardized evaluation of mental processes. Accordingly, it would be more sensitive to neurological conditions having an impact on higher mental functioning. Indeed, this is why suspicious findings on the PNE often may prompt the physician to refer the child for a formal NP assessment. An important distinguishing feature also has to do with the *standardized* nature of the NP assessment – even as it pertains to the evaluation of areas of lower functioning such as motor and sensory-perceptual abilities. In a standardized test or procedure, the components of the exam are administered and scored in a strictly defined manner and evaluated according to specific norms. This permits the measurement of more subtle variations – as, for example, mild decrements in fine-motor speed or control. With this, the NP assessment sometimes may be sensitive to milder or earlier functional changes accompanying a disease process.

The NP assessment can be further differentiated from other neurodiagnostic methods such as brain imaging. Whereas computed tomography (CT) or magnetic resonance imaging (MRI) may identify and localize an underlying brain injury, the NP assessment would instead be used to help specify the particular functional deficit(s) associated with it. Each set of methods occupy opposite ends of a *structural–functional assessment continuum*, with tools such as CT and standard MRI focusing on brain *structure* whereas the NP assessment deals with brain *function*. An abnormal MRI finding may lead to an expectation of a particular functional impairment (as, for example, indications of an injury involving the left temporal lobe suggesting that the child's verbal comprehension and memory may be affected), although this is only an educated inference needing confirmation by actual functional assessment. The reverse is also true – namely, that a particular pattern of performance on NP testing may suggest a particular type or localization of a brain injury, although that too is only an inference based on current knowledge of brain–behavior relationships. In some cases, the findings may diverge, as when abnormalities on NP assessment are not accompanied by abnormalities on brain imaging and *vice versa*. This may occur in cases with milder injuries, or where the NP finding may relate to other organic variations (such as abnormal blood flow or metabolism) rather than to structural deviations, *per se* [5]. A comprehensive evaluation of the brain injured child often requires an integrated and multimethod approach incorporating both structural and functional assessments.

Applications

Child NP assessment may be used in a broad range of clinical applications. These include: (i) aiding in the detection of brain dysfunction, (ii) providing a specification of the neurobehavioral effects of a known brain injury, (iii) helping to identify specific underlying dimensions of dysfunction in particular handicaps, (iv) using assessment data to help formulate effective treatment strategies, (v) helping to assess the child's prognosis and risk for certain developmental outcomes, and (vi) conducting follow-up assessments of functional change over the course of development and in response to particular interventions [6]. The relative importance of these different applications depends, in part, on the particular clinical population under consideration. Broadly speaking, there are four different but overlapping clinical populations to whom NP assessment may be applied. These include children with: neurological disorders, systemic illness, psychiatric disorders, and learning disabilities.

Children with *neurological disorders* comprise a very broad and varied category. The possible conditions are many, and include children with genetic disorders affecting the brain (e.g., Turner's syndrome), structural abnormalities (e.g., agenesis of the corpus callosum, hydrocephalus), traumatic injuries, epilepsy, and a variety of neuropathological processes such as anoxic episodes, encephalitis, toxic encephalopathy (e.g., carbon monoxide or lead poisoning), metabolic disorders, demyelinating diseases, neuromuscular disorders, brain tumors, and, more rarely in children, cerebral vascular accidents. The NP assessment may serve to identify functional impairments which, taken together with other appropriate evaluations, may lead to the diagnosis of a particular neurological condition. For example, NP findings pointing to a decline in a child's cognitive functioning may prompt a broader neurological work-up that ultimately leads to the diagnosis

of a degenerative disorder, such as metachromatic leukodystrophy – a progressive demyelinating disease of the brain. Or, the presence of localizing signs on NP assessment may prompt a more thorough exploration of a specific seizure focus in a child with epilepsy. This could have implications for possible neurosurgical intervention in the child with intractable seizures. However, there is a very important point to emphasize here. In neither of these examples is the NP assessment *diagnostic* of the condition in question; rather the findings may be part of a broader series of evaluations from which a diagnosis is ultimately made. A particular set or pattern of results on NP assessment may correlate with, but, taken by themselves, should never be considered to be diagnostic of these or other neurological conditions.

Besides the issue of detection, an NP assessment may be used to obtain a detailed appraisal of *what* aspects of mental or behavioral functioning have been affected by a known or suspected neurological condition. This was explained before in contrasting what is unique about NP assessment in comparison to other methods used in evaluating the brain-disordered child. The NP assessment is needed to determine what aspects of functioning have been *impaired or spared* as a result of neurological conditions such as epilepsy, congenital abnormalities, toxic states, and so forth.

An area of intensive NP investigation, and one of particular interest within a forensic context, has to do with traumatic brain injury (TBI) in children. The interested reader may wish to refer to one of the published works devoted exclusively to the topic (e.g., [7]). Briefly, some of the key issues in this area have to do with conducting a thorough assessment that is sensitive to the affected areas of functioning, establishing a preinjury baseline (which is especially problematic in younger children) against which current deficits may be compared, and determining not only recovery but possible longer-range developmental impact – especially in terms of delayed effects or deficits that may be "silent" until challenged more as the child grows older. These are among the issues that contribute to the evaluation of TBI and other acquired conditions often being more complicated in children than in adults (more on this later).

Another broad population or category for general application has to do with children having *systemic illness*. This category consists of children having one or more pediatric diseases or conditions, not primarily neurological in nature, which can have a *potentially* adverse impact on central nervous system (CNS) functioning. Examples would include neonatal complications associated with prematurity or very low birth weight, defects in specific organ systems (congenital heart disease, pulmonary or renal dysfunction), infections, metabolic disorders, autoimmune disorders, and cancer. Here too the interested reader is referred to *volumes* dealing thoroughly with the topic (e.g., [8, 9]). What is import to appreciate is that the NP assessment in this general category has become a growing area of need. Advances in medical care over the past several decades have brought about a dramatic increase in the survival of children with serious illnesses. However, with the decrease in mortality has come a corresponding increase in morbidity – as the conditions (or their treatments) sometimes will have an adverse impact on the developing brain and the child's later functioning. The effects can be subtle, and manifested sometimes in the form of low-grade problems with attention or learning. There clearly is a need for careful follow-up in which the NP assessment can play an important role.

Children with *psychiatric disorders* make up another group for whom the NP assessment can be important. This may be viewed from two perspectives. First, children with brain dysfunction are at higher risk for the development (or exacerbation) of a psychiatric disorder. In some cases the relationship may be direct, as when a frontal lobe injury may give rise to impulsive behavior problems. In other cases the relationship is more indirect, whereby brain dysfunction may set the stage for other factors to come into play which, themselves, act to produce or aggravate an emotional or behavioral disturbance [10]. For example, an underlying brain injury may give rise to one or more learning disabilities which may render the child more likely to encounter frustration or failure in school. This, in turn, may result in any of a variety secondary problems ranging from anxiety, depression or social withdrawal to defiance and other acting-out behaviors. Early identification of the functional deficits and behavioral risks in the brain-impaired child can be an important step in limiting the development or progression of a psychiatric disorder.

The other perspective with respect to psychiatric disorders has to do with examining the disorders, themselves, in terms of possible underlying neurobiological and NP abnormalities. Whether or not there is a history of known brain injury or neurological disorder in the case of an individual

child, there is rapidly growing evidence that disorders such as autism, attention-deficit/hyperactivity disorder (ADHD), childhood schizophrenia and other psychotic disorders, as well as certain forms of depression and anxiety disorders are each associated with abnormalities in underlying neural mechanisms and NP functioning. For many children with ADHD, for example, disordered frontal-striatal functioning appears to play a key role in the deficits in behavioral inhibition and task persistence commonly seen. Such a perspective has an important bearing on how the condition is approached both in assessment and treatment planning. The interested reader is referred *Tramontana* and associates [11] for a more complete discussion dealing with the neuropsychology of child psychopathology.

Children with *learning disabilities* comprise yet another important population or category for application of NP assessment. Here the interest is not so much on identifying whether or not the child is brain impaired. Nor is there necessarily a question that the child is experiencing a significant handicap in academic learning – whether it has to do with reading, math, writing, and so forth. Indeed, the assessment often may begin with there already being ample documentation that the child is struggling in one or more of these areas. Rather, the emphasis is on using the NP assessment to better understand how and why the learning process may be breaking down. For example, reading can be impeded by any of a variety of underlying problems, including deficits in phonological processing, visual pattern recognition, phoneme-grapheme association, segmentation and sequencing, grammatical awareness, as well as verbal comprehension and memory. The breadth of coverage typically involved in the NP assessment may serve to highlight deficits in relevant underlying component skills. Also, a NP perspective can integrate isolated findings into coherent patterns relevant to brain-based models of learning disabilities. This, in turn, can help to distinguish different patterns or *subtypes* of learning disability having different implications for prognosis and intervention. Here too there are volumes dealing specifically with this topic to which the interested reader may wish to refer (e.g., [12]).

Methods and Approaches

There are a variety of different approaches to child NP assessment. A *fixed-battery* approach is one that aims to provide a comprehensive assessment of brain function using an invariant set of validated test procedures. The composition of the battery is not tailored to the presenting characteristics of the individual child or to the specific clinical questions to be addressed. Rather, the emphasis is on administering a well-defined set of designated tests. It is assumed that individual variability is captured reasonably well as long as the battery is constructed in a fashion that covers a broad range of functioning. An important advantage of this approach is that it provides a standard data base on which different clinical groups can be compared.

Probably the most commonly known example of a fixed-battery approach is the Halstead–Reitan neuropsychological battery (HRNB; see [13]). There are two different versions of the battery for children depending on the age of the child (5–8 years and 9–14). These methods, along with supplemental tests commonly used, were the dominant approach to child NP assessment for decades. Golden [14] introduced a children's revision of a then newly developed NP battery for adults, the Luria-Nebraska Neuropsychological Battery, extending it downward for children ranging from 8 to 12 years of age Luria–Nebraska Neuropsychological Battery-Children's Revision (LNNB-CR). A detailed description and review of these batteries is beyond the scope of this article. These can be found elsewhere [6, 15].

One of the chief limitations of both batteries is that neither was originally developed with children in mind. Areas such as language processing or memory and new learning – areas highly pertinent in the evaluation of children – receive little coverage in the basic HRNB. The same can be said with respect to the area of executive functioning and the LNNB-CR. Neither battery provides an assessment of a key domain such as attention. Thus, more than simply distinguishing brain damaged and normal children (which each battery can do about equally well), an important goal of NP assessment should be to describe how a child is functioning in key domains such as these (more on this in a moment).

At the other extreme are various *flexible approaches* to NP assessment. In *qualitative approaches,* the examiner is less concerned with using methods to quantify the extent of deficits. Instead the emphasis is on determining *how* an individual passes or fails a particular task. Here, for example, the examiner would follow-up with informal inquiries or tasks

that may clarify the faulty retrieval strategies that the child used in failing to recall an item correctly. On the basis of this, the examiner may then branch out and select other tasks to gain an evolving picture of what is wrong. *Process-oriented approaches* represent a hybrid of quantitative and qualitative methods. An example is the *Boston Process Approach* [16] that draws selectively from a core set of standardized tests for a quantified overview of general functioning. Depending on the initial results, and guided by clinical hypothesis-testing, the examiner uses various "satellite" tests, including improvised procedures, in order to pinpoint the precise nature of the individual's deficits. Thus, although there are shared components, much of the assessment varies from patient to patient. Another hybrid approach is reflected in the NEPSY-II, (from NEuroPSYological Investigation for Children), which combines a core assessment along with a flexible assessment of selective areas of interest [17]. All of the components of the exam, including those dealing with selective processes, are on the basis of psychometric test scores.

Most neuropsychologists are probably not purists with respect to one approach or set of methods. Whether implicitly or explicitly, many tend to adopt an *eclectic approach* to the NP assessment. Any of a variety of available tests may be selected to quantify the extent of deficit in various areas of functioning. There usually is at least an implicit outline of the relevant functions and abilities to be assessed routinely. The psychometric properties of the tests (adequacy of norms, validated discrimination of brain dysfunction), as well as how well they complement each other in a test battery, are important factors guiding test selection. Qualitative analysis and other flexible approaches may be used to add richness and individualization to the examination, although most neuropsychologists would view these as supplemental rather than primary aspects of the exam.

Table 1 provides an outline of *key domains* for child NP assessment. It is based both on robust factors derived from statistical studies of fixed test batteries as well as a consideration, on conceptual grounds, of key areas that a comprehensive assessment of a child ought to include [6]. In general, the evaluation should include specific measures spanning the following areas: motor functioning, sensory-perceptual abilities, language and spatial processes, attention, memory and new learning, and executive functioning. Also, whether performed by the neuropsychologist or made available from another source, the evaluation should incorporate findings from tests of general intelligence, academic achievement, as well as measures of behavioral adjustment and personality functioning.

Table 1 Key domains in child neuropsychological assessment[(a)]

Motor control
Sensory-perceptual abilities

Executive functions

[(a)] A comprehensive evaluation also would include an assessment of intelligence, academic achievement, and behavioral adjustment

The foregoing has to do with the breadth or scope of the NP assessment. It defines a *horizontal analysis* that is fixed or invariant with respect to the key domains to be assessed. The particular tests used would depend, in part, on the age of the child. They would also depend on the extent to which there are concerns regarding specific areas or subcomponents of functioning on the basis of the history or referral questions concerning the child. Thus, within each domain, there would be a more in-depth or *vertical analysis* of specific areas for which there would be a flexible selection of appropriately normed and validated tests. Table 2 illustrates such an assessment framework. As an example, the domain of language is broken down into subcomponents from which one or more areas might be assessed. The more relevant the domain is in the case of the individual child or population studied, the more thoroughly it would be assessed.

Lastly, Table 3 provides examples of specific tests corresponding to each of the key assessment domains noted above. The listing is only a limited sampling of the possible tests available. There is a helpful volume providing a compendium of these and other NP tests by Strauss *et al.* [18].

Conceptual and Practical Issues

Applying a developmental perspective in child NP assessment means more than simply assuring that the tests and measures are appropriate for the age of the

child being assessed. It involves understanding how brain functions develop normally as well as under various pathological conditions. A child not only grows more competent with age, but also develops new and more efficient ways of completing tasks and solving problems. An injury or other brain abnormality seldom results in the obliteration of a function or ability. Rather, there often is some recovery of function or compensatory development, although the net effect may be that the function is executed less efficiently than would be true for a normal child of the same age and background. A

proper evaluation of a child's NP assessment must be guided by an understanding of concepts such as these.

There are many factors that can obscure or complicate the assessment of brain–behavior relationships in children. These include: (i) problems specifying the precise time of onset for various forms of brain pathology, (ii) the absence of a referential baseline of premorbid functioning in cases of early brain damage, (iii) the sometimes blurred distinction between neurodevelopmental anomalies and normal variations in the rate or pattern of acquisition of function, (iv) the extent to which deficits can sometimes be delayed or "silent" until later developmental periods, (v) the interacting effects of various nonneurological attributes within the child that may serve to compound or mitigate the effects of brain dysfunction, and (vi) the impact of environmental factors, including the family, in shaping the child's outcomes [6]. Although factors similar to these can play a role in the evaluation of adults, they generally are more prominent and complex in the case of the child.

There are practical issues as well. It is well known that an important challenge in working with children in this area has to do with maintaining behavioral compliance and sustained attention for what can be a fairly lengthy assessment. Also, the younger child may be unable to provide a reliable report of deficits and the circumstances in which they are problematic. Reports of parents and teachers often are crucial in providing accounts of the child's abilities outside of the testing situation. On the other hand, feigned impairments on the NP assessment are fairly uncommon in younger children, although distortions of one kind or another may invalidate the history and presenting complaints reported by parents. A careful appraisal of possible parental bias or embellishment in their report of the child's symptoms must be an important part of the overall assessment, especially in cases where litigation is involved.

Age-related constraints on the NP assessment are especially problematic in the evaluation of children during the first 3 or 4 years of life. The limited response repertoire of infants and toddlers, together with the degree to which their performance is state-dependent, place major constraints on formal NP assessment. This is why the bulk of practice in child neuropsychology has dealt mainly with children 5 years of age and older. (See [19], for a thorough discussion of the NP assessment in early childhood.) In a limited sense, however, the careful application of a NP perspective in the evaluation of standard developmental testing of very young children **is** a NP assessment – as long as it is embedded within a conceptual framework of developmental brain–behavior relationships as discussed above. Areas of potential developmental risk can be identified, on the basis of both known/suspected CNS insults coupled with direct observations of the child, which can then be highlighted for further, more formal NP assessment once the child reaches about 5 years of age.

Finally, there are unique challenges that arise in the evaluation of special populations. Included here are children with handicapping conditions such as sensory loss (blind and hearing impaired), physical deformities, motor disabilities, and language impairment. It is important to appreciate the impact of the handicap on the child's general functioning and adjustment. At the same time, special care must be taken to assure that the handicap does not overshadow and distort the picture of the child's functioning in nonimpaired areas. This is an area that calls upon specific skills, experience, and ingenuity on the part of the examiner. The same is true for working effectively with non-English speaking children and those with other cultural differences.

The foregoing provided a general overview of child NP assessment. Hopefully, with it, the reader has gained an understanding of how to conceptualize and contrast this type of assessment in comparison to other related evaluation methods for children. Major applications were discussed and there was a delineation of the various approaches and methods currently available in the field. Lastly, various conceptual and practical issues were highlighted – including the critical importance of a development framework in conducting and evaluating the child NP assessment, as well as the special challenges that present when evaluating various subgroups of children. The coverage was selective, but nonetheless should have given a general idea of the defining characteristics and current status of this field.

Neuropsychological Assessment: Head Injury *see* Head Injury: Neuropsychological Assessment

Northwest Juvenile Project

The Northwestern Juvenile Project (NJP) is the first large-scale, prospective longitudinal study of alcohol, drug, and mental (ADM) disorders in juvenile detainees. The NJP is funded by a consortium of nine federal agencies and five private foundations. The sample includes a diverse sample of 1829 youth, aged 10–18 years at baseline, who were arrested and detained between 1995 and 1998 in Cook County (Chicago metropolitan area), Illinois. Initially funded to examine the ADM disorder service needs and service use of juvenile detainees, the aims of the NJP have expanded to include an examination of (i) changes in ADM disorders and the comorbidity of disorders over time; (ii) patterns of mental health service use over time; and (iii) pathways and patterns of drug use, violence, and risk behaviors for human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) and other sexually transmitted infections (STIs) over time. The NJP tracks and reinterviews these youth wherever they are living, whether they are back in their communities or incarcerated. The NJP also obtains records cross-validating self-reported data on criminal justice

involvement, and mental health and substance use service utilization from 16 correctional and service agencies.

Background to the Northwestern Juvenile Project

Reports issued by the Surgeon General [1] and the President's New Freedom Commission on Mental Health [2, 3] note that the mental health needs of juvenile detainees are largely underserved. Under the Eighth Amendment (barring cruel and unusual punishment) and the Fourteenth Amendment (right to substantive due process for youths in the juvenile justice system) of the US Constitution, juvenile detainees with serious mental disorders have a right to receive needed treatment as part of the state's obligation to provide needed medical care. Providing appropriate services, however, requires accurate and reliable data on the prevalence of mental disorders among juvenile detainees. Data are necessary for planning how to best utilize the finite resources of the juvenile justice and community mental health systems to meet the mental health needs of detained youth.

Despite the importance of epidemiological data on the mental health and substance abuse needs of juvenile detainees, the juvenile justice system has not had comprehensive, accurate, and reliable data upon which to guide policy decisions. Although a number of studies have examined the mental health and substance abuse needs of detained youth, estimates of rates across studies are discrepant. For example, estimates of the prevalence of affective disorder vary from 5% [4] to 72%; [5] substance use disorders vary from 20% [6] to 88%; [5] and psychosis varies from 16% [5] to 45% [6].

The variability in rates may result from discrepancies in the methods of prior studies in the following areas:

Sample Composition

The composition of samples substantially varied across prior studies. The racial and ethnic compositions of the samples in many of these studies are not representative of the national juvenile justice population; some studies did not even report the racial or ethnic composition of the sample. Females, an increasing proportion of juvenile detainees, were excluded entirely from some investigations.

Small Size

Because of the difficulties associated with the study of detained youth, many studies had small samples. Small samples make it difficult for studies to generate reliable rates, especially for more severe mental disorders with low base rates in the general population (i.e., 1–4%). Many of the studies sampled too few subjects to generate reliable rates even for the more common mental disorders [7]. Most studies did not have enough participants in key demographic subgroups to compare participants by gender, race and ethnicity, or age.

Measurement

Some studies relied on nonstandard or untested instruments; others failed to consider impaired functioning or reported data on only one category of disorder (e.g., substance use disorders, anxiety disorders, and personality disorders) rather than a spectrum of disorders. Even when multiple disorders were assessed, most of the studies did not examine patterns of comorbidity between mental and substance use disorders.

The Northwestern Juvenile Project

The NJP was designed to overcome the methodological limitations of prior studies. The NJP has three interrelated goals:

1. To assess how ADM disorders develop over time among detained youth.

The NJP assesses persistence and change in mental and substance use disorders (including remission and recurrence) patterns of comorbid disorders, and associated functional impairments and outcomes during critical points of development: adolescence, emerging adulthood, and young adulthood.

2. To investigate barriers, pathways, and patterns of service use.

The NJP assesses if and when youth who *need* services *receive* them and from which sectors: corrections, child welfare, education, general health, mental health, and informal services. The NJP can also evaluate how patterns of service use are associated with longitudinal outcomes.

3. To determine pathways and patterns of drug use, violence, and risk behaviors for and prevalence of HIV and other STIs.
The NJP examines the development of these risk behaviors among our subjects, focusing on gender differences, racial/ethnic differences, the antecedents of these risky behaviors, and how these behaviors are interrelated. The NJP will also provide the first estimate of the prevalence and incidence of HIV and other STIs in this population.

Methods

The sample, longitudinal design, and assessments used in the NJP address many of the limitations of prior studies of detained youth.

Sample

Participants in the NJP were a randomly selected sample of male and female youth who were arrested and subsequently detained at the Cook County Juvenile Temporary Detention Center (CCJTDC) between November 20, 1995 and June 14, 1998. As part of the study design, selected strata were oversampled to obtain enough data within key subgroups. The sample was stratified based on the following variables: age (10–13 years or $\geq$ 14 years), gender, race/ethnicity (African-American, non-Hispanic white, and Hispanic), and legal status (processed as a juvenile or an adult). Sample weights were used in statistical analyses so that the findings reflect CCJTDC's population rather than the stratified sample. The sample provides several advantages over prior studies, including:

1. Large sample size.
The final sample includes 1829 participants, a sample size large enough to allow for reliable estimates of uncommon disorders, comorbidity of disorders, and high-risk behaviors.

2. A large subsample of females.
Because females were oversampled, the NJP has a large enough subsample of females (657 females; 35.9% of the sample) to examine differences by gender, as well as differences among females on other key variables. Studying females is critical because females make up increasing proportions of juvenile arrestees (24%), juvenile detainees (19%), adult arrestees (22%), and adult detainees (21%) [8–11].

3. Racial/ethnic diversity.
The stratification of the sample also provides the NJP with adequate participants to examine racial/ethnic diversity within the sample, including 1005 African-Americans (54.9%), 524 Hispanics (28.7%), 296 non-Hispanic whites (16.2%), and four from other racial/ethnic groups (0.2%).

4. Wide age range.
The age range of the sample is 10–18 years old (mean, 14.9 years) at baseline. Youth aged 10–13 were oversampled to provide adequate numbers to examine age differences.

5. Diversity of criminal behavior.
Because the NJP sampled participants from *all* newly arrested youth entering detention, it represents a variety of youngsters who are sent to detention centers. In contrast, other studies focus on specific subpopulations of juvenile detainees, such as serious and violent offenders (i.e., those adjudicated (convicted) of a felony, misdemeanor weapons offense, or misdemeanor sexual assault).

6. Youth processed as adults.
The sample of the NJP includes youth that are automatically transferred to the adult system for processing. These youth are excluded from the jurisdiction of juvenile court based on their type of offense, criminal history, and/or age.

Longitudinal Design

Although cross-sectional studies can be useful to ascertain basic epidemiologic data, a developmental epidemiologic approach requires prospective longitudinal studies [12]. Longitudinal studies allows researchers to (i) examine the antecedents of disorders and other behavioral problems within a temporal context, thereby providing the basis for understanding causal mechanisms [13]; (ii) reveal pathways, changes *within* individuals, variation *among* individuals, and, most important, *sequences* in the development of disorders and other problem behaviors; and (iii) examine age-dependent change, independent of disorder [12, 13].

The NJP is currently funded to collect 9 waves of data spanning 14 years. The longitudinal design

allows for the examination of detailed data on mental disorders, substance use patterns, criminal behavior (including violence), use of mental health and other health services, and HIV/AIDS risk behaviors across three critical developmental periods: adolescence (ages 10–18 years), emerging adulthood (ages 18–25 years), and young adulthood (ages 25–30 years). All participants are tracked until located, and subsequently interviewed wherever they are found. Records cross-validating self-reported data (e.g., on arrests, incarceration history, health, and service use) are also obtained from 16 correctional and community service agencies.

Measurement

The NJP employs standardized diagnostic instruments that are sensitive to the varying developmental stage of our participants. The Diagnostic Interview Schedule (DISC) version 2.3 (based on revised third edition of the Diagnostic and Statistical Manual for Mental Disorders (DSM)) [14, 15], the most recent English and Spanish version then available, was used for the baseline assessments. Diagnostic assessments were changed in accordance with changes in participants' age and improvements in diagnostic technology. For subsequent interviews, the NJP administered version 4.0 of the DISC (based on *DSM-IV*), modified by its authors for use with young adults. The Diagnostic Interview Schedule, version IV (DIS-IV) (based on *DSM-IV*) was used to assess disorders not assessed, or not adequately assessed by the DISC 4.0, including substance use disorders, schizophrenia, cognitive impairment, and antisocial personality disorder (APD) [16]. Most of the samples aged 18 years or older in 2002, at which time the NJP stopped using diagnostic tools designed for children and adolescents and began administering the World Mental Health – Composite International Diagnostic Interview (WMH-CIDI). The WMH-CIDI assesses suicidality and the following *DSM-IV* disorders: depression, mania, panic, generalized anxiety, and posttraumatic stress [17]. The WMH-CIDI represents the state-of-the-art in structured diagnostic interviews, building on earlier versions of the CIDI (World Health Organization (CIDI version 2.1); University of Michigan (UM-CIDI); and Munich, Germany (M-CIDI)) and the DIS-IV [17]. The NJP continues to use the National Institute of Mental Health DIS-IV to assess (i) APD, because it is not included in the WMH-CIDI 2000; (ii) substance use disorders, because the WMH-CIDI 2000 classified drugs into "other" categories rather than identifying specific drugs abused; and (iii) schizophrenia, because the WMH-CIDI 2000 only screens for psychosis.

In addition to the assessment of mental disorders, the NJP assesses the use of mental health services, risk behaviors for HIV/AIDS and other STIs, and a variety of risk and protective factors:

- cognitive and behavioral risk factors for HIV/AIDS and other STIs (self-efficacy, perception of risk, behavioral information and skills, HIV/AIDS knowledge, normative support for HIV prevention, and attitudes and beliefs about HIV prevention);
- functional and cognitive impairments;
- adverse life events, victimization, trauma exposure, and experiences of loss and death;
- criminal and violent activity;
- adult social role performance (education, employment, finances, residential stability, living situation, and parenting);
- physical health;
- mortality (including the cause of death);
- quality of life;
- general attitudes and beliefs (self-esteem, self-efficacy, attitudes toward deviance, stages of change, religiosity, and future orientation);
- characteristics of the family of origin;
- marital and intimate relationships;
- deviant associations;
- social network and support;
- acculturation; and
- neighborhood and community characteristics.

Overview of Published Findings from the NJP

Published data from the NJP have been cited in the Surgeon General's Report on Children's Mental Health and is used by national advocacy groups and in reports to Congress. Analyses of data from the NJP are ongoing. To date, articles have been published in *Archives of General Psychiatry, American Journal of Public Health, Journal of the American Academy of Child and Adolescent Psychiatry, Journal of Consulting and Clinical Psychology, Pediatrics*, and *Psychiatric Services*. The following is a brief summary of key findings.

- **Prevalence of mental disorders.**

Almost three-quarters of females and two-thirds of males had one or more mental disorders. Substance use disorders, the most common type of disorder, affected over 50% of males and 46% of females. Females had significantly higher odds than males of having any disorder. Non-Hispanic whites had significantly higher odds than the African-Americans or Hispanics of having any disorder [18]. Nearly 93% of participants reported 1 or more traumas; 11% met criteria for post-traumatic stress disorder in the past year [19].

- **Comorbidity of ADM disorders.**

Comorbidity was common. Significantly more females (57%) than males (46%) had comorbid mental disorders. Participants with major mental disorder (i.e., major depression, mania, and psychosis) were significantly more likely to have a substance use disorder than those without major mental disorders [20]. Log-linear and latent class models were used to empirically identify the most common combinations of alcohol, marijuana, and other drug use disorders. Over 21% had 2 or more substance use disorders. The most prevalent combination was alcohol and marijuana. Four of the five participants with an alcohol disorder also had one or more drug use disorders [21].

- **Substance use.**

Self-reported drug use had a high level of veracity for the use of cannabis; among detainees with positive urinalysis results, 88% reported use in the past six months. Combining self-report and urinalysis reveals a *minimum* prevalence of 85% for any illicit drug use in the past 6 months [22].

- **Prevalence of HIV/AIDS risk behaviors.**

Baseline HIV/AIDS risk behavior data were collected from 800 participants when funding for this component became available. HIV/AIDS risk behaviors were prevalent, irrespective of gender, race/ethnicity, or age; 95% engaged in three or more risk behaviors, and over 60% engaged in 10 or more risk behaviors. All specific risk behaviors were more prevalent in our sample than the general population. Significantly more African-Americans than non-Hispanic whites had *sexual* risk behaviors; significantly more non-Hispanic whites than the African-Americans had *drug* risk behaviors [23].

- **Substance use disorder, major mental disorder, and HIV/AIDS risk behaviors.**

Substance use disorder significantly increased the odds of engaging in HIV/AIDS risk behaviors. Among youth who had comorbid major mental and substance use disorders, 58% engaged in unprotected sexual activity while drunk or high, compared to only 7% of youth with a major mental disorder but no comorbid substance use disorder. Among the youth with a substance use disorder, more than 63% engaged in 5 or more sexual risk behaviors [24].

- **Development and persistence of HIV/AIDS risk behaviors.**

The development of HIV/AIDS risk behaviors among participants between their baseline and three-year follow-up interviews was examined. Among males, high-risk sexual behaviors were significantly more prevalent at the follow-up than at baseline. Significantly more females engaged in other sexual behaviors at the follow-up than at baseline, including trading sex and drugs and recent unprotected vaginal sex. Patterns of development of HIV/AIDS risk behaviors differed by gender and race/ethnicity. More males than females developed sexual risk behaviors; more females than males developed drug risk behaviors. Significantly more non-Hispanic whites and Hispanics than African-Americans developed drug risk behaviors [25].

- **Development of antisocial personality disorder.**

On the basis of a subsample of 1112 detained youth who were adults at the time of the 3-year follow-up interview, nearly one-fifth of the male juvenile detainees later developed APD. Significantly more males than females developed APD; no differences were found by race/ethnicity. Conduct disorder (CD) diagnosis and the number of CD symptoms were significantly associated with developing modified-APD (M-APD; APD without the CD requirement). *Post hoc* analyses, however, suggested a threshold effect: participants with five or more CD symptoms were significantly more likely to develop M-APD than participants with fewer than five symptoms. Analysis also indicated that several other disorders were significantly associated with the development of M-APD, including dysthymia, alcohol use disorder, or generalized anxiety disorder. Although some disorders were strong predictors of APD, none were useful for identifying which youth would later develop M-APD [26].

- **Detecting and treating mental disorder.**

Institutional records on the provision of mental health services by the detention center and public health system were examined for up to 6 months after intake to detention. Among detainees who had major mental disorders and associated functional impairments, only 15% were treated in the detention center and even less (8%) received treatment in the community. Significantly more females than males with major mental disorders were identified and treated for mental disorders. Detection of need for mental health treatment and undergoing treatment were predicted, in part, by clinical, demographic, and legal variables. Specifically, the odds of being detected or treated was greater among the youth with a major mental disorder, treatment history, or suicidality reported at intake, and lower among racial/ethnic minorities, males, older detainees, and detainees transferred to adult court for legal processing [27].

- **Mortality.**

Seventy-seven participants (4%) died since the study began. Mortality rates of the 65 (4%) who died before March 2004 were analyzed; 96% of these youth died from homicide or legal intervention (e.g., killed by police). Standardized mortality is more than *4 times* the general population rates. Mortality among females is nearly *8 times* the general population rates. African-American males have the highest mortality; yet, they have the lowest mortality *ratio* because their mortality in the general population is high [28].

Conclusions

A substantial number of youth are involved in the juvenile justice system. Approximately two million youth are arrested each year and over 100 000 juveniles are in custody on any given day [29]. The public health and justice systems must have accurate and reliable data from which to guide public policy for youth entering the justice system. The NJP provides data that are critical to improving the outcomes of one of our nation's most needful population of youth.

Nuclear Forensics

Introduction

Nuclear forensics (nuclear forensic science/nuclear forensic analysis) is the branch of science that seeks to examine the nature, use, and origin of nuclear (fissile) and radioactive (nonfissile) materials. Nuclear forensic analysis produces a characteristic "signature" for the material and therefore may provide major evidence for nuclear attribution. It is most often applied to investigations involving the malevolent use of nuclear or radioactive materials and is of assistance in determining adherence to international safeguards against illicit trafficking [1].

Nuclear forensic analysis aims to provide legally admissible evidence that could lead to prosecution of the offenders involved with trafficking of the illicit material. Thus, it assists law enforcement agencies in the fight against illicit trafficking in nuclear and radioactive material in order to minimize the likelihood of such materials being used by terrorists as weapons in the form of radiological or nuclear (R or N) agents. Together with specific chemical and biological (C and B) agents, they form part of the CBRN agents, sometimes also called *weapons of mass destruction* (WMD). CBRN is a commonly used acronym which refers to chemical, biological, radiological or nuclear weapons that can be used to kill or injure large numbers of people, damage infrastructure, damage the economy or damage the

environment in general (*see also* **Chemical, Biological, Radiological, and Nuclear Investigations**; **Biological Agents**; **Chemical Warfare Agents** and **Bomb Scene Management**).

Nuclear attribution is the process of identifying sources of an interdicted nuclear or radioactive material in order to determine its origin, intended or original use; the routes of transfer between the point where legitimate control over the material was lost and the point where the material was intercepted; and the perpetrators responsible for the illicit dealings with the material [1].

A nuclear forensic investigation is conducted in conjunction with traditional forensic examinations of the illicit material. Such examinations might include analysis of explosive residues, biological samples, documents, ballistics, hairs, pollens, fibers, and other associated physical evidence.

The desired outcome of the nuclear forensic analysis is the appropriate prosecution of offenders in a court of law. Therefore, implementation of scientifically defensible sampling and analytical methods and the need to strictly observe chain of custody requirements are essential.

Radiological and Nuclear Agents

Examples of fissile and nonfissile radioactive materials that might be of interest in illegal trafficking are listed in Table 1. The classification of the radioactive materials (sources) follows the five categories as defined by the International Atomic Energy Agency (IAEA) [2]. Apart from nuclear materials, the radioactive sources in Radioactive source Categories 1, 2, and 3 are of specific concern. This is due to both, their high activities and their ubiquity. Devices containing sources such as caesium-137, cobalt-60, or americium-241 are used heavily in industrial and medical establishments worldwide, with access to the materials often poorly controlled. Depending on their nature and the radiation characteristics, terrorists may use such materials in the form of an improvised nuclear device (IND), a radiological dispersion device (RDD; e.g., a "dirty bomb"), or a radiological emission device (RED).

An IND is a crude nuclear weapon constructed from material such as weapons-grade uranium (20–90% U-235) or plutonium. Its explosion would have similarly disastrous consequences, although most likely on a smaller scale, than a modern, dedicated nuclear weapon. The high degree of technical expertise and the cost of building a functional IND make this scenario less likely to occur.

A possible alternative to the construction of an IND is the acquisition of a nuclear weapon through the black market or from rogue nations, or *via* theft from the arsenal of a vulnerable nuclear-weapon state. Nuclear weapons, depending on the yield, have the potential to destroy entire cities. Their impact would be physically, psychologically, and economically devastating.

An RDD disperses radioactive material into the environment, resulting in radioactive contamination of an area. Perhaps the most well-known form of the RDD is the "dirty bomb", in which a conventional high explosive is combined with a radioactive material. Alternatively, specific installations (such as a nuclear reactor, nuclear fuel manufacturing or reprocessing plant, and a radiation source manufacturing plant or a radioactive waste disposal facility) could be targeted as a means of releasing radioactive material and causing contamination of the environment. The extent of radioactive contamination would depend on the size of the explosion, weather conditions, the nature of the affected environment, and the amount, type, and form of radioactive materials involved.

An RED is a high-activity radioactive source that emits energy in the form of highly penetrating gamma or neutron radiation under concealment in a frequented public place. Unlike an IND or RDD, a RED is not designed to cause destruction and/or radioactive contamination of an area, but is aimed at exposing people to high levels of radiation. The existence of the device may not be realized until radiation exposure symptoms are observed among the affected individuals or the perpetrators make the existence of the device publicly known. The detrimental health impact of such a device on the exposed would vary, depending on the total dose received by an individual and is influenced by the duration of their exposure, the activity of the source, and the type and the energy of the radiation emitted from the source. Exposure to high doses of radiation, of the order of sieverts (i.e., hundreds of rems), would cause serious adverse health effects within a short time, and could lead to death [4].

The severity of consequences associated with the use of a device and the probability that a device will

Table 1 Categories of nuclear and other radioactive material[a]

Category	Type of material or device	Radioactive components
Unirradiated direct-use nuclear material	High enriched uranium (HEU)	>20% U-235
	Plutonium and mixed U-Pu oxides (MOX)	<80% Pu-238
	U-233	Separated isotope
Irradiated direct-use nuclear material	Irradiated nuclear fuel material	In irradiated nuclear fuel elements or in spent fuel reprocessing solutions
Alternative nuclear material	Americium-241 Neptunium-237	Separated element or present in irradiated nuclear material, in separated plutonium, or in mixtures of uranium and plutonium
Indirect use nuclear material	Depleted uranium (DU)	<0.7% U-235
	Natural uranium (NU)	0.7% U-235
	Low enriched uranium(LEU)	>0.7% U-235 and<20% U-235 (typically 3–5%) U-235
	Plutonium (Pu-238)	>80% Pu-238
	Thorium	Th-232
Radioactive source Category 1	Radioisotope thermoelectric generators	Pu-238, Cm-244 and Sr-90
	Irradiators/sterilizers	Co-60 and Cs-137
	Teletherapy source	Co-60 and Cs-137
Radioactive source Category 2	Industrial gamma radiography sources	I-192[b]
	High/medium dose rate brachytherapy sources	Co-60 and Cs-137
Radioactive source Category 3	Fixed industrial gauges Well logging gauges	Co-60, Cs-137, and Am-241
Radioactive source Category 4	Low dose rate brachytherapy sources Thickness/fill level gauges Portable gauges (e.g., moisture, density) Bone densitometers Static eliminators	Co-60, Cs-137, and Am-241
Radioactive source Category 5	Eye plaques, permanent implants	Sr-90[b]
	X-ray fluorescence devices	Fe-55[b]
	Electron capture devices	Ni-63[b]
	Mössbauer spectrometers	Co-57[b]
	Positron emission tomographs	Ge-68[b]
	Medical diagnostic sources	Short-lived radioisotopes, e.g., I-131
	Fire detectors	Am-241 and Pu-238

[b] Information added by the authors.

be used is directly linked to the type of the device (Figure 1).

The most detrimental consequences would result from the use of a technologically sophisticated device, such as an illegally obtained nuclear weapon or the use of an IND. However, the difficulties associated with procuring a nuclear weapon or constructing an IND markedly diminishes their probability of being used. Perpetrators would likely favor the use of a device that is less complicated

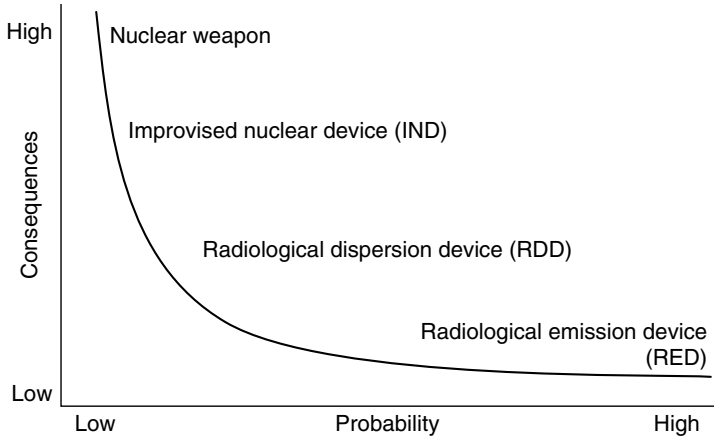

Figure 1 Relationship between the probability of the use of a given device and the detrimental consequences of its use. [Figure adapted from [5]]

and/or easier to procure, such as an RDD or a RED.

Nuclear Forensic Analysis

Nuclear forensic analysis involves physical characterization and subsequent forensic interpretation of nuclear or radioactive material [1, 3].

Characterization of the nuclear or radioactive material aims to determine the chemical and physical signature of a sample of the intercepted illicit material. A number of analytical tools may be utilized to determine the signature of the material being investigated. As in traditional forensic analysis, selection of a particular analytical method is often determined by the results obtained in the consecutive stages of sample analysis. These analytical methods can be grouped into three categories: bulk analysis tools, imaging tools, and microanalysis tools [3, 6].

Bulk analysis tools enable the determination of the elemental and isotopic composition of the material, including the presence and concentrations of trace constituents. They include chemical assays, high-resolution gamma spectrometry (HRGS), radiochemistry and radiation counting techniques, X-ray fluorescence (XRF) and X-ray diffraction (XRD) analysis, inductively coupled plasma–mass spectrometry (ICP–MS), thermal ionization mass spectrometry (TIMS), gas chromatography–mass spectrometry (GC–MS), and glow discharge–mass spectrometry (GD–MS).

Imaging tools are used to document the physical characteristics of the material such as size, shape, and topography. In addition, imaging tools allow the determination of the chemical composition across the material, such as identifying whether the sample is homo- or heterogeneous. Imaging methodologies include the use of visual inspection and photography, optical microscopy, scanning electron microscopy (SEM), and transmission electron microscopy (TEM).

Microanalysis tools are used to quantify individual constituents of heterogeneous samples *via* determination of elemental and isotopic composition. Examples of microanalysis tools include ICP–MS, TIMS, XRD, secondary ion mass spectrometry (SIMS), scanning electron microanalysis with energy dispersive sensor (SEM/EDS) or scanning electron microanalysis with wavelength dispersive sensor (SEM/WDS), and infrared (IR) spectrometry.

After the material has been characterized, the process of forensic interpretation begins. It involves matching analytical data to existing information about the origin of similar materials and the methods used in the production and processing of this material. In addition, potential similarities with previously investigated cases of illicit materials are examined. High-quality national and international databases of reference information, in addition to improved information sharing between nuclear forensic laboratories worldwide, promote a high degree of successful investigations.

Nuclear attribution is the culmination of the analysis and interpretation of nuclear and traditional forensic evidence. It is divided into two key areas: source attribution and route attribution [1]. Source attribution considers data on the investigated material, including physical characteristics and origin, in addition to the analysis of packaging and other collateral items, the point where the material was diverted from a legitimate pathway, and the potential for further supply of such material.

Route attribution focuses on the potential involvement of a black market trafficking network, the identities of traffickers, the throughput capability of the illicit network, the frequency of shipments, and the likely end-user applications.

To date, nuclear forensic analysis has been applied to investigate illicit dealings with nuclear or radioactive material with the potential for terrorist use [1, 7]. It also has been successfully applied to investigations of a criminal (nonterrorist) or an accidental nature. An example of the former is the 2006 political assassination of Alexander Litvinenko in London, United Kingdom, by targeted radiation poisoning with polonium-210 [8]. An example of the latter is the 1992 "Cold Fusion" experiment-related explosion in an electrochemistry laboratory at Menlo Park in California [1].

International Collaboration in Nuclear Forensic Science

Commencing in late 1980s, the nuclear forensic discipline has become established in an international arena as a primary technological tool employed to investigate intercepted smuggled or illicitly traded nuclear and radioactive material for the purpose of attribution. This has been possible due to an early international collaboration of nuclear forensic scientists, conducted predominantly within the framework of the 1996 chartered International Technical Working Group (ITWG) on combating nuclear smuggling and its subset, the 2004 chartered association of the International Nuclear Forensic Laboratories (INFL) [6, 9].

Odontology

Crime Scene and Recovery of Remains

Often the activity of an odontologist begins at the scene of crime, or where a body is found. All data useful for identification of an unidentified corpse or of an offender are therefore directly gathered by whoever has the knowledge to collect useful dental information. When dealing with charred (Figure 1), badly preserved, skeletonized bodies, some dental features, very important for individualization, could become very fragile or could be displaced from the mouth. During the recovery of a corpse, it should be mandatory to protect the oral area so as to preserve all useful information and to avoid the loss of teeth, bone fragments, or prosthetic devices. The oral region is therefore protected from any loss of data by using a fixative spray or means of mechanical protection; the scene is then accurately inspected to find any useful dental element or fragment (sometimes partially or totally charred).

In other crime scene scenarios, the odontologist may be useful for finding useful evidence that may help identify an offender by his lip prints or by his bitemarks on objects or food.

The Biological Profile

Teeth can provide useful information for biological profile reconstruction (*see* **Anthropology**), which is briefly summarized here.

Species

Knowledge of dental anatomy, when intact teeth are found, allows for an easy species attribution to

Figure 1 Surgical mask used to protect the oral region during corpse transportation

a trained eye (Figure 2) [1, 2]. When macroscopic morphology is not sufficient for a sure attribution of species or when studying small dental fragments, microscopic analysis of the teeth can sometimes solve the problem.

Microscopic observation of tooth enamel in fact can show the typical keyhole shape of the human enamel prisms.

Sex

The lack of reliable differences between sexes renders this approach redundant for sex determination for forensic purposes; so anthropological or genetic methods, through the extraction of genetic material from the pulp chamber, are to be preferred.

Race

Teeth can provide some indication about racial affiliation. Some characteristics are for example more frequent in Negroid subjects (as the presence of a diasthema between upper central incisors or an evident prognathism), in Mongoloid subjects (shovel-shaped teeth) (Figure 3) or in Caucasoids (Carabelli's cusp) [1, 2].

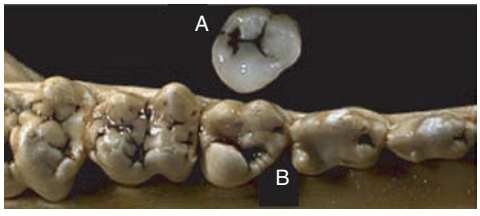

Figure 2 The very similar shape of a third human upper molar (A) and pig premolar (B)

Figure 3 Palatal view of upper dental arch where shovel-shaped incisors are evident

These dental features are not sufficient, however, for a definite race determination, and only add information to the study of the entire skeleton.

Age

Starting from intrauterine life till about 21 years of age (when complete maturation of the third molar occurs) teeth are a reliable indicator of biological age, correlated to chronological age [1–4]. The age of a fetus can be evaluated via odontological methods studying the mineralization of the cusps visible in a radiograph of the mandible (Figure 4).

Up to about 14 years of age, simple observation of the number of primary and permanent teeth allows for age estimation with a growing error starting from about three months (when aging subjects of a few months of age) to a maximum of 36 months (when aging subjects of about 14 years of age). By studying the maturation of teeth apices, it is possible to age subjects till about 21 years of age. Once dental development has ended it is possible to estimate the age of an adult via continuous tooth modification. Dental abrasion is usually used to estimate the age of ancient populations, but is not considered a valuable indicator for forensic purposes anymore. Other dental modifications such as root transparency, root reabsorption, migration of the periodontal junction, continuous apposition of dentin, and cementum are studied, categorized and measured to estimate adult subject age (Figure 5). Root transparency seems to be the variable most closely linked to aging.

There are also some more complex dental methods for estimating age, such as cementum annulation count, the quantification of aspartic acid in teeth or of artificial radiocarbon.

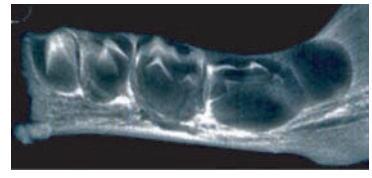

Figure 4 Mineralization of dental cusps in a radiograph of a fetus mandible. The presence of the cusps of the two deciduous molars denotes a fetal age of 38 weeks

Figure 5 Canine transilluminated section in which some features correlated to chronological age are visible: (A) root transparency, (B) apposition of dentin, (C) periodontal junction degeneration, and (D) occlusal abrasion

Aging the Living

Since teeth are a reliable indicator of chronological age, they are used to evaluate the age of individuals without valid documents, often to verify if they reached a specific age (for instance 14, 16, or 18). It is thus possible to establish with which probability a subject reached 18 years of age by studying the development of the third molar, to evaluate the age of a young subject via the ratio between the open apices and the length of the crowns or the age of an adult by observing the ratio between the area of a pulp chamber and the entire tooth.

A final remark should be made, before proceeding to the more common applications of forensic odontology (positive identification and bitemark analysis) concerning a frequently used sign in cases of suspected infanticide – the neonatal line. This is a defect in enamel (or dentine) formation occurring at birth which, in the case of enamel, shows up as a thin dense line visible microscopically which separates prenatal from postnatal enamel. The neonatal line is related to the physiological and temporary interruption of the continuous deposition of dentine and enamel and is an indicator of survival of a newborn for some hours after birth (when the body is decomposed and other markers of survival cannot be searched on soft tissue). Therefore, if the neonatal line is noticed on the dental cusps of a newborn skeleton this suggest that the baby was born alive and survived for some hours.

Positive Identification

Odontological identification is the restitution of identity to a decomposed, skeletonized, charred, or heavily traumatized corpse via oral and dental features [2–6]. Identification is probably the main activity of the odontologist as unidentified bodies are a reality in every country: giving back a name to a corpse is important for every culture either for moral, religious, criminal, or civil reasons. Teeth are the most resistant part of the human body, they are particular to each individual due to anatomical, pathological, and therapeutic features; they also are the only human skeletal/calcified part visible during the life of a subject; these considerations make teeth a good individualization tool. Some cultural modification as color alteration, nontherapeutic morphology modification, setting of stones or jewels in enamel, and nontherapeutic crowns, can provide information about a subject, sometimes these are geographical variants. Some habits or occupations (wind instrument players, pipe smokers, carpenters, or tailors who use teeth to hold metal objects) can leave distinctive marks making individualization much easier. Odontological individualization is based on the comparison between antemortem (AM) data (information about a missing person) and postmortem (PM) data (observation made on an unidentified corpse).

Antemortem Data

Odontological AM data include all information regarding teeth and the contiguous tissues, pertaining to a missing person who is believed to correspond to an unidentified corpse. In most industrialized countries such information is quite easy to find as most citizens have been visited at least once by a dentist who probably kept his or her patient's radiographs, casts or pictures. Precious individualization information can be found in dental files, in orthopantomographs (OPGs) in which it is possible to see all the teeth, in periapical radiographs with a better resolution than OPGs that allow the observation of even the smallest peculiarities, in lateral and anteroposterior skull radiographs which can show dental features (Figure 6), in every radiograph in which a part of the mouth is visible, in clinical pictures (often taken by dentists to document their works) and in normal portraits which show the teeth of the photographed subject.

All antemortem data are summarized in special forms (for instance the INTERPOL DVI form) devised to standardize data collection, to make the matching process between a missing person and an unidentified body easier, to avoid misunderstanding due to the use of different teeth nomenclatures or different scientific vocabularies.

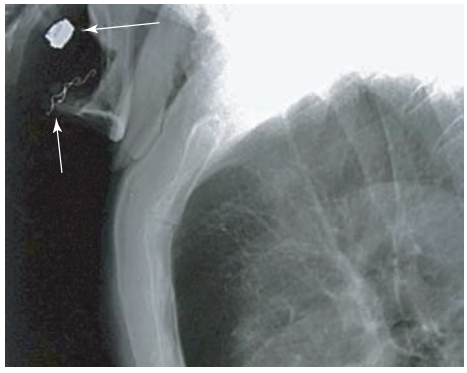

Figure 6 In this antemortem radiograph of a missing person, it is possible to see (white arrows) dental treatment useful for a positive individualization. It is thus possible to perform a positive odontological individualization starting from nondental radiographs

Postmortem Data

Odontological PM data includes all information gathered from an unidentified corpse and inserted into special forms similar to those used for AM-data collection. As unidentified bodies are usually charred, decomposed, skeletonized, or traumatized, oral structures can become very fragile and oral examination should be considered unrepeatable; therefore it is advisable to record and take pictures of every step of the examination procedures (especially if the case will be brought in a court of law). An elementary kit to perform a PM oral examination should include: oral mirrors, probes, scalpel, saws, brushes, sponges, ultraviolet light (to better detect aesthetic restorations) (Figure 7), a camera, radiographic instrumentation, and cast materials.

To collect all dental elements and dental works that could be displaced from the oral cavity a first inspection of the entire body could be necessary; some useful elements for individualization are often found in the pharynx, trachea, and esophagus or even in the bag used to carry the corpse. Especially in case of charred or mummified bodies, mouth opening could be a difficult operation. Temporomandibular joint disarticulation and removal of the entire mandible can be a solution; a quick way is to perform three cuts, using a "stryker" type saw, parallel to the occlusal plane: one passing through the nasal spine to remove the maxillary bone and two passing through the vertical parts of the mandible to remove the jaw (Figure 8).

Figure 7 Aesthetic fillings can be hard to find, especially if of good quality and if teeth are not perfectly clean. A UV light can enhance the shape of this kind of restoration

Figure 8 Maxillary bones and mandible after resection. Postmortem examination can be carried out accurately only if every dental surface is visible

Before taking the jaws from the body the type of occlusion should be recorded. Which teeth are present and which are not is then recorded (dental formula); if missing teeth are noticed it is important to chronologically place their loss by studying the bone remodeling process. Any kind of anomaly (in shape, size, and position) is recorded as well as the presence, type and location of every kind of oral disease. Very often dental individualization is based on the comparison of therapeutic features because they are usually well described in dental antemortem files (Figure 9). For each dental work, one must therefore carefully describe the type, location, and the applied technique and technology. Postmortem examination is then completed by taking dental impressions and radiographs.

Figure 9 It is possible to detect the presence of a filling even if lost. In this example the shape of the cavity on the broken premolar and the dark stain suggest the presence of an amalgam filling probably lost because of the trauma

Matching Process

During individualization processes all AM and PM data collected in the forms are compared to discover compatibility or incompatibility between a missing person and an unidentified body. Positive identification is commonly achieved via radiographic comparison, which nowadays is usually computer aided. In a radiographic comparison, for even the smallest anatomical, pathological, and therapeutic features, antemortem and postmortem radiographs are placed side by side, superimposed and eventually measured and quantified to establish if they come from the same subject (Figure 10).

Postmortem radiographs should be taken with the same technique and with the same projection used for the antemortem ones so that the results are reliable.

Figure 11 Postmortem dental profile superimposed to the picture of a missing person

Dental Superimposition

When dealing with missing persons who do not have clinical data dental superimposition is frequently a reliable identification technique (Figure 11) [5]. It is based on the superimposition of the teeth visible in a picture of a missing person to the dental cast of an unidentified corpse so as to study any incompatibility and correspondence.

Palatal Rugae

Palatal rugae are mucosal ridges on the hard part of the palate. They are morphologically peculiar in each individual and do not change shape for a long time during the life of an individual. When a superior dental impression is taken the palatal rugae configuration is recorded and then transferred onto the cast. All these characteristics make palatal rugae a suitable tool for individualization even with the limitation of being a soft tissue (think of modifications due to dehydration, decomposition, and carbonization). Morphological comparison of palatal rugae is usually performed by superimposition of scanned antemortem casts (provided by the missing person's dentist) and

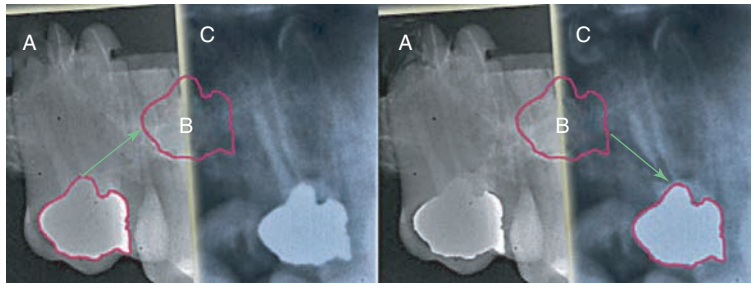

Figure 10 Postmortem radiograph (A) compared to antemortem radiograph (C). Filling postmortem outline (B) is superimposed to the antemortem one to increase comparison reliability

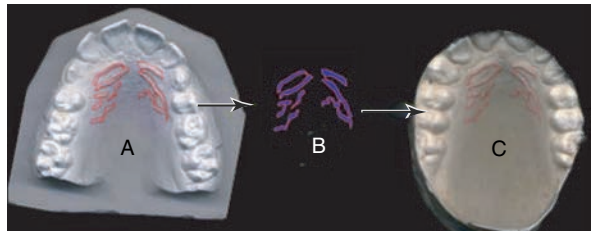

Figure 12 Antemortem (A) palatal rugae pattern (B) superimposed to postmortem cast (C). In this example of a positive identification case, more than 20 years had passed between the antemortem and the postmortem casts

of scanned postmortem casts of the corpse's palate (Figure 12).

Mass Disasters

The contribution of odontology in the identification of the victims of a mass disaster is often decisive. Subjects identified with odontological methods are often more than 80% of the victims [2, 3, 6, 7]. Therefore forensic odontologists should always be included in antemortem and postmortem identification teams. Identification methods applied in case of mass disaster are the same as those used in cases of a single unidentified body; special care is to be taken with respect to logistics, to the organization of the team work, and to the precise compilation of ante and postmortem forms.

Bitemark Analysis

A forensically useful bitemark is a physical alteration or a lesion showing some characteristic of the dental arches that produced it [3, 2, 8, 9]. Bitemarks can be found on a crime scene on objects or food, on the skin of a corpse or of an assaulted subject and can be used to identify who provoked them. The comparison between the dental status of a defendant and the bitemark is almost always done by a computer aided image superimposition: the occlusal pattern of the defendant's dental arches is superimposed to the bitemark image so as to analyze the similarity of the two patterns. Bitemarks are frequently found in sexual assault and the typical locations are arms, breasts, legs, and genitalia. The lesion is usually elliptic, with a central ecchymosis, and with tooth marks on its perimeter (Figure 13).

It is important to study a bitemark as soon as possible either on a living subject (because of morphological changes due to tissue healing), or on a corpse (to avoid postmortem alterations). First of all DNA swabs must be taken from the lesion as the aggressor could have left some genetic material on the skin. Then photographs are shot taking care to use a metric scale and to avoid any possible deformation or distortion (Figure 13). It is possible to produce a cast of the lesion by using dental impression materials (e.g., polyvinylsiloxane). The lesion can be excised from the corpse and if transilluminated can better show some important peculiarities. If the lesion is in a place which can be reached by the dentition of the victim it could be necessary to take his or her dental impression in order to exclude a self-inflicted bite. Some bitemarks can hardly be associated with a human bite because of the low-pressure applied (only a round ecchymosis is visible) (Figure 14), because of excessive pressure (tissue amputation), or if multiple, because bites are superimposed or partial or because they have been inflicted on a portion of skin which has an excessive curvature. Some objects with a tubular section can leave on the skin a mark

Figure 13 Typical elliptic bitemark found on the breast of a corpse: note the teeth pattern on its perimeter, the ecchymosis, and the presence of the American Board of Forensic Odontology (ABFO) ruler

that could erroneously be associated with the action of human dental arches.

Figure 14 Multiple bitemarks on a curved surface: it could be difficult to compare the dental pattern to a defendant's dental arch or even to associate this kind of lesions to a human bitemark

The defendant is usually subjected to a dental visit: missing teeth are recorded as well as any pathology, dental fracture, abnormal tooth position, rotation, or inclination; a dental cast is then produced from accurate impression materials so as to record even the smallest enamel peculiarity.

Opioids

Introduction

Natural and synthetic morphine derivatives possessing morphinelike actions are known as *opioids*. These include common drugs such as morphine, heroin, codeine, etc. and are collectively known as *opioids*. Other terms used to describe these drugs include narcotic analgesics and opiates.

After cannabis and stimulants, the most widely used illicit drugs are opioids. Legitimate opioids, such as morphine, codeine, oxycodone, and hydrocodone, are being consumed at an increasing rate. According to the International Narcotic Control Board, approximately 50 countries have increased their consumption of opioid analgesics by more than 100% during the last decade [1]. The increase is particularly evident in Europe and North America.

Globally, it is estimated that 16 million people take opioids, including 11 million who use heroin. In many countries, the majority of heavy drug users seeking treatment are primarily addicted to heroin; however, it is of increasing concern that legitimate opioids, such as oxycodone and methadone, are being diverted for illegal use.

The use of heroin is common in Asia (54%), Europe (25%), America (14%), and Oceania (6%) [1]. Evidence from national surveys and other data sources suggests that the prevalence of the use of heroin in general populations is relatively low (ranging from 0.2 to 2%). According to the USA 2005 National Survey on Drug Use and Health survey, 379 000 persons (0.2%) reported using heroin in the past year. It was estimated in the year 2000 that there were between 40 000 and 100 000 heroin users in Australia [2] comparable to Britain and other countries in Europe.

The worldwide production of heroin has more than doubled or even tripled since 1985. Scientific reports published by the United Nations Drug

Control Program [1] showed that there was a global increase in the production, transportation, and consumption of opioids, throughout the 1990s; however, in the last 5 years, the production of opium has steadily decreased. World events including the political changes in Afghanistan, the world's largest producer of heroin, led to significant decline in the supply and subsequent demand of the drug. In the golden triangle consisting of Laos, Myanmar, and Thailand, production has fallen by 85% from 1998 to 2006 [1]. Recent reports suggest that production is reaching the high levels of the 1990s.

The use of heroin, in particular, is causing widespread health and social problems in many countries. In Europe, heroin injectors who regularly consume large amounts of different drugs face a risk of death, which may be 20–30 times higher than non-drug users in the same age range. Since heroin is commonly used by injection, the health risks including that of human immunodeficiency virus (HIV) and hepatitis transmission are substantial.

The primary use of legal opioids is for the relief of pain. Depending on the severity of pain, different opioids can be used to diminish or relieve pain. Severe pain can be treated using fentanyl, hydromorphone, methadone, morphine, oxycodone, tramadol, and pethidine, while mild-to-moderate pain can be treated with codeine, dihydrocodeine, and dextropropoxyphene. Other opioids are used to induce or supplement anesthesia, such as fentanyl and the fentanyl analogues alfentanil, remifentanil, etc.

Some opioids (codeine, dihydrocodeine, and, to a lesser extent, pholcodine) can also be used as cough suppressants (antitussives). Methadone, buprenorphine, naltrexone, and naloxone can be used for the treatment of addiction to opioids.

Opioids can also be mixed with other pharmaceuticals (nonopioid drugs) to enhance analgesia (e.g., analgesic-antipyretic preparations and use with some phenothiazines). A summary of selected opioids and their uses are given in Table 1.

There are substantial region-to-region differences in the availability and usage of opioids. For example in 2004, the United States accounted for more than 99% of the global consumption of hydrocodone.

Sources of Opioids

Morphine and codeine are naturally occurring alkaloids extracted from the milky juice and stalks of the opium poppy, *Papaver somniferum*. The content of morphine in these plants can vary from as little as 5% to as high as 25%. Codeine is usually found in much smaller amounts (~0.2%) and the content of other naturally occurring opioids, such as thebaine (~0.1 – 0.3%), narcotine (~0.3%), narceine (~4 – 10%), and papaverine (~1%), can also vary depending upon the quality and origin of the plant [3]. Many semisynthetic opioid derivatives are made by relatively simple modifications of the morphine or thebaine molecule, e.g., heroin (diacetylmorphine) is a semisynthetic opioid produced from the acetylation of morphine. Other semisynthetic drugs produced from morphine or thebaine molecules include hydromorphone, oxycodone, and naloxone (Figure 1).

Pharmacology of Opioids

Effects on the Central Nervous System

Opioids exert their diverse pharmacological effects by binding to opioid receptors that are distributed in distinct patterns throughout the central nervous system (CNS) and peripheral nervous system. The major therapeutic use of opioids is the modulation or reduction in pain. When an opioid is administered therapeutically to patients suffering from pain, the sensation of pain is reduced and their distress becomes less intense. However, when an opioid is given to normal drug-free individuals, nausea and vomiting are more common symptoms along with drowsiness, lethargy, and a reduced physical activity. Patients may experience euphoria, and at increased doses side effects become more severe along with muscular rigidity and respiratory depression. Higher doses far in excess of those required to produce analgesia may lead to convulsions [3].

Respiratory Depression

Most opioids depress the respiratory center. The depression is a dose-dependent effect, which can be fatal. Opioids act to reduce the responsiveness of the brain stem respiratory centers to increased concentrations of arterial carbon dioxide. The subsequent effect of increasing concentrations of hydrogen ions as a result of dissociation of carbonic acid lowers blood pH that directly affects the pontine and medullary centers involved in regulating respiratory function.

Table 1 Selected opioids, the action at drug receptor, typical dose, half-life, and indication for use

Drug	Receptor action	Dose (mg)[a]	$T_{1/2}$ (h)[b]	Indication for use[c]
Naturally occurring				
Morphine	Agonist	5–20	2–3	Analgesia, moderate-to-severe pain, postoperative pain control
Codeine	Agonist	30–60	2–4	Analgesia, moderate-to-severe pain, cough suppressant
Semisynthetic				
Heroin	Agonist	5–10	0.03–0.05	Analgesia, moderate-to-severe pain, not available for therapeutic use
Hydromorphone	Agonist	2–4	1.5–4	Acute pain, chronic cancer pain
Naloxone	Antagonist	0.4–2	1–2	Used to reverse effects of opioids, such as heroin
Oxycodone	Agonist	5–20	4–5	Analgesia, relief of chronic pain
Synthetic				
Buprenorphine	Partial agonist	–	2–3	Analgesia, maintenance drug used to treat heroin dependence
Fentanyl	Agonist	0.05–0.2	1–6	Analgesia, strong pain, used in anesthesia as adjuvant
Methadone	Agonist	5–100	10–25	Analgesia, relief of chronic pain, maintenance drug used to treat heroin dependence
Pethidine	Agonist	50–100	3–10	Analgesia
Propoxyphene	Agonist	50–150	8–24	Analgesia
Tramadol	Agonist	50–400	4–8	Analgesia

[a] Common recommended therapeutic dose given orally
[b] Time for blood concentration to halve
[c] Most common medical applications

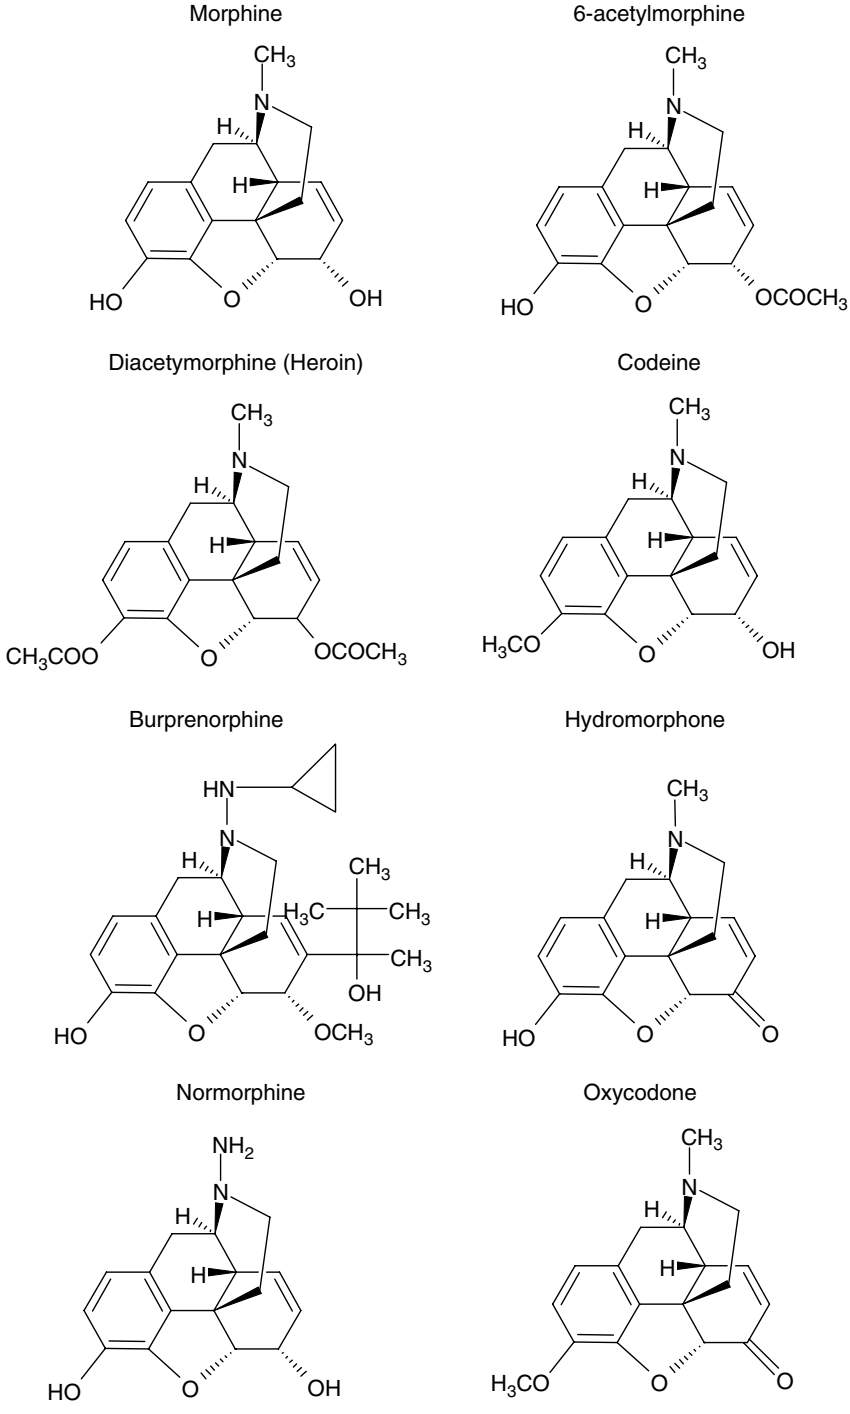

Figure 1 Morphine and selected structural derivatives of morphine

This has the effect of reducing the rate of breathing and with toxic amounts of morphine the rate may fall to 3 or 4 breaths per min instead of 12–16. Codeine is much less toxic than morphine and even in large doses does not appear to have the strong CNS depression characteristics of morphine.

Suppression of Cough Reflex

Opioids depress the cough reflex by a direct effect on the cough center in the medulla. There seems to be no relationship between the analgesic, respiratory-depressant action of opioids, and cough suppression; however, some opioids are more effective in depressing the cough reflex than others. Codeine and, to a greater extent, pholcodine are more effective than morphine in depressing the cough reflex [4, 5].

Nausea and Vomiting

Nausea and vomiting occur as a result of opioids affecting the chemoreceptor trigger zone in the brain. These effects are common initially but usually disappear with repeated administration. All clinically useful opioids produce some degree of nausea and vomiting [3]. Antiemetic drugs such as haloperidol and prochlorperazine are commonly used to treat vomiting in clinical situations. Metoclopramide is often useful if nausea and vomiting persist [5].

Effects on the Gastrointestinal Tract

Opioids cause varying effects on the gastrointestinal tract depending on the dose and the drug species. For example, morphine causes a marked increase in tone and a reduced motility, resulting in constipation, while codeine is less constipating than morphine and may be used to relieve abdominal pain. The emptying of gastric contents can also be delayed, which can further retard the absorption of drugs, a property shared by most opioids [3].

Tolerance and Dependence

Tolerance is a condition whereby after repeated administration, a given dose of a drug produces a decreased effect and increasingly larger doses must be taken to obtain the pharmacological effects observed with the original dose.

It is the level of tolerance that is of particular importance in heroin addicts. When the use of opioid becomes more regular, the intensity of response diminishes from one injection to the next. To produce the same response or as before, the dose of the drug has to be increased. Thus, in the course of days or weeks, tolerance may build up until many times a lethal dose can eventually be tolerated.

In humans, for example, an initial dose of 100–200 mg of morphine would be sufficient to cause profound sedation, respiratory depression, anoxia, and death; however, tolerant subjects can handle this and more. Tolerance diminishes rapidly (few days) after withdrawal so that a previously tolerated dose may prove fatal [4]. Tolerance to other opioids can also occur depending on the potency of the drug.

Dependence is a condition that has developed as a result of repeated drug administration and/or abuse. It is characterized by an overwhelming need to continue taking the drug, or one with a similar pharmacological property. Opioid analgesics, such as heroin, are abused for their euphoriant effects and dependence develops rapidly with regular use. Prolonged administration of heroin or morphine in a clinical environment is less likely to produce dependence as a result of therapeutic use and the dose of the drug can be reduced as the underlying pain decreases [6].

The abrupt withdrawal of opioids from persons physically dependent on them precipitates a withdrawal syndrome, the severity of which depends on the individual, the drug used, the size and frequency of the dose, and the duration of drug use. Opioid analgesics with some antagonist activity, such as buprenorphine, butorphanol, or pentazocine, may also precipitate withdrawal symptoms in patients who are dependent on opioid narcotics.

The onset and duration of withdrawal symptoms also vary according to the duration of action of the specific drug. Withdrawal symptoms may be terminated by a suitable dose of morphine or another opioid. Methadone is currently the most widely used pharmacotherapeutic agent for maintenance treatment of heroin addicts [7]. Methadone is effective in the suppression of withdrawal symptoms and in the reduction or elimination of an addict's compulsion to take heroin. The major objective of the methadone maintenance program is to achieve long-lasting stabilization of the user's drug dependence by providing

methadone indefinitely in doses large enough to produce a level of cross-tolerance that is sufficient to diminish the effects of ordinary doses of heroin.

Serious Adverse Effects/Toxic Reactions

Overuse of opioids can lead to depression of the CNS, slowing down breathing that may result in postural asphyxia or cardiorespiratory arrest. Intravenous drug abuse of heroin can lead to a number of other life-threatening side effects and/or complications. These can include neurological disorders, low blood pressure, swelling of the brain, stroke, death of vascular tissue, i.e., necrotizing angiitis, and nerve damage.

Intravenous drug users show a high susceptibility to infections and other diseases due to the suppression of their immune systems. The manifestation of infectious diseases in intravenous drug users plays a critical role in life-threatening complications for addicts. The factors below contribute to their diminished immune function. Factors such as needle sharing, unsafe sexual practices, under nourishment, poor hygiene, devastation of skin barrier, and the injection of unfamiliar substances into the body all increase the risk of acquired immune deficiency syndrome (AIDS), viral hepatitis, pneumonia, and tuberculosis. Infectious complications as a result of all these factors include endocarditis and septicemia, viral hepatitis, liver cirrhosis, meningitis, and tetanus [8].

Disposition of Opioids

Absorption and Metabolism

The extent of absorption depends on the type of opioid and the route of administration. When given orally, some opioids, particularly morphine and heroin, are removed from the portal circulation very efficiently by the liver and are metabolized extensively so that the amount reaching the systemic circulation is considerably less than the amount absorbed into the portal vein. This effect is known as *first-pass metabolism*. As a consequence the available dose is only a proportion of the dose taken. Oral administration of morphine is one-sixth as effective as parenteral administration. In contrast, codeine is well absorbed and quite active when given orally. In fact, codeine is approximately two-thirds as effective orally as parenterally [9]. Other opioids that are well absorbed orally include oxycodone and pethidine (meperidine).

Some opioids are also available as sustained release preparations (i.e., slow or controlled release). This means that a patient suffering from chronic pain may only have to take a tablet once or twice per day, which results in stable blood concentrations as a consequence of the drug's more predictable pharmacokinetics. Methadone and oxycodone rectal suppositories are useful alternatives to oral sustained release morphine preparations.

Opioids undergo extensive metabolism in humans. There are three main biotransformation pathways that have been established for the metabolism of opioids: hydrolysis, glucuronidation, and oxidation.

For example, following intravenous injection, heroin is rapidly converted (within seconds) to 6-acetylmorphine (6-AM), which is subsequently hydrolyzed (within minutes) to morphine. The conversion of heroin to 6-AM occurs both as a result of enzymes and spontaneous hydrolysis [10].

The majority of opioid metabolism in humans occurs in the liver through a process called *glucuronidation*; this occurs mainly in the liver and to a lesser extent in the intestine and kidneys [11, 12]. For example, morphine is conjugated primarily to morphine-3-glucuronide (M3G) and to a lesser extent the biologically active morphine-6-glucuronide (M6G) (Figure 2).

Excretion

Most opioids are excreted in the urine usually within the first 24 h following administration. The concentrations of conjugated metabolites usually exceed those of the parent drug and can be present for longer periods of time [13]. As with most pharmacokinetic parameters, there is great individual variation in the elimination half-life. This value is greatly prolonged in renal failure resulting in drug accumulation. Some opioids with long half-lives such as methadone can accumulate in tissues. Such accumulation can be toxic or even fatal if doses are not appropriately administered and the drug not given enough time to be cleared by the body. This can lead to prolonged respiratory depression and pronounced enterohepatic recirculation (excretion into the gastrointestinal system through bile followed by reabsorption) [14].

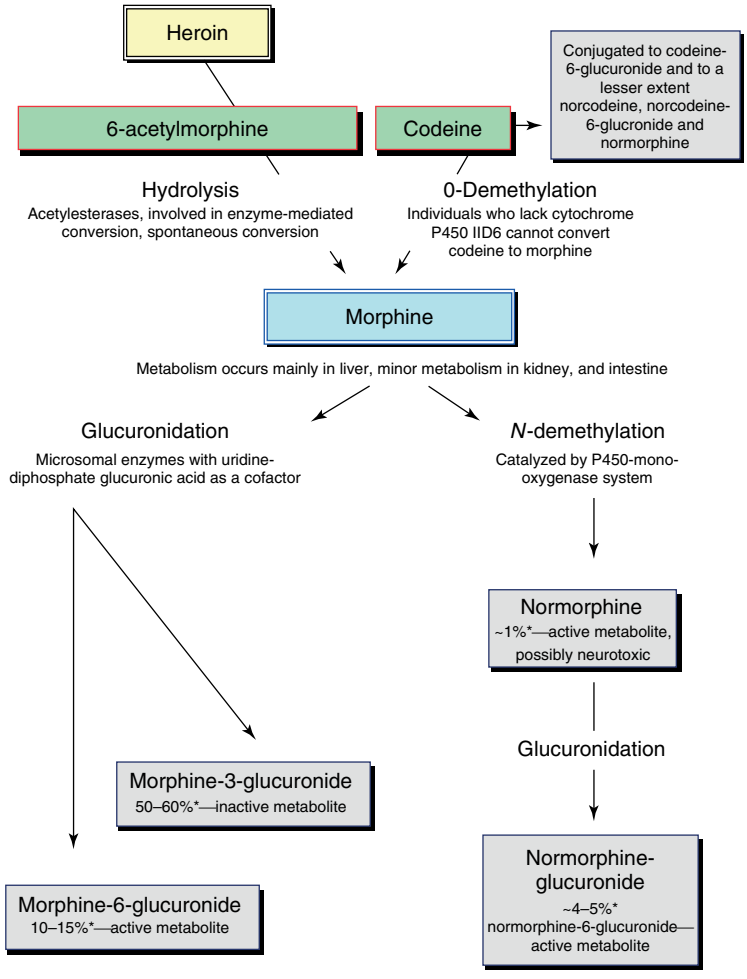

Figure 2 Fate of heroin, morphine, and codeine in humans (*urinary excretion, percent of dose)

Death from the Use of Opioid

The mechanism of death in opioid users is often uncertain, but it is likely to be multifactorial. For example, the use of heroin results in a wide range of adverse effects due to a variety of pharmacological and physiological responses to heroin, hypersensitivity reactions to the cutting agents or contaminants, and diseases associated with intravenous use. The largest numbers of deaths have been attributed to an acute reaction, whereby death occurs shortly after injection [15, 16]. Three overdose syndromes are recognized: death from profound respiratory depression, death from arrhythmia and cardiac arrest, and death as a consequence of severe pulmonary edema [17].

Death may also occur indirectly as a complication of unconsciousness. This is caused by a nonfatal dose, leading to airways obstruction in a setting of diminished respiratory function. Respiratory disease can also reduce the ability of person to tolerate a dose of opioid.

Fentanyl, methadone, oxycodone, hydrocodone, and morphine are the most common legal opioids known to cause death if misused [18].

Drug Interactions

Drugs such as alcohol, barbiturates, and benzodiazepines enhance the depressant effects of opioids on the CNS [19].

Opioid users frequently take benzodiazepines, e.g., diazepam, nitrazepam, etc., to reduce anxiety and to minimize the unpleasantness of any withdrawal symptoms. Drug combinations are therefore potentially serious complications in opioid users, particularly for heroin users. Data from a review of deaths in Victoria [20] show that benzodiazepines were the most prevalent drug group (~55%) and alcohol was present in ~30% of all heroin-related deaths. Amphetamines were also present in many cases (~13%) (*see also* **Benzodiazepines**).

Drugs such as the sedating antihistamines can prolong morphine metabolism, leading to increased respiratory depression. Phenothiazines, including promethazine and chlorpromazine, are also known to potentiate the effects of opioids by interfering with the metabolism of morphine [21].

One of the problems confounding the forensic toxicologist and pathologist is the relevance and interpretation of drug concentrations in different specimens following the use of opioids.

Interpretation of Toxicological Data; Difficulties for the Expert

The interpretation of postmortem tissue results is dependent upon number of considerations. These include chronic or acute use of the drug; concentrations of drug may be higher in those who are regular users, allowing some assessment of toxicity.

The route of administration is also important. Oral ingestion of opioids means that some of the efficacy of the dose is removed by the liver before the drug enters the blood stream (first-pass metabolism).

Another factor that will affect the interpretation of toxicology results includes the incidence of disease, i.e., AIDS, hepatitis, etc., presence of liver and kidney dysfunction as well as other immunological suppressive diseases that may affect metabolism and excretion of opioids and their metabolites. The accumulation of opioids may result in adverse effects and even death. Concurrent natural disease may predispose individuals to cardiovascular collapse and even unpredictable responses such as convulsions[3].

The presence of other drugs, the possibility of antagonism for one drug by another, and more often the additive or synergistic effects produced by the interaction of two or more depressant drugs must all be considered.

Tissue distribution and redistribution of opioids and its metabolites are also important in assessing postmortem contributions of opioids to adverse effects and death. The statistical data on body distribution and redistribution studies from fatalities associated with heroin, morphine, and other opioids use are invaluable in the evaluation of future toxicological findings (*see* **Postmortem Toxicology: Artifacts**).

Methods of Analysis

Initial Testing

Most clinical and forensic laboratories test for the presence of the class of opioids in the initial phase of their investigations. These immunoassays are effective for the more common opioids, such as morphine, codeine, and heroin metabolites. This technique using commercial kits enables all members of the class to be detected; however, owing to their differing immunoreactivities, the sensitivity to different opioids and their metabolites will vary, and for some may be quite poor. This applies particularly to the more synthetic opioids, e.g., oxycodone, buprenorphine, and methadone. Hence, more specific immunoassays are required to detect these drugs.

Initial tests are commonly conducted in urine since the concentration of the opioids or its metabolite is often much higher than blood. However, immunoassays designed for blood/plasma, or even oral fluid, are commercially available. An example of this is the enzyme-linked immunosorbent assay (ELISA).

When a class test is positive, further (confirmation) tests are required to detect the specific opioid (or its metabolite) that is causing this positive response (*see* **Toxicology: Initial Testing**).

Confirmation Testing

The definitive confirmation method in forensic toxicology is mass spectrometry. This can be gas chromatography/mass spectrometry (GC-MS) or liquid chromatography/mass spectrometry (LC-MS). liquid chromatography/tandem mass spectrometry (LC-MS/MS) or tandem LC-MS methods are now dominating the measurement for this class of drugs due

to its very high sensitivity and specificity and require very little or no chemical modification to permit chromatographic analysis.

Depending on the specimen, the metabolic pathway of the target opioid (or metabolite) will vary. When determining heroin, most if not all of the drug is metabolized to 6-AM and ultimately morphine, which are the main target metabolites, whereas for buprenorphine, the parent drug and metabolite norbuprenorphine are measured.

DIMITRI GEROSTAMOULOS

Oral Fluid Toxicology

Introduction

Over the last few decades, oral fluid has been evaluated as a diagnostic aid in medicine for determining oral and systemic disease markers as well as for monitoring the presence of numerous drugs, narcotics, and

hormones. The easy, rapid, and noninvasive nature of collection and the relationship between oral fluid and plasma levels make oral fluid a valuable clinical tool and an alternative specimen where blood sampling could be difficult to perform e.g., in children, in those with poor venous access, and in anxious subjects. Furthermore, it may provide a cost-effective approach for the screening of large populations. However, unlike plasma, the composition of oral fluid varies widely both intra- and interindividually. The result of any oral fluid analysis is influenced by many different factors, including the sampling protocol, which must be performed under standardized conditions.

Oral fluid analysis for drugs was first used almost 30 years ago for the purpose of therapeutic drug monitoring. At that time, it was already known that it is possible to predict the free fraction of a circulating drug by analysis of the corresponding oral fluid sample. Since abuse of drugs is now a widespread problem across society, its negative impact on performance and safety cannot be overstated. New strategies for drug testing should offer an effective solution to persistent problems such as the potential for sample adulteration and substitution and concerns over issues of individual privacy. These have resulted in the use of oral fluid for drugs of abuse testing in the workplace. Other areas of interest include testing of intoxicated drivers, monitoring illicit drug use in drug treatment, and oral fluid testing for drug detection in schools and in transportation and insurance industries. This article discusses developments in the field of collection devices, pharmacokinetics of common drugs of abuse in oral fluid, and recent technological advances and guidelines that increase the actual use of oral fluid testing in a legal context and its acceptance by the criminal justice system. Oral fluid testing is a reliable, new technology that overcomes many of the problems of older methods for drug detection.

Physiology of Oral Fluid

Oral fluid originates from three pairs of major salivary glands (parotid, submandibularis, and sublingualis) (Figure 1), a great number of minor salivary glands, the oral mucosa, and gingival crevices. The mixture of gingival crevicular fluid and mucosal transudate is referred to in the literature as “saliva”, “whole saliva”, and “oral fluid”. In addition to these fluids, oral fluid contains a certain amount of cell-debris arising from the epithelial cells of the mouth, together with food residues. Water is the major constituent (99%). Other components include mineral salts, proteins such as mucins (lipoproteins related to lubrification), and enzymes for digestion. The total protein concentration is less than 1% of that of plasma, but almost all of the organic compounds of plasma may be detected in oral fluid in trace amounts. The most important functions of oral fluid are as follows: (i) to moisten the mucous membranes of the upper aerodigestive tract in order to facilitate speech and solubilize food to ease swallowing; (ii) maintenance of oral health by controlling the bacterial flora of the mouth, and establishing defense and killing mechanisms; and (iii) to supply enzymes for food digestion, hormones, and other pharmacologically active compounds.

The detailed morphology of salivary glands has been reviewed by several authors [1–3]. The glandular tissue comprises acinar or tubular cells, specialized groups of cells arranged as endpieces surrounding a small central lumen. A narrow intercalated duct leads from the secretory endpieces to the striated ducts, which in turn drain into the secretory ducts to form a single main secretory duct that drains into the oral cavity.

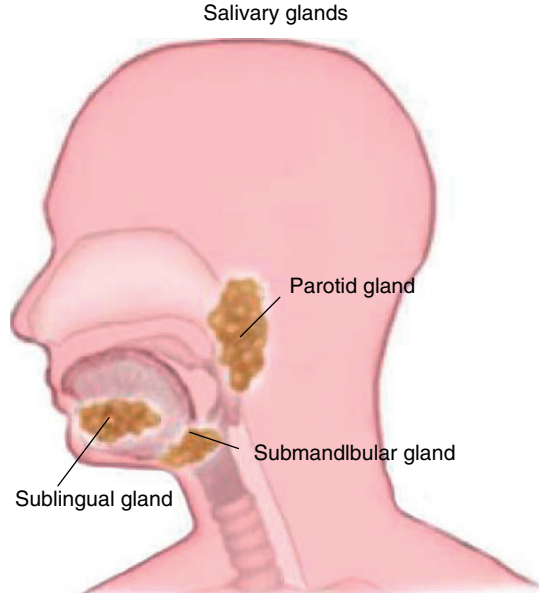

Figure 1 The three major salivary glands

Saliva contains the usual electrolytes of the body fluids. The formation of a primary saliva, isotonic compared to plasma, is situated in the endpieces of the salivary glands, and depends on the active transport of one or more of the principal ions (Na^+, Cl^-, K^+, and HCO_3^-) from the interstitial fluid to the acinar cells and the lumen. Water enters the lumen by osmosis. As this initial fluid moves down the ductal system of the salivary gland, both an active reabsorption of Na^+ and an active secretion of K^+ occur. The resulting saliva becomes increasingly hypotonic in the ductal system, the osmolality depending on the salivary flow (Figure 2). Generally, as the salivary flow increases, higher concentrations of Na^+ and Cl^-, and lower concentrations of K^+ are obtained in the final saliva. The excretion patterns of HCO_3^- are extremely variable among different glands. Usually, the bicarbonate concentration increases when the salivary flow increases, resulting in a higher salivary pH. The resting pH is about 6.8. Increasing the salivary flow results in a higher osmolality and a pH that approaches the pH of plasma or even slightly higher [4].

Under healthy conditions, adults approximately produce 500–1500 ml oral fluid per day. Salivary secretion is a reflex response controlled by both parasympathetic and sympathetic nerves. In addition, the fluids secreted by the various glands are considerably different from each other. The glandula parotis produces a serous fluid i.e., devoid of mucin, the glandula submandibularis a sero-mucous secrete, while the glandula sublingualis secretes a mucous saliva. Moreover, every type of salivary gland is stimulated to another degree by different stimuli, thus contributing differently to the total salivary production. Several factors are important such as the moment of the day (circadian rhythm), sex, age, nutritional or emotional state, and the type of the

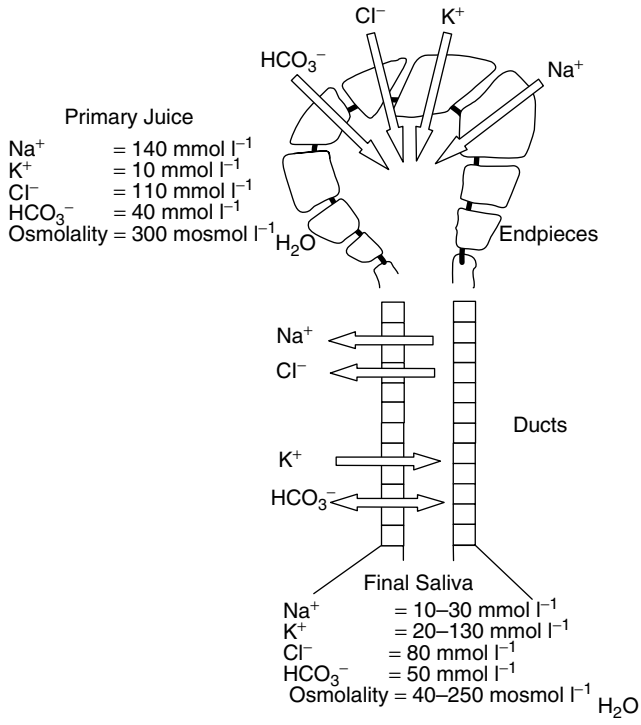

Figure 2 Hypothetical model of electrolyte transport to explain the two-stage formation of saliva. The isotonic primary fluid is produced in the secretory endpieces and is postulated to be either Cl^- rich or HCO_3^- rich. As the primary fluid passes down the gland duct system, Na^+ and Cl^- are reabsorbed while K^+ is secreted actively at somewhat lower rates. The result is the formation of a hypotonic final saliva, usually poor in NaCl and rich in $KHCO_3$ [Reproduced with permission from Ref. 4. © Central Police University Press, 1999.]

salivation stimulus [5]. Taste and olfactory stimuli, mechanical stimulation (chewing), pain, pregnancy-related hormonal changes, aggression, and sympathomimetic and parasympathomimetic drugs increase the salivary flow rate. Menopause-related hormonal changes, stress, antiadrenergic, and anticholinergic drugs decrease the salivary flow rate. An overview of the influence of different therapeutic drugs on salivation has been published recently by Aps and Martens [5]. For example, a typical β-adrenergic drug causes a viscous, protein and mucin rich, secrete. This type of saliva has a foamy appearance, while the volume produced is rather low. The cholinergic (parasympathetic) drug pilocarpine can be used, in some limited cases, to help patients complaining of dry mouth. Variations in salivary flow can also be affected, reversibly or irreversibly, by numerous physiological and pathological factors. This is the major difference between oral fluid and serum, in which the concentrations of the various components can only vary between narrow border values.

Mechanisms of Drug Transfer in Oral Fluid

Salivary glands have a high blood flow. Before any drug circulating in plasma can be discharged into the salivary duct, it must pass through the capillary wall, the basal membrane, and the membrane of the glandular epithelial cells, which is the rate-determining step. Different mechanisms are thought to occur: passive diffusion through the membrane, active processes against a concentration gradient, and filtration through pores in the membrane. Passive diffusion is by far the most common mechanism of drug transport, and is limited to nonprotein bound, nonionized molecules, with a molecular weight of less than 500 Da and a certain degree of lipophilicity. Oral fluid contains predominantly the parent drug because of the higher lipid solubility and, therefore, higher potential for passive diffusion.

In addition to the physicochemical properties of the drug (pK_a, lipid solubility, molecular weight, and spatial configuration) and the degree of plasma protein binding, this transport process is influenced by the pH of both media. Mathematical models have been developed for prediction of the saliva-to-plasma (*S/P*) drug concentration ratios for both acidic and basic drugs [6]. Especially for drugs with a pK_a close to the pH of saliva e.g., cocaine and most opiates, the degree of ionization changes drastically with small changes in pH, which is reflected in the *S/P* ratio. Calculated *S/P* ratios assuming a resting pH of 6.8 have been listed for a large number of substances [7]. The influence of salivary pH on the *S/P* ratio of many drugs is perhaps the reason why experimentally determined *S/P* ratios are different from the theoretical values. This phenomenon is also directly associated with the importance of the salivary flow and the collection protocol (with or without stimulation). Since only nonionized drugs can cross biological membranes and the pH of saliva is usually lower than the plasma pH (7.4), basic drugs usually concentrate in oral fluid due to ion-trapping. As such, oral fluid concentrations are much higher for these drugs than the corresponding plasma concentration [8–10]. In addition, in a controlled study with 3,4-methylenedioxy-*N*-methylamphetamine (MDMA), salivary pH appeared to be lowered by the actual intake of the drug itself, which explained to some extent the high *S/P* ratios observed, exceeding by far the theoretical calculated value [8, 11].

In contrast, there is very little partitioning of Δ^9-tetrahydrocannabinol (THC), the active ingredient of cannabis, between plasma and oral fluid. Since THC is a weak acid with a pK_a of about 9.5 and substantially plasma protein-bound, the calculated *S/P* ratio is 0.1. In practice, it has been demonstrated that shortly after drug use by smoking, oral ingestion, or nasal insufflation (e.g., heroin, methamphetamine, marijuana, and cocaine), contamination of the oral cavity can lead to dramatically elevated oral fluid concentrations of the parent drug, clearly inflated relative to concomitant blood levels. Only after a period of 2 h the oral fluid levels more approximately reflect blood levels. For THC, similarity in time profiles between oral fluid and plasma occur. This is possibly due to reserves of THC deposited in the oral mucosa that are leached out with time [12].

Collection of Oral Fluid

Any potential application for oral fluid testing needs a thorough understanding of the chosen collection method in order to interpret test results. In addition, the choice of a collection protocol should not only depend on the ease-of-use, but also the analytical considerations have to be taken into account. Common

methods of oral fluid collection are spitting, draining, suction, and collection on various types of absorbent swabs.

Since drug concentrations can be decreased when increasing the salivary flow, it might be advantageous to collect oral fluid without stimulation. Spitting itself is usually a sufficient stimulus to elicit a flow but the sample volume is often insufficient and the intra- and intersubject variability is large. Moreover, it is not a well-accepted and hygienic procedure for donor and acceptor and it is time-consuming in subjects suffering from dry mouth caused by stress, smoking, and the use of amphetamines and other psychotropic drugs that pharmacologically reduce salivation. In these circumstances, the flow can be stimulated mechanically (by placing paraffin wax, Teflon™, rubber bands, or chewing gum in the mouth) or chemically (lemon drops or citric acid crystals) to obtain a cleaner, more abundant specimen. A mechanical stimulus stimulates a flow of approximately 1–3 ml min^{-1}; citric acid stimulation may produce flows from 5 to 10 ml min^{-1}. It is also suggested that stimulation might decrease the intersubject variability [13]. Stimulation of salivary flow is not without drawbacks though. Different studies have confirmed that stimulation of oral fluid (citric acid) reduces drug concentration [10, 14–16]: two- to threefold for codeine and methamphetamine and fivefold for cocaine. These changes are attributed to a dilution effect by the increased output of oral fluid as well as a possible pH effect.

To allow the use of oral fluid testing for drug screening of large populations, a variety of devices have been marketed over the years. They promote an easy, quick, and reproducible collection and a cleaner specimen that is more suitable for analysis. As a general rule, they consist of a sorbent material that becomes saturated in the mouth of the donor, and after removal, the oral fluid is recovered by centrifugation or by applying pressure. Commercial devices include Omni-Sal® (Cozart Biosciences Ltd., Abingdon, UK), Salivette® (Sarstedt AG, Rommelsdorf, Germany), Intercept® (OraSure Technologies, Bethlehem, PA, USA), Finger Collector® (Avitar Technologies, Inc, Canton, MA, USA), ORALscreen™ (Avitar Technologies, Inc,), and Quantisal™ (Immunalysis Corporation, Pomona, CA, USA). Significant differences are reported in percent recovery from the sorbent material for various drugs and a large variability in the ultimately measured oral fluid concentrations [16]. For some devices, e.g., the Quantisal device, excellent recoveries were obtained [17], whereas for other devices, e.g., Salivette, a substantial sequestration on the cotton roll could be observed [18–20]. A typical example is the observation that THC remains bound to the sampling device and that an organic solvent is needed to release it [21–23]. A modification of the sampling procedure for the Intercept® collector (Figure 3), consisting of the addition of 2 ml of methanol to the elution buffer, resulted in complete recovery of THC over a large concentration range [22]. In addition, various pretreatment methods of the spitted samples can lead to significant differences in concentrations between collection protocols [23, 24]. The most recent study on this topic studied the recovery using three different collection devices supplied by Cozart, Immunalysis, and Microgenics [25]. Drugs studied were THC, benzodiazepines, methamphetamine, and morphine. Of the three systems studied, only the Cozart product gave acceptable recovery of THC from drug-spiked oral fluid.

Significant differences in analyte stability were observed for some compounds, e.g., THC and 6-AM (6-acetylmorphine), depending on the storage conditions and the sampling device used [16, 26–28]. In general, the presence of a stabilizing buffer guarantees the stability of the analytes for longer periods of time. The addition of buffer results in difficulties in estimating the actual volume of oral fluid collected [16, 25, 29]. It has been shown that for the Intercept® device, reliable quantitative results can still be obtained when applying a gravimetric

Figure 3 Example of an oral fluid collection device: Intercept®. After gently wiping the collector pad between gum and cheek for approximately 2 min (as a kind of toothbrush), the device is placed in the supplied vial, which contains a stabilizing buffer solution, and sealed. After centrifugation in the laboratory, the recovered fluid can be transferred and analyzed

determination of the amount of oral fluid [19]. An additional problem is that, even when using a collection device, the amount of oral fluid collected can be inadequate for analysis [20].

Pharmacokinetics and Interpretation

A large number of key publications contain valuable concentration kinetics data for oral fluid after controlled administration of the substance to volunteers. An excellent review on the pharmacokinetics of drugs in oral fluid has been recently published by Drummer [30].

Analytical Procedures

A comprehensive review of the analytical methods from 2000 to 2006 for the analysis of drugs of abuse in oral fluid, has recently been submitted [31]. A correct procedure for forensic toxicological analysis involves two different methods. In general, after application of an immunoanalysis technique, a chromatographic method is performed: the first allows for a preliminary monitoring of a large number of samples in a reduced period of time, while the second step provides the required specificity for confirmation. For oral fluid, the amount of matrix collected is smaller when compared to urine and blood and the target range of concentrations is generally lower than in the corresponding urine sample.

The assays routinely used for screening of blood and hair, have a high sensitivity and cross-reactivity for the parent drug and are therefore also advantageous for the analysis of drugs in oral fluid. Several microtiter plate enzyme immunoassays (EIA) have been evaluated for the screening of oral fluid specimens; they only need a limited amount of specimen [25, 28, 29, 32–41]. Erroneous quantitative results might be caused by eating or drinking shortly before sampling or by the collection technique itself, e.g., interference of citric acid or the cotton roll [12, 16]. Commercially available EIA kits are designed for use with specific collection devices. However, it was shown that the application of certain EIA kits was not restricted to the use with one single type of collection method through the validation of sensitive and specific assays [25, 39–41].

As for the confirmation analysis, oral fluid can be extracted and analyzed in the same manner as other biological fluids, such as blood. Although gas chromatography (tandem) mass spectrometry GC-MS(MS) is regarded as the standard technique for drug testing in oral fluid [21, 42], the use of liquid chromatography (tandem) mass spectrometry (LC-MS(MS)) for the analysis of this sample matrix has steadily increased [43–50]. Analytical sensitivity is a significant concern when conducting oral fluid drug testing. Decreased salivary secretion is a side effect of many drugs including stimulants yielding small volumes of oral fluid available for analysis. In addition, metabolite concentrations can be lower than parent drug concentrations, further elevating sensitivity concerns [30].

As oral fluid contains considerably less proteins and lipids compared to blood or plasma, it was suggested that this allows an easier and faster analysis [51]. However, in view of the higher protein, amino acid, and especially mucin content of oral fluid relative to the urine matrix [52], the development of fast and easy sample preparation methods could be hampered [51, 53]. In addition to the endogenous substances present in oral fluid, specific collection devices mostly include a preservation buffer containing other compounds such as stabilizing salts, nonionic surfactants, and antibacterial agents. Their presence can significantly impact precision and accuracy of subsequent LC-MS-MS measurements through a phenomenon called *ion suppression* or *ion enhancement* [54].

Cannabinoids

Cannabis is the collective term for the psychoactive substances of the *Cannabis sativa* plant and one of the most frequently used illicit drugs in the Western world. THC (Figure 4), the primary psychoactive analyte, is found in the plant's flowering or fruity tops, leaves, and resin. Cannabis is usually smoked but can also be ingested in preparations such as tea and cake. The composition of the cannabinoids in oral fluid samples remains a topic of interest for several research groups. For several years, the only compounds detected in oral fluid after smoking of cannabis were THC, cannabidiol, and cannabinol. As mentioned above, THC has a calculated *S/P* ratio of approximately 0.1 [7]. The Substance Abuse and Mental Health Service Administration (SAMHSA) proposes a screening cutoff of 4 ng ml^{-1} for THC as the target analyte for the initial screen and 4 ng ml^{-1}

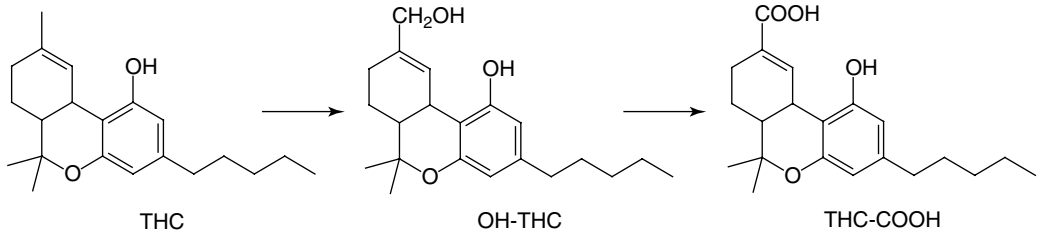

Figure 4 Major metabolic route for Δ^9-tetrahydrocannabinol (THC)

of THC in the confirmation analysis [55]. However, a recently published document by Standards Australia refers to target concentrations of 25 and 10 ng ml^{-1} for screening and confirmation analysis, respectively [56] (Table 1).

Since 2000, five studies investigating the pharmacokinetics of THC in this matrix have been published [12, 48, 57–59]. Substantial differences in THC levels were observed depending on the sampling method. In the studies by Niedbala *et al.* and Laloup *et al.*, oral fluid samples from volunteers having smoked a "joint" were collected with the Intercept® device and analyzed using GC-MS/MS (limit of quantification (LOQ): 0.2–0.25 ng ml^{-1}) or LC-MS/MS (LOQ: 0.1 ng ml^{-1}) [48, 57–59]. Average peak concentrations ranged from 31 to 596 ng ml^{-1} 15–20 min after smoking. Interestingly, doubling the THC dose and removal of tobacco did not result in a significant increase in the observed THC concentrations in oral fluid. A typical concentration profile for the detection of THC in these oral fluid samples is shown in Figure 5.

Collection of oral fluid by spitting after citric acid stimulation yielded much higher THC concentrations

[c] Approved target concentrations by Standards Australia for the detection and quantification of drugs in oral fluid, intended for workplace, medico-legal and court-directed issues [56]

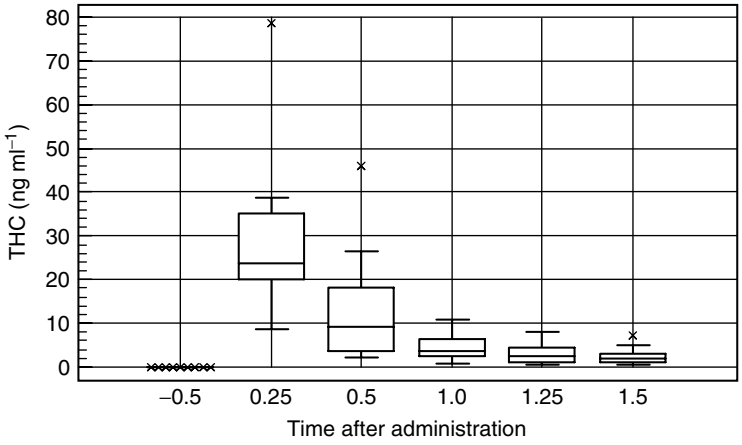

Figure 5 Box- and whisker plots of THC levels in preserved oral fluid samples from nine healthy volunteers following smoking of a single marijuana cigarette. Oral fluid samples were taken with Intercept® 0.5 h prior to smoking and at 0.25, 0.5, 1, 1.25, and 1.5 h after smoking. Concentrations plotted on the *Y*-axis are expressed as ng ml^{-1}. The central box represents the values from the lower to upper quartile (25–75 percentile). The middle line represents the median. The horizontal line extends from the minimum to the maximum value, excluding "outside" (not present) and "far out" values (cross marker) that are displayed as separate points [Reproduced from Ref. 48. © Elsevier, 2005.]

relative to the former collection method [12]. As discussed previously, this is probably due to the fact that THC was only partially recovered from the Intercept® sampling device [22]. In citric acid stimulated oral fluid, peak concentrations of 864 and 4167 ng ml^{-1} were observed 0.2 h after smoking of a 'joint' containing 1.75% (15.8 mg) and 3.55% (33.8 mg) THC, respectively. In addition, a close relationship between oral fluid and plasma concentrations of THC was observed, possibly due to reserves of THC deposited in the oral mucosa that is leached out with time. This was confirmed in a study by Ramaekers *et al.* [60], where a strong and linear relation between THC in serum and oral fluid was obtained after single doses of 250 and 500 μg kg^{-1} THC by smoking.

Irrespective of the collection method, the concentrations of THC in oral fluid appear to decline in a biphasic manner. After cannabis administration, peak concentrations observed in the first oral fluid specimen are attributed to initial contamination of oral fluid during smoking. The elevated THC concentrations in oral fluid due to this initial direct contamination dissipate rapidly (within 30 min) followed by a second phase of decline of oral fluid-sequestered THC in a similar manner as plasma THC. Estimates of the initial half-life of THC show a mean value of 21 min. Estimates of the terminal half-life of THC show a mean of 122 min [59]. Oral fluid concentrations generally declined below 1 ng ml^{-1} after 12–16 h.

After the oral consumption of 20–25 mg THC in the form of brownies, much lower peak oral fluid concentrations of about 4 ng ml^{-1} at 1–2 h were observed [57]. Concentrations declined rapidly and were below the limit of detection (LOD) of the GC-MS/MS by 16 h.

One additional issue in the use of oral fluid for drug screening is the possibility of passive contamination. Indeed, two recent studies demonstrated the presence of detectable THC concentrations in oral fluid from volunteers exposed passively to cannabis smoke in an unventilated room (area 36 m^2) [59] or van (15.3 m^2) [58]. Concentrations ranged from 7 to 26 ng ml^{-1} (mean 13 ng ml^{-1}) and from 4.5 to 7.5 ng ml^{-1} (mean 6.2 ng ml^{-1}), respectively. THC concentrations declined rapidly and became negative within 30–45 min. However, oral fluid collector devices exposed to circulating air inside the van but not to oral fluid were also highly contaminated with THC. Further analysis revealed that, when the subjects were removed from the space where passive exposure occurred prior to sample collection, the THC concentrations in oral fluid specimens were only minimal (0.0–1.2 ng ml^{-1}). Considering a SAMHSA cutoff of 4.0 ng ml^{-1}, passively exposed subjects are

considered to be negative by avoiding the environmental contamination.

Moore *et al.* and Day *et al.* recently demonstrated the presence of the principal urinary metabolite, 11-nor-9-carboxy-Δ^9-tetrahydrocannabinol (THC-COOH) in the oral fluid matrix [61, 62]. To approach the required sensitivity, oral fluid samples were analyzed using GC-MS/MS [61] or two-dimensional GC-MS [62]. Day *et al.* reported an LOQ of 10 pg ml^{-1} and concentrations up to 240 pg ml^{-1} present in the oral fluid specimens, previously identified as positive for THC. In a study involving a frequent marijuana user, THC-COOH could be detected in all samples collected at 15 min until 8 h after smoking (range 51–134 pg ml^{-1}) [62]. Interestingly, the last sample was the highest in concentration, which suggests that the increase may be reflective of deposition of this metabolite in blood. Therefore, THC-COOH could be a potential long-term marker of marijuana use since it is unlikely to come from oral contamination as is the case for parent THC. In another report of these authors, the same GC/GC-MS method was used to study the contribution of THC-COOH to enzyme-linked immunosorbent assay (ELISA) commonly used for oral fluid screening [63]. They have shown that the inclusion of this metabolite in the confirmation profile for cannabinoids in oral fluid increases the confirmation rate of the immunoassay result by at least 9.7% and minimizes the argument for passive contamination of the oral cavity.

Amphetamines

Amphetamine, methamphetamine, and the designer amphetamines are synthetic stimulants, with similarities to some naturally occurring weak stimulants such as ephedrine and pseudoephedrine (*Ephedra* species). The β-phenylisopropylamine backbone is the structural basis for many of the sympathomimetic amines. Substitutions on the nitrogen and the ring system account for most of the structural variations and differences in stimulating and euphoric effects. MDMA ('ecstasy') is increasingly used for its desired feelings of emotional closeness and sensory pleasure in the context of large, all-night dance parties where the drug is regarded as safe by the party visitors, and where multiple doses are consumed during the night [64, 65]. The calculated theoretical *S/P* ratios for amphetamine, methamphetamine, and MDMA are 2.2, 4.0, and 3.9, respectively [66]. However, the experimental values obtained always exceeded the theoretical value, possibly due to the effect of the salivary pH as discussed previously.

Proposed SAMHSA screening cutoff values are 50 ng ml^{-1} for *d*-methamphetamine as the target analyte and confirmation cutoff values are 50 ng ml^{-1} for amphetamine, methamphetamine, MDMA, MDA (3,4-methylenedioxy-*N*-amphetamine), and MDEA (3,4-methylenedioxy-*N*-ethylamphetamine). In addition, when methamphetamine is present in the specimen, it must also contain amphetamine at a concentration $\geq$ LOD. Standards Australia established similar screening cutoff values; however, the confirmation cutoffs were lowered to 25 ng ml^{-1} for amphetamine, methamphetamine, MDMA, and MDA (Table 1). In two controlled studies [8, 9] where healthy volunteers were administered a single dose of MDMA, the patterns of oral fluid and plasma MDMA concentration–time profiles agreed well. However, the intersubject variability was substantially higher for oral fluid [8, 9]. Peak MDMA concentrations of 1728–6510 ng ml^{-1} at 1.5 h after administration of 100 mg MDMA were observed, declining to a mean concentration of 126 ng ml^{-1} at 24 h [8]. A lower mean peak concentration of 1215 $\pm$ 944 ng ml^{-1} was noted by Samyn *et al.* 2 h after administration of 75 mg MDMA [9]. Levels of MDMA averaged 526 $\pm$ 372 ng ml^{-1} at 5 h after administration. Oral fluid samples were collected by spitting, without any kind of stimulation, and the salivary pH was determined for MDMA users and control subjects in one study [8]. MDMA levels exceeded the plasma concentrations by, on average, a 10-fold at peak concentrations declining to a lower more constant value (4–7) after 5–24 h. MDA, the metabolite of MDMA, was also present in these oral fluid samples, with concentrations representing about 4–5% of the concentration of oral fluid MDMA, as was also observed for plasma in this study [8].

One study documents the presence of MDMA and MDA in oral fluid samples collected with the Intercept® device [54]. Specimens were collected 1.5 and 5.5 h after the administration of a single dose of 75 or 100 mg MDMA. Analysis using LC-MS/MS (LOQ: 2.0 ng ml^{-1}) revealed a median MDMA concentration of 448 and 316 ng ml^{-1} after 1.5 and 5.5 h, respectively, in the preserved oral fluid samples. The corresponding MDA concentrations remained quite low, with a median concentration of 7.7 and 16.5 ng ml^{-1} respectively.

There is only one recent report dealing with methamphetamine and amphetamine pharmacokinetics in oral fluid after a controlled administration of methamphetamine [10]. Oral fluid specimens were collected using citric acid candy stimulation or Salivette® cotton swabs treated with or without citric acid after a single 10- or 20-mg dose of sustained release methamphetamine. Significant higher concentrations were obtained in oral fluid samples collected with neutral cotton swabs in comparison with those obtained from citric acid-treated swabs and after citric acid candy stimulation. Following citric acid candy stimulation, mean peak methamphetamine concentrations were 106 ± 25 and 192 ± 121 ng ml^{-1}, respectively, occurring 4–8 h and 2–12 h postdose. All citric acid candy stimulated oral fluid specimens collected at 24 h after drug administration were above the LOQ of the GC-MS method for methamphetamine (2.5 ng ml^{-1}). When using the SAMHSA-proposed cutoff values, only one of 13 individuals tested positive 24 h after a single methamphetamine dose. Oral fluid methamphetamine concentrations were double than those observed in plasma. However, a considerable within- and between-subject variability contributed to the poor observed correlation between plasma and oral fluid methamphetamine concentrations. Amphetamine, as the metabolite of methamphetamine, was not always detected in oral fluid specimens following administration of methamphetamine. When present, concentrations were about one-tenth that of methamphetamine.

Cocaine

Cocaine is an alkaloid obtained by extraction of the leaves of *Erythroxylon coca*, a plant that grows at 1000–2000 m elevations in the Andean mountains under warm tropical conditions. Cocaine has been used by the Peruvian Indians for centuries for the well being and increased endurance it produces after chewing the leaves of the plant. In the late nineteenth century, it was used medically as an anesthetic. It was not until the late 1960s that the recreational use of cocaine became a significant social problem in the Western world, especially in the US [67–69]. Cocaine is sold on the street in two forms: the hydrochloride (HCl) salt and the free base form "crack". Street purity ranges from 1 to over 90%, with cocaine HCl mainly used for intravenous injection and nasal insufflation, and the free base used for smoking (volatilization with a glass pipe and heat).

The metabolism of cocaine has been thoroughly studied (Figure 6) [67, 70, 71]. The main primary metabolites of cocaine are benzoylecgonine (BE), formed by chemical hydrolysis and enzymatic hydrolysis by a liver methylesterase, and ecgonine methyl ester (EME), formed by enzymatic hydrolysis by liver carboxylesterases and plasma butyrylcholinesterase. Both inactive metabolites are further metabolized to ecgonine [72]. Norcocaine is a minor metabolite in humans.

Cocaine is a highly lipophilic, basic drug and has a pK_a of 8.6. The theoretical *S/P* ratio calculated

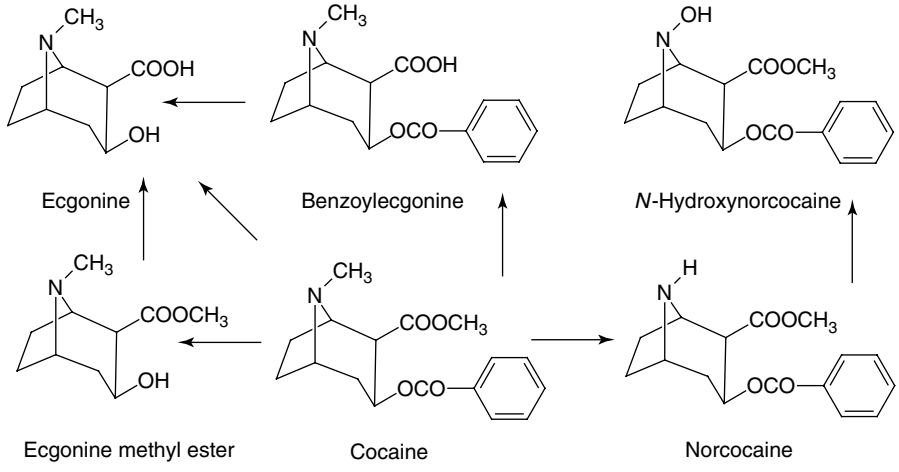

Figure 6 Main metabolic pathways of cocaine

for a salivary pH of 6.8 is 3.8 [7]. When assuming a pH in the range of 6.8–7.8 (depending on the nature of stimulation), *S/P* ratios of 3.82–0.44 were calculated. SAMHSA-proposed oral fluid cutoff values are 20 ng ml^{-1} for cocaine metabolites for screening assays and 8 ng ml^{-1} for cocaine or BE in confirmation analyses. Higher cutoff concentrations for cocaine and metabolites of 50 and 25 ng ml^{-1} for screening and confirmation, respectively, were adopted by the Australian standard (Table 1).

The Cone group published the most complete study on cocaine excretion in saliva in 1997 [73]. Cocaine appeared in saliva rapidly following different administration routes. Contamination of the oral cavity after smoking and sniffing was variable but significant during the first hours after administration of a single low dose of cocaine, resulting in high *S/P* ratios. BE and EME usually appeared in oral fluid between 0.08 and 1 h after administration. Typically, cocaine concentrations exceeded metabolite concentrations over the first 2 h, rapidly declining, sometimes below metabolite concentrations within 4–6 h. Anhydroecgonine methylester (AEME) is a pyrolysis product that also appears in oral fluid in high concentrations; it can be used as a marker of cocaine smoking.

Following repeated oral cocaine administration, the obtained pharmacokinetic parameters were generally comparable to those reported from acute dosing studies [74].

A study on the disposition and elimination of cocaine in self-reported users of cocaine (0.1–2 g smoked cocaine daily) showed cocaine oral fluid concentrations on average 2.4-fold higher than those found in plasma [75]. These findings suggest a prolonged elimination of cocaine in active street users than in occasional users, though the half-life of its main metabolite BE remains similar.

Opiates

The opiates are a large family of drugs with a mechanism of action and pharmacological activities related to morphine. Potent opiates such as morphine are particularly important in medicine due to their ability to relieve moderate to severe pain. Codeine is one of the most widely used opiates, and is easily available in some countries in low dose over-the-counter preparations with weak analgesic properties and as a cough suppressant. A number of synthetic opiates have been developed that resemble morphine when viewed as a 3D image on the receptor, although at first glance they do appear quite different.

Heroin is widely available as an illicit drug, and is produced in clandestine laboratories by synthetic acetylation of morphine from crude extracts of the exudates from the opium poppy (*Papaver somniferum*). Heroin is more lipophilic and crosses the blood–brain barrier more rapidly than morphine resulting in more intense euphoric effects. Heroin is injected intravenously (usual dose 10–15 mg), snorted or inhaled (by smoking the free base or inhaling the vapors of heated powder). Intravenous injection of heroin is common and is the fastest way to deliver the drug to the brain. Peak heroin plasma concentrations are obtained within 2 min, and are no longer detectable after 30 min. Heroin is almost immediately metabolized to 6-AM, which is detectable at 1 min and peaks at 5 min and which is rapidly transformed to morphine (Figure 7).

Heroin has a pK_a of 7.6, which results in variable *S/P* ratios, highly depending on the salivary pH. Morphine is less lipid soluble than heroin. It has a pK_a of 8.1 and is for about 65% bound to plasma proteins. The theoretical *S/P* ratio, assuming a salivary pH of 6.8, is 1.22. Since codeine has a pK_a of 8.2 and is only bound to plasma proteins to a minor extent, it has a higher theoretical *S/P* ratio of 3.32.

As for cocaine, heroin, and its metabolites 6-AM and morphine are detected in oral fluid after administration of heroin by different routes; concentrations are depending on the route of administration and on the salivary pH. For opiates, their levels in oral fluid appear to mimic blood levels suggesting that comparable results between these matrices can be achieved [76, 77]. The proposed SAMHSA cutoffs are 40 ng ml^{-1} for screening and confirmation, except for 6-AM, for which a 10-fold lower confirmation cutoff value was suggested. Laboratories are also permitted to initial test all specimens for 6-AM using a 4 ng ml^{-1} cutoff. Standards Australia recommends a screening target concentrations of 50 ng ml^{-1} with confirmation at 25 ng ml^{-1} for morphine and codeine and 10 ng ml^{-1} for 6-AM (Table 1).

The number of studies concerning heroin are limited. Heroin is detected within minutes in oral fluid following nasal insufflation (snorting). A 12-mg

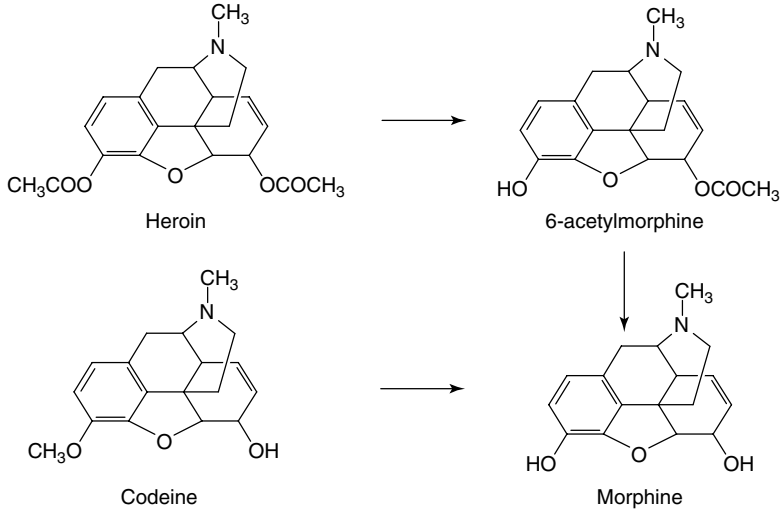

Figure 7 Major metabolic route for heroin

dose resulted in a peak heroin concentration of 300 ng ml^{-1} in oral fluid and it was detectable for about 1 h (LOD: 1.0 ng ml^{-1}). 6-AM and morphine were rapidly detected in oral fluid peaking at 60 and 25 ng ml^{-1} at 10 and 60 min, respectively [78]. Two subjects given 2.6–10.5 mg smoked doses revealed peak concentrations of heroin greater than 3000 ng ml^{-1}, but less than 10 ng ml^{-1} beyond 60–120 min. Much lower peak concentrations were detected after i.v. injection of heroin: up to 30 ng ml^{-1} after 3–12 mg doses. The mean *S/P* ratio was approximately 1 [76].

Intramuscular morphine sulfate at doses of 10 and 20 mg resulted in a peak concentration of 11 and 38 ng ml^{-1} in two subjects, respectively, using a stimulated collection process [79]. At 24 h, concentrations were barely detectable.

Codeine presence in oral fluid has been studied in four studies [15, 37, 80, 81]. Screening/confirmation cutoffs of 20/20 [80] and 30/40 ng ml^{-1} [37] have been proposed based on two studies with volunteers given 60 and 120 mg codeine.

Substantially different pharmacokinetic parameters were obtained for codeine with different collection methods [15]. After stimulation with citric acid, mean peak concentrations of 556 ± 301, 639 ± 64, and 1599 ± 241 ng ml^{-1} were observed following 30 mg liquid codeine phosphate and 60 and 120 mg codeine sulfate capsules, respectively [15, 81]. Although a high intra- and intersubject variability was observed, the time course of codeine concentration in oral fluid was similar to that seen in plasma [81]. Generally, codeine concentrations were higher in oral fluid than in plasma and codeine could be detected 5–9 h longer in oral fluid than in plasma when the LOQ of the GC-MS method (2.5 ng ml^{-1}) was used as cutoff value. Norcodeine was also detected in small amounts in oral fluid.

Dihydrocodeine is a weak narcotic analgesic and used as an antitussive [82]. Following a single 60-mg dose, peak oral fluid concentrations ranged from 423 to 1421 ng ml^{-1}, reached 2–4 h after dose. The concentrations of this compound in oral fluid samples from 20 chronic users (0.4–2.7 g daily) within 24 h after the last dose ranged up to 66 154 ng ml^{-1}. Samples were collected with the Salivette®. Dihydrocodeine was detectable until about 24 h after the last use with an LOD of 5 ng ml^{-1}.

Finally, one study was conducted to determine the concentrations of morphine in oral fluid and urine following the consumption of commercially available poppy seeds [83]. Oral fluid samples from volunteers who ingested in addition to one poppy seed bagel as many possible poppy seeds as possible (amounts ranging from 9.82 to 20.82 g), tested positive up to 1 h after ingestion with a concentration greater than the proposed SAMHSA confirmation cutoff for morphine.

Benzodiazepines

The benzodiazepines are a large class of prescribed drugs, used widely for different medical conditions such as the treatment of insomnia (mostly short-acting analogues), the treatment of anxiety-related conditions (mostly longer acting analogues), as muscle relaxants, and as anticonvulsants [84–86]. Some of them are abused, either by themselves or in combination with other drugs, particularly the narcotic analgesics (opiates). Their ability to suppress withdrawal symptoms and to boost the effects of heroin have made them a favored drug type among the drug-using population [87, 88]. They are also abused by cocaine users to increase the seizure threshold [84].

The benzodiazepine structure is based on the diazepine ring fused to benzene, with the nitrogens usually in the 1,4 positions. Substitution leads to varying degrees of metabolic stability, pharmacological potency, and lipid solubility (Figure 8). The 7-nitro substituted 1,4-benzodiazepines, such as flunitrazepam, are often abused. Somewhat newer analogues are based on the diazolo- and triazolo-ring types and include alprazolam and triazolam, very potent benzodiazepines requiring much lower doses. Zolpidem is an imidazopyridine derivative, with a chemical structure unrelated to benzodiazepines.

In general, *S/P* ratios below 1 are expected due to the extensive plasma protein binding of benzodiazepines.

Until now, five recent studies have examined the presence of benzodiazepines in oral fluid. Samyn *et al.* reported peak concentrations of flunitrazepam (0.29–0.58 ng ml^{-1}) and its metabolite 7-aminoflunitrazepam (0.94–3.05 ng ml^{-1}) at 1–4.5 h following the administration of 1 mg flunitrazepam to four subjects [89]. Owing to the extremely low concentrations of flunitrazepam and its metabolite in oral fluid, GC-MS in chemical ionization mode was used (LOQ: 0.10 and 0.15 ng ml^{-1}, respectively). Sodium fluoride preservative was required to detect flunitrazepam in the oral fluid specimens. These authors proposed a cutoff value of approximately 0.25 ng ml^{-1} of 7-aminoflunitrazepam in oral fluid to detect use of flunitrazepam within the last 6 h.

Following the ingestion of a single oral dose of 2.5 mg lorazepam to one volunteer, a peak concentration of 18 ng ml^{-1} was observed in oral fluid after 15 min of intake. Oral fluid samples were still positive for this compound after 8 h (0.3 ng ml^{-1}) [90].

Peak concentrations of midazolam in oral fluid samples following a single 2 mg bolus of the drug to three patients ranged from 1.42 to 13.98 ng ml^{-1} after 10–40 h [20]. However, substantially higher concentrations of midazolam in these specimens were obtained after continuous infusion of the drug.

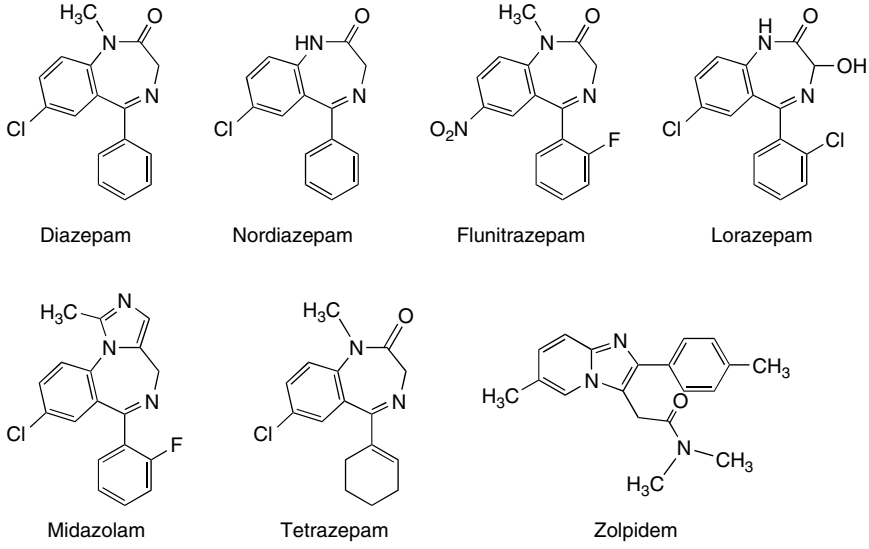

Figure 8 Structures of selected benzodiazepines and zolpidem

Oral administration of a single 50-mg dose of tetrazepam to one volunteer produced a peak concentration of 6.6 ng ml^{-1} after 150 min, which is approximately the time of peak plasma concentration [91]. Oral fluid tested positive for tetrazepam over 8.6 h with an LOQ of the LC-MS/MS method of 0.03 ng ml^{-1}.

After oral administration of 10 mg zolpidem to two subjects, peak concentrations of this drug were obtained after 150 min (53.5 ng ml^{-1}) and 180 min (75.7 ng ml^{-1}), respectively [92]. Oral fluid still tested positive for zolpidem at 8 h (9–15 ng ml^{-1}).

As suggested, an *S/P* ratio lower than 1 was obtained for the studied benzodiazepines [90–92].

Applications

Oral fluid drug testing has been used as an alternative matrix to blood and urine in clinical and forensic toxicology [93]. Owing to its particular advantages, interest in the use of oral fluid testing for drugs in the workplace [29, 94] and at the roadside [23, 95–97] is increasing rapidly. The use of oral fluid in drug treatment facilities [98] and for therapeutic drug monitoring [99–101] has also been reported.

Workplace Drug Testing

It is clear that laboratory-based analytical methods to measure drugs in oral fluid are robust and well developed. Many published studies have examined the known or potential rate of error of these tests (sensitivity, specificity, positive predictive value, negative predictive value, overall accuracy). There is certainly an acceptance of the accuracy and reliability of oral fluid testing within the scientific community. Unfortunately, there are no formal laboratory certification programs yet established for drug testing in oral fluid [102]. In April 2004, SAMHSA has published in the Federal Register a Proposed Rule for incorporating oral fluid in its federal workplace drug-testing program. This was followed recently by an Australian standard that is also intended for workplace drug testing (Table 1). In the United Kingdom, the UK Workplace Drug-testing forum is currently working on guidelines for oral fluid specimen analy-sis. However, to date, no published document is available. Alltrix, the largest specialist oral fluid drug-testing laboratory in Europe is using its own cutoff levels, which are based on the levels proposed by the manufacturer of the immunoassays (OraSure Technologies) for the screening assays (Clarke, J. Altrix Healthcare, *Personal Communication*, January 2007). All samples are collected using the Intercept® device.

The results of the first large-scale database on oral fluid testing in private industry were published by Cone *et al.* [29]. A total of 77 000 specimens were screened by the Intercept® immunoassay at manufacturer's recommended cutoff values for five drug categories (marijuana, cocaine, opiates, phencyclidine, and amphetamines). Presumptive positive specimens were confirmed by GC-MS. An overall positive rate of 5.06% was noted. The confirmed positive specimens consisted primarily of THC and cocaine (85.75%). In comparison to the corresponding urine samples, the prevalence of positives for cocaine and amphetamines was approximately 60% higher in oral fluid. Of the 48 morphine-positive specimens, 32 specimens were also positive for 6-AM. Considering the short detection window for this unique metabolite in urine (approximately 3.3 h following single dose administration of heroin), it is concluded that oral fluid is superior to urine in the confirmation of recent use of heroin [29, 103]. After a single administration of THC by inhalation, there was a substantially higher rate of detection of positive oral fluid specimens over the first 8 h in comparison to the corresponding urine testing [57]. This unique characteristic is of great importance when one considers the short time course of marijuana's effect on performance. In general, oral fluid is considered as the only other body fluid revealing recent drug use and therefore related to possible impairment, whereas urine testing is clearly more useful to detect past use of the drug.

Both SAMHSA and Standards Australia have also established guidelines for the collection and storage of specimens. For SAMHSA, the suggested minimum amount of specimen to be collected is 2 ml, which can be divided into 1.5 ml for the primary specimen and 0.5 ml for retesting. SAMHSA is presently recommending oral fluid sampling by spitting into a neat tube, whereas for Standards Australia specimens either collected by spitting or through the use of a device are accepted. However, to overcome the problems of adsorption of certain drugs to the devices (as discussed previously), each manufacturer is required to document recovery of all target analytes from the devices. In addition, some oral fluid specimen collection schemes involve collection on an absorbent swab

with subsequent transfer into a buffer, an issue that can cause difficulties for the interpretation of quantitative results. Another problem is that many devices cause either a mechanical or chemical stimulation of oral fluid flow. As already discussed above, this process affects the pH of oral fluid, and therefore the concentrations of drugs and metabolites in the oral fluid sample.

Owing to a lack of resolution of several of the above mentioned important research questions, SAMHSA has proposed a conservative approach to the addition of oral fluid testing to the different drug-testing matrices. In its proposed rules, SAMHSA noted that less is known about the pharmacokinetics and disposition of drugs in oral fluid as compared to urine. However, several authors have investigated these pharmacokinetics, and, therefore, it is important to note that although it may not be possible to answer some of these questions definitively, qualified experts may nonetheless be able to provide sufficient information to assist in its decision-making. The new SAMHSA guidelines also recommend collecting urine specimens simultaneously with oral fluid, because of the potential of passive contamination for THC, as discussed previously. However, the recent demonstration by Moore *et al.* and Day *et al.* of the presence of THC-COOH in the oral fluid matrix may eliminate the necessity of the additional urine sampling [61, 62].

Substance Abuse Monitoring

Drug testing of patients in treatment is generally practiced to provide objective assessment of patients' progress. Many treatment programs require individuals to detoxify from the offending drug(s) and remain drug-free throughout treatment. Other programs utilize substitution therapy in which the patient is switched from an illicit drug, e.g., heroin, to an acceptable substitute, e.g., methadone or buprenorphine, which is administered by treatment personnel. In most of the programs, patients' progress is monitored by urinalysis. However, interest in oral fluid as an alternative drug-testing tool has grown in this area. Oral fluid testing appears to be a good indicator of the validity and reliability of drug user's self-report data [101].

Dihydrocodeine, codeine, morphine, 6-AM, heroin, cocaine, BE, methadone, amphetamine, MDA, MDMA, MDEA were measured by GC-MS in oral fluid of donors being monitored in a drug misuse treatment program as part of the investigators' effort to evaluate the Cozart® RapiScan screening device and the Cozart® Microplate EIA [33–36, 104].

The concordance of oral fluid and urine opiate results for participants in drug withdrawal therapy was assessed [105]. Oral fluid specimens were collected with a Clin Rep® device from Recipe and analyzed by GC-MS for dihydrocodeine, codeine, 6-AM, and morphine. The authors found a good correlation between opiate results in both matrices, in specimens collected every 2–4 days over a 3-month period. They concluded that oral fluid was appropriate for analysis of drugs of abuse. Niedbala *et al.* [28] collected oral fluid and urine specimens from known opiate abusers in a drug treatment center and found an agreement of more than 90%, applying a cutoff of 10 ng ml^{-1} for one or more opiates in the collected oral fluid and a 2000 ng ml^{-1} cutoff for interpretation of the urine results. This was confirmed by Bennett *et al.* [98] comparing the accuracy of on-site testing of oral fluid with urine on-site testing in 157 drug-dependant persons and concluded that oral fluid testing is as accurate as urinalysis in detecting the presence of opiates and methadone.

Recently, Dams *et al.* [106] analyzed oral fluid specimens from 16 pregnant opiate-dependent women. Specimens were collected with the Salivette® oral fluid collection device. 6-AM, heroin, and morphine were the major opiates detected with median concentrations of 5.2, 2.3, and 7.5 ng ml^{-1}, respectively. Detection of 6-AM and/or heroin in 84% of positive oral fluid specimens proved heroin usage, rather than licit codeine or morphine, or ingestion of opiate-containing foodstuffs. In contrast, only 37 urine specimens collected the same day in the same subjects as the oral fluid samples were positive at a 300 ng ml^{-1} cutoff concentration of opiates in urine. Cocaine and BE had median concentrations of 6.4 and 3.4 ng ml^{-1}. The major analytes identified were cocaine and BE, detected in approximately 98% of all cocaine positive specimens. In contrast, only 22 urine specimens were positive for cocaine metabolites at a 300 ng ml^{-1} cutoff. These authors conclude that oral fluid is a promising alternative matrix to monitor opiate and cocaine use in drug-testing programs.

Acetylcodeine has also been reported as a marker of illicit heroin abuse in oral fluid samples [107]. A significant correlation was found between this new

marker and 6-AM ($r = 0.95$) in samples collected from patients attending a substance abuse clinic.

Oral fluid has also been examined as an alternative matrix for the therapeutic monitoring of methadone [108, 109]. A poor correlation between oral fluid and serum was obtained when considering total methadone concentrations [108]. However, a good correlation was found between both matrices when the enantiomeric ratios of methadone were taken into account. Methadone and its major metabolite, 2-ethylidine-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP), were examined in oral fluid and plasma as a function of salivary pH [110]. Oral fluid methadone ranged from 120 to 3460 ng ml^{-1} with *S/P* ratios from 0.6 to 7.2. For EDDP the ranges were 40–100 ng ml^{-1} for oral fluid, with an *S/P* ratio of 0.2–1.8. An inverse correlation was found between the methadone concentration and the oral fluid pH.

Roadside Drug Testing

While there is only limited knowledge of the prevalence of drugs other than alcohol in road traffic, it appears that drugged driving is a significant problem worldwide [111–113]. Since the late 1990s, several western countries have, in analogy to alcohol, introduced *per se* legislation for driving under the influence of drugs (DUID). The policy is in whole or in part based on the detection of any amount of illicit drug in blood or urine of the driver. However, a positive urine test is by no means an indication that the subject was "under the influence" at the time of sampling. The presence of certain illicit drugs or their metabolites in urine of potentially impaired drivers is merely evidence of relatively recent exposure, except for certain drugs such as cannabis. The urinary metabolite of THC can be detected in urine for days, or even weeks, after the last use in regular users. When the drug is detected in blood, there is a higher probability that the subject is experiencing pharmacological effects at the time of sampling. A recently published controlled study has approached the relatively obscure relation between THC concentration in serum and driver impairment [60]. It was concluded that a serum THC concentration of 2–5 ng ml^{-1} was associated to the limit for impairment in performance tests measuring skills related to driving.

Oral fluid is probably the only other body fluid that might parallel blood in some regards and therefore may be related to behavioral performance [4, 114]. Using receiver operating characteristic (ROC) analysis of data from 139 individuals suspected of driving under the influence of cannabis, Laloup *et al.* [115] calculated an optimal cutoff value of 1.2 ng ml^{-1} THC in preserved oral fluid to predict a positive plasma result (LOQ 0.5 ng ml^{-1}) (sensitivity: 94.7% and specificity: 92.0%). Several studies have shown that a reasonably good correlation can be found between the presence or absence of drugs in oral fluid and in blood [8, 23, 116, 117]. Moreover, oral fluid appears to be superior to urine in correlating with serum analytical data and impairment symptoms of drivers under the influence of drugs of abuse [95]. Epidemiological data from drivers (randomly stopped) and accident-involved drivers, respectively, have been collected by analysis of oral fluid samples in the context of the European project IMMORTAL (Impaired Motorists, Methods of Roadside Testing, and Assessment for Licensing) [97, 118].

Since many years, police officers involved in road safety have expressed the need for a rapid and reliable drug test that can be applied at the roadside. The on-site urine drug tests and the first generation of the oral fluid tests were thoroughly evaluated in the DG VII EC project ROSITA (Roadside Testing Assessment) [112]. At that time, three on-site tests for oral fluid screening were available: Drugwipe® (Securetec, Germany), RapiScan® (Cozart Bioscience, UK), and Oralscreen® (Avitar, US). A clear majority of the participants preferred oral fluid as the matrix of choice for on-site testing. The possibility of collecting oral fluid by nonmedical personnel and without the need for special facilities (i.e., sanitary van) was a distinct advantage. However, police officers and researchers encountered problems related to insufficient sample volume, the viscosity of the samples and insufficient sensitivity of the analytical methods. The on-site oral fluid screenings, particularly for testing of THC, required significant improvement [96].

As has been mentioned earlier in this article, steady progress has been made in the last five years in the field of sample collection and laboratory-based immunoassays and confirmation techniques. Most of the newer generation on-site devices offer the possibility to collect enough sample volume (sometimes diluted with buffer) that can be used

for confirmation analysis in the laboratory. In 2002, a compilation of the analytical advantages and test performances of out-of-lab drug-testing devices was published [119]. Several authors have compared the use of some of these on-site devices with laboratory results, including Cozart® RapiScan [37, 38, 104, 120–122], Drugwipe® [23, 123, 124], Toxiquick® [125], Dräger® DrugTest [115], Oratect® [126], and Oraline® [127]. However, the absence of internationally accepted cutoff values for oral fluid hampers the comparison of on-site test results with chromatographic results.

In an evaluation of six on-site test devices using spiked oral fluid samples [128, 129], it appeared that theoretical cutoff values for a specific analyte are considerably different across devices. The ability to accurately and reliably detect cocaine and amphetamine was dependent on the individual device. Most devices performed well for the detection of methamphetamine and opiates, but all performed poorly for the detection of THC. Two reasons appear to be apparent: (i) the devices target the wrong analyte (THC-COOH instead of THC) and (ii) the cutoff concentrations are too high considering the low concentrations of THC generally present in oral fluid.

In late 2003, the Rosita-2 project was started, involving six European countries and five US states [111]. Nine devices were evaluated: American Biomedica Oralstat, Branan Medical Oratect, Cozart Bioscience RapiScan (only in the United States), Dräger/Orasure DrugTest/Uplink, Lifepoint Impact, Securetec Drugwipe, Sun Biomedical Oraline, Ultimed Salivascreen, and Varian OraLab. For six devices, the number of failed test runs exceeded 25%, and their evaluation was stopped. During the study, two devices were withdrawn from the market: the Dräger DrugTest and Lifepoint Impact. At the end of the study, based on the analytical evaluation (comparison to reference methods in oral fluid and/or blood), no device was considered reliable enough to be recommended for roadside screening of drivers. The sensitivity of the on-site screening devices for cannabis and benzodiazepines needs to be improved dramatically. For example, the performance of the Dräger DrugTest to screen for THC in oral fluid was evaluated using oral fluid and plasma as reference samples [115]. Whereas the specificity of the test was high (93–100%), a sensitivity of only 50% was calculated, indicating a high number of false-negative test results. Despite these drawbacks, in a few countries, legislation was passed that allows the potential use of oral fluid as a matrix for screening or confirmation [96].

In the state of Victoria in Australia, legislation introduced in December 2003 allows police to perform random roadside oral fluid testing for cannabis, methamphetamine, and MDMA [130]. Police officers use the Drugwipe II® device (Securetec) to do the initial screening by wiping the tongue, when the driver is still in his car. If this test shows a positive result, for cannabis, methamphetamine, or MDMA, an oral fluid sample is requested so the police can do an immediate screening on-site with the Cozart RapiScan system for the same drug classes. When this second test is positive for either drug, the oral fluid sample is confirmed in the laboratory for amphetamines and THC using predefined cutoff values, and the driver can take the split sample with him. From the 13 176 drug tests performed at the roadside, 313 positive cases were selected for GC-MS analysis (2.4%). A high number of positive methamphetamine ($n = 269$; median: 1136 ng ml^{-1}) and MDMA ($n = 118$; median: 2724 ng ml^{-1}) findings are reported, and a relatively low number of THC positives ($n = 87$; median: 81 ng ml^{-1}) [131]. It would be interesting to analyze the data further with respect to THC levels in those cases where both oral fluid tests were positive for THC, and to know the prevalence of THC-only positives. Based on the results of Rosita-2, the relatively good performance of the test devices to pick up amphetamines should reflect in a high number of methamphetamine positive tests and the low sensitivity to detect THC in oral fluid, should lead to a serious underestimation of the number of cannabis positives. However, the aim of this type of random roadside drug testing is to have a deterrent effect on drugged drivers and ultimately decrease the accident risk. One major risk is the possibility that drivers will realize that they often test negative after having used cannabis.

Conclusion

Oral fluid appears to sufficiently meet the requirements to be added to workplace drug-testing laboratory-based programs. There are adequate methods available for screening and confirmation in the laboratory and the relevant drugs and metabolites have been identified. External proficiency testing is

being developed and cutoff concentrations have been proposed by scientific organizations. Appropriate certification of laboratories worldwide and introduction of legal provisions in several countries is the next step. In different environments such as drug treatment facilities, oral fluid has become an interesting alternative matrix for drug testing. Advantages of oral fluid testing include noninvasive sample collection, and the ability to collect the sample under observation reducing the opportunity for adulteration. The potential to estimate circulating drug concentrations and therefore closely associated to 'being under the influence', make it the matrix of choice for police officers and law enforcement agencies for screening of intoxicated drivers. However, the search for an on-site screening method that can provide acceptable accuracies for the detection of cannabinoids in oral fluid remains a major hurdle. Additional considerations that have received attention are the variability in the volume of sample collected and the drug recovery from the many different specimen collection systems on the market.

Packaging and Transport

General Issues

Anticontamination and Continuity Measures

Where an investigation involves more than one scene (a location, vehicle, or subject), no person should recover or package items from more than one of them. All subjects, victims and suspects, should be kept apart and transported in different vehicles using different officers.

Whenever possible, packaging material should be taken to the location where evidence is found and packaged *in situ*. Vital evidence may be lost if evidence is transported to a different location for packaging. Every item of evidence must be packaged separately in a sealed container, bag or box. The package must be sealed with tape to prevent tampering with the evidence. While normal adhesive tape is permissible in some countries, some jurisdictions disapprove of the practice and require tamperproof evidence tape be used to seal evidence.

Staples, pins, and paperclips must *never* be used to seal forensic packaging or attach evidence vouchers to the packaging. They will puncture the packaging and it could be alleged that cross contamination of hair, fibers, microscopic pieces of glass and paint could have occurred through any holes caused.

While contamination and cross contamination have always been issues for any evidence types in forensic science, the increasing sensitivity of DNA profiling have made anticontamination measures even more important.

Storage and Transport

All storage of exhibits must be in secure facilities. The basic requirements for exhibit storage are a secure store or locker, depending on the size of agency. If secured by key, there should only be one available to personnel and agencies should have protocols governing entry and documentation of such entry. If entry is by keypad or swipe card, this must be linked to a computer that records entry and exit.

A suitable freezer and refrigerator are also required for biological and other exhibits and access should be *via* a secure exhibit storage facility.

Some larger crime labs and agencies have adopted the use of radiofrequency identification (RFID) tags to track the location of exhibits.

Items from one subject (suspect or victim) or scene must *never* be stored or transported in the same box or large paper sack containing items from any other subject or the scene they are suspected of involvement in. This will prevent any accidental cross contamination.

Packaging of Exhibits

Clothing, Footwear, Bedding, and Similar Items

Dry items, such as clothing, bedding and footwear, should be placed in separate paper bags. These bags are also referred to as *Kraft* bags in some

areas. The top of the bag should be folded over about 1 in. (2.5 cm) and then folded over the same distance again. The bag should then be completely sealed, using 2-in. (5 cm) wide adhesive tape or, if not acceptable in the jurisdiction, an approved tape. Where protocols dictate, it may be necessary to sign across the seal, half on the tape and half on the bag. Where bags have no chain of custody details printed on them, the relevant evidence voucher (*see* **Crime Scene Documentation**) should then be attached using an approved tape. Where the item is too large to fit in standard paper bags, it should be carefully wrapped in one or more sheets of brown paper, fully sealed to prevent contamination of the item. As an extra preventative measure, a second layer of wrapping may be employed.

In the United Kingdom, advice from forensic laboratories is that dry items must *never* be placed in polyethylene bags as it is possible that a buildup of moisture could degrade any biological or trace evidence. However, advice in other countries may vary and it may be permissible to ensure items are completely dry before placing them in polyethylene bags.

Wet or Damp Items

With the exception of footwear, damp or wet items recovered from scenes or subjects should be placed in individual polyethylene bags. Items of footwear must *never* be placed in polyethylene bags as they will become moldy.

Wherever possible, polyethylene bags with self tamperproof seals should be used as a normal adhesive tape will lose adhesion and compromise the integrity of the exhibit.

Never seal or store damp or wet items in polyethylene bags without freezing at the earliest opportunity. Frozen items must not be allowed to thaw during transportation to the laboratory. When folding, personnel should avoid folding the item in such a manner that could affect bloodstain patterns.

Where facilities, such as forensic drying rooms and cabinets are available, the items should be air dried prior to being repackaged as per the guidelines for dry items. The air-drying process should not include heating to accelerate the drying time. The items should be hung separately and a large sheet of paper placed below to collect any debris that may fall off during the drying process.

The polyethylene bag should then be packaged and labeled as an exhibit.

Where no forensic drying cabinets are available, extreme care should be taken when choosing a drying location. Careful consideration should be given to the possibility of infection from the person shedding the blood, not only to prevent any accidental contamination or interference with the evidence but also where the item is bloodstained.

When dry, the items should be carefully moved using appropriate anticontamination and protective measures. The item should be carefully folded as necessary and placed in a paper bag and sealed and labeled accordingly. If the item is bloodstained, in addition to protective clothing and gloves, personnel dealing with the clothing should wear a protective mask and goggles to prevent any possible infection from airborne dried blood particles.

The sheet of paper placed below the item should be packaged separately and treated as a new exhibit. The clothing, polyethylene bag, and paper sheet should all be sent to the laboratory for examination. In this way, all debris that may have detached from the exhibit can be examined if necessary.

Weapons, Tools, and Miscellaneous Items

There are many flat-pack forensic boxes of many different sizes available. They vary from small boxes through some similar to pizza boxes to others capable of containing a rifle or possibly a baseball bat.

Weapons and tools should be placed a suitable flat-pack cardboard box. Ensure that adhering debris is protected by paper folded around the tip and shaft. The implement should then be tied securely in place with string to prevent movement. This is achieved by piercing holes in the box close to the item and threading string through them. The knots should be on the inside of the box, to prevent accidental or deliberate interference and the holes created to thread the string through must be sealed with an approved tape. The box should be fully sealed around the edges, with an approved tape. Where protocols dictate, each piece of tape should be signed, half on the tape and half on the box to prevent any allegations of tampering. Some evidence boxes come with a card insert with a grid of prepunched holes, to allow items to be secured without the need to pierce the box.

The relevant evidence voucher (*see* **Crime Scene Documentation**) should then be attached using an approved tape.

The box should always be stored and transported flat, with the securing string to the bottom. The box should be labeled to indicate which way up the box should remain and also if it contains a sharp object and any health hazards such as bodily fluids.

Wherever possible, rigid knife tubes should be used to package knives and other sharp instruments. These are two plastic tubes, open at one end, which fit inside each other by means of a spiral groove and hold the item in position at either end. The tube is then sealed in the same way as a box and an evidence voucher attached.

Firearms should be made safe by an authorized officer, under the supervision of crime scene investigators (CSIs). Where protocols dictate, an appropriate certificate should be attached to the outside of the exhibit. A suitable box should be used, sealed, and labeled as above. Ammunition and magazines should be packaged separately.

A magazine should be packaged in a box as above. Dependent on local protocols, ammunition may need to be removed from the magazine or chamber of a revolver. It is good practice to mark a revolver to show the relative position of the chambers at the time of recovery.

Ammunition, either projectiles or shell casings, spent or otherwise, should be packaged in small plastic pots padded with tissue paper to prevent damage. The pots should be individually sealed and the appropriate evidence voucher attached.

A recent suggestion for the packaging of spent shell casings is to insert a dry swab into the open end and place the casing in a plastic urine pot. Those pots with a conical base mean that only the smallest part of the rim is in contact with anything. The swab is then broken at the lip of the pot allowing the casing to be held in position. This method prevents possible damage to the casing and any fingerprints on it.

Footwear Impressions

Where a footwear or tire impression has been cast, they too are placed in a cardboard box. The cast is placed soil side up in the box. The soil should not be removed as this provides a sample from exactly where the offender stood or the vehicle was driven. The cast is tied into the box, sealed, and labeled as above.

If a footwear impression in dust has been recovered using an electrostatic lifting apparatus (ESLA), it is also packaged in a box. The foil is placed black side up in the box and taped into position in each corner. If the impression was recovered from a movable object, such as paper strewn across the floor, this too is taped into a box. The boxes should be sealed and labeled as above.

Glass Exemplars

Whenever glass has been broken at a crime scene, *exemplars*, also known as *control samples*, should be taken and packaged in a cardboard box. The box should be sealed and labeled as above.

Storage. Store all the above "right way up" in a dry exhibit store.

Transport. No special requirements other than keep "right way up".

Dry Miscellaneous Traces

Paint flakes, exemplars or unknown source, powders or other debris, should be placed in folded paper, druggists' wraps. The wrap should then be sealed in a polyethylene bag, and the appropriate evidence voucher completed and attached.

Damp or Wet Miscellaneous Traces

Items such as oils and greases should be submitted in the original container if available. If not, they should be recovered into a suitable container, sealed in a polyethylene bag and the appropriate evidence voucher completed and attached.

Storage. Store all the above "right way up" in a dry exhibit store.

Transport. No special requirements other than keep "right way up".

Fiber Tapings

Each recovered taping should be sealed in a polyethylene bag and the appropriate evidence voucher completed and attached.

Storage. They should be stored in a dry environment.

Transport. No special requirements.

Accelerants or Volatile Substances

Liquid Samples – Packaging and Storage. These must be packaged in a nylon bag, tied, and sealed at the top with a swan neck. This bag should then be placed in a polyethylene bag, again tied and sealed with a swan neck. An evidence voucher must be attached using string (*see* **Crime Scene Documentation**). Do *not* use an approved tape to attach an evidence voucher to the packaging. Containers with rubber or plastic seals and plastic vials should *not* be used. They should be stored in a dry environment, isolated from other items.

Transport. When transporting, the sample bags should be placed in a rigid outer container, and suitably padded to prevent impact damage.

Clothing. Clothing should be searched prior to submission. It should be loosely packaged in a nylon bag, tied, and sealed at the top with a swan neck. This is achieved by twisting the top of the bag tightly until a long "spout" is made. This is then tied around itself and then the knot is tied with string to secure it. No form of adhesive tape should be used to secure the knot. This bag should then be placed in a polyethylene bag, again tied, and sealed with a swan neck. An evidence voucher must be attached using string (*see* **Crime Scene Documentation**). Do *not* use any type of adhesive tape to attach an evidence voucher to the packaging. They should be stored in a dry environment, isolated from other items.

Transport. When transporting, the sample bags should be placed in a rigid outer container, and suitably padded to prevent impact damage.

Fragile Items from Fire Scenes. Fragile items should be packed in a sealed sturdy box or tin.

Transport. The items should be carefully transported. They should be transported personally to the laboratory.

Accelerant Samples from Fire Scenes. These must be packaged in a nylon bag, tied, and sealed at the top with a swan neck. This bag should then be placed in a polyethylene bag, again tied and sealed with a swan neck. An evidence voucher must be attached using string (*see* **Crime Scene Documentation**). Do *not* use an adhesive tape to attach an evidence voucher to the packaging. Leave a quantity of air above the sample, often known as a *headspace*. Unused glass jars with well-fitting caps can be substituted for nylon bags.

Where methylated spirits are suspected, a glass bottle with a well-fitting cap should be used. Double wrapping in nylon bags may be used as an alternative.

Samples should be submitted as soon as possible.

In some cases, items suspected of containing accelerants will have sharp or broken edges or protrusions. Any sharp items should be placed in a rigid box, sealed in a nylon bag. The packaging should be marked to clearly indicate that a sharp item is contained within.

Biological Samples

Swabs. Swabs as an evidence type are the most complex as regards packaging. What is accepted practice in some jurisdictions is frowned upon in others. Reference must be made to local protocols.

In many US states, swabs are air dried. They may be placed into sample envelopes to dry prior to submission. Some jurisdictions use a small box with an insert designed to allow the swab to be held in position away from the box and air dried in that. The box is sealed and the details documented on an evidence voucher.

In some jurisdictions worldwide, swabs from subjects and also crime scenes are frozen as soon as possible and submitted frozen. In others, swabs from subjects are frozen but scene stains are air dried.

In England and Wales, where the majority of swabs are frozen, standard medical swabs are used for crime scenes, including victims and suspects. They are sealed in the tube provided, placed in a polyethylene bag and the appropriate evidence voucher attached.

Cigarette Ends. They can be placed in individual polyethylene bags, envelopes or paper bags, sealed, and the evidence voucher attached. If dry they are stored in a dry environment. If wet they are frozen.

Storage. Frozen samples should remain frozen. Air-dried samples should be stored in a dry environment.

Transport. Frozen samples should remain frozen in transit. Air-dried samples should remain in a dry environment.

Condoms. Condoms should be knotted to prevent the loss of any liquid inside. They should be placed in a rigid plastic pot. The pot should be placed in a polyethylene bag, sealed, and the appropriate evidence voucher attached. The exhibit should be frozen as soon as possible and remain frozen in storage and transit.

ALLAN MATHIESON SCOTT

Paint

Introduction

Paint can be defined as a coating applied to a surface to provide decorative, protective, or other properties. In the context of forensic trace evidence, paint can be encountered in a range of situations, from traffic accidents and criminal damage, through burglaries and art fraud, to murder and terrorist activity.

"Essentially, a paint consists of a pigment dispersed in a resinous binder, reduced to an acceptable application viscosity with solvent. One or more additives may be incorporated to modify one or more of the paint's film properties, application, or storage characteristics [1]."

Paint is a common material in everyday life: buildings, vehicles, furniture, tools, and even fashion accessories can be painted. However, each of these uses is different; there are very many colors and shades of paint available; the composition of paints can vary widely; each additional layer of paint adds to a paint flake's individuality. Traces of paint can be transferred from one item to another, or to a person in contact with a painted item, and this can have major forensic significance.

Forensic Aspects

The forensic characterization of a paint usually involves microscopic examination allied to some chemical analysis of the organic and/or inorganic components.

Forensic paint analyses and comparisons are typically distinguished by a small sample size that precludes the application of many standard industrial paint analysis procedures or protocols. The forensic paint examiner must address concerns, such as the issues of a case or investigation, sample size, complexity and condition, environmental effects, and collection methods. These factors require that the forensic paint examiner choose test methods, sample preparation schemes, test sequence, and degree of sample alteration and consumption that are appropriate for each specific case.

Forensic science is concerned with generating information, which can be used to support or refute propositions made within the legal context, principally in courts of law. It is important at the outset, therefore, to identify the nature of the customer's proposition and any reasonable alternatives in some detail, to enable the correct approach to be followed to obtain all the relevant data.

Paint investigations are mostly requested in relation to incidents where cars have been involved (e.g., hit and run accidents, a raid on a bank where a car has been used to crash through a window, or a murder where a body has been carried in a car) or to incidents where paint has been transferred to or from a tool or another painted object (e.g., burglaries or assaults).

Normally, the request will be to determine if there is a link between a microtrace of paint found on one object/person and another painted object. In hit and run cases, the request may be to determine from paint microtraces which model of car, and from what year, has been involved in the incident.

Two stages can be distinguished in many investigations:

- In the *investigative stage,* the customer is interested in clues which help him to determine which avenues of investigation appear to be most fruitful. Speed of the response is normally more important in this phase than the strength of evidence.
- In the *evidential stage,* a suspect has been found and procedures have been started to determine if the suspect should be prosecuted in court. In this phase, strength of the evidence is normally more important than the speed of response.

During the paint investigation, the emphasis of the request may shift from speed of response to strength of evidence. Normally, from the request it can be deduced what the current phase of the investigation is and what the priorities of the customer are [2].

In the majority of cases involving paint, the requirement is for the laboratory to compare samples of paint to see if they could have a common origin. This will mean the application of a range of techniques from low-power microscopy to more specialized analytical methods.

Other cases require that the paint samples submitted to the laboratory are examined to assist an investigation where there is as yet no comparison sample. Such cases include traffic accidents where automotive paint databases are searched for paint matching traces recovered from an injured person's clothing to help identify the vehicle involved.

Paint Composition

In the past, it was easy to define paint. Paint in its simplest form was composed of four main types of ingredient described as follows:

1. Resin (also referred to as *polymer* or *binder*)

This is essentially the "glue" that binds the pigments and additives in place and dries to a solid "film". The polymeric binder (or resin) provides the continuous matrix for the paint film and gives the paint its adhesive quality, durability, flexibility, and chemical resistance. Sometimes a modifying resin is also used with the primary resin.

2. Pigment

Finely divided particles, which are dispersed throughout the liquid paint and give the dried paint film: color, opacity (hiding power), film reinforcement and functionality, gloss, and permeability.

3. Solvent

The solvent is the volatile portion, which is used to provide application-related properties including flow and dry time. Often this "solvent" is primarily water. Several "solvents" may be used in a coating. Upon drying of the paint film, the solvent is evaporated and eventually lost. Proper drying of the paint film is essential to achieve desired film properties.

4. Additives

Additional components, which lend added properties to the finished film and/or make application and manufacturing easier. They also contribute to gloss, viscosity, and other properties.

Today, with the advent of high technology, paint is still essentially as described above; however, certain types of coatings – such as most powder coatings – are 100% solid and do not contain solvent [3].

Paint Application

Different paints can be applied to surfaces by several means: for example, by brush and roller, by manual or robotic spraying, by dipping or as a powder coat [4].

Architectural or domestic paints are most often applied by *brush,* at least in the case of the paint types submitted for forensic examination. Manual application will typically lead to more variation in thickness and in homogeneity than more controlled industrial application procedures. This may mean that a greater number of control or known samples will need to be taken from the surface to ensure that the examiner has a representative sample for comparison.

Other decorative finishes featuring paint can also be found on items like furniture, or on products like fire extinguishers and domestic appliances, but these are encountered less frequently in case work.

Where paint is *sprayed*, either from an aerosol can or using a compressed air or pump paint sprayer, layer thickness and homogeneity may also vary. There may also be a contribution from paint that was previously sprayed using the same equipment (for example, traces of mica or aluminum particles from an "effect" paint carried into a solid paint). Stray paint droplets ("overspray") can drift during spraying onto nearby surfaces, which are not being painted, resulting in microscopic droplets of a different color on the surface, which individualize the paint further.

Robotic application, for example, in the motor industry, gives very reproducible results, with even layers of a consistent thickness. On a continuous production line, the color of the applied paint can change to meet the requirements of the product: the undercoat color of cars can change to suit the topcoat color, and during the change there may be a variation from the front to the back of a single vehicle.

Dipping a vehicle body into an electrostatic paint bath is a technique, which allows paint to penetrate into cavities that would otherwise be inaccessible, and is used for applying anticorrosion paint. Again, the results are consistent in terms of layer thickness and anticorrosion coatings may be very thin.

New technologies and environmental, health, and economic considerations have meant that water-borne paints, paint with less solvent, and powder coating (where no solvent is present) have become more common. The phasing-out of pigments like lead chromate was also a feature of paint development in the late twentieth century.

Transfer Mechanisms

Dry paint is normally transferred by direct contact. As paint is designed to bind strongly to a substrate, unless the paint is old and flaking, it will require some force to remove it. Scene of crime examiners will be familiar with the difficulty of removing samples from surfaces like automobiles. For this reason, paint may not transfer unless sufficient force is involved. In a minor traffic accident where there is a glancing blow at a shallow angle, only a smear of paint may be transferred, or none may be transferred at all. If a more severe impact occurs, one or more layers may be transferred, in one or both directions. There may also be smearing and mixing of the layers, indicating impact. The more layers transferred, the stronger the evidential value.

In a burglary, where a window is forced open with a tool such as a jemmy or pry bar, paint may be transferred from the window to the tool and from the tool to the window, while there may also be other evidence types like toolmark impressions, fingerprints, fibers, or DNA involved [5, 6].

Transferred smears of paint can indicate forceful contact, as in a collision between two cars, but the examiner should be cautious in arriving at a conclusion as to the color of the offending vehicle based only on smears of paint. Paint smeared thinly onto a light colored surface can appear a lighter color than the paint from which it came and the reverse may be true with paint smeared onto a dark surface. With effect paints or paints with a clear topcoat, if only the top layer (the *clearcoat*) is smeared, it may appear white, though it is usually colorless.

Wet paint can be transferred by direct contact with a painted surface, by splashing or spraying. A vandal painting or spraying graffiti could get paint splashes or droplets on their shoes, skin, or clothing; an intruder's clothing in contact with a newly painted surface could transfer paint to the clothing.

Loose paint particles can flake from a surface and be recovered at a scene. If this is a possibility, the examiner should consider whether there might be physical matches (also called *physical fits* or *fracture matches*) between pieces of recovered paint and a painted item. The author has encountered a case where a white-painted metal bar was used to break into motor cars. Flakes of paint were left inside one of the cars. Some of this recovered paint was found to fit precisely back onto the metal bar so as to show that it had come from this item.

On a larger scale, pieces of automobile body filler left at accident scenes can also provide scope for physical matches as well as for paint layer examination.

Persistence

In contrast with glass, there has been little published on the persistence of transferred paint. Published clothing surveys for paint describe work by Lau *et al.* [7] and Pearson *et al.* [8].

Other Paints

Other types of paint may be encountered from time to time. One such paint is anticlimb paint, which is designed to remain slippery and not to dry, to deter burglars or intruders from climbing on buildings. These paints may have additional components added as markers in the paint to help identify offenders when caught.

French scientists have studied the paint from weapons rockets to try to identify the types of rockets used in terrorist attacks [9].

Layer Structure

It is a combination of the layers and colors, which give paint flakes their individuality. It is easier to discriminate colored paints microscopically than black or white paints because they have a range of shades of color. The greater the number of layers, the more distinctive the paint will be. If a paint has many layers, the examiner may decide that no further examination is needed, other than microscopy, as the paint is already sufficiently characterized. This is more likely to be the case with an architectural paint, particularly from an old building, but it could also apply to a vehicle that has been repaired and repainted. Laboratory policy and an examiner's own judgment will determine whether chemical analysis, in addition to microscopic comparison, is required.

Where fewer layers are present, the examination should include some analysis of the paint. In most forensic laboratories, this means that Fourier transform infrared (FTIR) spectroscopy follows comparison microscopy. The availability of other instrumentation, the judgment of the examiner and laboratory policy will again provide guidance as to the tests conducted on a sample.

Paint Recovery

Paint flakes may have been recovered by a scene of crime examiner and submitted to the laboratory, or an item may have to be examined in the laboratory to recover paint from it. Paint traces can be very small ($<1\,mm^2$) so that appropriate anticontamination measures must be adopted throughout the examination.

The combination of a searching microscope and a fine forceps will allow even very small paint flakes to be recovered. This method will also allow the precise location of recovered flakes to be recorded, unlike brushing or shaking where the paint could have come from any part of an item or garment.

Paint may be recovered from tools or clothing under a searching microscope (magnification of 10× to 100× or so) or loose flakes can be recovered from clothing by brushing the surface or shaking the garment over a large sheet of paper or a special collection receptacle (e.g., a stainless steel funnel. See Figure 1).

Although the collection of paint at scenes using adhesive tape can be convenient for scene of crime examiners, the submission of paint flakes on tape lifts is not recommended as it can be difficult to remove the paint from the adhesive and the presence of adhesive traces can cause difficulties in interpreting infrared spectra. The best method is to remove the paint down to the underlying surface with a clean scalpel blade and place the paint flakes in a suitable

Figure 1 Brushing paint from clothing into a stainless steel funnel

container like a self-seal (e.g., Ziploc) plastic bag, which can be labeled.

Laboratory Examination. A possible stage-wise scheme for comparison of paint samples is shown below. The aim is to discriminate the paints using the techniques available. If at any stage significant differences are noted the examination may be stopped and the paints reported as different.

Sample description
Examine physical characteristics: potential physical match?
Evaluate sample for analytical approach: sufficient quantity? sequence of tests?
Comparison microscopy
FTIR analysis of selected layer(s)
Additional analysis: e.g., elemental analysis (scanning electron microscopy with energy-dispersive X-ray spectrometry (SEM–EDX); X-ray fluorescence spectroscopy (XRF)), fluorescence microscopy, pyrolysis gas chromatography–mass spectrometry (PGC–MS), and microspectrophotometry (MSP).

Microscopic Examination

Following the recovery of any paint, the first examination step is normally comparison microscopy (See Figure 2).

The human eye is capable of distinguishing over 100 000 different colors [10] and microscopy is an extremely powerful tool for the paint examiner. The subsequent laboratory analysis will depend on the instruments available.

Samples of control (*known or "K"*) and transferred (*questioned or "Q"*) paint are mounted on microscope slides and placed on the stages of a comparison microscope. The top and bottom surfaces of a paint flake can be viewed at a magnification of 250× using incident light. Cross sections of the paints can be prepared and mounted on the same slides as the surface samples.

If multiple layers are present they can be recorded in notes, diagrammatically or photographically. Layers of similar colors (e.g., shades of white) may be examined using UV light: any fluorescence may help discriminate the layers.

Cross sections of multilayer paint flakes can be prepared using a microtome, with or without embedding, or by the technique of "thin peels" where the edge of the flake is shaved with a scalpel blade to remove a sample containing all the layers.

"Effect" paints can contain aluminum flakes, mica (for a pearlescent appearance) or other particulate components. A feature of metallic paints is the form of the aluminum flakes, which should be noted; these can be rounded ("dollar") or with indented edges ("cornflake"). Effect paints may have one or both types of aluminum, with or without mica, or interference pigments (for example, mica coated with metallic oxides) to give color, which varies with coating thickness, illumination angle, or viewing angle.

Figure 2 FT-IR microscope and bench

Other microscopic examinations (involving polarized light microscopy, cathodoluminescence, or high-power microscopy) can also be used to characterize paint components.

Analysis

Following microscopy, the normal procedure is for an analytical scheme, which allows both the organic and inorganic components of a paint to be examined,which can cope with small samples, and which, as far as possible, uses nondestructive techniques [11].

Fourier Transform Infrared (FTIR) Spectroscopy. Most modern forensic laboratories use FTIR spectroscopy to analyze paint flakes, which are indistinguishable by comparison microscopy. This technique has the advantage of being fast, nondestructive, requiring little sample preparation and, when the microscope attachment is used, being able to cope with small sample sizes (See Figures 3 and 4).

Figure 3 Comparison microscope

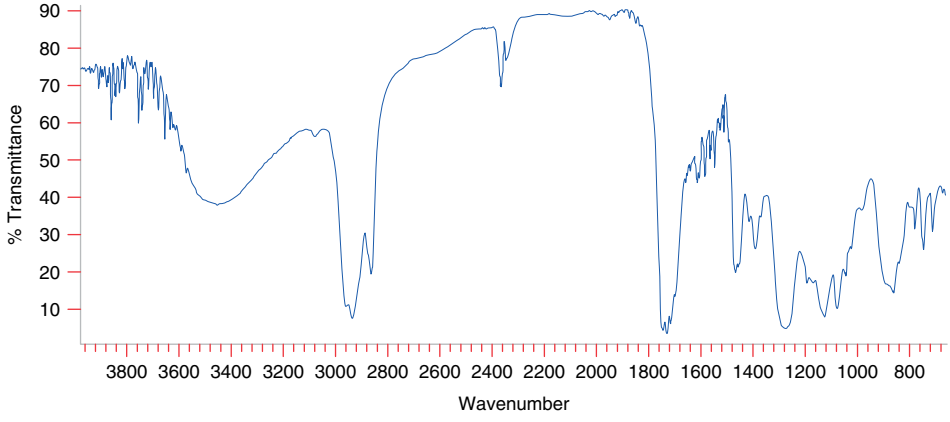

Figure 4 Infrared spectrum of paint

The mercury cadmium telluride (MCT) detector currently fitted to many FTIR microscopes has a wave number range from 4000 to 650 cm^{-1}, allowing the organic and some inorganic components to be detected. Wide-band MCT detectors are also available, providing a range of 4000–450 cm^{-1} but with lower sensitivity.

FTIR microscopes generally have an FTIR bench associated with the microscope, with a deuterated triglycine sulfate (DTGS) detector. If sufficient sample is available it may be possible to use this detector, giving a range of 4000–200 cm^{-1}, allowing the examiner to obtain more information about the inorganic components of the paint. This may be particularly useful when looking at vehicle undercoats.

Infrared (IR) spectroscopy deals with the infrared region of the electromagnetic spectrum. It covers a range of techniques, the most common being a form of absorption spectroscopy. It can be used to identify compounds or investigate sample composition. Infrared spectroscopy exploits the fact that molecules have specific frequencies at which they rotate or vibrate corresponding to discrete energy levels (vibrational modes).

The infrared spectrum of a sample is collected by passing a beam of infrared light through the sample. Examination of the transmitted light reveals how much energy was absorbed at each wavelength. This can be done with a monochromatic beam, which changes in wavelength over time, or by using a Fourier transform instrument to measure all wavelengths at once (FTIR). From this, a transmittance or absorbance spectrum can be produced, showing at which IR wavelengths the sample absorbs. Analysis of these absorption characteristics reveals details about the molecular structure of the sample. Current models of instrument are normally Fourier-transform infra red spectrometers which can collect a spectrum in seconds rather than minutes required for an older grating instrument. A further refinement, the addition of a microscope, means that very small samples can be analyzed with little sample preparation. Spectra can be presented in either transmittance or absorbance mode.

A detailed account of this technique is given by Beveridge *et al.* [12].

Elemental Analysis

Further information on a paint can be obtained by elemental analysis. Because of the small size and the condition of the samples typically encountered in forensic science laboratories, the examiner may be limited in what tests can be performed.

SEM–EDX is a technique used quite widely in forensic laboratories for elemental analysis. The technique is nondestructive and can cope with small samples. Some sample preparation is normally required (usually mounting and coating with carbon to make the surface conductive), but if a paint flake has been embedded and cross sectioned, only a very small additional amount is required for SEM.

If a low-vacuum or environmental SEM is available, no sample preparation may be needed [13, 14].

XRF and micro-XRF are techniques, which may also be applied to obtain elemental information. These require no sample coating but require larger samples than SEM.

SEM and XRF analysis can be done as a comparative test (semiquantitatively) or quantitatively by using either standards of known elemental composition or using the instrument's software to calculate percentage composition.

The scanning electron microscope is widely used as an analytical tool in forensic laboratories. The main advantage of this instrument is that multidimensional information may be gathered: chemical visualization by means of back-scattered electrons (BSE) and X-ray mapping, topographical information, detection of secondary electrons (SE), and qualitative and quantitative elemental composition collected by the energy-dispersive spectrometer (EDS). It is a nondestructive technique requiring some sample preparation but can be applied to samples of $<1\ mm^2$.

XRF is the emission of characteristic "secondary" (or fluorescent) X-rays from a material that has been excited by bombarding with high-energy X-rays or γ rays. The phenomenon is widely used for elemental analysis. Instruments can either use energy-dispersive X-ray (EDS or EDX) or wavelength dispersive X-ray (WDX) detectors. Little sample preparation is required and both qualitative and quantitative analysis can be performed.

Pyrolysis Gas Chromatography. PGC, usually coupled with PGC–MS, can be used to analyze organic material such as paint, plastic, or rubber. Although it is a destructive technique, it can be used on quite small samples. If suitable databases are available, it can also be used as an investigative tool to identify unknown samples such as flakes of car paint or plastic at an accident scene.

Some work has also been done on characterizing automotive clearcoats and coatings on plastic headlight lenses using PGC–MS.

Without the mass spectrometer, however, PGC alone may add little additional information because of the difficulty in identifying peaks in a chromatogram with certainty [15].

PGC–MS or PyGC–MS is a method of chemical analysis in which the sample is heated to decomposition (pyrolysis) to produce smaller molecules that are separated by GC and detected using MS. Although it is a destructive technique, it is useful in identifying and comparing polymeric materials like plastics, rubber, or individual layers of paint.

Microspectrophotometry. Microspectrophotometry using visible light and ultraviolet light (UV-MSP) can also be used as a comparative technique to provide objective information about whether two paints can be distinguished on the basis of their color. The MSP can produce a graphical printout of the color spectrum or can process the results into tristimulus values or color coordinates.

In certain situations, two paints may be visually indistinguishable even though the color has been achieved in different ways (e.g., by using different pigments). This phenomenon (metamerism) may be identified by MSP.

Though MSP is often used for fibers, it can also be used with paint using transmitted or incident light. Transmitted light is preferred as it eliminates any problems associated with sample preparation, surface features and illumination angle, although the thickness of the cross sections from paints being compared must be the same.

For color measurement and comparison, paint sections of approximately 3-μm thickness are prepared, while for the examination of UV-absorbers in clearcoats, thicker sections (20 μm) are required [16–18].

Hand-held spectrophotometers are available for objective color measurement. While they may have applications in collecting data for inclusion in databases, their use in the laboratory is limited because of their inability to measure the small samples (<3-mm diameter) usually seen in casework.

MSP is the technique used to measure the color spectrum of a microscopic sample. Depending on the type of sample it can be operated in the transmission mode (e.g., for fibers) or the reflectance mode (for opaque samples). Some instruments can also measure in the ultraviolet range.

Raman spectroscopy

Raman spectroscopy is a vibrational spectroscopy technique that is becoming more common in forensic laboratories. Raman spectrometers are becoming smaller, less costly, and more user-friendly. Raman spectroscopy can provide complementary information to that provided by infrared spectroscopy and can be useful in comparing and identifying pigments, extenders, and other components [19].

Raman spectroscopy is used to study vibrational, rotational, and other low-frequency modes in a system. It relies on inelastic scattering (Raman scattering) of monochromatic light, usually from a laser in the visible, near infrared, or near ultraviolet range. Infrared spectroscopy yields similar, but complementary information. In the past, photomultiplier tubes were the detectors of choice for dispersive Raman setups, which resulted in long acquisition times. Modern Fourier Transform Raman instruments have shorter acquisition times. In paint examination, Raman spectroscopy is a useful technique for analyzing pigments.

Other Analytical Techniques

Some laboratories may have other instruments available to them, which can be used for paint analysis. One example is *inductively coupled plasma mass spectrometry* (ICP-MS), possibly with laser ablation (LA-ICP-MS). Although it is a destructive technique, the amount of sample consumed in analysis is very small, and it can provide information on the elemental composition of paints, though currently it is more usually associated with glass analysis. These instruments are becoming smaller and more affordable and should become more common in forensic laboratories in the future [20].

Another analytical method being developed is *laser-induced breakdown spectroscopy* (LIBS), which may, in the future, provide a fast and relatively inexpensive alternative to LA-ICP-MS [21].

Investigative Examination

Most of the techniques and procedures referred to above relate principally to a comparison of a recovered sample of paint with a control or reference sample.

Cases also arise where only a recovered paint sample is submitted and the examiner is requested to establish its origin or provide the investigator with some other information to assist the enquiry.

Cases of this type include the identification of automotive paint to establish what type of vehicle it came from. Much work has been done in this area by expert paint working groups and databases of automotive paints from Europe, North America, Japan, and other countries have been built up over the years.

It may be possible to identify the source of a flake of automotive paint recovered from the clothing of a traffic accident victim by examining the color, layer structure, and chemical composition of the recovered paint layers. At best, the make, model, year, and manufacturing plant could be identified. In other cases, useful information on the source can still be provided to the investigator; for example, the likely manufacturer of the vehicle, the approximate age and the range of models to which this particular paint was applied.

These results depend on having the full original layer structure present. If the vehicle has been repainted or if only certain layers are present, the information available will be reduced, or it may not be possible to provide any useful information at all.

Both the European Network of Forensic Science Institutes (ENFSI) European Collection of Automobile Paints (EUCAP) [22] and Scientific Working Group on Materials Analysis (SWGMAT) Paint Data Query (PDQ) [12] search procedures can provide information on automotive paint. It should be remembered that not all car paints are in the databases and certain categories of paint (e.g., commercial vehicles and motorcycles) are not currently included.

Significance and Reporting

Following laboratory examination, the examiner's next step is to report the results. One approach to assessing the significance of results is to review the information available before starting any laboratory work. The examiner may need to make some enquiries as to what happened, what the prosecution and defense positions are, whether all relevant material has been submitted, etc. The examiner may then develop an examination plan and also formulate a set of expectations and alternative propositions. For example, the examiner may decide that, in a certain set of circumstances, there should be transfer of a large amount of multilayer paint between two items. If the result of the examination shows this to be the case, then the evidence supports this particular version of events; if the results do not match the expectations, then the results may favor

an alternative version of events, perhaps favoring the defense hypothesis; in some situations, the results may not be clear-cut and may add nothing to the existing knowledge about what really happened. This approach will depend on whether the legal system in the particular jurisdiction will allow it.

Reporting results should be done in a descriptive, factual way, bearing in mind that the reader is unlikely to have scientific training and – if the evidence is presented in court – those hearing the evidence presented may not have the written version in front of them but may have to rely on hearing the oral evidence only.

There have been publications on assessing the significance of paint evidence using Bayes' Theorem and work on this aspect of reporting physical evidence is continuing [23–25].

In order to assess the significance of a result, it may be necessary to refer to collections of paint color frequency data or national vehicle populations, or information may have to be collected to address specific issues in particular cases.

In general, the higher the number of layers present in a paint flake, the more individual a paint will be, and the more significance will be attached to a positive result. Two-way transfer of paint flakes (e.g., between two vehicles or between a tool and a point of entry) will be more significant than one-way transfer, but the assessment of the significance becomes more complex because the two-way transfers are not independent events. Further discussion on this area is beyond the scope of this article.

Reporting paint results from clothing will require knowledge of transfer and persistence studies, to reflect the prevalence of paint flakes on the clothing of relevant populations. Studies by Lau *et al.* [7] and Pearson *et al.* [8], for example, have documented the frequency of finding paint flakes and glass on clothing from dry cleaners and on students' clothing, and are valuable starting points.

Further Information

An excellent source of up-to-date information on forensic examination of paint is the Best Practice Guidelines produced by forensic expert groups such as the ENFSI Paint and Glass Working Group or its North American equivalent, the SWGMAT Paint Group. Details of these can be found on the ENFSI and Federal Bureau of Investigation (FBI) web sites www.enfsi.eu and www.fbi.gov.

In addition to these expert working groups, Interpol organize a triennial International Forensic Science Symposium. Part of this meeting is a review of all relevant papers published in the preceding three years, which is a very valuable resource on current work. Further information can be found on the Interpol web site www.interpol.int.

Periodic reviews of the current literature are also published in the scientific journals (for example, Ryland *et al.* [26]).

Case Histories

Green River Murders. In 1982, five women were murdered and left in or near the Green River, Washington, USA. Over the next several years, more bodies were found in the same area. In many cases, months or even years had passed since the victim's disappearance, and all that was found were skeletal remains. Eventually, 49 victims were listed as victims of the Green River Killer. The murders remained unsolved for nearly two decades.

In 1987, police took saliva samples and other evidence from a man called Gary Ridgway but did not find anything that linked him to the murders.

By 1991, the killings stopped and the case was dormant. Then in 2001, with DNA testing technology becoming more widespread, police began reexamining some of the evidence they had collected during the 1980s. They discovered a DNA match between Ridgway and semen taken from four of the victims.

Police arrested Ridgway and charged him with murder. He appeared to have been absent or off duty from work on every known occasion when a victim had disappeared.

His attorney planned to make the argument that the DNA evidence proved nothing more than that he had been a customer of the women. Prosecutors were hesitant about basing their case nearly exclusively on the DNA evidence. Police turned to forensic scientist Skip Palenik in an effort to find additional evidence to link Ridgway with the victims.

Ridgway had a job painting trucks during the time when the murders occurred. Paint samples had been collected from his car, clothes, and work locker and also from the victims. Several thousand small paint samples associated with Ridgway were analyzed by FTIR microscopy. When Palenik found a sample

with a matching infrared spectrum, he examined it using high magnification polarized light microscopy to identify the pigment, and X-ray spectroscopy to determine the elemental composition. While there were a number of initial spectral matches, none of the samples held up all the way through the analysis process.

"I had completed my assignment but I had a hunch that there was a lot more to this aspect of the case than met the eye," Palenik said. "I asked the prosecutors to provide me with Ridgway's and the victims' clothing so I could take a much closer look."

Palenik used reusable cassette-type filters connected to a vacuum cleaner, and collected particles with sizes in the 20–100-μm range, only about one hundredth the size of the particles he had examined in the first phase of his analysis. Spray painting guns, such as those used by Ridgway in his job, generate tiny spheres of paint in the micron range that are so light they float in the air rather than fastening themselves to the object being painted.

Palenik collected tiny particles and then, viewing them through a powerful optical microscope, picked them out with tungsten needles and placed them on microscope slides for analysis.

The fact that no further sample preparation was required for IR microscopy was essential because it would have been difficult or impossible with samples this small. It was possible to generate usable IR spectra from particles as small as $10\,\mu m \times 10\,\mu m$.

Palenik said, "As the Green River investigation demonstrates, the smaller the particle you can analyze the better chance you have to solve the case. This investigation also illustrates another important advantage of this instrument. It can save huge amounts of time by automating the process of checking a sample against a reference library."

He found hundreds of these tiny spheres in many colors on the clothes of six of the victims, including two that had been linked to Ridgway by DNA evidence. Most of the samples were of Imron paint, a very rare type that was used extensively in the paint shop where Ridgway worked at Kenworth Trucks. Working with Dupont, who manufactured the paint, he was able to tie the samples to paint that Ridgway had been using around the time of the murders.

On the basis of this evidence, prosecutors charged Ridgway with further murders. In November 2003, shortly before the trial was to begin, Ridgway confessed to murdering 48 women. He said that these were only the ones he could remember out of a total that he estimated at 70.

Ridgway's attorney was quoted in the press as saying that the paint evidence was crucial in his client's change of heart. "When this paint business came up, here you have something other than DNA – it's a particular paint you can link to Gary – and you start saying 'Well, here are seven dead women and they all can be linked to Gary one way or another,' Savage said." "What are the odds of that happening by accident?" [27].

Murder of Lord Mountbatten. In Europe, paint has also provided crucial evidence in high profile court cases. One of the first major cases in which the Irish Forensic Science Laboratory in Dublin was involved was the murder in 1979 of Lord Mountbatten, a cousin of Britain's Queen Elizabeth II, by the illegal Irish Republican Army (IRA).

He was going fishing in his green, wooden boat, *Shadow V*, when an explosion ripped through the vessel, killing him and three others and badly injuring three more.

That morning, before the explosion, two men were stopped by a police checkpoint more than 100 km away and questioned. One denied putting any bomb on the boat – but at this stage there had been no explosion and the police did not know what he was talking about. The second man, Thomas McMahon, was a known IRA man and explosives expert.

When news came of the explosion on Lord Mountbatten's boat, the two suspects were detained and their clothing and samples from their car were taken.

At the laboratory, flakes of two-layer green paint were recovered from McMahon's jacket and boots and from the passenger seat of the men's car. This paint matched the green paint recovered from the bodies and taken from the boat.

In addition, grains of sand and traces of nitroglycerin recovered from the suspects added to the trace evidence in the case against them. McMahon was convicted of murder and sentenced to life imprisonment [28].

Graffiti. Graffiti is a widespread phenomenon arising, for example, from simple vandalism or from the actions of racist or activist groups. The financial cost

of removal can be substantial and it is treated very seriously by transport police.

Allegation of criminal damage involving one suspect and two submitted control scrapings from a control box at the side of a London underground station.

A suspect was arrested running from a scene where the spraying of graffiti had been witnessed. A hooded top, seized soon after arrest, was submitted to the laboratory and microscopically examined. It was found to have a moderate concentration of paint balls on the outside surface, the majority of which were located on the front of the right sleeve and cuff. Both control paints were red and were optically indistinguishable from each other, but were chemically different when tested using FTIR. Red paint was the only color found on the surface of the hooded top. When tested microscopically, this red paint was indistinguishable from both of the red control paint samples. Both the control paints and these recovered paint balls contained red and brown particles when examined with transmitted, polarized light and did not fluoresce when observed under light passed through blue and ultraviolet filters. The recovered paint was indistinguishable from one of the submitted controls when analyzed by FTIR. The finding of red paint, indistinguishable from one of the submitted control samples on a hooded top, was deemed to provide *moderately strong scientific support* for the proposition that the wearer of the top had been in the vicinity of this graffiti while it was being sprayed [29].

JOHN MCCULLOUGH

Paint: Interpretation

Introduction

Paint may be used as an investigative or an evaluative tool. Here, the focus is on interpretation, which is fundamental for paint and other transfer evidence (*see* **Paint**). When comparing two paint samples with a given analytical sequence, two main outcomes are possible. They are the following:

- The two samples can be differentiated.
- The two samples are not differentiated, they are analytically indistinguishable.
- There is a physical fit (rare).

In the first scenario, given that the reference paint is representative of the source material, a common origin can be excluded. In the second scenario, the examinations reveal a concordance in properties, but are these properties common or rare?

The authors believe that the forensic scientist is in the best position to give an opinion on the value of this concordance. In general, paint interpretation is based on the frequency of occurrence of the measured characteristics. Very common paint types have less evidential value than very rare paints. An estimate of the frequency of occurrence of the different characteristics measured for each paint type would be an invaluable tool.

Even if the literature on paint interpretation is rather sparse in comparison to other trace evidence like fibers or glass, there are surveys or information that can help the scientist to evaluate the strength of evidence. The main ones are the following:

Frequency figures:
- population studies and frequency distribution;
- information on batch variations; and
- databases/reference collections.

Others:
- expert opinion;
- paint found at random on clothing and surveys on paint traces;
- transfer and persistence; and
- a likelihood ratio approach.

Paint experts also rely on data concerning the discrimination power of the technique, or the sequence of techniques, used to present their findings. The discriminating power is calculated according to the formula from [1] and is usually mentioned in population studies.

Automotive Paints

Introduction

In the automotive industry, the application of the different paint layers to the metallic automotive body follows several steps. The process stages for original equipment manufacturer (OEM) paints can be simplified as follows [2]:

- *Metal pretreatment*: degreasing, passivation, phosphatage layer.
- *Electro dip coating*: application of the primer layer by electro deposition.

Table 1 Automotive paints, population studies

Authors	Countries	Number of samples	Methods	Number of nondifferentiated pairs
Gothard [3]	Australia	500	Optical: color, layer sequence Chemical tests Analytical: infrared spectroscopy, emission spectrography, pyrolysis GC	2
Ryland and Kopec [4]	USA	200	Optical: color, layer sequence Chemical tests Analytical: infrared spectroscopy, emission spectrography, pyrolysis GC, X-ray fluorescence, NAA	0
Gothard and maynard [5]	Australia	500	Optical: color, layer sequence Chemical tests Analytical: infrared spectroscopy, pyrolysis GC	3
Massonnet [6]	Switzerland	124 Gray metallic	Optical: color, layer sequence Analytical: infrared spectroscopy, MSP	4
Reeza Alwi and Kuppuswamy [7]	Malaysia	100	Optical: color, layer sequence	0
Edmonstone *et al.* [8]	Canada	260	Optical: color Analytical: infrared spectroscopy	2 (1 with the analysis of all layers)

- *Fillers*: application of the primer surface layer.
- *Finish or topcoat*: usually applied in one layer for solid paints and in two layers for metallic or effect finishes (first the effect layer is applied then a clearcoat).

Other original layers can be added to this sequence like protection against chipping by stone, sealing layer, or other extra layer to increase the quality of the final product. During this process, nonoriginal or repair layers can also be added at any step if paint defects are observed.

Automotive paint traces are mostly found in road accident and are transferred to the recipient surface when contact occurs. Paint can be transferred to vehicles, pedestrians, or fixed objects. Paint may be the only evidence in hit-and-run cases. Paint smears or fragments may also be found on objects or bodies transported in cars.

Population Studies

Several authors published comprehensive studies concerning the differentiation of paints collected at random on vehicles in different countries [3–8]. A summary of these surveys is presented in Table 1. These researches provide details on the distribution of automotive paints using a chosen analytical sequence.

Some general conclusions may be drawn from these population studies as follows:

- Optical examinations alone are very discriminating. According to Ryland and Kopec [4], 87% of their sample set is discriminated on the basis of color and layer sequence.
- All the authors agree that the layer sequence is the most significant point of comparison. Figure 1 shows the frequency distributions of the paint samples according to their number of layers in the different surveys. Gothard [3] states that "a large number of layers agreeing with regards to color, thickness, and layer sequence can be taken as proof of common origin without further examination". According to Ryland and Kopec [4] "... the probability of two paint chips originating from different sources is extremely remote

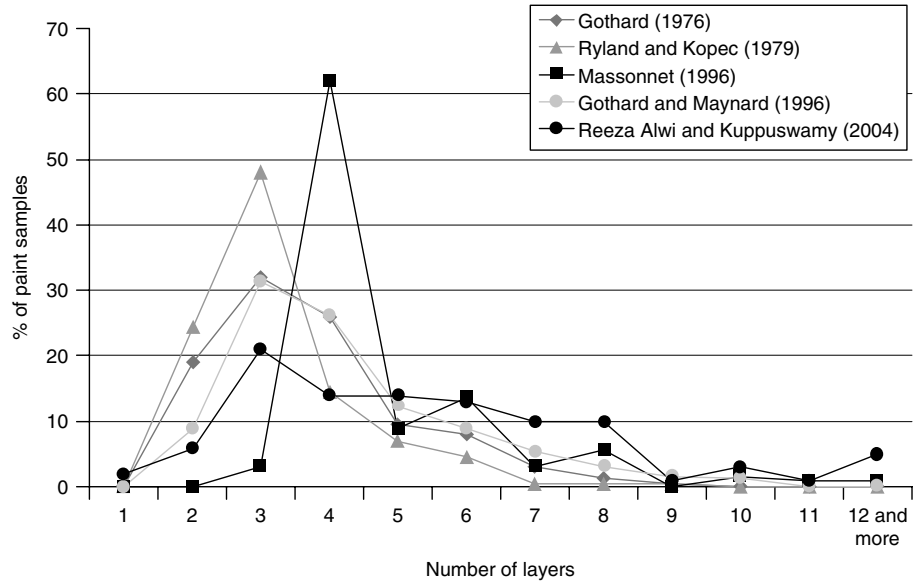

Figure 1 Frequency distribution of the paint samples in the different surveys according to their number of layers

when they have numerous layers (six or more) consistent in color, tint, type of finish, and layer thickness".

- When a complete sequence of analysis (optical and analytical) is applied, non-OEM or refinished paints are easily differentiated. The number of nondifferentiated pairs is low (between zero and four) and these samples are all OEM paints belonging to vehicles of the same make, model, color, and approximate year of production.
- Edmonstone *et al.* [8] compared the topcoat only (microscopy and chemical composition). Only two sample pairs were indistinguishable: they belonged to vehicles of the same make, model, and production plant. The first pair belonged to vehicles from 1995 and 1997, and the second pair had been produced the same year (1989). When all layers where compared and analyzed using FTIR, samples from the first pair were distinguished, and the second pair remained nondifferentiated.

Globally, these surveys show that if two paints with numerous nonoriginal layers are indistinguishable using a state-of-the-art analytical sequence, there are generally few doubts that they have a common origin [2].

Vehicle Topcoat Colors: Frequency Distribution

Several authors worked on the frequency distribution of vehicles' topcoat color [9–14]. Vehicles in circulation were counted according mainly to their topcoat color, but sometimes also considering their make, model, or year of production.

The main outcomes of these surveys are the following:

- Color categories chosen by the authors are more detailed than the one used in the official statistics and can include the difference between effect and solid paints. The frequencies obtained are lower than in the official register. The most common color group depends on the country considered and has a frequency of occurrence between 20 and 25%.
- When combining detailed color group and car make, the most common combination has a frequency of occurrence of less than 5% (between 3.2 and 4.8% depending on the survey). Thus, the occurrence of vehicle from particular make and color on the road can be considered from a statistical point of view as an unusual event.
- Globally, there is a rather good accordance between the data observed (color and make) and

the corresponding numbers in the official statistics of vehicles in a given country or geographic area.

Tippett [9] counted the number of cars from a specific make and color in 100 groups of 100 cars. Two car makes were chosen, one being the most common (10.8%, frequency of occurrence) and the other one being rare (1%). He found that the data obtained follow a Poisson distribution and thus that they can be statistically predicted. With this model, it is possible to predict the number of times a particular colored model is seen on the road in a given time frame depending on the density of traffic.

McDermott *et al.* [14] collected and used the data obtained in a likelihood ratio framework for the interpretation of automotive paint evidence.

Batch Variations

The conclusion that was drawn from population studies is that if two multilayer paint systems are nondifferentiated with a complete sequence of analyses, they are original OEM paints from vehicle of the same make and model and approximate year of production.

The next question is, are we able to distinguished OEM paints or, according to Stoecklein and Palenik [15]. "In how many vehicles produced by one manufacturer and painted in the same color, can the paint be distinguished?"

Different batches from three of the most frequent colors applied to vehicles produced between 1989 and 1994 were analyzed by [15]. Their conclusions are that by using a broad spectrum of analytical techniques (microscopy, fourier transform infrared spectroscopy (FTIR), Microspectrophotometry (MSP), Raman, and pyrolysis gas chromatography mass spectrometry (Py-GC-MS)), it is possible to discriminate between OEM topcoat of different batches. Within one batch only a limited number of automobiles can be coated. After being in use, only few of these cars have coatings, which still show the same physical and chemical features. Therefore, one can assume that by analyzing OEM paints, the expected weight of the evidence will be strong or very strong [15].

To evaluate the correspondence of OEM multilayer paint systems, the following facts must be considered [2]:

- One batch of paint (topcoat) can be used to paint 8–3,500 vehicles.
- About 40% of the cars are locally repainted at the production plant.
- Change in batches can also occur for the other layers.
- In circulation, paints are differently affected by weathering and can be repainted after damage.

When using a comprehensive range of methods, in particular quantitative analysis instead of only qualitative, it is possible to differentiate between batches as well as between different conditions of weathering [15, 16]. Thus, the number of vehicles on the street with exactly the same OEM layer sequence is very low. Stoecklein [2] concludes that "there is very little likelihood of a second vehicle, with an identical characteristic profile of its coating material, being on the street at the time of the accident, in the vicinity of the scene of crime. The evidential value of such result is to be regarded as very high".

Databases/Reference Collections

Two main databases of automotive paints are available to police forces. Paint data query (PDQ) is mainly used in Canada and in the United States [17, 18]. The European collection of automotive paint (EUCAP) is used by the European laboratories [2]. Japanese police forces also have their own database for Asian cars. These collections are continuously updated.

The aim of these databases is to provide information to the police about cars (make, model, color, and production years) based on the analysis of paint traces found in hit-and-run accidents. Infrared spectra of thousands of samples are recorded for each different paint layer.

These databases can also provide information concerning the commonness/rarity of different paint types. For example, a clearcoat based on acrylic melamine and styrene will be present on several different vehicles and thus will have a rather low evidential value. On the other hand, a very special paint corresponding to only one vehicle will have a higher evidential value. Care should, however, be taken as the frequency distributions obtained in such databases do not represent the population of vehicles in circulation in a specific country but the variations observed between the different car make and color present in the database.

More generally, there should be reference collections available for each of the techniques used in

Table 2 Conclusions used by paint examiners for paint exchange scenarios [21]. Reprint with permission of Thomson Publishing Service

	Conclusion (%)				
Scenario	Slight support	Support	Strong support	Very strong support	Conclusive

G, multilayer nonmanufacturer's finish transferred in one direction;
H, multilayer nonmanufacturer's finish transferred in each direction.

the different laboratories. A few surveys can also be found in the literature. For example, using Raman spectroscopy it was determined that 59% of the 27 light red automotive paint samples analyzed contain a specific red pigment (CI PR254). As this pigment is very commonly used in red paints, the evidential value of such finding will be low. On the other hand, a very rare combination of pigments will have a higher evidential value [19].

Expert Opinion

McDermott and Willis [20] circulated a questionnaire to 235 paint examiners. Different hypothetical automotive paint transfer scenarios were presented and the respondents were requested to use a scale of conclusions ranging from slight support to conclusive. Table 2 illustrates the hypothetical transfer scenarios and the answer given by the paint experts [21].

This survey gives an insight into the value placed on such evidence by forensic scientists working in the field of paint analysis. This survey globally shows that a multilayer repaint system has more evidential value than a multilayer OEM paint system and that a multilayer paint has more evidential value than a single layer paint. Scientists also give more evidential value to cross transfer compared to a single direction transfer if the same type of paint is considered [20].

Household Paints

Introduction

Paints covering surfaces other than vehicles are commonly called *household paints* [21]. The interpretation of this kind of paint evidence is quite different from the interpretation of vehicle paint. Vehicle paint follows a definite sequence of color, number, and thickness of layers, which are specified by the manufacturer. Household paint is more often encountered in single layer, but is considered to provide strong evidence due to the large range of paints available.

Household paint traces encountered in forensic cases can originate from buildings (architectural paints), tools, spray cans, etc. In a burglary, paint traces can be transferred on the tool used to force a door, and if the tool is covered by a paint layer, paint particles from the tool can be possibly found on the door. In graffiti case, the paint can be compared with a reference spray can, but microscopic wet aerosol paint droplets can be transferred on the clothes and on the hands of the offender and could provide highly significant evidence. In these two examples, three kinds of paints (building, tools, spray) and four kinds of supports (door, tool, clothes, hands) are encountered. To evaluate the evidential value of these paint traces, the forensic expert will need information about the frequency of the analytical characteristics of the

type of paint encountered, and about the frequency of pounding randomly paint traces on the kind of support on which the traces were found.

Population Studies

Several authors have studied the discriminating power of an analytical sequence on different populations of household samples [22–29]. Table 3 shows a summary of these surveys.

These researches show that certain binder types are more commonly encountered. They also demonstrate the high potential of common analytical sequences to discriminate between household paint samples, even for samples of the same color and binder type.

Table 3 Household paints, population studies

Authors	Samples	Methods	Commonest binders/ extenders combinations		Number of subgroups (maximum number of items per group)	Discriminating power of the whole sequence
Tippett *et al.* [22]	200 paint samples from buildings	Microscopy	–			0.999
		Solvent tests				
		Spectrography				
		Py-GC-MS				
May and Porter [23]	31 household gloss paints (11 white, 10 red and 10 green)	Microscopy	ALK	80%	8 (3)	0.93 (white)
		Emission spectrography	ALK + PUR	10%	10 (1)	1 (red)
		Solvent tests	ALK + fire retardant	10%	10 (1)	1 (green)
		FTIR				
		X-ray diffraction				
		Py-GC-MS				
		Py-FTIR				
Laing *et al.* [24]	169 household gloss paints (divided in 12 color categories)	Microscopy	–			0.89 to 1
		MSP				
Castle *et al.* [25]	100 case-openers	MSP	ALK	61%	–	–
		Py-GC-MS	ALK + STY	8%		
			EPOXY	8%		
			ALK + VINYL TOL	6%		
			ACR	6%		
Buzzini and Massonnet [26]	40 green spray paints	FTIR	ALK OPH + NCL	28%	31 (6)	0.98
		Raman	ACR	23%		
			ALK OPH + $BaSO_4$	15%		

(*continued overleaf*)

Table 3 (*continued*)

Authors	Samples	Methods	Commonest binders/ extenders combinations		Number of subgroups (maximum number of items per group)	Discriminating power of the whole sequence
Govaert and Bernard [27]	51 red spray paints	Microscopy	ALK + NCL	45%	37 (4)	0.988
		FTIR	ALK	24%		
		X-ray fluorescence				
Buzzini *et al.* [28]	41 blue crowbars	FTIR	ALK OPH + NCL	71%		
			ALK OPH + $CaCO_3$	17%		
			ALK OPH	7%		
Gosse *et al.* [29]	38 black spray paints	FTIR	ALK OPH +NCL	42%	34 (2)	0.994
		X-ray fluorescence	ALK OPH	21%		
		Py-GC-MS	ACR	13%		
			ALK OPH +NCL + STY	11%		
Gosse *et al.* [29]	38 black spray paints	FTIR	ALK OPH +NCL	42%	34 (2)	0.994
		X-ray fluorescence	ALK OPH	21%		
		Py-GC-MS	ACR	13%		
			ALK OPH +NCL + STY	11%		

ACR, acrylic; ALK, alkyd; ALK OPH, orthophthalic alkyd; NCL, nitrocellulose; PUR, polyurethane; STY, styrene; VINYL TOL, vinyl toluene

For example, all the red spray paints analyzed by [27] are alkyd based, but these samples can be classified into 37 different groups. The discriminating power of this sequence (microscopy, FTIR, and X-Ray fluorescence) is 0.988.

Batch Variations

As for vehicle paints, if two household paints are indistinguishable, the question of batch to batch variation is asked. Could this paint trace come from any other batch of the same brand, or is it possible to exclude other batches and to link the trace to a given batch?

Inkster *et al.* [32] compared 14 batches of the same architectural acrylic white paint by microscopy, microspectrophotometry, FTIR, micro-XRF and Py-GC-MS. Only one batch could be differentiated from the other. In this study, only qualitative analysis was used. On the other hand, [33] observed significant differences between two pairs of batches, using statistical analysis of the results by principal component analysis (PCA). These results suggest the high potential of chemometric tools or semiquantitative analysis to differentiate between closely related spectra.

Databases/Reference Collections

Databases for household paint are less developed than for vehicle paints. However, some specific databases exist. For example, the European database of spray paint contains the infrared spectrum of 209 spray paints. This database can be used to identify an unknown spray paint trace, but also to evaluate the frequency of the infrared characteristics of a given spray paint. The French database of black

spray contains the infrared spectrum of 38 black spray paints with information about the Py-GC-MS results [29].

Each laboratory has the opportunity to create their own databases, for example, containing traces found in caseworks or various reference samples.

Paint Found at Random on Clothing and Surveys on Paint Abrasion Traces

Introduction

When paint cannot be unambiguously attributed to criminal activity, it is then necessary to assess if it could be present as background. Population studies demonstrate the potential of analytical methods, but cannot be used to evaluate the frequency of paint traces found on different kind of supports. To do so, it is necessary to collect and analyze traces, and not control samples. Indeed, background paint may not have the same origin (i.e., vehicle, household, tools) as samples. These backgrounds or so-called random paint studies are more complicated to carry out, because of the difficulty of pinding samples and the time needed to collect and count them. These studies often contain information about the frequency of the color, the size, and number of layers of the traces. Analytical results are less often available.

Paint Found at Random on Clothing

The two available studies about paint found at random on clothing show contradictory results. Lau *et al.* [31] found that on the majority of searched items no paint traces are recovered. If traces are recovered, it is rare to find more than one fragment. On the other hand, in the study of [30] four or more fragments are recovered on 80% of the items. This difference, also observed for glass, as the authors looked at both paint and glass sample, could be explained by the size of the fragments: for 52% of the recovered fragments by [30] the size is less than 0.3 mm. Lau *et al.* [31] indicate that the majority of the recovered paint fragments were smaller than 1×1 mm, but no information is available about the minimum size considered. In addition, it must be noted that Pearson *et al.* looked at particles recovered in pockets and cuffs, where one might expect to find more particles, because of longer retention time. Table 4 shows a summary of the main results obtained in both studies.

Table 4 Paint fragments found at random on clothing

Authors	Items searched	Commonest colors of paint traces		Number of paint fragments on each item
Pearson *et al.* [30]	100 suits	Red	29%	0 : 3%
		Green	23%	1 : 8%
		Cream	14%	2 : 3%
		Blue	12%	3 : 6%
				4 and more : 80%
Lau *et al.* [31]	216 upper body garments	Yellow	31%	0 : 86%
		Pink	18%	1 : 12%
		Red	15%	2 : 1%
				3 : 1%
	213 lower body garments	Yellow	32%	0 : 88%
		Pink	22%	1 : 10%
		White	8%	2 : 2%
				3 : 0.5%
	164 pairs of footwear	White	27%	0 : 77%
		Red	21%	1 : 10%
		Black	15%	2 : 4%
		Yellow	13%	3 : 2%
				4 and more : 5%

Table 5 Survey of abrasion paint traces

Authors	Items searched	Commonest colors of paint traces		Number of types of paint traces on each item
McDermott *et al.* [14]	1000 vehicles	–		0 : 91% one and more : 9%
Ranzi *et al.* [34]	147 foreign traces found on damaged cars	Gray	26%	–
		Red	22%	
		Blue	17%	
		Green	6%	
		White	6%	
		Yellow	6%	
		Black	5%	
Buzzini *et al.* [28]	207 crowbars	White	61%	0 : 34%
		Red	18%	1 : 50%
		Green	7%	2 : 13%
		Brown	5%	3 : 2% 4 : 1%

Surveys on Paint Traces

Studies on paint found on clothing concern paint fragments, which have to be differentiated from paint abrasion traces. A few studies on paint abrasion traces are available for cars [14] and tools [28, 34], see Table 5.

Transfer and Persistence

Again, when paint cannot be unambiguously attributed to criminal activity, knowledge of transfer and persistence phenomena becomes important to assess the value of paint traces.[a] The expert should be able to evaluate if the quantity of paint recovered is consistent with the alleged contact. However, transfer experiments are difficult to perform, especially with vehicle paints. For this reason, the number of studies involving transfer experiments is low.

Generally, a strong contact is necessary to remove paint from its support (metal, wood, etc.). This can be caused by an impact or an abrasion. The quantity of paint transferred depends on the force applied, the condition of the paint, the duration of the contact, and the nature of the object in contact with the paint. This concerns dry paint, but sometimes wet paint could be transferred, for example, in cases involving spray paint, where wet paint could be transferred on the hands and on the clothing of the suspect [21]. Moreover, the persistence of wet paint is expected to be very good, because after drying the paint is strongly attached to the recipient.

Krausher [35] studied the transfer of droplets of paint to clothing during the use of aerosol paint. The density of droplets on the clothing of a sprayer is high, especially in areas exposed to the paint cloud. The size of the paint droplets is generally about 10–40 microns. Owing to their small size, the persistence of the paint droplets is lower than that for large wet paint transfer. The droplets are easily removed from the surface by washing. Marin *et al.* [36] have also studied the transfer of paint droplet from spray paint and obtained quite similar results.

Buzzini *et al.* [28] studied the cross transfer of paint between a crowbar and a painted wooden surface. In every simulated contact, a reciprocal transfer of paint was observed. A correlation between the quantity of household paint transferred in one direction and the quantity of tool paint transferred in the other direction was observed.

A Likelihood Ratio Approach Within a Hierarchy of Propositions

Bayes theorem shows how the evidence influences the probabilities associated with two alternative hypotheses. Three different levels of hypothesis can be considered: source level, activity level, and offense level [37]. For example, in a case where paint traces are recovered on a tool and compared with the paint of a forced door, the hypothesis could be as follows:

Source level

H_p: the traces found on the tool come from the paint of the forced door;
H_d: the traces found on the tool do not come from the paint of the forced door and are present as background.

Activity level

H_p: the tool has been used to force the door;
H_d: another tool has been used to force the door.

Offense level

In most cases, the information to consider is neither known by the forensic scientist (e.g., modus operandi of the suspect), nor in his/her field of expertise. It is therefore very rare for paint specialists to assess likelihood ratios at the offense level, such as follows:

H_p: the suspect has forced the door using that tool;
H_d: the suspect has not forced the door.

The assessment of the source level depends on analytical information obtained during examination [38]. The frequency of the analytical characteristics of the evidence is the important factor of the likelihood ratio. This frequency is evaluated in a given population. The choice of the relevant population is crucial, because a wrong population could drastically change the value of the frequency. In transfer evidence, the relevant population is often traces found on a given support. For example, in the case of paint traces recovered on a tool, the relevant population could be paint traces recovered on a population of tools seized by the police on suspects. Paint traces studies give the appropriate information to the evaluation of the frequency. However, the number of population studies of paint traces is quite low and in some cases the corresponding trace population study is not available. In this situation, general population studies could be used. Generally, the role of the expert is to make an inventory of all the information found in the literature, and to estimate the frequency of the paint trace on the basis of these studies.

The assessment of the activity level is more complex. In addition to the frequency parameter, transfer and background parameters have to be taken into account. Transfer parameters concern the probability that paint traces were transferred to the given support, persist, and are recovered. Compared to glass or fiber evidence, the phenomenon of paint transfer is not fully understood, especially the transfer of vehicle paint. Background parameter concerns the probability of finding such a paint trace at random on this given support. Background parameter could be estimated on the basis of population studies of traces.

The number of studies about Bayesian interpretation of paint evidence is limited. McDermott *et al.* [14] and Willis *et al.* [21] calculated the likelihood ratio for various transfer scenarios for automotive paints and [28] used the Bayesian approach to evaluate the value of a cross transfer of paint between a tool and a forced door.

Conclusion

The ability of the expert to estimate the frequency of a specific paint type will rely mainly on experience and familiarity with the relevant literature as well as on access to representative databases. Other information like paint found at random or other expert opinion is also a great help to the interpretation of some cases.

Background data are available in the literature to help the scientist to assess the evidential value of his/her paint examination (automotive and household). Databases are very important to provide frequency of occurrence on different paint categories. If possible, these databases should be local to take into account the population of paint in a given geographic area. More work is needed principally on traces population studies and on paint interpretation using a likelihood ratio approach.

End Notes

[a.] If the paint is unambiguously attributed to the criminal activity, the probability of the evidence

being transferred, having persisted and being recovered, is one under the prosecution's proposition (i.e. Vehicle A*** hit vehicle B). The probability of the evidence given the defense proposition (i.e.Vehicle A*** did not hit vehicle B) is the frequency of the observed characteristics in the suspect population. It is certain that the evidence is not background.

Palmprints *see* Friction Ridge Examination (Fingerprints): Interpretation of

Palynology

Introduction

One of the newer techniques now being used more frequently is forensic palynology: the collection and examination of pollen and spores associated with crime scenes, other types of illegal activities, or terrorism. The value of using pollen and spores (collectively called *palynomorphs*) as forensic tools relies on four important aspects.

First, many types of pollen and spore-producing plants disperse vast quantities of these palynomorphs into the air that are carried by air currents and eventually fall to the ground in a thin coating called the *pollen rain*. In some regions, the amount of pollen and spores dispersed is so great that exposed land and water surfaces turn yellow from the pollen rain. Although not a precise measurement of the surrounding vegetation, and thus by inference the climate of the area, the pollen rain in each region of the world is nevertheless a snapshot of that area and becomes a "pollen print" that can be used to assist in identifying the region.

Second, pollen and spores are microscopic in size, invisible to the naked eye, and can become trapped on almost any type of surface. This means that at any geographical location, pollen or spores from plants in that region, or more specifically, the pollen and spores from a specific crime scene can become evidence that will link a suspect or some object with the region or crime scene.

Third, there are nearly one-half million different plant species that produce either pollen or spores. Fortunately, each of these species produces pollen or spores that can be identified as coming from the parent plant; however, often differences in the pollen and spores of closely related species or even related genera may appear so similar that precise identification can only be achieved through detailed studies using the resolution capabilities of a scanning electron microscope (SEM) or transmission electron microscope (TEM).

Fourth, most pollen and spores are highly resistant to destruction or decay. This means that pollen and spore evidence from a region or crime scene can remain intact for years, hundreds of years, or even thousands and millions of years. This means that if crime scene evidence is handled correctly and

stored safely, years or decades later the trapped pollen and spores can still be recovered and used to assist investigators.

Even though the first reported use of pollen to help solve a crime occurred nearly 50 years ago, very few attempts to use this forensic tool occurred in the meantime, and even then the number of times it was used has been rare. Only recently, during this century, the number of applications and attempts to use pollen and spore evidence for forensic use has been increasing. As the number of times that pollen and spores are successfully used as evidence in forensic cases increases, so does the range of its potential applications. Recently solved criminal cases demonstrate that the forensic use of pollen and spores can be applied to cases of forgery, production and distribution of illegal drugs, assaults, robbery, rapes, homicide, genocide, terrorism, arson, hit and run crimes, counterfeiting of currency, identifying the origin of fake prescription drugs such as Viagra, and various other types of criminal activity. Pollen and spore evidence has been used to resolve a variety of civil cases involving forged documents, fake antiques, authentication of paintings by master artists, removal of artifacts from historic or archaeological sites, illegal poaching of animals or fish, and cases involving illegal pollution of the environment [1].

Successful use of pollen and spores in forensic applications may depend on the palynologist's knowledge and experience. One must know and understand the plant ecology and plant communities in and around the crime scene area or the region where pollen samples were collected. A sound understanding of palynology including knowledge of the production, dispersal patterns, preservation potential, and identification of pollen and spores is essential to understand and interpret the expected total palynomorph assemblage recovered in forensic samples. As with most types of forensic evidence timing is critical. The sooner the palynologist is called to investigate a crime scene, the more likely will be the potential value of the collected samples. Because pollen and spores are small, light, easily recycled, and present in abundant amounts in the atmosphere, a crime scene can quickly become contaminated by recycled palynomorphs accidentally carried into the area on the clothing or shoes of crime scene investigators, deposited out of the atmosphere, or from other noncrime scene sources if the forensic pollen sample collection is delayed or collected improperly. Under ideal circumstances, and with proper and timely collection of forensic pollen samples, one might even be able to determine the season of the year when a crime was committed and occasionally how long ago a crime was committed. Much of that information pertains to knowing the pollination cycles of various plants and being able to check for the presence of cytoplasm and the innermost wall of pollen grains, called the *intine*, which is composed of cellulose and degrades fairly rapidly after pollen grains are dispersed [2].

Pollen Types

Some of the most useful types of pollen and spores for forensics are the wind-pollinated types. This group includes the spore-producing plants such as fungi, ferns, and mosses as well as a wide range of pollen types produced by the gymnosperms (nonflowering seed-bearing plants such as pines, cedars, and spruce), and a significant number of angiosperms (flowering seed-bearing plants such as aspen, elms, and chestnuts). Because wind pollination is an inefficient method of dispersion, these plants must produce vast quantities of pollen or spores that are usually lightweight and are aerodynamically designed to travel easily in air currents. The enormity of pollen production in many of the wind-pollinated (anemophilous) plants is exemplified by statistics such as the following: a single shoot of marijuana (*Cannabis*) produces about 500 million pollen grains, one dock (*Rumex*) plant produces about 400 million pollen grains, a single panicle of sorghum (*Sorghum*) disperses 100 million pollen grains, and just one male strobilus on a branch of a lodgepole pine (*Pinus contorta*) produces over 600 000 pollen grains. In addition to these examples, many of the other wind-pollinated plants such as ragweed, grasses, some species of eucalyptus, oaks, hickory, walnut, birch, alder, and elms produce between 10 000 and 100 000 pollen grains per anther (the part of a flower that produces and contains pollen and is usually borne on a stalk). Other anemophilous plants, some of which are low pollen producers, still produce more than 10 times the amount of pollen per anther and flower than almost all species of insect-pollinated plants. The amounts of pollen dispersed annually by the wind-pollinated plants is so vast that their pollen can be found in almost every environment in the world and

the distribution of those pollen types in the pollen rain (total pollen deposited annually at any given location) of each region gives each locale its own pollen print. As such, these pollen types are the most common ones found in the fossil pollen record of a region and are also the most common types found in forensic pollen samples [3].

Some flowering plants live completely submerged in water, release their pollen underwater, and then rely on the pollen to float to the surface or ride water currents in an effort to accomplish fertilization. This method of transport, like the wind, is an inefficient method of pollination; therefore, like wind-pollinated plants, submerged plants produce high levels of pollen. These types of pollen could be found on the clothing, in the lungs, or possibly in the stomach of individuals who drown or were thrown into lakes or streams after being killed. Nevertheless, these types of pollen are often of little potential value for forensic work because they decay very easily and are difficult to recover without accidentally destroying them in the process.

The largest group of flowering plants is the insect or animal-pollinated types (entomophilous). This group depends on the transport of their pollen grains from the anther (male portion) of one flower to the stigma (female portion) of another by some type of insect (bee, wasp, beetle, moth, mosquito, and ant) or by some type of animal (hummingbirds, lizards, nectar-feeding bats, or other small mammals). The pollen grains produced by these entomophilous plants are generally ornate, have a surface covered with sticky lipids and waxes so that they attach easily to insects and mammal hairs, and most of these pollen types have a strong, thick outer wall (exine) that protects them from abrasion during transport and from rapid changes in humidity [4].

Because of the pollination efficiency of entomophilous plants, pollen productivity per anther and flower is much less than that in wind-pollinated plants. In maples (*Acer*), for example, each anther often contains no more than 1000 pollen grains and in flax flowers (*Linum*) each anther may contain as few as 100 pollen grains. In spite of the low pollen production in most entomophilous plants, they can often provide some of the most useful forensic clues. Because these pollen types are often large and heavy, and have a sticky surface, they are rarely cast adrift in wind currents and thus are rarely found in the normal pollen rain of a region. This means that it would be extremely rare to find these types of pollen grains in the natural deposits of an area and thus they would rarely be an important type found in a region's pollen print. These attributes are both good and bad. They are good because if any of these types of pollen grains are found on objects at a crime scene or in another type of forensic sample, it generally means that the object or sample came in direct contact with the flowers or perhaps the leaves of the parent plant. This becomes an advantage because it often means that one can confidently conclude that an item or person was associated with a crime scene or some other specific locale where those parent plants and pollen types are found. It also provides a high degree of confidence that the pollen in the forensic sample belongs with the sample and that the pollen was not an atmospheric "contaminant". The downside of entomophilous pollen types is that so little pollen is produced by each plant that the chances of those pollen grains being transferred from the plant to some foreign object or person is often reduced.

Interpretation of Pollen Data

Understanding the rules that govern pollen production and dispersion are essential factors, which must be considered before evaluating forensic samples. Other important factors that will affect forensic pollen samples include how rapidly different types of pollen and spores settle out of the atmosphere (sinking speed), how well various types of pollen and spores remain preserved once they are deposited, and what types of clues indicate that pollen grains may have been recycled after they were deposited.

How rapidly airborne pollen and spores sink to the surface will determines how much and which species of pollen and spores will actually becomes part of the pollen rain and thus the pollen print of a given locale or region [5]. For example, marijuana, alder, juniper, and birch pollen are very small and very light pollen grains that have a sinking speed of about 1 or $2\,\mathrm{cm\,s^{-1}}$. This means that finding a few of these pollen grains in a forensic sample does not necessarily mean these plants are actually growing at the sampling spot. Instead, it might mean that the pollen resulted from long distance transport from sources many miles away. Before being able to determine this possibility, one would need to calculate how much pollen from these airborne types occurred in a forensic sample, how strong and from which direction the

prevailing winds are in the sampled region, and what the total pollen concentration value (amount of total pollen deposited and subsequently preserved in one unit of deposit such as pollen per cubic centimeter or pollen per gram) is for the pollen rain of the sampled region. On the other hand, if one were to find anemophilous pollen types such as maize (*Zea mays*), wheat (*Triticum*) spruce (*Picea*), Douglas fir (*Pseudotsuga*), or fir (*Abies*) pollen in a forensic sample, it generally means that either someone may have carried those pollen grains to the sample site or those source plants were growing very close to the sampled area. The reason one could make that assumption is because the sinking speeds for these pollen types are very fast causing them to fall to the surface at a rate of $6-12\,\mathrm{cm\,s^{-1}}$, which is 4–6 times faster than the lighter ones. Each pollen type has its own sinking speed, which will cause it to be dispersed either very close to the parent plant or scattered over a wide area. In addition to sinking speeds, pollen grains of different sizes and mass will be more or less subject to be scoured out of the air currents when they are hit by raindrops or when they hit objects of various sizes, such as twigs, leaves, or various manmade objects. All of these factors must be carefully calculated for each locale in order to determine the potential, or expected, composition of the pollen rain in a given region. Once those data have been determined, then the pollen print for that region can be used for comparison against forensic samples that are suspected to have come from the same region. Depending upon how well the comparison of pollen spectra match, the palynologist may conclude that there is, or is not, a valid relationship between both samples. One way this is done is by using the likelihood ratio, which is based on using Bayes' theorem and considers how well the pollen spectra match and what are the probabilities of finding similar pollen assemblages in other locations [6].

Pollen degradation can also become an important factor in some types of samples. Pollen samples that might be only days or weeks old usually do not suffer much pollen destruction; however, pollen samples associated with buried objects or buried bodies might become degraded or in some cases completely destroyed by a variety of conditions. However, the potential of pollen destruction caused by germination is not a factor. When examining forensic pollen samples associated with buried objects, the palynologist must consider how much, and which types, of pollen or spores may have been destroyed. Depending upon a variety of conditions, the total pollen and spore spectrum of a sample might be altered due to the differential pollen preservation and degradation. Those potential changes in the overall pollen spectrum of a sample must be considered when trying to interpret the overall pollen assemblage for a sample [7].

Some of the important factors, which will affect pollen and spores and can, cause the total loss of certain taxa include the degrading effects caused by microbial activity, high soil pH and Eh (oxidation/reduction potential as judged by whether on not it is an oxygen rich or oxygen poor environment) that can cause mechanical breakdown of soils, various types of soil movement such as solifluction (a type of mass wasting where waterlogged sediments slowly move downslope over impermeable material), frequent changes in the level of soil moisture, and the inherent strength and durability of the pollen grain's outer wall. A number of previous studies have demonstrated that some very durable types such the spores of ferns and lycopods and the pollen from grasses, pigweed, amaranths, composites, oaks, and pine often remain preserved even in fairly harsh environments where most other pollen and spore types are totally destroyed by oxidization or have become so broken and degraded that they are no longer recognizable. Being able to recognize the levels and types of pollen grain and spore damage and destruction in forensic samples are critical aspects that must be recognized and understood before trying to interpret the overall pollen data. Although a few deposited pollen grains might occasionally burst open or rarely a spore might germinate, these potential problems are not of major concern.

Pollen recycling is another aspect that one must recognize when examining pollen samples. Understanding the vegetational environments where recycling occurs and being able to recognize the severity of recycling become important interpretive clues when examining pollen samples. Sometimes ancient fossil pollen and spores will erode from deposits thousands or millions of years old and will be recycled into contemporary samples. Such recycling might prove extremely useful because different fossil pollen or spore types tend to be deposited, and later eroded out from different aged sediments. An example of this type of clue became the key evidence leading to the conviction of a murder suspect who could be placed at the crime scene because of

a unique, 20-million-year old Miocene-age hickory pollen grain that eroded out of a sediment outcrop, became recycled, and then got trapped as part of the dirt (*see* **Soil: Forensic Analysis**) in the tread of the suspect's boots [8]. In some cases, such as this example, the recycled fossil pollen provided the precise clue needed for identifying the exact location where the crime was committed and where the victim's body was buried. In other cases, recycled pollen from fairly recent deposits might combine with modern pollen in ways that might mislead some palynologists into making an incorrect interpretation.

Depending upon what types of sediments have yielded recycled pollen grains and depending on how badly the contemporary fossil pollen has been degraded, those recycled pollen types may, or may not be easily separated from the actual modern pollen rain at a given locale. If the recycled pollen grains cannot be distinguished from the modern pollen rain, the addition of recycled pollen may mask the true identity of an actual locale by producing a combined pollen spectrum quite different from the expected pollen print for that locale. Nevertheless, most skilled forensic palynologists with years of experience would not mistake most types of recycled pollen for contemporary pollen deposited by the local pollen rain.

There are several techniques palynologists have used to try to correctly identify fossilized recycled pollen in modern pollen samples. O'Rourke [9] tried to separate recently deposited pollen from recycled pollen by staining them with basic fuchsine. She found that the different layers in a pollen wall stain differently depending on their molecular structure. Modern pollen, she found, still contained the innermost cellulose layer in the pollen wall called the *intine*, which stained a light pink as opposed to the outer layers in the pollen wall that stained dark red. During her subsequent study of the pollen spectra from modern samples, she considered only the pollen still containing an intine as being part of the normal pollen rain; all other pollen grains that stained dark red were considered to be recycled pollen. That technique is useful in some situations but not others. For example; the destruction of a fresh pollen grain's cytoplasm and intine layer can occur very rapidly in warm and moist environments where oxidation rates are rapid. In cold and dry regions fresh pollen grains are slower to lose their cytoplasm and intine. Unless one knows for certain what environmental conditions exist and how rapidly fresh pollen lose these aspects, this technique should be considered fairly unreliable. Likewise, the degree to which a pollen grain's wall will absorb stain, such as basic fuchsine or Safranin-O, and thus will appear as being lighter or darker depends on a number of factors including the thickness or the pollen wall, the percentage of the pollen wall that is composed of cellulose and protein molecules, and the amount of sporopollenin (a very durable substance composed of long-chains of carbon-based molecules that are similar to structure to carotenoids) present. Sporopollenin is a group of highly resistant organic molecules that are unique to various types of palynomorphs, including pollen and spores. In pollen and spores this molecule does not absorb stain but forms a latticework in the pollen and spore walls that help gives them shape, durability, and structure. As pollen and spores slowly degrade, the cellulose and protein molecules in the walls break down into compounds that no longer absorb stains. Eventually, degraded pollen and spores have very little cellulose and protein left and yet may maintain their shape due to the durable sporopollenin latticework remaining in their walls. When pollen and spores reach this point of degradation most will become very lightly stained or almost completely transparent even when immersed in pure stain. Because different pollen and spore taxa have different wall thicknesses and different proportions of cellulose, protein, and sporopollenin molecules in their outer walls, staining alone is not a reliable indicator of recycling. Different degrees of staining often reflect different levels of decay and recycling, but those differences might also reflect the innate differences found in the outer walls of various taxa of pollen or spores (Figure 1).

Another technique sometimes used to try to identify recycled or reworked pollen from modern examples is fluorescence microscopy [10]. The theory behind using both staining and fluorescence is the belief that recycled pollen and spores have different depositional histories than recently released pollen assemblage and thus will make the recycled grains appear as being different. What makes fluorescence perhaps a more useful technique for determining recycled pollen and spores is that pollen, spores, and other types of organic materials in different stages of preservation, or in different stages of carbonization, will emit light of varying intensity and wavelengths [11]. These differences can be detected under

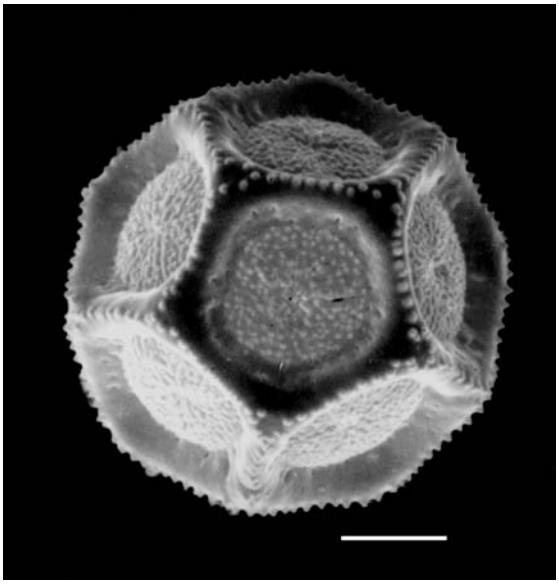

Figure 1 This is an SEM micrograph of *Alternanthera philoxeroides* (K. von Martius) A. Grisebach. This plant is in the Amaranthaceae plant family and the common name is alligator weed. The bar scale is 5 μm long [Courtesy of Gretchen D. Jones, Ph.D., & Ester F. Wilson, USDA-ARS, APMRU.]

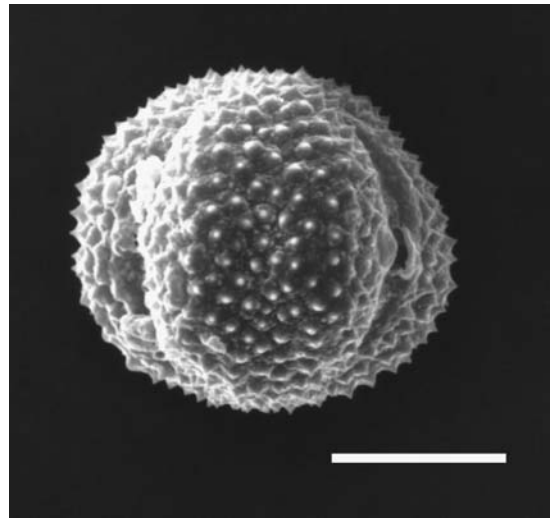

Figure 2 This is an SEM micrograph of *Artemisia californica* (Less). This plant is in the Arteraceae plant family and the common name is California sagebrush. The bar scale is 10 μm long [Courtesy of Gretchen D. Jones, Ph.D., & Ester F. Wilson, USDA-ARS, APMRU.]

ultraviolet light during fluorescence studies because those differences will give various pollen and spores different color hues.

Although differential staining and fluorescence microscopy has proven useful for some types of pollen studies, neither has helped us very much in forensic applications, thus there are reservations concerning their applicability in most forensic pollen work. In a laboratory experiment we conducted we "spiked" 18 000-year-old peat sediments collected from a subarctic environment with modern pollen from tropical plant taxa. Those combined samples were then processed using standard laboratory techniques for pollen recovery. After staining the recovered pollen and spores with Safranin-O, we found that only a few (less than 10%) of the added tropical pollen grains could be recognized strictly by differences in either staining or their fluorescence. In a similar study conducted in Arizona by Shellhorn *et al.* [12] they found that fluorescence microscopy did not help them separate modern surface pollen taxa from fossil pollen types known to be recycled from 20 000-year old deposits of the Wilcox Playa.

In forensic work we have found that a better guide to recycling seems to be the overall condition of the individual pollen grains and spores in a sample. Pollen samples recovered from crime scene locations in deserts, steppes, and semiarid regions where vegetation is usually minimal and where high winds are frequent, usually contain a wide variety of examples of degraded pollen and spores. The degrading process from those regions often produces grass pollen that is cracked, broken, crumpled, or shredded; pine and other types of bisaccate (conifer pollen types with a pair of air bladders to help keep them aloft after dispersion) pollen grains that usually have one or both bladders detached or broken and often are reduced to broken fragments of the main body of the pollen grain; and broken or fragmented parts of fragile pollen types such as the polyads (groups of individual pollen grains united into one large grain) of acacia (*Acacia*), and the inaperturate (pollen grains that lack any type of aperture) pollen grains produced by sedges (Cyperaceae), popular (*Populus*), cypress (*Cupressus*), and junipers (*Juniperus*) (Figures 1–10). The overall species composition of a pollen sample, the specific pollen types and the condition of the pollen in a sample can usually provide essential

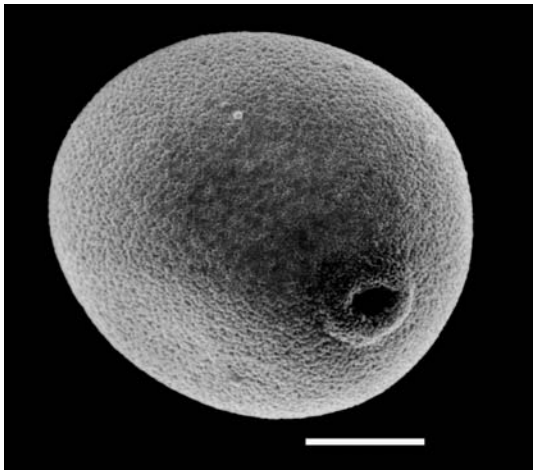

Figure 3 This is an SEM micrograph of *Arundinaria gigantea* (T. Walter) G. H. Muhlenberg. This plant is in the Poaceae plant family and the common name is giant southern cane. The bar scale is 10 μm long [Courtesy of Gretchen D. Jones, Ph.D., & Ester F. Wilson, USDA-ARS, APMRU.]

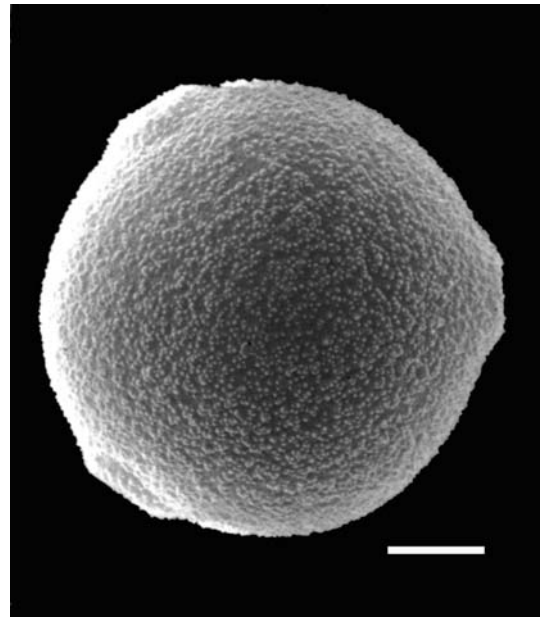

Figure 4 This is an SEM micrograph of *Cannabis sativa* (C. Linnaeus). This plant is in the Cannabaceae plant family and the common name is marijuana. The bar scale is 5 μm long [Courtesy of Gretchen D. Jones, Ph.D., & Ester F. Wilson, USDA-ARS, APMRU.]

clues about the ecology of a region where the sample originated as well as the degree and frequency of the recycling process. Once familiar with the types of potential degradation and overall appearance of pollen spectra from various types of environments, one can almost immediately determine, within broad parameters, whether the sample comes from an arid, semiarid, temperate, tropical, or arctic type of environment.

Collection and Extraction of Forensic Pollen Samples

Collection and extraction of forensic pollen and spore assemblages must be done with great care. If possible, the palynologist should be given access to a crime scene before other investigators arrive and begin collecting their samples. As a forensic specialist I realize that nearly "everyone" working a crime scene believes that they must be the first to visit the area. Nevertheless, the pollen and spore composition of the crime scene is extremely fragile and can easily be inadvertently altered, removed, or contaminated by the action of other forensic and crime scene investigators who also arrive to complete their own investigations. In addition, the use of improper collection techniques and/or accidental contamination of collected materials may render a sample useless for forensic pollen use and will provide a basis for the dismissal of forensic pollen evidence in court (*see* **Error Rates in Forensic Methods**). Whenever possible, forensic pollen samples should be collected by a trained forensic palynologist or someone immanently familiar with proper collection protocol. This type of training generally comes from working with established professional forensic palynologists or gaining the basics from attending short courses on proper collection procedures. Collection by these types of specialists will ensure that the samples are collected correctly, that they remain contamination-free through all stages of storage, and that the samples will be processed and analyzed correctly. When forensic palynologists are present, others members of the crime scene investigation team should follow prescribed protocol to ensure that all forensic pollen samples are collected properly and that the samples remain contamination-free. In all cases, as with other forensic samples, it is essential to keep detailed and accurate records and pictures

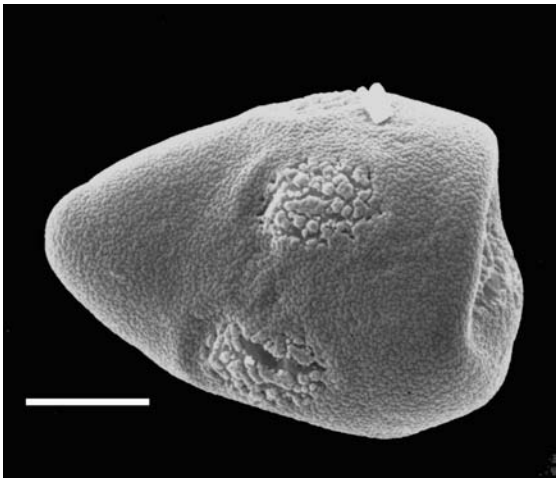

Figure 5 This is an SEM micrograph of *Carex microdonta* (J. Torrey & W. J. Hooker). This plant is in the Cyperaceae plant family and the common name is little-toothed Caric-sedge. The bar scale is 10 μm long [Courtesy of Gretchen D. Jones, Ph.D., & Ester F. Wilson, USDA-ARS, APMRU.]

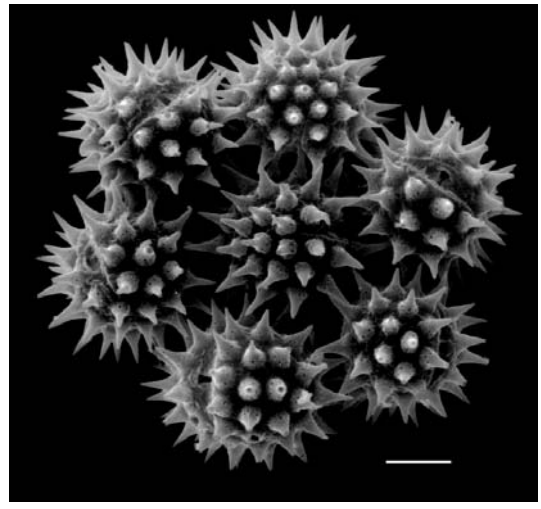

Figure 7 This is an SEM micrograph of a cluster of seven pollen grains stuck together of *Helianthus annuus* (C. Linnaeus). These are in the Asteraceae plant family and the common name is common sunflower. The bar scale is 10 μm long [Courtesy of Gretchen D. Jones, Ph.D., & Ester F. Wilson, USDA-ARS, APMRU.]

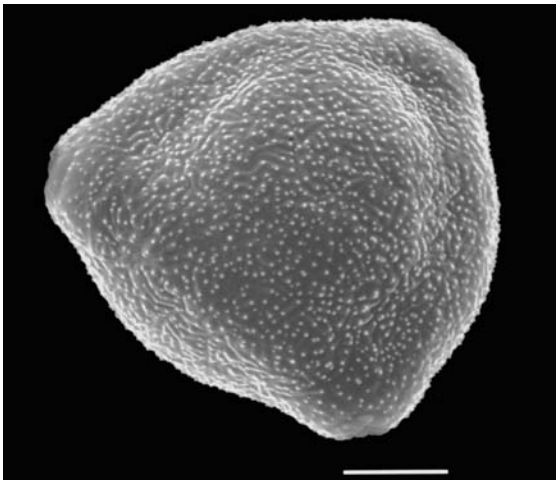

Figure 6 This is an SEM micrograph of *Corylus americana* (Walter). This plant is in the Corylaceae plant family and the common name is American hazelnut. The bar scale is 5 μm long [Courtesy of Gretchen D. Jones, Ph.D., & Ester F. Wilson, USDA-ARS, APMRU.]

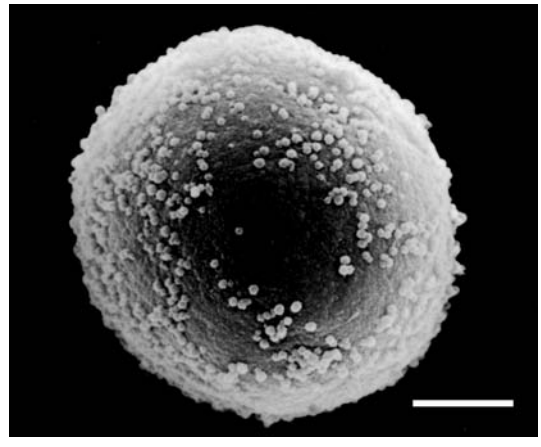

Figure 8 This is an SEM micrograph of *Juniperus virginiana* (C. Linnaeus). This plant is in the Cupressaceae plant family and the common name is Virginia red cedar. The bar scale is 5 μm long [Courtesy of Gretchen D. Jones, Ph.D., & Ester F. Wilson, USDA-ARS, APMRU.]

of how and where each sample was collected, what happened to each sample from the time of collection until it is analyzed, and the security of all pollen evidence until reports are written or statements are presented in court. If any hint of contamination, either natural or unintentional can be implied or proven, then doubt can be cast upon the resulting interpretations. Herein lays one of the greatest problems facing

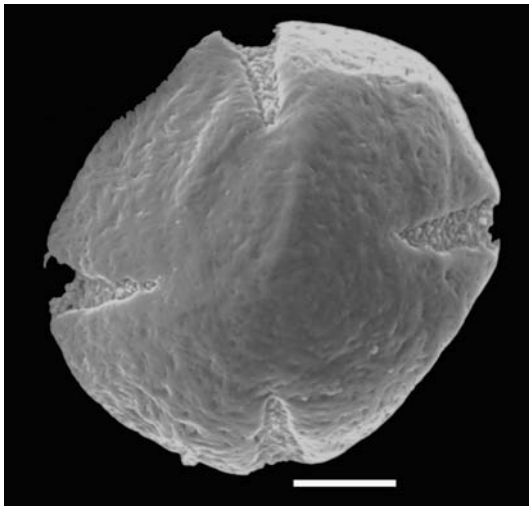

Figure 9 This is an SEM micrograph of *Melia azedarach* (C. Linnaeus). This plant is in the Meliaceae plant family and the common name is Chinaberry tree. The bar scale is 10 μm long [Courtesy of Gretchen D. Jones, Ph.D., & Ester F. Wilson, USDA-ARS, APMRU.]

forensic palynology. Because there are so few forensic palynologists, most crime scene pollen samples are collected by other people. Although most forensic personnel and other crime scene investigators can be trained to collect samples using proper protocol, and even though a crime scene photographer might take ample photographs, there are still other, subtle observations that only a trained forensic palynologist might notice as being important. Often the composition of the plant associations at and near the crime scene (*see* **Botany**), damage to individual plants, or evidence that someone brushed against a bush, or the presence of some exotic or unusual outcrop nearby each might become a vital clue when trying to understand and interpret the collected forensic pollen evidence from the crime scene or match pollen evidence collected from some suspect at a later time. These are reasons why, under ideal circumstances, the forensic palynologist should be present and should collect the samples.

An essential part of any forensic pollen investigation is the collection of control (also called *comparator*) samples. Control samples are samples of surface dirt, dust, fibers, or other materials at, near, or directly associated with a crime scene. The control samples are essential for any forensic pollen study because their pollen spectra provide a "baseline" of pollen information about the "expected pollen assemblage" from a specific object or the pollen print from a given

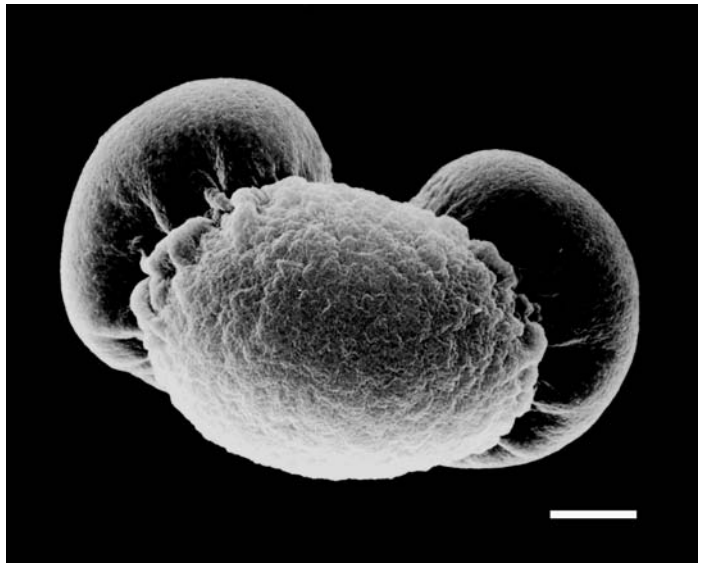

Figure 10 This is an SEM micrograph of *Pinus echinata* (P. Miller). This plant is in the Pinaceae plant family and the common name is short-leaf pine. The bar scale is 10 μm long [Courtesy of Gretchen D. Jones, Ph.D., & Ester F. Wilson, USDA-ARS, APMRU.]

crime scene or locale. Once the baseline of expected pollen data are determined from the various control samples, then the pollen recovered from a suspect or from forensic specimens thought to be associated with the object or crime scene can be compared against the control data to see if both match. One example involved a pollen control sample consisting of surface dirt collected from the ground where a sexual attack occurred. A forensic pollen study of the woman's soiled clothing matched the pollen types found in the control sample, confirming that she had been attacked at that location and had struggled with her assailant. Later, a suspect was identified and a search warrant revealed a soiled shirt and pants containing a pollen spectrum matching the control sample collected from the location where the sexual attack occurred. The pollen evidence alone did not confirm the suspect's guilt, but it did confirm he had been at that precise location, which was an area he said he had never visited.

Knowing how many control samples to collect from the scene of a crime is difficult. The more control samples one collects, and examines, the more pollen information one has about the locale where a crime was committed. Because the pollen spectrum in each control sample may vary slightly in reference to pollen types and percentages of each type, their combined spectra offer a potential range of pollen variation that can be expected for the actual crime scene. These types of data make matching the pollen results found on objects or suspects thought to be associated with a crime scene either convincing or obviously not similar. Not having enough or not having adequate control samples from a crime scene prevent a forensic palynologist from knowing what pollen types, and in what percentages, he or she should "expect" to find at the crime scene location. Without that knowledge, it becomes difficult to argue either for or against the confirmed association of the pollen assemblage found on a suspect's shoes, or car, or clothing, with the pollen types found at the actual crime scene.

Often a forensic palynologist has only a very small amount of material available for analysis. A few examples that I have examined in the past include the dust collected from the top of a table, a tissue wipe of the surface of a sandal, a piece of crumpled wire from some type of electrical device, a piece of electrical tape 3 cm long, one shoelace, a tiny piece of torn tissue no larger than a postage stamp, a sticky tape of dust collected from the dash of an vehicle, small tuffs of human hair from a body, the remains of a few bugs caught on the windscreen of a car, moths, honeybees, and a few pollen grains vacuumed from an item of clothing. Sometimes, when I have been fortunate, I could examine pollen trapped in a few specks of dirt trapped in the tread of a shoe or dirt caught in the carpet of a car. Once, the pollen recovered in the tiny bits of "fuzz" trapped in the bottom of the pockets of a pair of corduroy pants helped solve a murder case. There is almost no limit to what types of samples one can collect for potential use in forensic pollen studies. Nevertheless, often these types of samples create two major challenges for the forensic palynologist. First, there will rarely be enough material in a sample to try different extraction techniques. Second, there is rarely enough material to conduct a second test if something goes wrong during the initial pollen extraction and recovery process (e.g., centrifuge tube breaks, a beaker spills, a sample is dropped or accidentally mixed, a microscope slide breaks, etc.). For these reasons, the pollen extraction and recovery process must be conducted with the utmost care. In addition, in an effort to remove and concentrate the durable pollen and spores in forensic samples, it is generally necessary to destroy all of the nonpollen components. This means a sample's matrix will not be available later for other types of forensic testing. Studies of the DNA, trace elements, hairs and fibers present, or particles of dirt and sand in a forensic pollen sample must be conducted before pollen extraction occurs. Such studies, however, must be completed carefully and must not increase the risk of potential pollen contamination

Almost anything can be tested for forensic pollen. Dirt and dust trapped in almost any object often contain pollen and spores from the locale where the object originated. The following case illustrates this point. In New Zealand a man robbed a store and escaped on a motorcycle. Police gave chase and almost caught the thief, but at the last minute the thief abandoned his motorcycle and ran up a muddy hill and escaped into a wooded area. The next day a man reported that his motorcycle had been stolen the day before. When the claimant arrived to recover his motorcycle, the police realized he closely resembled the suspected thief. Armed with a search warrant, the police recovered a pair of muddy boots owned by the suspect. When asked about the mud, the suspect said that the mud came from the farm where he

worked and denied that he has ever been in the area where his motorcycle had been abandoned. A forensic palynologist collected a series of control soil samples from areas on the farm where the suspect worked and examined them to obtain a pollen print of the farm region. Next, the palynologist collected a series of control soil samples from the muddy hill where the motorcycle had been abandoned and examined them for their pollen contents. Finally, after examining the pollen trapped in the mud on the suspect's boots, the palynologist could confidently say that the pollen assemblage matched the pollen print from the muddy hill, and not those of the control samples from the farm. This type of forensic sample discrimination between two or more different locales is one of the common ways in which pollen evidence is being used to aid in criminal investigations (*see* **Soil: Forensic Analysis**).

Almost any item of clothing becomes an ideal trap for pollen. Clothing made from wool, linen, and cotton are among the best pollen traps, while garments made of leather, nylon, rayon, and other types of materials often make good potential pollen traps. In a murder case from Australia a man killed his girlfriend and then drove her car 50 km to a remote coastal park where he then hid her body under some wattle (*Acacia*) brushes that had been planted to stabilize coastal dunes. After returning home he parked her car at her home and then thoroughly washed his clothing. Later, when he became a suspect, police collected items of his clothing and gave them to a forensic palynologist to examine. In spite of the suspect's attempt to thoroughly wash and clean his clothing, a few pollen grains from two different species of wattle bushes remained trapped on his clothing. Although one species of wattle plants were quite common in that region of Australia, the second species was not native and was imported to help stabilize coastal dunes. The imported species occurred only in the coastal park region but grew close to other native species of wattles. The trapped pollen from both species of wattle bushes had already been found in the victim's car and now both were also found on the suspect's clothing. Eventually, it emerged that the suspect had driven his estranged wife's car to the coastal crime scene where he hid her body under wattle bushes and also brushed against other species of native wattle bushes growing in the car parking area near the coast. Although the pollen evidence alone did not provide proof that the suspect was the murderer, it did place him and his wife's car at the crime scene. In spite of his vigorous denial that he had not used his wife's car and had never visited to the coastal park, the pollen evidence placed him at the crime scene and helped to convict the suspect [13].

In a recent murder case, a young teenage girl, believed to be hitch hiking or a runaway, was killed in 1979 and left abandoned in a field with no identification. Her fingerprints were not on file and she was killed before DNA studies became routine in forensic work. Her identity remains a mystery even today and the murderer is still at large. However, nearly 30 years after her death, her clothing was thoroughly examined for traces of pollen and spores. Time had not degraded any of the pollen and spore evidence and wisely all of her clothing had been sealed in sterile containers and stored in a contamination-free environment for decades. On the basis of the forensic pollen studies in 2006, her identity could not be determined, but the pollen assemblage found in the pockets of her clothing and the inner lining of her jacket strongly suggested that she had very recently visited or had lived in a region more than 2000 miles west of the place where she was murdered. Among the pollen evidence recovered from her clothing were pollen grains from she oaks (*Casuarina*), which is a tree native to Australia and now grows only in restricted coastal areas of frost-free southern California and in similar regions in Southern Florida. These trees have never grown in New York because of winter freezes. In addition, it is highly improbable that even a single pollen grain from a she oak tree could have traveled 2000 miles from its source to the region of New York where the body was discovered. Other pollen from inside the murdered girl's pockets included species of spruce and birch that are common in the mountain flora of California, but do not grow in the region of New York where the body was discovered.

At the time of her death, authorities believed she was a local girl and thus searched only for missing person cases in the immediate vicinity of the crime scene. What made this case (one of the author's) interesting was how a rare combination of pollen can convincingly point to the victim's direct association with a distant region on the West Coast of the United States even though she had been murdered near the East Coast. This case also illustrates that if forensic samples are stored properly, decades later they can

still reveal their pollen evidence [14]. At the time of this writing authorities are now searching the missing person records for the West Coast of the United States for the years of the late 1970s and early 1980s.

Vehicle air filters can also become good sources of forensic pollen evidence. Pollen evidence from vehicle air filters have been used to reconstruct the regions where the vehicle had traveled. A case from the 1980s, that illustrates this point occurred on the island of Oahu in Hawaii. A stolen van was used in a bank robbery in Honolulu and then abandoned only a few miles away. A forensic pollen study of the air filter in the van contained not only pollen types typically found in the city of Honolulu, but also unusual tropical pollen and spore types found only in the nearby Koolau Mountains in the center of the island of Oahu. Using the forensic pollen and spore evidence as intelligence information rather than direct evidence, Honolulu police began interviewing residents in the Koolau Mountain region. A grocery store worker remembered the van visiting his store on several occasions and later seeing the van parked near a small cabin in the area. That information led to the capture of the bank robbers who were hiding in the cabin until they could safely leave the island.

Human and other types of animal hair are ideal pollen traps for pollen from given locales [15]. Therefore, when a person or animal travels to another region and their hair is examined fairly soon after arrival, the analysis of the pollen still trapped in the hair would provide a pollen print of the previous, not the current location. This type of use for pollen data was applied to a murder case in Texas where it was hoped that forensic pollen studies of hair samples would provide a key to where five murdered women had lived. Hair samples collected from the five bodies of the unidentified women found buried in a series of shallow graves were examined for pollen in hopes that it might provide a clue as to where the women had lived before being murdered. Soil samples collected from the graves and from the surface soil in nearby areas of the pine forest provided the control samples and the "expected" pollen prints from that region. The recovered pollen assemblages from the women' hair were then compared to the pollen prints of the crime scene to find major pollen differences. As in the case with the murdered teenage girl, it was hoped that the forensic pollen samples might provide suggestions regarding where each of the women may have lived before being killed. Authorities hoped that such information could help them search in the appropriate geographical regions for the identity of the missing women. Unfortunately, the recovered forensic pollen samples from the women's hair closely matched the pollen prints of the crime scene. This led to the suggestion that either the hair samples had become so contaminated by local pollen from the pine forest and from the soils in the grave site that it obscured any original potential pollen present, or perhaps all of the women came from areas of East Texas. Many areas in East Texas have pine forests and each area produces a fairly similar pollen print making it difficult to distinguish them apart. As of this time, those answers have not yet been resolved.

Like human hair, animal hairs are also excellent pollen traps. In New Zealand a rustler stole 300 sheep from a ranch and weeks later tried to sell them at a livestock auction. Although the sheep had no markings on them, the auctioneer became suspicious because he knew the seller was selling more sheep than the pastureland on his small ranch could support. The police were called in and they impounded the sheep. The original owner believed they "might" be his sheep, but had no proof so the police sheared a small patch of wool from the backs of several impounded sheep and sent them to a forensic palynologist for study. Control pollen samples were collected from sheep in both areas and also the surface soils in various locations on both the seller's and original owner's pasturelands. The pollen prints from each control sample was compared with the pollen assemblage recovered from the sheep's wool, which closely matched the control samples from the original owner's pasturelands. The thief complained that the pollen trapped in the sheep's wool had no relationship to pollen found in the surface soils of the two pastures. Countering this argument, the palynologist pointed out two important facts. First, the natural pollen rain in both regions would deposit airborne pollen on any surface in the pastures including the backs of sheep, the ground, or on the surface of several ponds and thus the pollen prints would indeed be similar. Second, there was a much different vegetational assemblage in and around each of the two pastures, which therefore produced very different types of pollen prints, as was noted in the pollen profiles of the various control samples. Thus, the pollen evidence proved critical in showing a clear discrimination between the expected pollen

rain and pollen prints of each of the two different pasturelands. As a result, the sheep were returned to the original owner and the rustler was convicted and sent to prison [16].

A shipment of 500 g of cocaine hydrochloride was seized in New York City. A portion was sent to a forensic palynologist for analysis. In similar situations, previous examinations of illegal marijuana (*Cannabis*) seized in New Zealand had revealed two important clues. First, the pollen print recovered from the seized sample contained not only marijuana pollen but it also contained many pollen types indicating the plants had been grown in Asia and not at any location in New Zealand. Second, pollen studies of marijuana samples seized in different drug raids carried out in widely dispersed regions of New Zealand revealed that all the samples contained very similar pollen spectra. This indicated that the illegal marijuana seized in all the raids came from the same, large imported shipment originating in Asia. It also suggested that the marijuana was being distributed through a single distribution network. A similar type of reconstruction was attempted for the seized cocaine from New York. After processing the sample, the recovered pollen assemblage provided three important clues about the cocaine. First, some of the trapped pollen came from tropical plants that typically grow in regions of Bolivia and Colombia where coca plants are grown commercially. Those pollen types linked the origins of the cocaine to those regions of tropical South America. A second group of pollen grains recovered from the cocaine came from subalpine conifers including Canada hemlock (*Tsuga canadensis*) and jack pines (*Pinus banksiana*). These two species of conifers do not normally grow in the same habitat, but both are found growing together in only limited regions of Eastern Canada and the Northeastern US. Therefore, the occurrence of pollen from both of these conifer types in the same sample suggests the cocaine was smuggled into North America someplace in Eastern Canada or the Northeastern United States. Once in North America, the cocaine was apparently opened, and exposed to airborne pollen types while it was being "cut" with powered sugar to increase its value. If that had occurred in any other region, then both conifer pollen types would not have been present in the same cocaine sample. Finally, the remaining pollen found in the cocaine came from weeds and plants (composites, grasses, birch, goosefoot and pigweed, etc.) commonly found growing in vacant lots in the urban slums of New York City. It is suspected that when the cocaine reached New York City it was again opened and cut further before being packaged for distribution on the street. It was during that time that the cocaine was again exposed to airborne pollen, which then became trapped in the sample [17].

A European manufacturing company shipped a number of crates filled with expensive machinery to a company in Asia. The ship carrying the cargo stopped at a number of ports between Europe and its final destination in Asia. When the crates were opened at their destination in Asia, the machinery was gone and had been replaced by bags of soil of approximately the same weight. Since the ship had stopped at a number of ports it was unknown where the machinery had been stolen and replaced with dirt. An analysis of the dirt revealed a wide variety of pollen and spores that closely matched the pollen composition found in soil samples collected from the port area in Capetown, South Africa. Although the pollen analysis did not solve the question of who stole the machinery, it did suggest that the switch had occurred in Capetown, which was one of the more than a dozen potential ports where the theft could have occurred. Thus, the pollen identified the location and therefore narrowed the search for the missing machinery to only one location between the ship's departure in Europe and final arrival in Asia [16].

Pollen evidence has also been useful in helping to resolve details about events in the past (*see* **Length Measurement**; **Archaeology**; **Mass Grave Investigation**. In a recent example, a mass grave containing the remains of 32 young males was discovered in 1994, in Magdeburg, Germany. An examination of the bodies revealed that they had been shot, but the unanswered question was who did it. Bits of clothing and other evidence found with the bodies did not provide conclusive proof about who killed them. Two possibilities emerged. Some believed they were partisans who were captured and killed by the Nazi Gestapo in the spring of 1945 before the area was overrun by advancing Soviet troops. Others believed the Soviet Secret Police captured and then killed a number of Russian soldiers who refused to kill local German citizens who rioted in late summer of 1953 against Soviet rule. The nasal cavities of seven skulls were rinsed and the material was examined for trapped pollen. The pollen analysis revealed high amounts of pollen from plants that

pollinate in the late summer, not plants that are spring pollinators. Comparisons of pollen types found in the dirt at the burial site confirmed that high levels of pollen from late summer blooming plants found in the nasal cavities must have been inhaled just prior to death and had not come from pollen in the dirt of the burial site. Thus, the pollen study confirmed that the victims probably died in late June or July, not during the spring and therefore were probably Russian soldiers killed by the Soviet Secret Police in the late summer of 1953 [18].

Summary

Although the use and application of forensic pollen studies are relatively new in many areas of the world, there is growing evidence that its use has a bright future. As more and more crime enforcement agencies become aware of the potential value of forensic pollen work, the need for trained personnel in the field will increase and will provide the emphasis needed to encourage the establishment of training centers for these specialists. Some countries and some law enforcement agencies are already aware of the value of pollen studies as a forensic technique and therefore conduct these studies routinely. In other countries pollen evidence is rarely collected at crime scenes and there appears to be little interest in using pollen for its potential forensic value. Perhaps one way to draw attention to this underutilized forensic tool is to briefly outline some of the important ways in which pollen evidence has already proven useful in helping to solve criminal and civil cases. Some of the crimes that pollen evidence has already helped to solve include instances involving homicide, terrorism, genocide, bombings, forgery, theft, rape, arson, counterfeiting, manufacturing and distribution of illegal drugs, assault, cases of hit and run, poaching, and identity theft.

Potentially, pollen evidence could be used to help resolve a wide range of circumstances associated with crime scene investigations. For example, pollen evidence could help relate a suspect to the scene of a crime, confirm that some item was associated with a crime scene or that some item left at a crime scene belonged to some suspect. Other types of information derived from pollen evidence might include proving or disproving a suspect's alibi, it might help narrow down a list of potential suspects to only one or two individuals, it might help track the travel route of some item or suspect, or provide the geographical source of some item. In other circumstances, pollen evidence has proven useful in helping authorities find human remains and clandestine graves, determined the season or sometimes even the general time of death, and confirmed the illegal poaching of wild animals or the adulteration of commercial foods.

VAUGHN M. BRYANT

Paper Analysis

Introduction

Writing and printing papers are largely composed of bleached botanical fiber and mineral fillers to which can be added fluorescent whitening agents (FWAs) to enhance the whiteness of the paper or organic dyes to make papers of different colors. The purpose of the fiber is to form a bright contrasting flat surface to which darker inks, pigments, and toners can be applied. Fillers (usually in the form of finely ground calcium carbonate or various mineral clays) are also added to increase sheet opacity and improve the printing or writing surface. Modern printing papers (and much less commonly writing papers) may also have a coating, comprising calcium carbonate and/or clay, and/or titanium dioxide mixed with an organic polymer binder on one, or more frequently both sides of the sheet.

This article deals mainly with A4 and A3 copy papers, bond papers, and standard US Letter "A" paper, as these papers are now the most common hardcopy medium for commercial, legal, and personal communication. The principles, practices, and tools discussed below can be applied to all samples of paper, paperboard, ("cardboard" in common parlance) and fiber-based packaging materials.

Ever since monetary, commercial, and legal transactions have been committed to paper they have been subject to fabrication and fraud. Sometimes spurious documents remain in currency undetected but at other times, for various reasons, they fall under suspicion. A few examples among many are the fabrication of whole documents which are backdated, fabrication of company documents, minutes and receipts, fabrication of wills, fabrication of certificates and academic qualifications, and the manufacture of spurious historical documents.

Often fraudulent documents are exposed by discrepancies or inconsistencies in their written content (i.e., structure of signatures, dates appended, poorly composed letterheads, logos, etc.) and sometimes by the chemistry of the inks, pigments, and toners employed in their manufacture. For instance, the printing technologies with which the ink is applied, or the chemistry of the ink or toner itself can demonstrate that the document in question is either inconsistent with the purported date, or the period in which an undated document is represented to have been written or printed. These areas fall within the realm of the document examiner, ink and printing expert, and forensic chemist.

Another useful technique in exposing fraud is the field of "paper and fiber analysis" in which the paper on which the document is written can be characterized and differentiated from properly validated samples. Paper properties, both physical and botanical, although outwardly similar in appearance to the layman, can be, and often are, distinctly individual to a particular hemisphere, country, company, and even papermaking machine.

In the course of any investigation, the paper is first characterized for a range of physical properties which include basis weight or mass per unit area (commonly called *grammage* in countries using the metric system of measurement), caliper (or apparent thickness), sheet density, filler content, filler type, paper chemistry, direction of cut, etc. After these initial tests are completed, a small but representative portion of the paper can be mechanically broken down and dispersed into a dilute aqueous suspension of individual fibers. A few milliliters of this dilute suspension is placed on a standard microscope slide, dried, stained, and then examined under low magnification ($\times 40$ or $\times$ 100) to determine paper or fiber "furnish". Fiber furnish is basically the particular combination of pulp types, or the "pulp recipe",

a papermaker, or individual paper mill uses to create a particular grade of paper.

"Fiber furnish analysis" can be a powerful tool. In essence, it is the identification of the various pulp types found in a particular sheet of paper and the determination of the ratio in which they occur. The technique can be further refined by identifying the various plant species from which the fibers derive. This latter identification, in combination with the other factors, is very useful in determining the possible origin (or, conversely, rendering that it came from a particular country or source highly improbable) with regard to hemisphere and region, and sometimes even country, company, and mill, depending on the depth of industrial knowledge of the forensic analyst. As in most aspects of forensic analysis, great care should be exercised when drawing conclusions and some common pitfalls will be detailed later.

Even if the origin of a sample of paper cannot be established, it is often just as important to determine whether the paper used in a document is consistent with similar material emanating from the same government body, public company, or private premises at the time the document was alleged to have been produced. Also, if there is a belief that a particular page has subsequently been appended to the front or back, or inserted within the body of a document, the page in question can be analyzed and compared with those adjoining. Paper examination can also be useful in such circumstances when, for example, narrowing down possible origins of a ransom note. If the paper on which the note is written is of an unusual type, and it cannot be differentiated from the remains of an open ream or loose sheets found at the suspect's premises, these findings could add weight to circumstantial evidence against the suspect.

It is fortunate for forensic science that technology and manufacturing processes are in a constant state of flux as commercial companies are either trying to improve their product or make changes to it to maintain a competitive edge. These changes, and knowledge of when they were made, are an invaluable tool in determining the legitimacy or otherwise of certain articles. The same is true within the paper industry and knowing the manufacturing history within various geographic regions, countries, and companies within these countries, is of great advantage to the forensic examiner.

To an industry outsider, however, it is almost a matter of impossibility to keep track of all these changes so it is very useful for the analyst to maintain strong links with the key personnel within a country or locality's paper industry. It is also important for the paper analyst to regularly examine locally produced, "off the shelf" paper products in order to keep familiar with these changes. When purchasing photocopy or bond papers for examination, it is always useful to retain the ream wrapper (outer packaging) as it also contains much useful information together with a dozen or so sheets of the content as a growing archive. Apart from obvious general information such as country of origin, company, brand, grade, grammage, etc., wrappers often carry a discretely positioned inkjet printed company code that can inform the manufacturer when, and at what mill and on what machine, the paper was manufactured.

Most paper companies retain a history of when various manufacturing changes take place and, for their own protection, usually retain (often for many years) a swatch of "out-turn" paper sheets sampled from every commercial machine roll of paper produced. In the case of criminal investigations, most companies will willingly assist in providing samples for comparison with police evidence.

As a considerable quantity of paper is traded internationally and individual grades from a single paper machine can be packaged in a dozen, or more ream wraps for large volume purchasers (so-called home brand papers) the archive kept by each analyst can become very valuable in determining that a particular sheet of paper could have been produced, for example, in an Indonesian paper mill and purchased at a large retail office stationary chain in the United States in a given year. A year later the same US stationary chain might well be purchasing its "home brand" copy paper from a mill in China, or Thailand, or Finland, depending on the market price fluctuations.

Some Notes of Papermaking and Paper Testing

Paper is made by a formula of raw materials, set by individual paper mills, depending on the desired performance qualities required in the end product. The inclusion of certain raw materials is also governed by availability and price. As already stated, paper is largely composed of botanical fiber, be it softwood (gymnosperm) fiber, hardwood (angiosperm) fiber, Gramineae fiber (grass fiber such as that derived from cereal straw, sugar cane, or bamboo), or other

plant materials such as cotton, cotton linter fiber, or (rarely) fiber extracted from more exotic sources, such as the paper mulberry tree. The common factor between the vast majority of botanical fibers used in the papermaking process is that they are derived from the modified cell walls of elongated structural cells (i.e., fibers). Adventitiously, smaller quantities of other nonfibrous types of plant cells, such as vessel cells and ray cells will also be included with the fibers. Broadly speaking, all plant cells used in papermaking are largely composed of cellulose. In the living plant (and in some types of paper), these cellulose structures are impregnated with, and tightly bonded to adjoining cells with two organic bipolymers known as *hemicellulose* and *lignin*.

Fibers are extracted or freed (prepared) from the plant matrix by various chemical and mechanical means. These processes, particularly the chemical processes, are designed to liberate individual fibers from the plant material by dissolving or making soluble the lignin component that bonds the cellulose and hemicellulose materials together. Chemical pulps, as the name implies, are prepared by "cooking" the raw plant material in a chemical cocktail (usually weak acids or strong alkalis) at elevated temperature and pressure to facilitate the transformation of lignin into water-soluble products that can be separated from the fibers by washing. Often 50% or more of the original plant material is lost during this procedure but a very strong and flexible fiber, ideal for later use in writing and printing papers, is produced. In the case of most printing and writing papers (excluding newsprint and many cheaper magazine and catalog papers – see below) the freed fiber or pulp has to be further chemically treated by bleaching to remove the last traces of lignin giving the desired whiteness.

In contrast, heat in combination with various mechanical processes is also employed by the paper industry to separate the fibers from the wood matrix. These "thermomechanical" processes leave most of the lignin *in situ* around and within the fiber. The lignin can be made almost colorless in a second processing stage using oxidizing chemicals, such as hydrogen peroxide, however, this change is not permanent and the paper will start to show the yellow–brown color of unoxidized lignin after a period of days to months depending on the conditions of storage. Therefore, pulps produced via these latter thermomechanical methods are usually not used in high-quality writing or printing papers, but form the basis of many ephemeral products, such as newspaper and cheaper magazines and leaflet/catalog grade papers as they tend to form a weak sheet and "yellow" rapidly in sunlight. The main advantage of such papers is their lower cost of production stemming from the fact that almost twice the quantity of mechanical grade paper can be made from each tonne of wood, compared to chemical or "woodfree" papers. The most prevalent of these pulping processes, and their importance to the paper and fiber analyst, will be gone into more detail later. Combinations of smaller amounts of chemical processing with heat and mechanical energy are also used to produce the so-called chemimechanical and chemithermomechanical pulps and papers.

Physical Properties of Paper

As already mentioned, when characterizing a sheet of paper, it is not only the composition of the sheet that is important but also the paper's physical properties. For evidence to hold up in a legal enquiry, it must be demonstrated that, as far as physically possible, the paper from a document has been tested scientifically, and according to the accepted standard test methods. Like most other manufacturing industries, the paper industry globally has a recognized system of standard pulp and paper test methods that are overseen and continually reviewed by a number of industry-related organizations; a selection of these being the Scandinavian Pulp and Paper Association (SCAN), the US Technical Association of the Pulp and Paper Industry (TAPPI), and the Australian Pulp and Paper Industry Technical Association (APPITA). Many of these methods refer back to fundamental ISO standard methods.

Industry methods usually specify the minimum number of tests and the minimum area or number of sheets from which these tests must be taken (e.g., for grammage of photocopy paper, 10 individual measurements must be derived from 10 individual A4 sheets selected from specified positions throughout the ream). A common handicap for the paper and fiber analyst, however, is that there is usually only a very limited amount of sample to work with (often a single page) and the police or investigating body are often loathe to let it out of their hands, leave alone have part of it irretrievably destroyed for the purposes of testing. In these cases, the analyst can only stick to

the standard as close as possible, taking note of where deviations from the method occur, and the reasons why, for later inclusion in their report. Physical test results derived from limited sample should be treated as indicative only.

Further information in this article is presented in three sections; Some Basic Paper Properties, Fiber Analysis Using Light Microscopy & Fibre Sources for the Paper Industry.

Some Basic Paper Properties

For standard test methods for measuring the physical and chemical properties of paper and paperboard samples, readers are recommended to contact the national standard setting organizations in their respective countries. For convenience, some standards specified by TAPPI (North America) are provided in the Reference Section at the end of this article.

Moisture Absorbent Properties of Paper/Paper Conditioning Prior to Testing

One important property of paper is its moisture content. All commonly encountered paper sheets absorb between 5 and 12% of moisture from air depending on the ambient relative humidity and an equilibrium exists between water absorbed and the vapor in the atmosphere in contact with the paper, so water is an integral part of the sheet [1].

The amount of moisture a paper carries can significantly affect properties such as sheet weight, thickness, tensile and tearing strength, and optical properties such as brightness and opacity. Therefore, for results generated by one laboratory, to be comparable with those generated by another, paper and paperboard products are tested under strictly controlled atmospheric conditions. The International Organization for Standardization (ISO) standard environmental conditions for paper testing are as follows: relative humidity $50 \pm 2\%$ and temperature $23 \pm 1^{\circ}C$.

Most paper strength properties show hysteresis behavior with respect to moisture content, so it is important that papers are dried in an atmosphere at 25% relative humidity at $25^{\circ}C$ before being allowed to equilibrate under the atmospheric conditions specified by ISO prior to testing. "Conditioning" as this equilibrium is called, usually takes 24 h and sometimes longer if the paper or board sample is coated, exceptionally compact or thick.

Anisotropic Properties of Paper

Commercially made papers are anisotropic materials, meaning that almost all physical properties differ depending on the direction in which the measurement is made within the plane of the sheet. Papermakers often refer to paper as having a "grain" that will generally run along the longer axis of the rectangular sheet (long grain) or less commonly along the perpendicular shorter axis of the sheet (short grain).

The anisotropy of the sheet results from the process by which paper is manufactured. A dilute suspension of pulp fibers in water together with any mineral filler particles and chemical such as sizing agents, filler retention aids, and FWAs are dewatered on a revolving fine mesh forming fabric (commonly called a *wire*) moving at speeds that can range from $100\,m\,min^{-1}$ on machines making heavier basis weight paperboards to $2000\,m\,min^{-1}$ for lighter weight papers, such as newsprint. The continuous wire rotates around two drive metal cylinders that rotate about an axis that runs from the back of the machine to the front – the so-called cross direction (CD) of the machine. The axis that is perpendicular to the CD that runs longitudinally parallel to the length of the machine is called the *machine direction* (MD) – this is the direction in which the paper is formed. The fluid dynamics that applies to the fiber suspension as it impacts the forming fabric causes the majority of the fibers to align in the "MD". Some directional-dependant paper properties are tensile strength (greater in the MD), stretch (greater in the CD), tearing strength (greater is the CD), and paper stiffness (greater in the MD).

When reels of office papers are slit and cut into A4 or quarto sheets, the long direction of the sheet is usually aligned in the MD. Occasionally, however, certain photocopy and bond papers are found where the MD of the paper is orientated across the short dimension of the A4 sheet. "Direction of cut" is usually decided on the basis of which cut will minimize the "trim" (paper that must be deliberately cut from the front and back edges of the machine reel in order to guarantee an acceptably straight smooth edge on every sheet). Given that the cross directional width of the forming fabric (the "deckle width") is fixed at the time the machine is built, the minimum trim wasted will be achieved when either the MD or the CD dimension of the cut sheet is an integral factor

of the trim width of the machine. "Direction of cut" is sometimes useful in distinguishing a sheet made on one machine from a very similar sheet made on another machine (perhaps in a different mill) with a different deckle width.

For the sake of completeness, it should be noted that the remaining axis of the paper sheet that is orthogonal to both the MD and the CD is referred to as the *Z direction* (ZD).

Paper has many physical properties that are routinely measured by the manufacturer against either internal specifications or those specified by the mill's customers. The suite of tests is chosen depending on the ultimate end use. For the purpose of characterizing photocopy, bond and security papers, the forensic scientist would initially be interested in the following:

- sheet dimensions (metric, American or Imperial);
- grammage (basis weight);
- caliper (thickness);
- sheet density (calculated from sheet dimensions, grammage, and caliper);
- basic paper chemistry (is the sheet acid sized with a pH between 3.5 and 4.5, neutral sized with a pH between 6 and 6.5 or "alkaline" sized with a pH between 7.0 and 7.5 – "permanent paper")
- filler content and type;
- ISO brightness, opacity, and CIE color coordinates (L* a* and b*); and
- fluorescent properties under UV light (FWA content).

Photocopy and Bond Paper – Standard Paper Dimensions

The nominal dimensions of an A4 sheet are 297 mm $\times$ 210 mm $(L \times W)$ and an A3 sheet, 420 mm $\times$ 297 mm. These dimensions are governed by the ratio $1 : \sqrt{2}$ or $1 : 1.414$ such that sheets of diminishing sizes in the A series (and the B series) decrease by 50% in area in going from A1 to A2 and from A3 to A4, so there is zero wastage when the paper is cut to standard sizes.

Using this principle, two A5 sheets cut from a "long grain" A4 sheet will be 210 mm long $\times$148.5 mm wide and will be "cross grain". To elaborate on this discussion is beyond the scope of this article but an excellent explanation titled "International standard paper sizes" is given at the Internet site http://www.cl.cam.ac.uk/~mgk25/iso-paper.html. The purpose of discussing sheet dimensions here is to state that, for various reasons, sheets are not always cut exactly to these dimensions, and because a typical writing paper can expand and contract by up to 4% in the CD and 1.5% in the MD as the moisture content goes from 12 to 5%, the length and width of the conditioned sheet must be accurately remeasured after conditioning.

Grammage (Basis Weight)

In countries using the metric system of measurement, a basic property of paper is "grammage" or the weight of the sheet in grams per square meter (gsm). General use photocopy paper is usually manufactured to a grammage specification of 80 gsm but cheaper A4 "draft papers" are often made to lighter grammages (e.g., 65 and 70 gsm). Higher quality specialty printing and bond papers can have specific grammages in the 90–120 gsm range [2].

Continental North America runs to a different system. The dimensions of a standard US Letter "A" Paper (commonly used in North American homes and offices) is 11 in. $\times$ 8.5 in. or 280 mm $\times$ 216 mm. The basis weight of US Letter paper can range from 16 lb to 24 pounds (lb).[a] An explanation of the American paper basis weight system is also given at the above quoted website but a simpler explanation can be found under "Weights & Sizes of Paper" at http://www.inkjetart.com/weight.html.

Calculation of Paper Grammage for an A4 sheet – An Example. Area of an A4 sheet = 62 370 mm^2 (i.e., length by width in millimeters, assuming the dimensions of the conditioned sheet are 210 mm $\times$ 297 mm). This is equivalent to 0.06237 m^2.

Factor (No. of A4 sheets per square meter) = 1 m^2/0.06237 m^2 = 16.03

For this example, the conditioned weight of a single A4 page was found to be 4.97 g.

Therefore 4.97 g $\times$ 16.03 = 79.7 gsm.

Some notes on Grammage. Grammage with regard to copy and bond paper will not give the forensic investigator much information in itself as all paper manufacturers strive to produce paper within a certain grammage specification (e.g., copy paper with a nominal grammage of 80 gsm may have a product/manufacturing specification "Aim" grammage of 79.5 gsm with an "upper control limit"

of 80.7 gsm and a "lower control limit" of 78.5 gsm. Often manufacturers will endeavor to run the machine in the lower portion of the product range but keep within specification. A small saving in raw materials over each production run can result in large cost savings annually. Copy and bond paper is sold by area, not by weight – each ream containing normally 500 sheets (31.2 m^2 of paper), but sometimes 750 or 1000 sheets in "economy reams". On modern paper machines, grammage between sheets should not vary by >2%.

The importance of grammage is in the later calculation of sheet density. Every paper machine is unique. Despite, in this instance, copy paper being made to a nominal grammage of 80 gsm, depending on the pulp type, the amount of mechanical work done to the pulp (refining), filler content, calendering, and other machine parameters, thickness, and sheet density may vary significantly. If the authenticity of a page from a particular document is under suspicion, and its caliper and density differ significantly from measurements on other pages in the document, the discrepancy often warrants further investigation.

Sheet Thickness – Single or Bulking Thickness

Often a document examiner has only the document at hand to examine and, as already mentioned, the document may constitute a single sheet or even a fragment of a single sheet. Bulking thickness, determined on a stack of 10 sheets, is the preferred method when sufficient sample is available. Determination of thickness on a single sheet should be treated as a sighter measurement only. Determination of thickness, like grammage, should be done on fully conditioned sheets. Single sheet thickness or caliper is measured using a specialized "dead weight" paper micrometer fitted with a wide diameter foot (16 mm) to compensate for the paper's inherent surface variability. The deadweight pressure between the two measuring platens must be 100 kPa ± 10. The weighted foot should rest on the paper's surface for at least 2 s and no greater than 5 s before a reading is taken. For writing and printing papers, as with most other papers, thickness is recorded in micrometers. Readings should be evenly spaced over the CD of the sheet as this is the direction of greater variability. "Apparent thickness" is what is actually measured, not true average thickness (refer to *TAPPI test method*) [3].

Apparent Sheet Density

Sheet or paper density can be determined by calculation using the grammage and thickness data obtained. Paper density is usually quoted as kilogram per cubic meter. There are many different ways to calculate the sheet density. One format is given below.

Consider a stack of sheets cut into squares measuring 1 m × 1 m. If the sheets are neatly stacked one atop another until they reach a height of 1 m they would take up a volume of 1 m^3.

Calculation. Each sheet being a meter square would weigh 79.7 g or 0.0797 kg. (see previous calculation). For the purpose of this example, 20 individual thickness measurements for the sample gave an average caliper of 104 μm.

The apparent volume of each sheet is therefore $1 \times 1 \times 0.00104\ m^3$.

Therefore apparent density = mass per unit apparent volume = $0.0797\ kg/0.00104\ m^3 = 766.3\ kg\ m^{-3}$

Wire and Felt Marks

One final and potentially useful characteristic for confirming that two samples of paper came from the same ream when all the other analyses point to this being highly likely is the characterization of the subtle indentations left on the surface of many office, printing and writing papers by the forming fabric (or "machine wire"), and/or the drying felts on the paper machine. These markings can be made visible by very low angle illumination (typically 5–°10) and image capture using a low magnification (typically × 10) microscope, followed by contrast enhancement using image analysis software.

If a fast Fourier transform is performed on the enhanced image, and then all sections of the transformed pattern are deleted and the pattern "reverse transformed", a useful image of the particular weave pattern used in making the forming fabric is often obtained. If the weave pattern obtained from the evidentiary document (e.g., a ransom note) is identical to the weave pattern from samples of paper taken from the suspect's home, or office, and all other features of the sample are identical, this is fairly strong evidence that the paper sheets are from the same ream.

If, alternatively, the weave patterns are not identical, caution must be exercised. Nonidentity of the weave patterns does not necessarily mean that the

sheets are not from the same ream as five to six different machine rolls (made at different times on the same machine when the machine was "clothed" using forming fabrics of different weaves) may have been cut simultaneously to produce the ream of cut sheets. In a case where the first sheet from the ream gives a different pattern, it would be necessary to examine up to six sequential sheets from the ream in order to determine whether all the rolls that were sliced and cut to produce the ream have the same nonidentical weave pattern. In the event that all the six weave patterns from the sequential sheets taken from the ream are identical, but different to the evidentiary sample, then it can be concluded that the evidentiary sample is not from that source. The way in which common A4 (or US Letter) sheets are cut and compiled into reams involves cutting and sheeting between four and six machine rolls simultaneously in the same sequence.

To take a specific example, if mill personnel had taken six machine rolls from the reel store of which five rolls were made between October and December when the machine was clothed with a forming fabric with the weave pattern "A" and one roll was made in, say, January (following a holiday maintenance shut when the old forming fabric was replaced with a new forming fabric having a weave pattern "B"), then the sheets in the ream when subjected to image analysis above would show the sequence . . . A,A,B,A,A,A,A,A,B,A,A,A,A,A,B,A,A, . . . and so on, repeating this pattern with one sheet of pattern B separated by five sheets of pattern A down through the ream. If the identity of the mill that produced the paper is known and accessible, consultation with the mill staff will be a useful way of confirming how the reams from that mill are normally made up and whether or not there were changes made to the machine fabrics during the period in question.

An Introduction to Paper Chemistry

Major chemical properties of paper are also important in characterizing samples of paper. One of the quickest and simplest chemical tests is the pH of the sizing agent used when the paper was manufactured. A "pH pen" (a felt-tipped pen filled with an aqueous solution of pH indicator dye, phenol red) will produce a yellow spot on older "acid sized" papers and a violet spot on more modern "alkaline sized" sheets (i.e., 7.0–7.5 pH). Although convenient, the results of this simple test can be difficult to interpret if the paper has been sized with a modified "neutral" rosin size with a pH between 6.0 and 6.5 when a grayish color results. More certain data is obtained using TAPPI methods T509 and T435, or American Society for Testing and Materials ASTM D778.

Most commercial office, printing and writing grade papers contain mineral fillers in quantities up to 25% of the mass of the paper. Most alkaline sized papers (paper sized with the synthetic chemicals alkyl ketene dimer (AKD) or alkenyl succinyl anhydride (ASA)) will usually contain calcium carbonate as a filler, whereas the most common filler in acid sized (using emulsions made from natural softwood rosin soaps precipitated onto the fibers using aluminum sulfate) and neutral sized (using chemically modified rosin soaps and aluminum sulfate) papers is kaolin. Talc, calcium sulfate, barium sulfate, and titanium dioxide are also used as fillers but much less commonly. Paper made from de-inked recycled fiber will usually contain a mixture of many mineral pigments.

If the paper contains calcium carbonate, bubbles of carbon dioxide will form if a drop of dilute hydrochloric acid is placed on the surface. The amount of calcium carbonate present can be determined by ashing a portion of the sheet in a muffle furnace at 520°C and taking note of the weight of the ash obtained. The same sample is then further heated to 925°C to drive off carbon dioxide after which it is again weighed. The calculation of how much carbonate (as equivalent $CaCO_3$) was present in the original sample can be determined by simple stoichiometry. The mineral content of the residual ash can then be further analyzed using electron dispersive spectroscopy. Access to a scanning electron microscope can be invaluable in fully characterizing papers.

The presence of fluorescent whitening agents (FWAs), less correctly called *optical brightening agents* (OBAs) can be established by examining the paper sample under a UV light source in the 350–390 nm wavelength range. The paper will fluoresce if FWA's have been used during manufacture. More definitive results can be obtained by measuring ISO Brightness using one of the many light and colour measuring instruments now available. This is achieved by measuring the paper's brightness with the UV filter absent, and then present, in the incident light beam. By subtracting the former value from the latter, a measure of fluorescence can be obtained.

Most office papers also contain cooked starch to impart strength to the surface of the sheet. Spreading a few drops of dilute iodine solution in aqueous potassium iodide on the surface will confirm the presence of starch by the appearance of a characteristic but transient blue-black color.

Fiber Analysis Using Light Microscopy

Fiber Analysis

As previously mentioned, "fiber analysis" is the technique of breaking down a representative portion of a sheet of paper into its individual fibrous and nonfibrous cellular components, dispersing the resultant dilute suspension on a microscope slide and then drying and staining the fiber for microscopic analysis [4–9].

The cellular components are examined from two perspectives; firstly, to determine pulp types (and the proportion of each type in the total furnish) and secondly, the identification of the various wood or nonwood species represented in the furnish. Species from which the fibers derive can be identified by their morphology (i.e., shape and structure) and pulp types can be determined by the way individual fibers react to, or take up, chemical stain. The reaction to a particular stain is very much influenced by the chemical processes employed in producing or treating the raw plant material to produce the particular papermaking pulp.

It is impossible to cover the subject of fiber analysis in detail within this article but a full and broad understanding of the techniques can be gained from the above listed the standard methods sighted in the Reference Section. Distinguishing fibers from different trees, for example, is not a skill that can be picked up immediately and it often takes many years of gaining experience examining fibers from well-documented sources before a fiber analyst can feel fully competent in his or her abilities.

The fiber analyst's main tool is a binocular compound light microscope fitted with a mechanical stage and Abbe condenser capable of making observations at $\times 40$, $\times 100$, and $\times 400$. Higher magnification is of no advantage. One eyepiece should be fitted with a crosshair. A multistation tally counter, similar to that used to count blood cells, is also required.

Briefly, in the course of an analysis, the investigator would prepare two or more representative slides. After staining and the application of a cover slip, a few minutes should be allowed before observing to allow let the stain develop. It is recommended that the investigator first scan the slide at $\times 40$ to gain a general feel for the pulp types and species represented. Only then should they increase the magnification to $\times 100$ to make a formal analysis.

The analysis would start by the investigator moving to the top left or right hand corner of the cover slip, and moving vertically down the slide – by means of moving the mechanical stage – record each fiber passed over by the crosshair, taking note of its pulp type and whether it is a softwood, hardwood, or nonwood fiber. Each fiber and its pulp category must be immediately registered on the multistation tally counter and the traverse continued. When the investigator reaches the bottom of the cover slip the slide should be moved a few mm across and the traverse continued in the opposite direction until the cover slip has been fully examined. This process is continued until at least 800 fibers are counted. During or after the count, the individual species encountered should be noted for later inclusion in the investigator's report, if relevant. Sometimes, in species identification, $\times 400$ is used to clarify species by allowing closer examination of microstructure (e.g., hardwood vessel elements or softwood crossray pitting).

Fiber or Pulp Weighting

It will be obvious to the observer that not all fiber types are the same with regard to length and cross-sectional area and, if the proportion of each fiber type is to be reported as a weighted percent of the total, a weight factor must be applied. A list of generic weight factors for various pulp types and species is given in the right hand column of Table 1 – but it is recommended that each fiber analyst further refine these factors by calibrating their own observations against manufactured "dummy" furnish samples of known composition. It is also recommended that the analyst regularly cross-check their observations against those of other analysts. Between trained analysts, the weighted results obtained for each fiber type should not vary by more then 3%.

An example of a typical fiber analysis report compiled by the author is given in Figure 1. In this particular instant, the report pertains to a customer complaint where the printing company thought they were using paper from a local manufacturer but

Table 1 Stain reaction and weight factor for various fiber types

Pulp type	Norval–Wilson stain resultant color	Graff C stain resultant color	Fiber weighting
Unbleached chemical hardwood (kraft and soda pulp)	Dark or navy blue through to pink	Dark or navy blue through to pink	0.4
Bleached chemical hardwood (kraft and soda pulp)	Dark or navy blue through to pink	Dark or navy blue through to pink	0.4
Unbleached sulfite softwood pulp	Light brown	Usually yellow	1.0
Bleached sulfite softwood pulp	Lavender	Purplish blue	0.9
Unbleached kraft softwood pulp	Brown	Yellow to brownish yellow	1.0
Bleached kraft softwood pulp	Bluish gray	Blue to gray	0.9
Semichemical hardwood pulp	Khaki green to yellow brown	Brownish orange	0.6
Thermomechanical softwood pulp	Golden yellow	Bright yellow	1.7
Bleached chemi-thermomechanical softwood pulp	Copper brown	–	1.6
Cereal straw	Green to blue	Greenish yellow to greenish blue	0.4
Rag/linen/cotton	Pink	Red to pink	1.0
Jute/manila	–	Yellow orange	0.6
Esparto	–	Blue	0.5

were actually using an imported grade. Details of the various parties involved have been changed in order to maintain commercial confidentiality. An example of how fiber is weighted and calculated as a percent of the total is shown in the table included in the Figure 1 report. The reader will also note that the weight factors used by the analyst differ from the generic weight factors. These have been refined through trial and error to correlate with the author's own observations.

Fiber Sources for the Paper Industry

Common fiber sources used in the paper industry are categorized as wood fibers and nonwood fibers.

Wood Fibers – Two Types. *Gymnosperms (i.e., Wood Fibers from Coniferous (Cone Bearing) Trees).* Some examples of families of coniferous trees used commercially are pine, fir, spruce, cedar, larch, and hemlock. Conifers are often referred to as *softwoods*. Softwoods produce "long-fibered" pulp and are ideal where high tearing strength is required in the paper (e.g., paper sacks and bags). Addition of small percentages of long-fiber pulps also provide wet strength to office, printing, and writing papers (that are made mainly from short hardwood fibers (see below)) so that manufacture and converting operations can be carried out at higher line speeds. Depending on the species, average fiber length can range from 2 to 7 mm but most species fall within the 2–4 mm range with a wide distribution of lengths present within almost all the samples of fiber. Softwood fibers are called *tracheids*. Their function is to provide both mechanical support and the conduction of fluids.

Angiosperms (Flowering Plants). Angiosperms produce flowers and fruit and have a more complex and specialized vascular structure within their woody tissue. In the case of trees, angiosperms include both deciduous and evergreen examples. Angiosperm trees are generally referred to as *hardwoods* because of the normally higher density of their woody tissue compared to woods derived from most gymnosperm trees. Some examples of angiosperm tree families are elm, maple, alder, birch, poplar, eucalyptus, acacia, dipterocarps, and other tropical hardwoods.

Hardwoods produce "short-fiber" pulps. Average fiber length ranges from 0.7–1.5 mm depending on the species, with again a wide distribution of lengths being present in almost all samples observed. Hardwood fibers have a narrow diameter (typically 10–50 μm), compared with softwoods fibers and lack pits in their walls. Hardwood fibers (referred to as

CURRAWONG PAPER TEST LABORATORIES

Test Report

1st November 2007

Subject: Fibre Analysis Report

Emporium Sales Catalogue

An Emporium Pre-Christmas Sale brochure (valid from Wednesday Dec. 8th until Sunday Dec. 19th, 2007) which manifested unacceptable levels of print mottle has been subjected to examination by optical microscopy in order to determine whether the paper on which it was printed is Australian product, or otherwise. The results of this investigation are given below.

Fiber Class	Chemical Hardwood*	Chemical Softwood#	Semi-Chem. Hardwood$	Mechanical Softwood**	Total
Fiber Count	12	328	444	61	845
Factor	×0.33	×1.0	×0.6	×1.8	
Weighted Factor	4	328	266	110	708
%	<1 (Trace)	46	38	16	~100

* Chemical Hardwood Component – Birch (Exclusively)
\# Chemical Softwood Component – Scot's pine (in the majority) & Norway Spruce (in the minority).
$ Semi-chem. Hardwood Component – Aspen (Exclusively)
** Mechanical Softwood Component (TMP) – Norway Spruce

Fibre Analysis according to AS/NZS 1301-451rp using Norval-Wilson stain.
Date analysed – 31.10.2007

Conclusion: The paper used to produce this brochure is not Australian made. The mix of species noted in the paper's furnish point strongly towards a European origin.

libriform fibers) are ideal for producing printing and writing papers as they form a very flat, uniform, smooth surface.

Nonwoods (Angiosperms that Include Grasses and Shrubby Plants). The stems from wheat, rice, sugar cane, bamboo, papyrus, kenaf, sisal, jute, hemp, flax and the bolls, and the seed coat (linters) from cotton are all used to make paper in countries that lack adequate forest resources.

For the purposes of papermaking, nonwood fibers can be broadly broken down into "bast fibers" (from the outer tissues of the stems of sisal, jute, hemp, and flax plants) and Graminaceae (grass) fibers. Graminaceous fibers can be further broken down into cereal straw fibers (e.g., wheat, oats, and rice) and noncereal stems (e.g., reed, bamboo, and sugarcane (bagasse)).

Cotton, collected from the cotton boll and seedpod coverings of the cotton plant, falls into a category of its own. Cotton as a papermaking fiber is very much in decline, except for use in specialty writing papers, surgical tissues, and laboratory filter papers.

An excellent resource for the fiber analyst is a publication from the *Springer Series in Wood Science* titled *Fiber Atlas, Identification of Papermaking Fibers* by Marja-Sisko Ilvessalo-Pfäffli ([10]/ISBN 3-540-55392-4). This publication gives a thorough description of fiber morphology for species identification.

Common Pulp Types

The four most common pulp types employed in the paper industry today are chemical hardwood pulp (kraft or sulfite pulping process), chemical softwood pulp (kraft or sulfite pulping process), semichemical hardwood pulp (pulping processes using mechanical and heat energy with small quantities of chemicals), and thermomechanical softwood pulp (pulping processes using a combination of heat and mechanical energy and no chemicals (other than water)).

Other pulp types less commonly used in developed countries in recent years are "soda pulp" (chemical) and "groundwood" (mechanical).

1. Kraft process (also known as the *sulfate process*). Woodchips are cooked using NaOH and Na_2S in water at 170°C and 8 atm. This process takes place in alkaline conditions and produces very strong pulps used for both packaging and writing papers (kraft is German for strength). Extensive chemical processing is followed by minimal mechanical processing. If the pulp is going to be used to produce photocopy/printing/writing papers pulping is followed by a multistage bleaching process that can be based on chlorine, chlorine dioxide (elemental chlorine free (ECF)), or ozone and hydrogen peroxide (totally chlorine free (TCF)) that dissolve the last traces of brown-colored lignin.
2. In sulfite cooking the "cooking liquor" a mixture of water, calcium, or magnesium bisulfite (referred to as *combined* SO_2) and free SO_2 in excess. The excess SO_2 reacts with water to form sulfurous acid and therefore the cooking is acidic in nature. This process is also conducted at 170°C and pressure in excess of 8 atm and produces a very light-colored pulp with high opacity that is relatively low in strength compared to kraft pulp. Extensive chemical processing is followed by minimal mechanical processing. If the pulp is going to be used to produce photocopy, printing, or writing papers, it is followed by a similar multistage bleaching process to that used to bleach kraft pulps.
3. The semichemical method involves treatment of woodchips with lower quantities of either sodium sulfite (at pH 7–9) or sodium hydroxide at pH 12 followed by considerable mechanical processing. Cheaper to produce than full chemical pulps, bleached chemi-thermomechanical hardwood pulps (BCTMP) are sometimes added to lower quality writing papers to increase opacity and bulk.
4. To make thermomechanical pulps (TMP) softwood chips are pretreated with steam and then broken down into fiber by extensive mechanical processing. Comparatively the pulp is low cost to produce and is used in ephemeral products such as newspapers, magazines, junk mail, low cost paper back books, and writing pads. TMP has comparatively low-strength properties and readily yellows when exposed to sunlight and other light sources containing UV wavelengths.
5. Soda pulp is produced by cooking wood chips using sodium hydroxide in water as the sole chemical agent. As with sulfate and sulfite pulps, lignin removal is achieved at elevated temperatures and pressures.

6. Groundwood pulping is achieved by pressing whole logs against a heavily burred rotating grindstone.

Fiber Staining

The most common microscopy stain used for plant fiber identification is Norval–Wilson stain. Another useful stain is Graff C. Norval–Wilson and Graff C stain termed as *differential* stains. They are capable of staining different classes of fiber with different diagnostic colors depending on the chemical or mechanical processes utilized to produce them as shown in Table 1.

Softwood Identification

As stated earlier, softwood fibers are called *tracheids* and provide both mechanical support for a plant and also act as a conduit for the conduction of fluids to all the living parts of the plant. Fluids are transferred from fiber to fiber via "pits" in the tracheid wall. These pits act as valves to prevent the flow of liquids reversing. Basically there are two types of pitting. "Bordered pits", which convey fluid from tracheid to tracheid in an axial direction, and "crossray" pits, which convey fluids throughout the plant in a transverse direction. The structure of crossray pitting is particularly useful in identifying the species. "Spiral thickenings" can also help to identify species, as in the case of the commonly utilized softwood fiber from the Douglas fir (*Pseudotsuga menziesii*). See *Fiber Atlas, Identification of Papermaking Fibers,* referred to in section 2.3, or a similar publication.

Hardwood Identification

Hardwoods, and in fact all angiosperms, use fibers for structural support and use an auxiliary specialized vascular system for the conduction of fluids. These conduits, called *vessels*, are made up of smaller units or "vessel elements" which act in a similar fashion to man-made water conduit pipes laid end to end. These vessel elements are separated during the pulping process but remain mixed with the fibers in the pulp after the pulping and bleaching process. Fortunately for the fiber microscopist, vessel elements have very distinctive morphology depending on genus, and can be readily utilized to identify the various species of angiosperm present in a paper's furnish. See *Fiber Atlas, Identification of Papermaking Fibers* referred to in **Fiber Sources for the Paper Industry** section, or similar publication.

Comments on Indigenous and Exotic Species

Tree and other plant species can help identify the continent and sometimes country of origin of a paper sample. This, however, is becoming increasingly more difficult as plantations of various exotic species are becoming evermore prominent in paper-producing countries far from the regions in which they occur as natives. For example Spain, Portugal, South Africa, South America (and now, Southeast Asia) grow substantial plantation stands of eucalyptus for papermaking. This genus was once only indigenous to Australia and parts of New Guinea. One species, *Eucalyptus deglupta* is also native to the Celebes and the Philippines. It is worth noting that some species that were formerly classified within the genus *Eucalyptus* have recently been separated into a new genus, *Corymbia* by taxonomists, while retaining their specific names. *Corymbia maculate maculate* (spotted gum) and *Corymbia maculate citriodera* (lemon-scented gum) are the only two Corymbia species that may rarely find their way into commercially produced papers and neither species is cultivated in plantations as a papermaking resource.

The Monterey pine (*Pinus radiata*), originally native to a very confined region of the west coast of the United States, is now grown widely in Australia, New Zealand, South Africa, South America, and countries surrounding the Mediterranean. Outside its country of origin, it is a very fast growing tree and an ideal wood pulp resource. The same is true for Douglas fir, which can be found in plantation in Britain, Portugal, central Europe, and New Zealand.

Further Notes on Fiber Furnish

Identification of paper can sometimes be further refined by measuring the proportion, or percent, of different fiber types in a paper furnish (provided the paper manufacturing specifications are known). An example is given below.

Although bleached hardwood is the ideal raw material for the manufacture of photocopy paper, paper manufacturers in the southern hemisphere and tropics add a small portion of bleached softwood

to improve wet strength and speed of manufacture, and to also add dry strength for converting and cutting process (i.e., roll to ream). Until recent decades, there was insufficient capacity for producing bleached softwood fiber in the southern hemisphere (although Brazil, Chile, and New Zealand now have substantial output) and in countries such as Australia, for instance, that still import all their bleached softwood requirements, this material is an expensive impost. Most bleached softwood pulp arriving in Australia comes directly from New Zealand, Canada, and the United States but ever-increasing amounts are sourced from other regions such as Brazil and Chile depending on quality, availability, and price. As the imported softwood pulp is comparatively expensive, machine operators try to keep this component of the furnish down to 10 or 15% of the total fiber furnish (for an 80 gsm sheet). Indonesia, on more modern paper machines, can run with softwood concentrations as low as 1–3%. Information such as this can be very useful to the fiber analyst in identifying likely country of origin.

Recycled Fiber

A point of caution when examining paper furnish is to be certain that the paper does not contain recycled de-inked bleached fiber as this will greatly obscure the country of origin and could cause the analyst to reach quite misleading conclusions. To determine whether a paper contains recycled fiber or only virgin stock, it is good practice to first examine the intact sheet under $\times 10$ magnification using a stereo (binocular) microscope to pick up any signs of debris on the surface. The debris could be in the form of ink particles, toner particles, unbleached fiber or minute globules of adhesives (called *stickies*). Valid conclusions from such an examination will be made increasingly difficult if the sample has become soiled or dirty during the suspected or alleged criminal activity.

Acknowledgment

The author would like to gratefully acknowledge the assistance, guidance, and technical input of Dr Warwick D. Raverty, CSIRO Forest Biosciences, Bayview Avenue Clayton Victoria 3168, Australia.

End Notes

[a.] Approximate conversion from lbs (pounds per 100 square feet of paper) to gsm:

- 16 lb ~ 60.2 gsm
- 18 lb ~ 67.9 gsm
- 20 lb ~ 75.2 gsm
- 24 lb ~ 90.3 gsm.

Paraphilia ***see*** Sex Offenders: Treatment of

Parental Alienation

History of Parental Alienation

In the context of divorce, the pathological alignment of a parent and a child resulting in the child's rejection of the alienated parent was originally described by Wallerstein and Kelly (1977, 1980). Gardner (1987) [3] later introduced the term, *parental alienation syndrome*, to describe a diagnosable disorder occurring in the context of separation and divorce. Although Gardner contributed a good deal by describing the features of parental alienation, his work has been criticized because of his use of the word, "syndrome". Almost all mental health professionals who work with children of divorce agree that the phenomenon occurs, that is, children of high-conflict divorces sometimes gravitate to one side of the conflict and view that parent as totally good and the other parent as totally bad, all without a good cause. However, many professionals who work in this area do not refer to this phenomenon as a syndrome. Thus far, parental alienation syndrome or disorder has not been adopted into the *Diagnostic and Statistical Manual of Mental Disorders.* Most professionals in the family law setting – including judges, lawyers, and custody evaluators – simply refer to *parental alienation* and do not use the term, *parental alienation syndrome*.

Role of the Evaluator

Often the family law court is faced with a situation where a child is rejecting a parent. Sometimes the child is refusing to spend time with the parent, and sometimes the child is alleging that the parent is emotionally, physically, or sexually abusive. The rejection could be mild ("I just don't want to spend a lot of time with him.") or sizable ("I never want to see him again.")

There are three main reasons for a child's rejection of a parent: (i) The accused parent is indeed abusive and the child's rejection is appropriate and understandable. This is *not* considered parental alienation. (ii) The aligned parent (or another person) is responsible for the child's rejection of the other parent. This may result in parental alienation. (iii) The child is rejecting the alienated parent for the child's own inappropriate reason, despite the efforts of the nonalienated parent to support the relationship between the child and the alienated parent. This may also be called *parental alienation*.

Faced with the situation of a child who is rejecting a parent, the reason for the rejection may be obvious to the court. For example, the hated parent may have a long history of abusing the child, documented by child protective service investigations and/or admissions of abuse by the parent. At other times, the court may be convinced that the aligned parent is responsible for the parental alienation, for example, if there is clear proof to that effect. In these cases – when the cause of the child's rejection is obvious to the court – the court may not order an expert to evaluate the family for parental alienation. The court will base its conclusions and orders on these certain, proved reasons for the rejection.

Much of the time, however, the court is not certain. The aligned parent's argument that the alienated parent is abusive is persuasive, as is the alienated parent's assertion that the aligned parent is behind the alienation. The court may decide that an evaluator should interview the child, in the hope that the result of the interview will provide enough information to resolve the issue. The child interviewer often will inform the court about the content of the interview and provide an opinion regarding the believability of the child's statements. Sometimes, the court believes that the issues are too complex for a child interview to elucidate the truth and orders a full custody evaluation.

In some jurisdictions, there are other possibilities for the court to secure the truth. In Los Angeles, for example, the court can order a limited or "solution-focused evaluation". This involves a court evaluator's speaking to both parents and the child individually, observing the parent–child relationships, interviewing collaterals, and reviewing records, all in the short time frame of one morning. In the afternoon, the evaluator testifies to his or her opinion.

Occasionally, the alienated parent and attorney believe that they can persuade the judge by retaining an expert to opine after performing a limited investigation. For example, the expert would review records, interview collaterals, or interview the alienated parent and then, based on this limited information, render an opinion. Sometimes, the expert's opinions are helpful for clarifying the issue, despite the opposing side's argument that the retained expert's opinion is biased.

Experts performing these tasks need to limit their opinions as they have not performed an entire custody evaluation (*see* **Visitation Rights**).

Aligned Parents' Contributions to Parental Alienation

An aligned parent's behaviors may have contributed to the child's stance of refusing visitation. The aligned parent may have repeatedly expressed extremely negative views to the child such as, "She never wanted you", "He is a horrible mean man", or "He is an adulterer and caused the divorce"! Alternatively, the aligned parent's criticism may not be so overt. The criticism may merely contain innuendos that the alienated parent is dangerous: "Call me immediately if he tries to hurt you."

The aligned parent may contribute in other ways to the child's refusal of the alienated parent. For example, the aligned parent may tell the child that the other parent did not call, when the parent had. The aligned parent might discard letters from the other parent to the child. The aligned parent may not inform the alienated parent about school events important to the child, such as back-to-school nights and school performances. The rejected parent's parenting and personality flaws may be exaggerated and continuously discussed with the child. The aligned parent may praise the child ("That's right. Stand up for yourself.") when the child criticizes the other parent, and scorn the child when the child compliments the rejected parent ("You don't know what you're talking about. He's not smart at all.").

Sometimes the parent may cause the child's alienation from the other parent, but has not done so on purpose. For instance, the mother may be an anxious person who is unaware that she is communicating her anxiety to the child. She may start crying or be noticeably worried when the child leaves for visitation, but insist that the child should go and "have a good time". Similarly, a child may be so concerned about the depressed parent that the child feels that he or she needs to provide emotional support to that parent instead of going on the visitation with the other parent. The continuous drumbeat of negative statements, whether direct or indirect, and actions by whatever method may cause the child to adopt the aligned parent's negative feelings and reject the other parent.

Child's Contribution to Parental Alienation

Despite a parent's best efforts to support the other parent's relationship with the child, sometimes the child alienates an otherwise appropriate parent for no good reason.

Oppositional Child

The child may be oppositional and defiant and reject the parent who does not succumb to the child's demands. He or she may choose the parent who is least restrictive and vehemently reject the rule-setting parent.

Worried Child

The child may be worried after the departure and loss of the nonresidential parent, so the child becomes fearful that he or she is also going to lose the remaining residential parent as well. As a result, the child experiences an attachment to the residential parent that is greatly exaggerated, and fears separation from that parent.

Stubborn Child

Although the child has a good attachment to both parents, the child may be very upset that they have separated and divorced. That is, the child is upset (for example, sad, angry, resentful, worried) about the situation and doesn't want to participate in the process. The child expresses his or her feelings by objecting vehemently and stubbornly to the visitation, even though ordinarily he or she enjoys being with the other parent.

Child Escaping Conflict

Finally, there is a common psychological mechanism – cognitive dissonance – through which the child's affections can become extremely polarized. Specifically, the child's intense like of one parent and dislike of the other becomes his or her way of resolving the psychological tension that he or she experiences. For example, if the mother and father have been actively and visibly fighting with each other, the child would experience cognitive dissonance when trying to have affection for both of them

at the same time. The child is unable to reconcile two dissonant thoughts, "My mother is right" and "My father is right". The dissonance creates a tension in the child's mind, which is resolved by believing that he or she loves one parent and hates the other.

Other Alienators' Contributions to Parental Alienation

At times, the alienating party is a person other than one of the parents. That is, despite one parent's actively supporting the relationship between the other parent and the child, another person is actively indoctrinating the child against the other parent. The alienator could be a grandparent, stepparent, girlfriend, boyfriend, or even a sibling. The reasons for the alienation are diverse: a grandparent may be seeking revenge against the parent who left his or her child; a stepparent may be worried that the child will see the parent as a "real parent" and the stepparent as some unimportant figure; or perhaps a sibling may be trying to punish the parent who "caused" the divorce.

Court Orders for Treatment of Parental Alienation

Family court orders for a fractured parent/child relationship should match the reason for the relationship problems.

If the parent is truly abusive and the child's rejection is justified, the family court may order the parent to participate in parenting classes or enact other orders aimed at rehabilitating the abusive parent. The court will likely order any visitation to be monitored until the parent shows that he or she will behave appropriately. Therapy for the child should include the following components: supporting the child for having been abused ("What a difficult thing that you went through. You did not deserve to be abused."); teaching the child how to stay safe in the presence of the parent ("If he ever hits you again, call me immediately."); and education ("Not all authority figures are abusive."). Conjoint therapy involving the child and the abusive parent may help them reestablishing a healthy and mutually satisfying relationship.

If an alienating parent is found to be a source for the child's rejection of an appropriate parent, the court's approach varies. If the alienation is severe, the court may order that the child's time with the alienating parent be limited and monitored. If the child is refusing to live with the alienated parent and the court fears that the child may run away or hurt the alienated parent, the court may order the child to live with a third party until therapy corrects the situation. At times, in extreme circumstances (suicidality, running away, poor school performance, or delinquent behavior), the court may order that the child be placed in a residential facility.

In cases where the alienation is not very severe, the court may order therapy without removing the child from the alienating parent's custody. The ordered therapy may include "reunification therapy". The role of the therapist is to aid in building a better relationship with the alienated parent ("Tell me about a good time you had with your father."). Occasionally, the reunification therapist may choose to bring the alienating parent into therapy. The alienating parent may also be ordered into individual therapy. The individual therapy for the alienating parent should include education about the damaging effects of parental alienation on the child and the consequences of alienating behavior within the legal system ("The judge will never allow unmonitored visitation if you continue criticizing the mother in front of the child."). The therapist should monitor for alienating behavior and express praise when the alienating behavior is improving ("I spoke to the monitor and she says that you are doing a great job at not criticizing the father in front of the child."). The therapist should also express disappointment if the alienating behavior continues ("The letter you wrote your child stating 'your dad is a jerk' was inappropriate. I know you can do better."). The individual therapist should speak with the conjoint therapist and with others, so that alienating behavior can be promptly addressed. Both the conjoint therapist and the individual therapist may be asked to provide updates to the court regarding progress so that custody and visitation orders can be modified. An individual therapist for the child may be ordered by the court as well.

If the child is alienating a parent even though the favored parent is supporting the alienated parent's relationship, the focus of the therapy should be to stop this oppositional behavior. The child should be confronted with his manipulative ways and told that the behavior should stop. He should not be rewarded for refusing visitation; he should be disciplined. If the child cannot be forced to have visitation, his

privileges should be withdrawn. Behavior such as making false allegations should be similarly punished. The individual and conjoint therapists may be ordered to accomplish these treatment goals. Residential treatment may be ordered in special circumstances.

One of the important treatment goals in circumstances of alienation is for the child to learn proper conflict management skills. Prior to terminating therapy, the child should experience that it is unacceptable to lie, vilify, and reject those with who they are in conflict, especially loved ones.

Parental Rights and Prerogatives

Introduction: Parent, Child, and State

Parental possession and exercise of rights concerning their children must be understood in context. The rights of parents, the rights of children, and the interests of the state form a triangle. Laws affecting the parent–child relationship reflect the three legs of this triangle. The sources of such laws include the United States Constitution and the legislative, executive, and judicial branches of the federal and of state governments. Traditionally the states, as opposed to the federal government, are the primary source of law concerning families and there is considerable variation in statutes, regulations, and case law (court decisions) among states. Therefore, a forensic expert should not assume that, for example, laws defining sexual abuse or a parental duty to provide health care are exactly the same in every state; rather, the expert should take steps to inform him or herself about the law of the state where the expert is asked to work. Experts should also be aware that a state constitution may provide parents or children with rights beyond those guaranteed under the federal constitution, and that these rights will be enforced by that state's courts.

The parent–child relationship itself is the source of both parental rights and duties. A parent has the right to custody and companionship of his or her child – and a corresponding duty to provide the child with care and support. Generally, under the United States (federal) Constitution, a parent has a fundamental right to raise a child as the parent sees fit. The parent may exercise rights and prerogatives (and the law will defer to the parent) up to the point where there is actual harm or a substantial risk of harm to the child. At that point the state can intervene and impose restrictions upon the parent and child relationship.[a]

Thus, for example, the state can make education compulsory for children between certain ages (typically 6 to 16). It can enforce this requirement by prosecuting at criminal law parents who do not send their child to school. It can also act through the juvenile justice system against children of school age who are truant – whether or not the parent knows of or condones the truancy. However, the parent has a constitutional right to choose for the child's education a public or private school, or alternative types of education such as homeschooling.[b] The child does not have the legal right to choose how or where he or she will be educated. However, the state's interest in educating children and the child's interest in being educated are enforced by state curriculum and record-keeping regulations, which nonpublic schools, including homeschools, must satisfy.[c]

Similarly, parents have the right to give or deny their children permission to engage in paid labor. However, the state has power to limit the types of work, hours, and conditions under which children can be employed.[d] And although traditionally parents were entitled to their children's wages, state and federal laws now impose trustee obligations on parents

of child entertainers, athletes, models, etc. to manage and preserve the earnings for the benefit of the child.[e]

Parents have a "privilege" to use "reasonable, nonexcessive force" to discipline their children, including using physical restraint and corporal punishment. "Privilege" means that the parent has a right to do something to the child (confinement, infliction of pain) that would be otherwise be unlawful. The parent may delegate the privilege to a third party (a baby-sitter, a private school teacher) but cannot authorize any action that would exceed the scope of parent's own privilege. The privilege only applies to "reasonable, nonexcessive force". The state can act to prosecute criminally a person whose punishment of the child exceeds the scope of that privilege, can find the child abused under dependency court protection, or permit the minor through a legal representative to sue the person at civil law (in tort) for battery.[f]

The state's authority to do all this derives from two sources: the police power and the state's role as *parens patriae.* Under police power, the state can act to protect the child from harm and to protect the community from danger caused by the parent and possibly the child: for example, through criminal laws against child abuse and the juvenile justice system for children who commit acts that would be crimes if the minors were adults. *Parens patriae* means the state is acting as a parent. Under this source of authority, the state can use law to encourage and help parents carry out their duties of care and support, and to provide for and protect children whose parents are unable or unwilling to do so. Citing the special vulnerability of minors, states invoke *parens patriae* to justify individual laws such as special curfews for minors,[g] as well as dependency court jurisdiction over abused, neglected, or abandoned children.[h]

Juvenile Justice System

Juvenile justice courts generally have jurisdiction over three categories of children: those who have committed offenses which would be crimes if committed by adults (delinquents); those who have committed offenses that were against the law only because of the status of being a child (status offenders); and those who have been abandoned, abused, or neglected by their parents or guardians (dependent or neglected children). The juvenile justice system is a civil rather than a criminal one, and uses a distinctive terminology reflecting its original nonpunitive, rehabilitative purpose.[i] In the adult criminal justice system, the state files charges alleging that the defendant committed a crime; the case title reads "State (or Commonwealth) versus Name, Defendant". By contrast, in a juvenile delinquency, status offense, or dependency case, the state files a petition "in the matter of [first name and initial], a minor". The subject of the petition is referred to as *the minor*, rather than *the defendant,* and the petition contains not "charges" but reasons why the minor should be taken under the court's jurisdiction: the minor is a delinquent, the minor is a status offender, the minor is dependent or neglected. The court does not find the minor "guilty" or "not guilty" in delinquency or status offender cases, but rather sustains or denies the petition for jurisdiction. The hearing at which the court does this is called *an adjudication* rather than a trial. If the petition is sustained (that is, the court finds jurisdiction over the minor), the next step is "disposition" rather than "sentencing" of the minor. If the petition is denied, the case is dismissed. Similarly, in dependency cases the court does not find the minor's parent or parents "guilty" of abuse or neglect – rather it does or does not find the minor to be abused, neglected, or dependent. Only if the court sustains the dependency petition can it proceed to disposition and impose restrictions on the parent–child relationship up to and including termination of parental rights.

Delinquency

Under state codes, "delinquent" acts generally include the full range of behaviors considered criminal for adults, from minor crimes (misdemeanors) such as petty theft or disturbing the peace, to major crimes (felonies) such as robbery, rape, and murder.

The US Supreme Court has ruled that children who are the subject of delinquency petitions have the fifth amendment constitutional right against self-incrimination (also known as *the right to remain silent*) and the sixth amendment right to the assistance of an attorney (at state expense if the child is indigent)[j] Moreover, the state has to prove each element of the alleged delinquency beyond a reasonable doubt – the same standard of proof required in adult criminal cases.[k]

Minors alleged to be delinquent have most of the same rights to due process as are provided to adults in criminal proceedings, with two exceptions. Minors do not have the right to bail, nor the right to a jury trial.[l]

Dispositions in delinquency cases may range from "home on probation" to placement in "boot camps" or "group homes" to confinement in secure state youth facilities barely distinguishable from adult prisons. In most states, the maximum age for persons over whom the juvenile court has jurisdiction is 18 years. The age of jurisdiction refers to the age of the juvenile at the time the offense was committed. In the great majority of delinquency cases, the disposition imposed will end when the minor turns 18. However, for extremely serious offenses (such as murder) a juvenile may remain under the court's authority until age 21 or even 25, serving the years after age 18 in the adult prison system.[m]

Every state's juvenile justice system provides for some minors to be tried in adult court. Some state laws permit the district attorney to file charges directly in adult court when minors above a stated age are accused of a serious crime. Most states begin the case in juvenile court and hold a "fitness" or "waiver" hearing to determine whether the minor should be tried as an adult. "Fitness" refers to the minor's fitness to remain in the juvenile justice system: 'waiver" to the procedure under which the juvenile court waives jurisdiction over the minor in favor of transfer to the adult criminal court. Minimum age at which a minor can be transferred to or tried in the adult criminal court varies from state to state (from 10 to 16 years).[n] An adjudication of guilt in adult court exposes the minor to the same penalties for crime established by statute for adults, with the sole exception of the death penalty. The United States Supreme Court has declared it unconstitutional to execute an individual for a crime committed before his or her 18th birthday.[o]

In delinquency cases, parents' rights are minimal. The minor, not the parent, is the subject of the proceeding and his or her rights are those at stake. The minor, not the parent, has the right to assert or waive the 5th amendment right to remain silent, the amendment right to counsel, and the minor alone can choose to waive trial and enter a plea.[p] State laws typically give the parent a right to notice that a delinquency petition has been filed concerning the child, and the right to be present at critical stages of the case, such as a detention hearing or adjudication. However, the parent is not a party in the delinquency case and does not have a right to be heard by the court. The state can call the parent as a witness against the minor, however, and if the parent refuses to testify, the court can impose contempt penalties.

Because the *minor* has a constitutional right to counsel in a delinquency case, one will be provided at public expense if he or she cannot afford one. Of course, a parent may hire a private attorney to represent the child's interests; but whether private or public defender, ethically the attorney is bound to follow the minor client's instructions and serve the client's interests. The parent can urge the child to follow a particular course of action (for example, enter a guilty plea), but the attorney's advice to the minor client must be independent of the parent's wishes. Neither the parent nor the attorney can waive the minor's constitutional rights. Moreover, the attorney cannot reveal attorney–client communications to the parent, and with good reason. In the great majority of states, there is no parent–child privilege, so the parent can be forced to disclose confidential communications made by the child.[q]

Status Offenses

Depending upon the particular state code, "status offenses" may include behaviors such as truancy from school, running away from home, being habitually disobedient or "beyond the control of parents", or violating a local curfew law. These behaviors may be combined under a single label such as "children in need of supervision (CHINS)", "juveniles in need of supervision (JINS)", or "persons in need of supervision (PINS)".

States vary in the degree of procedural protections provided to minors who are the subject of status offender petitions.[r] Since status offenses are not "crimes", children in these proceedings may not be entitled to the 5th amendment right against self-incrimination. The US Supreme Court has not yet ruled on this matter. Under most state laws, children in status offense cases have the right to notice of the allegations against them, the right to a hearing, and right to the assistance of counsel. The standard of proof is only *preponderance of evidence*: that is, to take jurisdiction over the minor the judge need only find it *more likely than not* that the allegations have been proved. Federal and state laws prohibit "secure confinement" (placement in a locked facility such as a juvenile hall) of status offenders except in cases where a minor has been held in contempt for violation of a valid court order.[s]

Parents are likely to have greater involvement in status offense cases. The parent may have contacted the police or the juvenile court asking for help in controlling a child who is habitually disobedient or "incorrigible". In such a case, the parent will likely be the state's primary, if not sole, witness at the adjudication hearing. If the petition is sustained, the judge will try to order a disposition that will reinforce parental authority (often probation with specific conditions that the minor must obey her parents, avoid certain "bad influence" peers, submit to drug tests, etc.). If the minor violates these conditions, the parent can notify the court and the state can file contempt charges as discussed above.

However, the state is not required to file a petition just because the parent wants state reinforcement of his or her authority. The probation officer or prosecuting attorney may decide, rather than filing a petition, to refer the parent and child to family counseling or other services on a voluntary basis. Similarly, the state can file status offense petitions for truancy and curfew violations regardless of the parent's wishes, and may take action against a parent who has condoned the child's unlawful behavior. Once the court has sustained the petition, it can order the disposition it believes is best for the child, even if the parent opposes it.[t] If the court orders placement of a status offender in a foster home, group residence, or other out-of-home program, the parents may be required to pay the costs, as part of their duty to support their child.

Dependency Cases

Every state provides for protective action to be taken where a child is abused, neglected, abandoned by parents or guardians or otherwise "dependent" upon the state.[u] In some states, the "dependency" cases will be heard by the juvenile court: in others by the family court that also hears cases of divorce and child custody. Unlike family law custody cases, however, dependency proceedings are not conflicts between two private parties; rather, the state petitions the court to take jurisdiction over a child as "dependent" because of the acts or failure to act of parents or guardians.[v]

The degree of state intervention into the parent–child relationship through the dependency court can vary greatly. It may be temporary, as when life-saving surgery for a child is authorized by the court over parental objection yet care and custody of the child are returned to the parents immediately after the medical procedure.[w] It may last for months, as one or both parents try to regain custody of the child through compliance with a "reunification plan" designed to remove or alleviate the conditions that caused harm or put the child at risk.[x] It may be permanent, as where all parental rights are terminated, severing the legal relationship between parent and child. (Termination means total parental loss of rights to custody, visitation, and communication. The child becomes eligible for adoption by new parents, or for permanent placement with a legal guardian or foster family where adoption is not possible or appropriate.)[y]

Under the 14th Amendment to the United States Constitution, parents whose rights to care and custody are at risk in dependency proceedings must receive due process of law. Parents are entitled to notice of the allegations supporting the dependency petition and have the right to appear and be heard at the detention hearing (to decide where the child should live pending adjudication), the adjudication, the disposition hearing, and any hearings to review the status of the case. A dependency petition can be sustained at adjudication on a mere preponderance of evidence, because taking jurisdiction over the child is only a temporary deprivation of parental custody. Parental rights cannot be *terminated* without a finding based on clear and convincing evidence.[z] Nevertheless, the United States Supreme Court ruled that indigent parents are not always entitled to the assistance of counsel at public expense before termination of their rights: judges should consider parents' request for court-appointed free counsel on a case-by-case basis.[aa] In practice, most states do provide counsel for indigent parents in cases where termination is proposed.[bb]

The minors who are alleged to be "dependent" have an interest in reunification with their parent or guardian if this is possible without "detriment" or serious harm. If reunification is not possible, however, the child has an interest in permanent placement with legal guardians or adoptive parents who can and will provide appropriate care. Thus both the attorney representing the petitioner state and the attorney(s) for the parent(s) will argue that their client's proposed action also will benefit the child! The dependency court has the power to appoint counsel for the minor, however, and this is

increasingly becoming routine.[cc] As in delinquency cases, a minor's attorney, whether paid by the state or retained privately, is ethically required to represent the minor's interests. When the minor is old enough to consult with the attorney and reason out a position, the attorney must inform the court of the minor's wishes. When the minor is too young to do this (in some cases the minor can be an infant), the attorney must act as a *guardian ad litem* and recommend to the court what the attorney believes is in the minor's best interests.[dd] Therefore, minor's counsel may support parents' position or the state's recommendation – or advocate a different disposition from that proposed by either of the other parties.

End Notes

[a.] It is cardinal with us that the custody, care and nurture of the child resides first in the parents, whose primary function and freedom include preparation for obligations the state can neither supply nor hinder . . . And it is in recognition of this that [cited] decisions have respected the private realm of family life which the state cannot enter. But the family itself is not beyond regulation in the public interest . . ." *Prince v. Massachusetts*, 321 U.S. 158 (1944).

[b.] Parents Authority over the Education of Their Children: *Pierce v. Society of Sisters*, 268 U.S. 510 (1925) (establishing "the parent's authority to provide religious and secular schooling and the child's right to receive it, as against the state's requirement of attendance at public school").

[c.] Child's wishes not considered: *Wisconsin v. Yoder*, 406 U.S. 205 (1972) (holding that state compulsory education law is unconstitutional as requiring Amish parents to send their children to school for 2 years of high school . . . without regard to the wishes of the child).

[d.] State enforcement of child labor laws: *Prince v. Massachusetts*, 321 U.S. 158 (1944) (upholding enforcement of child labor law to prohibit 9 year old Jehovah's Witness from distributing religious publication on street).

[e.] For example, California Family Code Section 6750 authorizes the superior court to approve or disapprove minors' contracts "for the provision of artistic or creative services". Based on the "Coogan Law" first enacted in 1939, California Family Code Sections 6752 and 6753 require a portion of the minors' earnings to be set aside in trust until the minor reaches the age of majority (18).

Parenting: Assessment of Capacity

Child maltreatment (abuse and neglect) is a serious problem that often surfaces with reports of suspected abuse being made to Child Protective Services (CPS) or law enforcement. In cases where serious maltreatment has occurred or where risk cannot be contained, children may be removed from the home by court order and placed in custody of the state. In such cases, there is often involvement of psychologists along with other professionals providing information to the courts about the individuals in the family, their intervention needs, whether maltreatment

likely occurred, and suggested ways to deal with risk factors.

In the United States, only in the past 40–50 years have there been national laws regarding the maltreatment of children and widespread state mandated reporting laws. Some of the first interventions for protection of children in this country were offshoots of efforts to control cruelty to animals [1, 2]. The hesitancy to establish state authority in this area was based on notions that children were possessions, that children were undeveloped morally and must be strongly disciplined in order to attain civility, and that family matters were best left to families to work out internally. It was only in the mid-nineteenth century that children came to be regarded as more than chattel, and it was as late as the seventeenth century before parents were prohibited from killing their children. Even then, they were not required to provide basic necessities for their offsprings [3, 4].

A paper by Kempe, a physician, in 1962 introduced the term *battered child syndrome* and urged physicians to inquire about etiology of broken bones, bruises, and soft tissue damage when children were presented for medical care [5]. Kempe's one-year study had found that 39% of the identified battered children suffered permanent brain damage or death. State mandatory reporting laws for physicians followed publication of the paper, and other professionals were later included. In line with this rising awareness of abuse, in1974, the Child Abuse Prevention and Treatment Act, the first national legislation directly addressing child maltreatment, was passed and defined abuse and neglect as the physical or mental injury, sexual abuse or exploitation, negligent treatment, or maltreatment of a child under the age of 18, or the age specified by the child protection law of the state in question, by a person who was responsible for the child's welfare. This federal law required states to adopt similar definitions in order to get child welfare funds [6]. Government reports indicated in 2004 more than 872000 children and youth were found to have been abused or neglected on the basis of investigation of an estimated 3 million referrals. For 1387 children, the maltreatment was fatal. Another half million had been removed and were living in foster care; of these, 117463 would not ever return to parents but were awaiting adoption by someone else [7].

Maltreatment Effects

Physical Effects

Efforts to study the effects of maltreatment on children are made more difficult because of the frequent co-occurrence of other aversive factors, such as family stress, dysfunctional patterns of family interaction, parental psychopathology, child psychopathology, and chaotic home environment. In addition, the age at which abuse or neglect occurs seems to make a difference in sequelae for children [8]. For instance, younger children are at more risk for death from their injuries than are older children because of greater vulnerability to physical damage, lack of ability to seek medical care for themselves, and lack of ability to inform others about risk factors [9].

Even when death does not occur, results can be very tragic as in cases of shaken baby or trauma to the head. Acceleration, deceleration, and twisting of the brain within the cranial vault, produced by shaking or throwing the child, can lead to life threatening emergencies such as hemorrhage and brain swelling [10]. These conditions can result in mental retardation, speech and language delay, and learning disorders. Some research shows significantly lower cognitive skills in abused children even when there is no evidence of head trauma. Some of these deficits may be attributed to physical neglect, malnutrition, or exposure to toxic substances and other factors, which complicate efforts to identify the particular effects of physical abuse [11].

Psychological Effects

Physically abused children have been found to show increased noncompliance, more aggression, deficits in social skills and peer relationships, less empathic tendencies, and worse adjustment to school compared to control groups [8]. Condi [12] listed several factors found to be associated with physical abuse of younger children: developmental delay, anxious attachment to parents, withdrawal or apathy, and hyperarousal. Older children with abuse history have been found to have more problems with social cognition, self-esteem, conduct problems, and substance abuse. Some studies have found over one-third of physically abused children meet criteria for posttraumatic stress disorder (PTSD) with about 10% meeting the criteria as long as 2 years after initial diagnosis [13].

Diagnosis of PTSD is also often justified when children have been sexually abused, and more than one-third continue to meet the criteria for the diagnosis as adults. These children and their grown-up fellow survivors are more likely than their peers to be depressed and to attempt suicide, to have sexual behavior problems, and to engage in self-mutilation [14]. Fortunately, even with the harsh sequelae for some survivors, literature reviews indicate that from 25 to 40% of sexually abused children do not show psychological symptoms in the short term. Of those having initial symptoms, more than half later show improvement [15].

Children who have been neglected show increased behavior problems, aggression, and school maladjustment. In childhood, they are often anxiously attached to parent figures with some studies showing up to two-thirds of neglected one-year olds lacking secure attachment. They often become angry and unaffectionate but highly dependent on caregivers; they tend to lack persistence, to be noncompliant and negativistic, and to be more unpopular than nonneglected peers. They are at greater risk than peers for academic failure and for dropping out of school [16].

Protective Factors

Several protective factors associated with less severe sequelae from sexual abuse were reported by Berlinger and Elliott [14] and include: less serious and less frequent or single occurrences of abuse; perpetrator not a central person in child's life; child informing parent who was then protective and supportive; child having a close bond with supportive parent; child having stable and mature family with limited dysfunctional patterns; child not being subject to lengthy court testimony or repeated interviews; and child being provided stress inoculation and support if facing testimony. In a study of 369 sexually abused children, Conte and Schuerman [17] found the one variable with the greatest predictive power for impact on the child was a poorly functioning family.

For maltreatment in general, research in the field suggests the long-term effects of abuse are ameliorated by the child having a loving, supportive adult who provides a distinct model of a caring child–adult relationship and offers the child a positive way to form a self-concept. Another factor found to be predictive of less harmful adjustment is successful participation in psychotherapy to enhance emotional stability and maturity as well as to facilitate the integration of the maltreatment into a coherent view of self (rather than becoming dissociative or fragmented) [18, 19]. In addition to these environmental or situational factors, internal factors such as flexible coping style (suggestive of emotional maturity), resistance to self-blame, at least average cognitive abilities, self-confidence, and active coping have been found to be helpful [14, 20].

Factors Associated with Maltreatment

Theories of Causation

As the problem of maltreatment has come to be seen as more complex, the models of explanation have likewise shifted from single causes to more multifactorial models which take into account potentiating and protective factors as well as complex interactional factors (information processing, stress management, developmental stage of the child, environmental factors, and interpersonal skills). A critical decision in development of a theory of causation (and its application for treatment approaches) is whether to see abuse and normal parenting as dichotomous or as points on a continuum. Those who hold a dichotomous view see parental maltreatment as the result of permanent "defect" (mental retardation and character disorder) while those who see a continuum of behavior patterns tend to look for parenting "deficiencies" (amenable to change) or "disruption" (changeable social or interpersonal forces interfering with appropriate parenting on a situational basis). A blended approach sees "differences" or mismatches between parent and child (needs, abilities, temperaments, and interactions) which to some degree can be ameliorated. The position one takes regarding the nature of maltreatment shapes the approach to evaluation and intervention [21].

Sociobiological Model. Child abuse is not limited only to humans, and studies show similarities of factors for human and nonhuman parents. A study covering 12 years of records for monkeys kept in a primate lab at the University of Colorado found abuse involving 28% of the infants; abuse was defined as physical abuse or neglect resulting in a medical problem. Of the abused infants, 62% died. Data supported hypotheses that abuse resulted from learned

aggression (intergenerational transmission of parenting patterns), aberrations of attachment, social alienation, and overcrowding. The fact that causative factors are similar to those for humans but incidence rates are different in this colony compared to statistics with human studies suggests factors such as cognitive beliefs and/or social norms may function in a protective manner [22].

Belsky [23] pointed out that from a biological perspective, interests of parent and child are not always the same and may even be in direct conflict for success even if not for survival. This may be particularly evident in situations of limited resources (such as poverty or single-parent household) coupled with excessive demands or competition (large families, unplanned pregnancies, ill or handicapped children). This biological/evolutionary model may also explain the higher occurrence of maltreatment of stepchildren or by young mothers (who are more capable of bearing additional children than are older mothers) or on young children (who are not reproductively mature and thus more expendable).

Intergenerational Transmission. This explanatory model is largely based on the recognition that abused children when grown-up are more likely to be abusive to their children than are parents who were not abused or neglected in childhood. But review of research finds intergenerational transmission rates of about $30 \pm 5\%$ meaning that two-thirds of abused children do not grow up to be abusive (at least during the brief windows of time on which research studies focus) [23, 24]. These figures are compared with self-reported figures obtained in epidemiological studies in which incidence rates in the general population are about 1% [25].

Information Processing Theory. Crittenden [26] presented a cognitive model with four elements which are involved in decisions and ultimately lead to behavior. These elements are perception (affected by biases); interpretation (affected by schemas and attributions); response selection (limited by repertoire and influenced by expectations); and implementation of behavior (affected by available resources and hierarchy of conflicting demands). Parents who become neglectful or abusive may be influenced by thinking errors, such as bias against a child, filters which block out or minimize significant positive information, faulty attributions such as parental helplessness or meanness of the child, or role reversing choices based on expecting children to be responsible for the wellbeing of parents.

Other elaborations on this model have been provided by Dix [27] and Azar [21, 28]. Azar's model posits that in the situation of a parent with bad schema for understanding child behavior combined with high risk personality factors (poor empathy, low flexibility, high distress, impulsivity), the abuse unfolds in four stages: (i) parent has unrealistic standard; (ii) child fails to meet standard; (iii) parent misattributes negative intent to the child or blames self when intervention does not change child's behavior; and (iv) parent overreacts and punishes excessively.

Presented below are factors which have been found across reviews of research in the field of child maltreatment. Most of the literature relates to neglect or physical abuse rather than sexual abuse although these categories are by no means mutually exclusive. However, there are also some significant differences between sexual abuse and other forms of maltreatment. For instance, although females (mothers) more often than males are identified with physical abuse or neglect, males by far outnumber females as reported perpetrators of sexual abuse. Also, physical abuse and neglect are almost always perpetrated by parent or other primary care giver while only about one-third of sexual abuse perpetration is by parent or primary care giver [17]. Sexual abuse has other unique dynamics as well such as family enmeshment and deviant sexual arousal patterns or practices of offenders [29].

Contextual Factors Associated with Maltreatment

Many specific contextual factors have been found to be predictive of abuse or neglect [16, 23,30]. For instance, poverty and scarcity of resources have consistently been predictive of higher rates of neglect and physical abuse. Living in a neighborhood with poor social fabric, no community pride, poorly organized resources, or an atmosphere of violence and aggression increases likelihood of maltreatment. Belsky [23] noted that cultures in which corporal punishment was rare had low rates of abuse. Chaotic home environment, occurrence of domestic violence, social isolation of the family, or presence of physically or emotionally demanding child care situations tend to increase risk of abuse.

Parental Factors Associated with Maltreatment

Identified parent factors are more numerous than contextual factors. Some are biological in nature (young age of parents and strongly aroused physical reactivity to stressful stimuli), whereas others are psychological. The neurotic triad of depression, anxiety, and hostility increases risk. Epidemiological studies [25] have found depressed parents have four times the risk for being abusive as nondepressed parents although Belsky [23] stated the association is curvilinear for abuse (greatest for moderate levels of depression) and linear for neglect (greatest for highest levels of depression). Maltreating parents also tend to be impulsive and to have poor self-esteem and low ego strength. The Minnesota Mother–Child Project, which followed at-risk first-time mothers, found emotional stability was the greatest single predictor of good caretaking *versus* maltreatment [31].

Behavioral patterns of parents differentiate maltreating from nonabusive parents. The maltreating individuals tend to be strict disciplinarians (abuse group) or inconsistent (abuse and neglect groups). They tend to use physical punishment or coercive discipline in preference to other forms of guidance and thereby place themselves at greater risk; if they are also more physiologically reactive and psychologically distressed, physical punishment can get out of hand and quickly become violent aggression. They are less effective at managing problems with children. They tend to be less responsive to needs and emotions of children, to have fewer play items for children in the home, and to engage in less communication and physical interaction with their children. Substance abuse is a strong predictor which was found in epidemiological studies to increase risk for neglect fourfold [25]. They tend to isolate themselves, to be more transient than nonabusers, and to remove themselves from social supports that are available to them.

Cognitive factors differentiating maltreating and other parents include more emotion-based than reason-based problem solving. The maltreating parents have less cognitive flexibility and more rigid thinking even though attention, distractibility, and verbal fluency are not found to be significantly different. These parents often have a negative attitude toward their children and tend to see negative behaviors of children as internally caused and stable, whereas positive behaviors are seen as externally caused (perhaps attributed to the parent) but not stable [13]. As a result, abusive parents tend to develop a negative, adversarial schema that leads to misinterpretation; neutral or ambiguous behaviors are seen as examples of misbehavior or even malice on the part of the children. Neglectful parents also have a negative schema but tend to believe that relationships will not be fulfilling. Finally, the internal model for parenting behaviors is often a deficient one as many maltreating parents have themselves been reared by neglectful or abusive parents [23, 30].

Treatment Interventions with Parents

Funding from the Child Abuse and Prevention Treatment Act of 1974 [6] led to many well-developed intervention projects, which were then evaluated in efforts to discover what was effective. Daro [32] reviewed results from 19 demonstration projects and found relapse rates ranging from 20% (sexual abuse) to 66% (neglect). She noted family therapy, individual problem-solving training, and group therapy tended to be associated with more successful results. She also reported on 89 programs involving over 3200 families [33], which found the best outcomes were associated with intensive services initially and a long maintenance period. Better results were also found with use of lay services (volunteers in the homes of target families) and use of groups for the parents (group therapy and classes). Interventions shorter than six months or longer than 18 months were less likely to show progress. Results suggested intervention should be comprehensive in addressing concrete (housing and medical services) and interpersonal needs (social support and faulty interaction patterns), but the most effectively spent money was for prevention.

Other research [34] found in reviewing control study research that a multifaceted, behavioral approach was most effective in reducing posttreatment relapse rates (10% in treated *vs.* 21% in control groups); but also found brief treatment did not work well. Home-based services with practical skills training and with family therapy showed vastly better rates for children remaining in home at one-year follow-up (74% with such services *vs.* 45% without). One example (Project 12-Ways) of this intensive, comprehensive model has been well described by Lutzker [35–37].

Legal Context for Considering Parenting Evaluations

The legal context for most child protection matters is domestic court or family court although criminal courts may become involved where evidence of maltreatment is sufficient to lead to an indictment and criminal prosecution. Domestic courts are not constitutionally established but arise from English common law where chauncery courts or common courts addressed marital disputes and matters concerning children. Although hesitant to become involved in matters of the family until there is breakdown of the family unit and/or harm to a child, the courts have a significant societal interest to take action when natural parent and child bonds are no longer sufficiently effective to assure the best interests of the child are being addressed by the family [3].

Even though parents are under statutory obligation to provide basic needs (physical, medical, and educational), they are mostly free to make decisions about residence, family structure, discipline, religious practices, social activities, financial arrangements, and even educational choices as long as basic needs are addressed and peace and order accomplished. Balanced against this deference to parents and privacy of the family are legal precepts recognizing the rights of children (protection of their best interests in disputed matters) and the obligation of the state to intervene when children need protection. This intervention is based on the concept of *parens patriae*, which regards the state as the protector of those citizens unable to care for themselves [38]. With origins in Roman law incorporated into English common law in the eleventh century, the concept extends the state's interest into the family and other matters when children (or disabled individuals) are unable to be guardians of their own interests.

Below are some of the legal cases from US courts, which help define the balance of interests in child-dependency cases.

Griswold v. State of Connecticutt (1965) [39]: prohibited undue government intrusion into "zone of privacy for family implied by Bill of Rights and 14th Amendment".

Parham v. J.L. & J.R. (1979) [40]: allowed parents to maintain substantial role in decision making for child unless abuse, neglect, or evidence contradicting assumption of parent acting in best interest of child.

Ingraham v. Wright (1977) [41]: corporal punishment not cruel and unusual for child; 8th Amendment protection only for convicted citizens and does not apply to children.

Deshaney v. Winnebago County Department of Social Services (1989) [42]: state is not liable for failure to protect child from injury by parents; 14th Amendment designed to protect citizens from state, not insure state protects individuals from each other.

Santosky v. Kramer (1982) [43]: threshold for permanent removal of children must be clear and convincing evidence of abuse; due process must be afforded to parent.

South Carolina Department of Social Services v. the Father and the Mother; In the Interest of the Child (1988) [44]: court affirmed religious freedom for beliefs but regulation of behavior by laws in case where parents claimed religious right for corporal punishment which left bruises on child.

State v. Evans (1992) [45]: unmarried father not living in home guilty of criminal neglect when child died of malnutrition; father did not assure child received care.

In re Glenn G. (1992) [46]: mother neglectful for failing to protect children from abusing, battering father.

E.C. v. District of Columbia (1991) [47] and *Egly v. Blackford County Department of Public Welfare* (1992) [48]: mental illness or mental retardation alone not grounds for termination of parental rights but effects on child and ability to handle needs of child must be considered.

In *Matter of Joshua O.* (1996) [49]: state must present clear and convincing evidence parent is currently and will remain incapable of caring for child if seeking termination of parental rights.

Assessment Issues

Psychologists and other mental health professionals often are asked to become involved in assessment tasks in cases where child maltreatment has occurred or is deemed to be a significant risk. Evaluators are asked to provide information about risk factors and prognosis for change, risks and benefits for parent–child contact or reunification, services needed, and ability to use services if provided. Reports may be used for treatment planning, case planning, or termination of parental rights suits. Because these cases

are always either court cases or have the potential to become such, evaluators are admonished to approach them carefully as the reports may have lasting effects on the lives of the people involved [12, 50]. These evaluations blend elements of clinical assessments and forensic evaluations and are conceptually related most closely to custody evaluations [4, 51]. The following discussion includes the literature from child custody evaluations because of this close relationship and because more research has been conducted on custody evaluations than on care and protection evaluations.

Factors to be Considered in Parenting Evaluations

Lack of Definition of Parenting. Evaluators seeking to conduct assessments within this area of high scrutiny where there is high likelihood of reports being used in an adversarial legal context are handicapped by lack of universal standards or behavioral criteria regarding minimal parenting practices. In addition, there is scarcity of appropriate tools for assessment of parenting skills. In a context of cultural pluralism and social class differences, evaluators provide information so that decisions can be made about "good enough" parenting, a concept arising from a British pediatrician-turned-psychoanalyst, D.W. Winnicott. Winnicott believed that child resilience made up for a host of parental limitations and mistakes.

Conceptual Approach. Grisso [52] proposed a model, which has become well accepted for exploration of various capacities and resulting reports in forensic matters. He suggested five components. "Functional" assessment explores a person's skills and deficits and often uses clinical as well as specialized forensic assessment instruments; it measures what a person is able to do. The "causal" component explains why these deficits occur; sometimes there is a connection between the deficits and a mental health condition. Thirdly, the "interactive" component, too often neglected in forensic reports, applies the functional limitations to the particular forensic context; it states or predicts what a person is specifically able or not able to do in terms of expected behavior in a particular required task. The other two components, "judgmental" and "dispositional", belong not to the evaluator but to the decision maker to determine if the person's abilities are adequate for the task and how the case proceeds. Such an approach to parenting evaluations does not stop with description of skills and deficits of the parent but relates these factors to specific effects the parent's behavior has or is likely to have on the particular child [4].

Common Elements of Parenting. Hoghughi's conceptual model has been used to simplify the myriad of parenting tasks to three elements: care, control, and development. Care refers to provision of physical needs as well as emotional factors; control refers to guidance and discipline; and development refers to those resources and conditions necessary for a child to mature according to developmental milestones. In order for parents to be successful with these tasks, they must have knowledge, motivation, resources, and opportunity (access) [53]. Another simplification has resulted in a model of two basic tasks: protection and care of the child for the purpose of socialization. The parent must know the child and attend to limits and discipline [54].

Factors Associated with Adequate and Inadequate Parenting. White [50] proposed flexibility as the hallmark of good parenting and suggested it was evident in the sustained pursuit of provision of the child's needs through accommodation to the changing environment and the changing child. Some factors which researchers have found to be identified with adequate or good parenting include being supportive and responsive or 'joining' the child, providing instruction and guidance, providing nurture and showing affection through talk and touch, having clear boundaries between parent and child, and maintaining a mutual positive emotional attachment. In contrast, features that have been associated with inadequate parenting or maltreatment include being controlling or power oriented with the child, being hostile or rejecting, being unresponsive or detached, using inconsistent or physical discipline, having high stress and poor coping skills, being emotionally immature or impulsive, having unrealistic expectations of the child, having substance abuse problems, and having poor frustration tolerance or hyperarousal tendencies [2, 55, 56].

Structuring the Assessment and Report

Guidelines. Guidelines provided by the American Psychological Association (APA) offer help in conducting parenting assessments [57]. Principles of

good practice begin by letting the referral question direct the scope of the evaluation, which then develops through the use of multiple methods to gain multiple sources of information. The parent must be informed of the nature and purpose of the evaluation and the limitations on confidentiality. The examiner is cautioned not to make inappropriate interpretations of test data and to tie any recommendations to potential welfare for the child in the matter.

Structure. The assessment process usually involves face to face contact as well as testing, extensive review of records, and use of collateral sources for obtaining information (extended family members, teachers, day care workers, medical personnel, neighbors, and friends). The process usually is structured into three areas: evaluation of the parent, evaluation of the child, and interaction between parent and child [12, 54]. The parent evaluation explores ability of the person to care for self and to care for the child, significant problems (such as substance abuse, mental illness, serious physical limitations, and behavior problems), problem solving and stress management skills, parenting skills and knowledge, access to resources, and empathy or bonding to the child. The child's evaluation includes exploration of progress with developmental milestones and any serious limitations, social and peer relationships, school adjustment, temperament, bonding with the parent, and physical and emotional health.

Observation of parent-child interaction is strongly recommended in this type evaluation although it is not always possible, particularly when termination of parental rights is the case at hand. A report about parent–child interaction should include comments about mutual attachment and boundaries, enmeshment and use of coercion, complementarity or reciprocity of interactions, parental responsiveness, and "goodness of fit" with temperament and needs of the child. Some suggest adding a fourth area for consideration of systemic factors (social context, environmental risk factors, and extended family issues) [50].

Problems Associated with Parenting Evaluations

Difficulties with Testing. Research published about custody evaluation methods led Brodzinsky [58] to criticize indiscriminate use of tests which results partly because psychologists are trained to test and therefore do it and partly because there is financial incentive to produce billable services. There was also note that clinical tests were developed for other purposes and often lacked research applying to the particular legal issue. Although an aura of science is associated with use of tests, use for purposes unsupported by research is deceptive. Finally, there was criticism of poor interpretation practices and not basing interpretation on clear research.

Others have pointed out a major difficulty involved in testing parents in this type evaluation is the response bias problem or socially desirable responding [59, 60]. Parents, usually wanting to present self in the most favorable light in order to impress the decision makers, will often resort to minimizing any difficulties and exaggerating reports of desirable traits and behaviors. Carr [61] reported base rates of compromised validity in these evaluations ranged from 20 to 60%, discouraged the use of tests without validity scales for measuring such response bias, and strongly discouraged adoption of separate validity norms for parents in this type evaluation. The Minnesota Multiphasic Personality Inventory 2 (MMPI-2), Personality Assessment Inventory (PAI), and Child Abuse Potential Inventory (CAPI) were noted to have good validity scales (*see also* **Psychological Testing**). Two other frequently used tests were noted to have deficiencies in the detection of bias: Parenting Stress Inventory (PSI) which has a poorly discriminative measure for defensiveness and Adult–Adolescent Parenting Inventory (AAPI-2) which has no validity scales. The CAPI has a validity scale specifically designed for use with this population. Whether the positive response bias is the result only of the evaluation context or is representative of an actual personality trait of this type parent is a question raised by the author.

Heilbrun [62] made three other suggestions for use of psychological test instruments in a forensic context. First, the instrument should be commercially available with a manual for administration and scoring and should have been reviewed in major publications. The psychometric properties should show reliability measures of $r \geqslant 0.80$. Finally, the test should produce data relevant to the legal issue or construct. There should be available appropriate research published in peer reviewed journals, which provides validity for using the instrument for the particular purpose of the evaluation. Added to these criteria would be an expectation the assessment instrument could pass Daubert [63] criteria if challenged in court.

Problems Associated with Parent–Child Observation. With a single event of limited duration, it is easy to place too much emphasis on what is briefly observed and to overinterpret the behaviors. The observer, who may be unaware of personal bias, may make inaccurate interpretations of behaviors as well; the parent–child dyad may have particular, unique patterns or rituals as well as subculture patterns of interaction. The observer must also be cautious about assuming the observed interactions are representative of the way the parent and child would normally behave if not in the unique situation which undoubtedly makes them anxious. In addition, the child may feel torn between loyalty to parent and perceived necessary alliance with foster parents and child protection workers who control life for the time being. It should also be noted that play activity interactions do not necessarily represent level of bonding, nor do displays of affection or failures to display affection [50, 59, 64].

There is, in addition, a problem with perceived expertise when none exists. Starr [65] found that untrained undergraduate students were better at identifying parent–child dyads with a history of abuse than were seasoned professionals in a parent–child observation task even though neither group was correct by more than chance. Examiner bias (personal prejudice), confirmatory bias (selective attention to information supporting favored hypothesis and disregard for data challenging it), and overuse of experience-based schemata (expectancy and overconfidence leading to premature conclusions) pose substantial threats to accurate perception and good decision making in these observations.

Suggestions for improving parent–child observations and the usefulness of resulting data have been offered in articles and books [56, 66, 67] Some basic recommendations include informing the participants and preparing them for the interaction in order to minimize anxiety, holding the event in a naturalistic setting and providing ample time for getting comfortable with the task, providing opportunities to observe free play as well as chores or structured activity, and minimizing observer interaction during the exercise. Whenever possible, it is useful to observe the child with another caregiver to get a sense of what is unique about interaction with the parent. It is also highly recommended the observer have a system for observing and recording actual behaviors rather than only making conclusory notes that provide little more than overall impressions. One tool which helps is the Keys to Interactive Parenting Scale (KIPS), which is provided by its author along with training and certification for its use [68].

Criticisms of Reports. Budd and colleagues [59, 69, 70] have taken the lead in researching parenting evaluations in child maltreatment cases although their work is largely confined to looking at practices in Cook County (Chicago), Illinois. They have noted several limitations of reports in these cases: failure to clarify and/or note in report the referral question; failure to document informed consent and discussion of limitations of confidentiality; failure to address the believability of the results; and failure to comment on limitations of the methods used in the evaluation and the conclusions provided. Oberlander [71] added a criticism that reports (and conclusions) relied heavily on personal clinical experience and prior courtroom experiences of the evaluator and lacked ties to research findings and professional literature. She also noted reports often failed to protect the rights of parents who were potential defendants as cases developed. Jacobsen *et al.* [72] noted that reports failed to address minimal rather than optimal level of parenting and failure to address cultural practices in discussion of parenting abilities and deficits.

Recommended improvements for parenting assessment reports include the following: clarifying the referral question; articulating parental strengths and available resources as well as problems and risks; using valid and reliable assessment tools but taking a conservative approach by acknowledging limitations of assessment tools and current knowledge of outcomes of differing parenting practices; focusing on direct assessment of parenting skills, preferably in a home setting; maintaining open inquiry which continues to pursue and incorporate information from diverse sources; addressing issues of cultural context and potential observer bias and misinterpretations; and provide information for the decision makers rather than addressing ultimate issue question as psychologists (and other evaluators) have no specialized knowledge or training qualifying them for such conclusions [59, 72].

Current Practices in Assessment of Parenting

Most of this information is taken from research conducted about parenting assessment in the context

of custody evaluations as there is more published literature about these evaluations. Bow [73] reviewed results of five major published surveys of custody evaluators. These studies were originally published between 1986 and 2004 and covered in excess of 500 evaluators in the United States and Canada. In conducting the evaluations, most time was spent interviewing the parents with testing, review of records, and parent-child observations taking time in descending order. The MMPI-2 and the Millon Clinical Multiaxial Inventory (MCMI) were the most widely used tests with trends across time showing consistent use of Rorschach Inkblots (about 40%), declining use of intelligence tests, and increasing use of Parenting Stress Inventory (PSI) and Parent–Child Relationship Inventory (PCRI).

A more recent survey by Bow [74] of 89 psychologists who conducted custody evaluations (averaging one-third of their practice) indicated the primary use of testing was to rule out presence of psychopathology; other primary uses were assessment of personality functioning and analysis of parental strengths and weaknesses. The MMPI-2, typically used by 91% of the respondents, was the most widely used test instrument followed by the MCMI (typically used by 58%; no version specified) and the PSI (27%). The Personality Assessment Inventory (PAI) was typically used by 18% of the group. The Child Abuse Potential Inventory (CAPI), not designed for use in such evaluations, and PCRI were listed without percentage of use by respondents who as a group failed to have any clear opinion regarding whether these two instruments met Daubert [63] criteria for admissibility in court (*see* **Psychological Testing**).

Budd's report [69] on Illinois parenting evaluations conducted between 1995 and 1997 contained a subset of 124 evaluations likely conducted by psychologists but for a variety of referral questions. Projective personality tests were used in 81% of these evaluations, cognitive tests in 73%, and objective personality tests in 64%. Parenting questionnaires were used in only 4%, and parent–child observation was present in only 17%.

Summary

There are no specific forensic assessment instruments which have been developed for child protection cases, and there is no consensus as to what constitutes minimally adequate parenting, much less how to measure such a level. The role of the examiner is to collect and interpret data and to present the results to decision makers who combine those results with other factors such as legal standards, case laws, and community mores and practices. General principles of assessment apply such as clarifying. The referral question, informing the examinee of the nature of the evaluation and limits of confidentiality, using appropriate assessment methods and acknowledging limitations of the tools, and use of multiple sources of information with particular attention to written records and collateral source material. Use of clinical personality tests, parenting inventories, and parent–child observation is recommended although there is caution about using clinical assessment instruments for forensic purposes [75].

Other Resources

Professional organizations have published guidelines offering recommendations about conducting assessment in parent–child forensic contexts [57, 76–79]. White [50] has an excellent literature review; she and Otto and Edens [4] offer critical information about specific test instruments. Condie [2, 12], Gould and Martindale [56] and Dyer [80] provide very useful resources for exploring issues of parenting assessment. Finally, Heilbrun [81] presents an example of a report on a forensic parenting evaluation (*see also* **Parental Rights and Prerogatives**; **Visitation Rights**; **Capacity Assessment**; **Psychological Testing**).

Particles: Form

Forensic trace evidence includes small fragments of material (particles) that can be used to assist with an investigation into crimes and accidents [1]. Particles are ubiquitous – cosmetics, pollen, fibers, glass, and minerals to name a few. There are usually many thousands of particles virtually on all exposed surfaces. They can originate from distant sources and be transported through air, sea, or the surfaces of animals, including people. Particles adhere to vehicles, tools, clothes, and objects creating a signature of particles with an almost infinite variety. The potential to relate where something was manufactured, where it has been, and who could have been associated with it is sometimes possible with critical examination. Forensic scientists analyze particles using microscopy and instrumental analysis to characterize, identify, and associate materials; to determine provenance, and link people, places and objects to assist the judicial system (*see* **Microscopy: Light Microscopes**).

Particles with considerable diversity of form can originate from botanical materials, such as pollen, spores, diatoms, seeds, plant hairs, grass including *Cannabis sativa* L., leaves, needles, rootlets, and phytoliths. Botanical materials are cultivated, altered, and consumed by man and animals as food. From Wonder Bread to Wheaties, from the corn in corn dogs, to the seeds in feces, small particles abound in the plant kingdom. Animals also have or produce an array of particles such as hairs, feathers, eggs, skin cells, teeth, scales, and processed body parts. Natural inorganic particles are ubiquitous in a multitude of types from minerals and rocks, microfossils, deposits evaporated from water, and cosmic particles such as micrometeorites and tektites.

Traces formed by the interaction between man and the environment have increased the range of particles. Botanically derived particles can originate from foodstuffs and vomit. Man-made particles can be derived from the breakdown and disintegration of building materials such as concrete and wallboard. Vehicles contribute metals, fibers, paint, polymers, tire rubber, glass, lubricants, and fuel. Clothing materials often shed fibers. Wood and paper products can form chips, dust, and pulp fibers. Man-made particles can be formed from metals, gunshot residue (GSR), explosives, tapes, putties, corrosion, drugs, fertilizers, insecticides, poisons, toxins, and cosmetics. Particles can be composites from multiple sources such as dust, paint chips, chemicals, and combustion products.

Particle size and shape are fundamental properties that can provide important information in identification, comparison, and provenance. The Particle Atlas [2, 3] uses an ingenious six-digit code and binary sum to classify particles in the process of identifying unknowns. There are six basic classification characteristics in the code: transparency, color, isotropy/anisotropy, refractive index, shape (first characteristic), and shape (second characteristic). The system uses either a "0" or a "1" to signify the absence (0) or presence (1) of the six different particle characteristics. Specifically, the fifth and sixth digits are used to describe a particle's shape or form:

1 1 – elongated and flattened (ribbon, blade, and lath)
1 0 – flattened but not elongated (plate or tablet)

0 1 – elongated but not flattened (needle or rod)
0 0 – neither elongated nor flattened (equant particle).

Particles can exist in crystalline or noncrystalline form. The study and characterization of crystals is known as *crystallography*. Solid particles form into one of six "crystal systems". A crystal system is a category of space groups, which characterize symmetry of structures in three dimensions in three directions, having a discrete class of point groups. The six crystal systems are cubic (isometric), hexagonal, tetragonal, orthorhombic, monoclinic, and triclinic. Crystalline particles can form on any scale, from large particles visible to the naked eye, to submicron crystalline particles that can only be examined microscopically. Cubic crystals are in the shape of a perfect cube. The crystallographic axes used in this system are of equal length and are mutually perpendicular, occurring at right angles to one another. A grain of common table salt is a good example of a cubic crystal. Examples of minerals which crystallize in the cubic system are halite, magnetite, and garnet. Minerals of this system tend to produce crystals of equidimensional or equant habit. A crystal form is a collection of equivalent crystal faces related to each other by mineral symmetry [4].

Trace evidence particles are collected and initially examined by stereomicroscopy at low magnification from 4× to 100×. During this screening process, particle form is often the first characteristic that is recognized. Forms, shapes, structures, angles, etc., between things can be obviously different. The same is true in the examination of particles in trace evidence, even on the microscopic scale.

Pollen

The study of pollen, spores, and other acid resistant microscopic plant particles is called *palynology* and is highly useful in paleoecology, paleontology, archaeology, and forensics. Pollen grains are microscopic in size (10–100 μm), occur abundantly in soil and dust on any exposed surface, are resistant to decay, and as different from each other as the plants that produce them. Pollen assemblages found in soil and water bodies at a crime scene often reflect the vegetation and environment of the area. Pollen grains come in a wide variety of shapes, sizes, and surface markings (Figure 1). The pollen grain has three walls

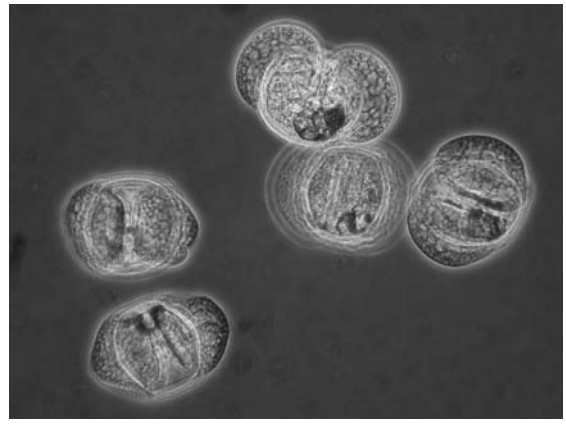

Figure 1 Pollen from *Pinus taeda*, loblolly pine. Phase contrast, original magnification 400×

or layers. The outer wall is most often sculptured, covered with any combination of spines (echinae), pores, ridges (rugulae), or bumps (scabrae) that help in identifying the grain. The middle layer contains the enzymes necessary for plant recognition in pollination. The third layer is a bottom wall and sometimes has columns rising up to the outer wall. Palynologists have classified pollen using two principal morphological features: pori (pores) and colpi (furrows). Pollen grains are divided into groups by the number, position, and shape of their pori and colpi. Pollen grains having only pores are called *porate*, those with only colpi are called *colpate*, and those with both are called *colporate*. The number of pores and colpi is denoted by attaching prefixes such as mono-, si-, terta-, and penta-. Further divisions are made by an examination of the fine structure and patterns observed on the outer layer. Descriptive terminology such as gemmate, pilate, regulate, scabrate, etc., are used [1] (*see* **Palynology**).

Diatoms

Diatoms are unicellular algae that live in any water body, large or small, from fresh to salt and brackish types. A characteristic feature of diatom cells is that they are encased within a unique cell wall made of silica (hydrated silicon dioxide) called a *frustule* or *test* (Figure 2). These frustules show a wide diversity in form, some very beautiful and ornate, usually consisting of two asymmetrical sides. The identification

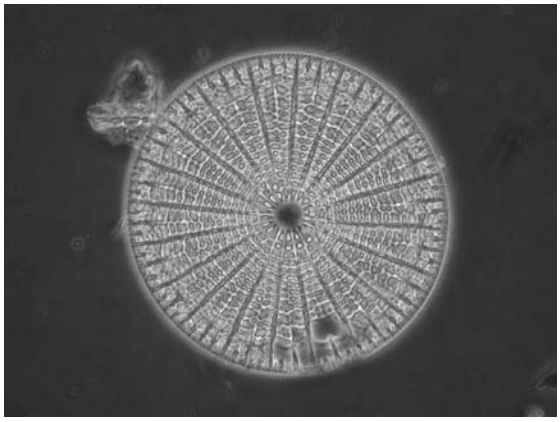

Figure 2 *Arachnoidiscus,* a diatom from San Pedro, California. Phase contrast, original magnification 400×

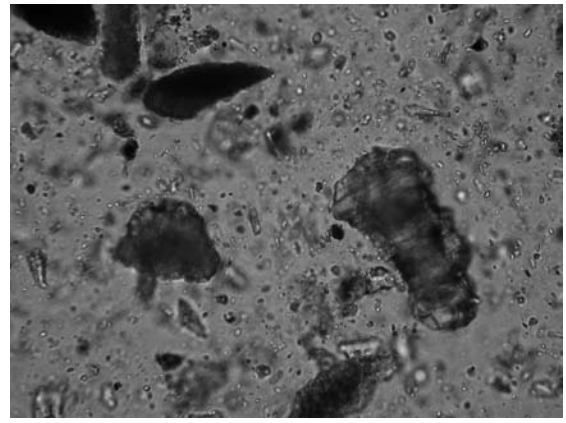

Figure 3 Malachite. An artist's paint pigment, naturally ground. Original magnification 400×

of diatoms is based on the morphology of the test. Two major groups of diatoms are generally recognized: the centric diatoms exhibiting radial symmetry (symmetry about a point) and the pennate diatoms with bilaterally symmetrical (symmetry about a line). Another particle with some similarities to diatoms are radiolarian, single-celled plankton in the kingdom Protista, which secrete silicate exoskeletons. They have lots of spines radiating outward. Seafloor deposits that are formed from radiolarian are called *radiolarian ooze*. This ooze forms a sedimentary rock known as *chert*. Decomposition and decay of diatoms may form diatomaceous earth, which can be mined and processed for use in a variety of products including paint, insulation, abrasives, and filtering agents (*see* **Diatoms**).

Paint Pigment

Paint pigment particles range from ground minerals used since antiquity to processed precipitated types used in the automotive industry. Pigments are often crystalline and tend to influence their external shape. Lead white forms as 1–50 μm hexagonal platelets. Zinc white forms as less than 2-μm rounded particles, many with spiked arms that look like children's jacks using 1000× oil immersion microscopy. Some crystalline pigments are too finely divided to show crystallinity. Titanium dioxide pigment, probably one of the most common, is less than 1 μm in size and is subrounded in shape. A few pigments are noncrystalline glasses and show conchoidal glassy fracture such as cobalt blue and gamboge. The shape of a particle tells how it was prepared, such as pigment formed by precipitation from a solution or vapor as in zinc oxide. Others are simply ground minerals like quartz, anhydrite, and malachite (Figure 3). The particle size of pigments is usually helpful in distinguishing between synthetic and natural varieties. Synthetic zinc white, titanium oxide, cadmium red, and lamp black are all up to about 1 μm in size. Natural quartz, gypsum, azurite, and ultramarine are much coarser, usually 5–10 μm (*see* **Paint: Interpretation**).

Paint chip particles may show a layer structure in cross section, originating from successive paint applications over time. The layered paint chip may also originate from an automobile having anywhere from three to six original paint layers. Paint chips having embedded reflective glass beads originate from highway fog marker/centerline paint. Still other paint particles may contain remnants of underlying surfaces such as plaster or wood. Microscopic rounded paint beads formed during aerosol deposition via spray painting have been found as associative physical evidence in many homicides including the Green River murders in Washington State.

Mineral and Rock Fragments

Minerals in the size range of fine sand are often examined in forensic soil cases. In the microscopic examination of mineral form, the shape of grains

can be described in two categories: thin sections (a mineralogical specimen that has been glued to a microscope slide and ground and polished down to approximately 25 μm, thus allowing examination by transmitted polarized light microscopy) and individual detrital grains mounted in immersion liquids. Grains with well-formed crystal faces are termed *euhedral*. Grains without crystal faces are called *anhedral*. In glassy rocks where crystallization abruptly stops, minerals may show crystallites and microlites [5]. The term *crystal habit* describes the favored growth pattern of the crystals of a mineral. A crystals habit may show little relation to the form of a single, perfect crystal of the same mineral, which would be classified according to crystal system. Crystal habit is often useful in identification. Mineralogists and microchemists use many descriptive terms to describe form such as blocky or equant, tabular, lamellar, flaky, micaceous, elongated, columnar, prismatic, bladed, acicular, platy, scaly, granular, radiating, foliated, felted, and fibrous. Many minerals have certain crystallographic planes where chemical bonding is weaker. These planes of weakness along which a mineral may break are called *cleavage planes*. When a mineral is broken or crushed it may also break along the fracture surfaces, which are unrelated to the mineral's crystal structure. One common crystal observed in soil derived from igneous and metamorphic rocks is zircon. Euhedral zircon crystals, forming in the tetragonal crystal system, are quite distinctive (Figure 4). The surface textures of

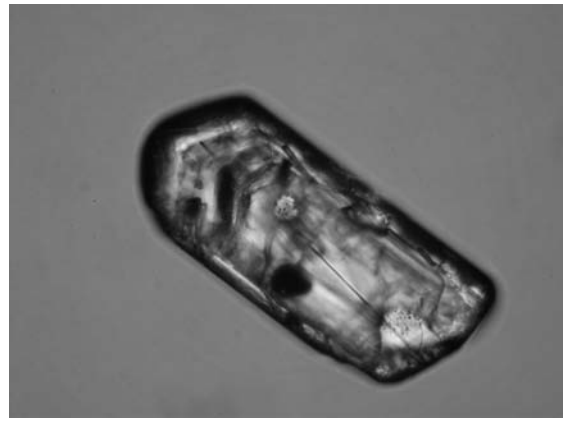

Figure 4 A crystalline zircon crystal. Original magnification 200×

sand grain and microfeatures observed by scanning electron microscopy can be used to link them to specific environments and geologic events (Figure 5) [6] (*see* **Soil: Forensic Analysis**).

Glass

The American Society of Testing Materials (ASTM) describes glass as an inorganic product of fusion that has cooled to a rigid condition without crystallizing [1]. Variables in physical properties of glass include thickness, curvature, manufacture marks, presence of mirror glass, and recognition of finely crushed

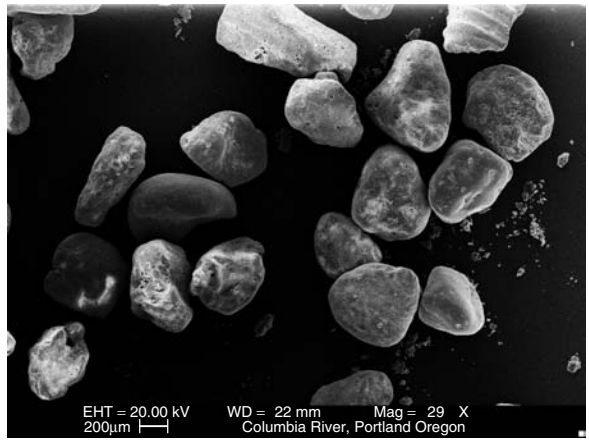

Figure 5 SEM photomicrograph of beach sand along the Columbia River near Portland, Oregon. Original magnification 29×

Figure 6 Glass particle showing conchodial fracture. Original magnification 40×

powdered glass originating from impact damage. Glass particles when broken show sharp, jagged edges known as *conchoidal fractures* (Figure 6). Tempered glass particles form "diced" pieces. Glass particles that have been annealed by coming into contact with a hot surface, such as a halogen lamp filament often have a molten smooth, beaded texture. Other glass particles such as pumice that originate from volcanism can show flow banding (Figure 7), glassy beads or glassy coatings on other mineral surfaces. Some glass particles have what are known as *hackle marks* on the edges, which are useful in interpreting the side of the glass where the force was applied when it broke. It have been reported that glass particles recovered as forensic evidence average from 0.35 to 1 mm in size, whereas fragments >5 mm are most likely to be easily lost [7] (*see* **Glass Evidence: Bayesian Approach to**).

Wood

Particles of wood can be identified by their relatively soft, porous, and fibrous texture. If the particle is large enough, the differentiation between softwood and hardwood can be made on the presence or absence of resin canals and vessel elements. The particle may be rough surfaced and torn, suggesting chainsaw wood chips or fine and powdery in form such as sawdust. Some particles may have attached bark and accessory decay particles. Softwood and hardwood fibers found in paper products can be identified microscopically based on fiber anatomy. Softwood fibers, called *tracheids*, are distinguished by bordered pits along their length (Figure 8). Ray cross-field pitting locations have very specific pits that are classified into groups: fenestriform, pinoid, taxodioid, cupressoid, and piceoid, characteristic of softwood species. Hardwood species are identified by

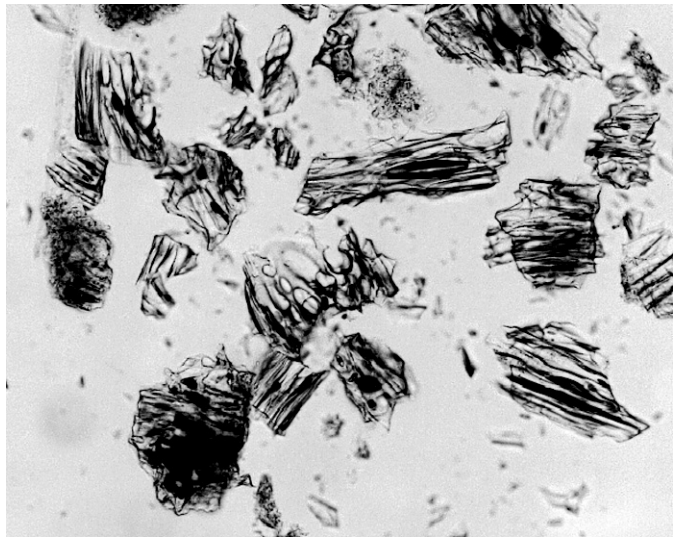

Figure 7 Pumice

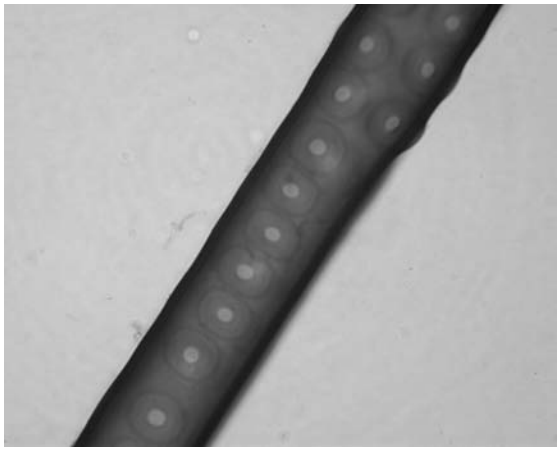

Figure 8 Softwood fiber from *Pinus Ponderosa*, Ponderosa Pine showing bordered pits. Original magnification 200×

their unique water-conducting structures called *vessel elements*. These tube-shaped structures separate out into discrete particles when the wood is pulped (*see* **Wood**).

Fibers

Fibers are often defined as particles having a high length to width ratio. Fibers are classified into groups: manufactured (nylon, polyester, etc.), natural plant (cotton, jute, hemp, etc.), and inorganic (asbestos and glass fibers). Physical characteristics of manufactured fibers include diameter, cross-sectional shape, crimp, striations, and damage. The cross-sectional shape of nonround fibers is often patented and very unique. Many types are extruded through a spinneret, a device having a series of engineered holes that a molten polymer travels through. The fibers leaving the spinneret have a cross-sectional shape matching the holes of the spinneret. Fibers such as nylon can have cross-sectional shapes ranging from round, delta, trilobal, and multichanneled just to name a few (Figure 9). Bicomponent fibers are comprised of two polymers of different chemical and/or physical properties extruded from the same spinneret with both polymers within the same filament. Most commercially available bicomponent fibers are configured in a sheath/core, side by side, or eccentric sheath/core arrangement. Natural plant fibers may be encountered

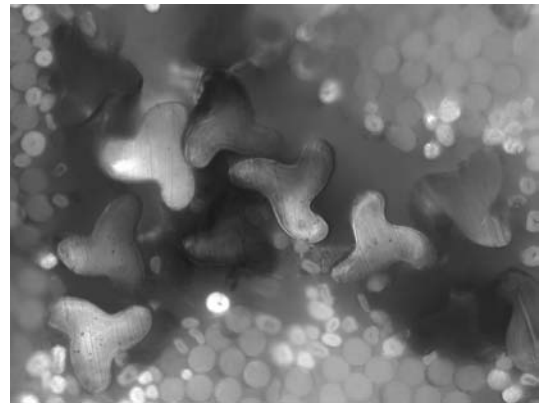

Figure 9 Trilobal nylon fibers encased in cotton backing fibers. Original magnification 200×

as the technical fiber (cordage, sacks, mats, etc.) or as individual cells (fabric and paper). Relative cell wall and lumen (canal in central shaft of fiber) thickness, cell length, and presence of surface markings, crystals, and twists are important characteristics to observe [8]. Mineral fibers in the asbestiform group range from chrysotile, having a soft, wavy texture, to the long, straight, inflexible fibers of amosite. Glass fibers can be placed into three catagories: fiberglass (continuous and noncontinuous), mineral wool (rock wool and slag wool having exotic twisty blob-like shapes), and refractory ceramic fibers that have exotic shapes, but are thinner in diameter compared to the others (*see* **Fibers**).

Hairs

Human hairs can be distinguished from other animal hairs by examining features such as the scale pattern, medulla, root, length, and shaft configurations (Figure 10) [5]. Specific terms used to describe human hair shaft form are straight, arced, wavy, curly, twisted, tightly coiled, and crimped. The cross-sectional shape in human hair can vary from rounded, oval, triangular, to flattened. The shaft can appear as buckled, convoluted, undulating, and split, [5]. The somatic origin of human hairs can often be determined by morphology (*see* **Hair: Microscopic Analysis**; **Hair: Animal**).

Many other trace evidence particles can present a variety of forms. Smokeless powder (commonly

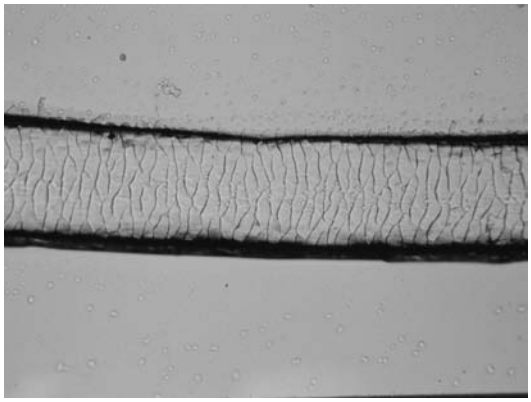

Figure 10 Caucasian head hair showing an imbricate scale pattern typical of man. Original magnification 200×

called *gunpowder*) can be manufactured in ball, flattened ball, disk, and tubular shapes. Databases have been developed, in which these morphological criteria are used to distinguish the different brands. GSR analysis relies on the identification of lead, barium, and antimony residues originating from the primer cap of cartridges. One criterion for identification is the minute (often less than 5 μm), rounded particle form characteristic of GSR.

Peak Height: DNA

Peak Height

The height of a peak on an electrophoretogram is measured in relative fluorescent units (rfu) and is a measure of the intensity of light detected by a DNA analyzer as sample is passed through a column. It is roughly proportional to the amount of DNA present, and is expected to be within a

certain range of values for standard analyses. For example, using the protocol validated by Applied Biosystems Inc. for the SGM Plus kit, 1–2.5 ng of input DNA will give peaks with heights in the range 150–5000 rfu.

As with any technology for measurement, there is a baseline "noise" that is recorded in the absence of sample, and is related to the sensitivity of the detection machine. There is some debate about the threshold value above which a peak can be declared as a "real" peak that represents a piece of DNA, as opposed to chance occurrence of noise of sufficient intensity to appear as a peak. Different laboratories use different thresholds, decisions that may be based on objective principle, scientific validation, or rule-of-thumb experience.

Two alleles of a heterozygotic locus will give heights that are roughly equal in height, and for the same amount of DNA under the same conditions, a homozygote would produce one peak that is roughly twice the height of the heterozygote peaks. Generally, alleles of smaller size (fewer repeats) (*see also* **Short Tandem Repeats**) amplify better than larger ones and so will have a slightly higher peak. Owing to variation in the analytical chemistry, this correlation is not absolute, but two peaks of a heterozygote are almost always more than 60% in proportion, smaller : larger or larger : smaller, and such peaks are said to be balanced. The loci that have been designed to give smaller (molecule length) PCR products, e.g., D3 *versus* D2 in the SGM Plus kit, will also often produce higher peaks than for the larger loci. This effect may be particularly obvious if the sample of DNA is partially degraded and is due to an increased chance of larger DNA molecules being degraded (and so unavailable for PCR amplification) rather than smaller molecules.

Peak heights may be used to interpret the DNA being analyzed. For example, when two peaks being compared are not above the 60% ratio, this is called peak height imbalance. When imbalance is seen, it is usually an indication that the peaks in question come from DNA that is partly or entirely from different contributing sources, i.e., there is a mixture of contributors. This information is used in conjunction with the number of peaks seen at each locus of a profile to identify the presence of a mixture. When a mixture of DNA sources exists, peaks will be seen that are roughly in proportion to their relative contributing amounts. Where alleles are common to more than one contributor, the rfu for each allele will be added to give a combined higher peak. Looking at the peak heights of a profile at each locus and all loci together, it may be possible to interpret all or part of at least one of the contributors. This is true especially for what are termed major/minor mixtures where there is a much greater proportion of one source compared with another. The major profile will be more completely decipherable than the minor one since some of the minor peaks may be masked by overlapping with peaks from shared alleles of the major profile. Mixtures of DNA in less extreme proportions are much more difficult to interpret objectively, assisted only when there is a reasonable expectation of DNA from one of the sources.

For a discussion of the use of peaks in mixture interpretation, see Gill *et al.* [1] and Clayton *et al.* [2]. Peak values in LCN analysis are discussed in Whitaker *et al.* [3].

Peer Review as Affecting Opinion Evidence

Obtaining the Approval of One's Peers in Science

Peer review is a term that, in scientific, publishing, and other circles, has a number of different meanings. The principal definition, however, describes a method whereby the appropriateness of research project results, as well as of articles, papers, and books based thereon, have been judged as worthy contributions to the scientific or professional field in which they belong. In some academic fields, peer review is referred to as *refereeing* [1–4]. No matter what the process or the end result is, the material under review is a document.

The purposes of peer review are to determine which research proposals will receive grants or monetary support to allow the research to go forth; whether an article of book is worthy to be published; and to evaluate the comparative ranking of researchers, scientists, or academics for advancement, remuneration, professional self-improvement purposes, as well as for comparative ranking among colleagues. Many journals publish guidelines for reviewers and these will usually explain the journal's purpose in using peer review. Not all materials published in peer reviewed journals are actually peer reviewed. For example, letters and correspondence may be peer reviewed in some journals but not in others.

The customary peer review process is applied to matters that include, for example, the dissemination of research results, an article or book on a method or topic. It involves the scrutiny of an impartial panel of several experts (usually two or three) on the same topic with which the research or publication deals. The process takes place prior to, and as a condition of acceptance and publication. Sometimes, peer review occurs by comments in the professional forum (bulletins, publications, or at meetings) made *after* and as a result of a project's publication.

There are many reasons for subjecting a project to an examination by such a panel. Primary among them is to determine whether the methodology followed by the researcher is suitable to support the conclusion. The vast majority of published work is not the final say on a topic, but a contribution to the knowledge in that field.

The possible results of peer review are;

1. outright rejection;
2. suggestions that the paper would be suitable if rewritten with identified problems corrected;
3. accepted with minor amendment; and
4. accepted as is.

Rejection may be for presentational, appropriateness to the readership of the journal, or other reasons not connected with the scientific content.

The end result of peer review does not, ordinarily, carry with it the implication that the approved work came to a correct conclusion, but means, instead, that it is sufficiently worthy of being exposed to the broader professional discipline for judgment, further study, examination, comment, or falsification (**Falsifiability Theory**). This is a frequent source of misunderstanding and even misrepresentation in courts.

In some cases, peer review proceeds anonymously, with reviewers having no prior knowledge of the identity of the authors. This is intended as a protection against bias, although it is sometimes possible to make a good guess at the source just from the content of the article.

Most frequently, the peer review process follows these steps.

Step 1. The project's methodology or an article's conclusions is submitted to a panel of experts, who may or may not know who designed the research project or wrote the article intended for publication and who may also not know who the other reviewers are.

Step 2. The reviewers make comments on the project's worth to a project evaluator or publisher's representative and make a recommendation as to whether the project rests on sound methodological applications of appropriate scientific principles, or whether the conclusions drawn from a research project are deemed to contribute to the body of knowledge and literature in the field. These reviewers recommend approval, rejection, or suggest changes, mandatory, or optional.

Step 3a. If the recommendations of at least two of a panel of three reviewers approve of the

project's methodology or the soundness of a paper, it is typically approved for acceptance and/or publication.

Step 3b. If recommendations for changes are made by the reviewers, these comments may be transmitted to the original researcher/author with a request to consider a redesign of the project or a rewrite of the paper. The originator of the project are, most often, not be told who the reviewers were.

The system is not necessarily democratic, with managers of the reviewing process or editors appointed by the publisher retaining the privilege to disregard the opinions of reviewers, appointing new reviewers, or deciding contrary to reviewers' recommendations.

Peer Review in Some Forensic Sciences

In a few forensic disciplines, peer review may have a totally different meaning, one that is more akin to verifying the accuracy of a particular examination result. The scrutiny is provided by having the prior result obtained during an examination of evidence verified by other experts of more advanced or equal stature in the profession.

The purpose of such verification is to determine whether the original conclusion is deemed accurate and trustworthy.[a] The verifier independently retraces the steps of an examiner to see whether the same result is reached by other skilled examiners.

Sometimes, the verifier may not know who the individual is who has reached the original result – a process sometimes referred to as *blind verification*. If the verifier is not aware that an examination was originally done by someone else, the process may be called *double-blind verification*.

Criticism of Peer Review

To accept a publication or a report based on a novel methodology after submission to peer review does not signify the reviewers agree with its conclusions, but rather whether it is deemed worthy to be submitted to the scrutiny of the field. Many studies that have been published are roundly criticized by others even after or as a result of their acceptance or publication. Others may cause the originators to modify or withdraw their original conclusions as a result of input received from reviewers or from others in the field that have become acquainted with the project.

In the traditional publishing business, the peer review process is also extremely cumbersome and time consuming. Most hard-copy peer reviewed journals work on a schedule involving many months of copy evaluation, submission to reviewers, returning comments to the original researcher, and receiving rewrites or revisions, leading ultimately to approval, copy preparation and publication. By the time publication occurs, the conclusions may already have been altered or, in some cases, shown to be in error.

The Internet is providing an alternative to the traditional peer review process by the existence of blogs, online-only publications, and an almost instantaneous exchange of views on any topic at virtually no cost through interactive science publishing. The Internet also provides a readier tool for identifying plagiarism before publication.

Also, because most novel techniques are developed by pioneers in a field, there is an inherent bias against conclusions reached that may go counter to those of peer reviewers who are considered the "established power structure" in a discipline. These individuals may well have a vested interest in safeguarding their own prior positions on the same topic or the positions which they have spent careers supporting or defending, to prevent them from being replaced by newer approaches. At the other end of the spectrum, some reviewers, in evaluating the worth of a project, may tend to have a bias in favor of conclusions that are in agreement with their own expressed views.

The inefficiency in identifying fraudulent conduct is also seen as a serious drawback of the peer review process. Most professions as well as science publications can offer examples of cases in their own areas wherein researchers who had come to be respected were thereafter exposed as having created fraudulent data or falsified the outcome of research to support their conclusions.

Peer Review in American Law

In American legal circles, the words "peer review" have taken on essentially the first one of the approaches to peer review described herein, as a

result of the momentous United States Supreme Court decision in *Daubert v. Merrell Dow Pharmaceuticals* [5] (*see* ***Daubert v. Merrell Dow Pharmaceuticals***), a court opinion that forever changed the legal landscape on how the decision on the admissibility of expert opinion testimony is to be made (**Expert Opinion: United States**).

Peer review, in *Daubert*, came to be lauded as a desirable, though not an essential, factor whereby the soundness of a scientific methodology utilized by particular experts can be judged. As a result, some forensic disciplines that consider peer review as synonymous with "verification of a result obtained in an analysis" have met some resistance in courts in having their conclusions deemed as satisfying a *Daubert*-style of peer review.

Thus, in *United States v. Mitchell*, the court, in examining whether "fingerprint identification" satisfied the peer review factor of *Daubert*, recognized that the type of verification required of latent-print examiners in the analysis, comparison, evaluation and verification ACE-V methodology might "not be peer review in its best form, but, on balance, the peer review factor does favor admissibility" [6]. The overwhelming majority of court decisions of appellate tribunals have reached similar decisions in allowing the "V" in the ACE-V methodology to satisfy the *Daubert* "peer review" factor.[b]

There remain critics of those forensic practices involved in individualization who would like to see the courts reject the admissibility of examination techniques wherein the "scientific" model of peer review is not strictly followed. Defenders of those practices respond that inasmuch as the existence of a peer reviewed literature guarantees neither accuracy nor reliability of an examination result, to impose such a high standard on the verification process in forensic science is probably unwarranted in light of the precise language in the United States Supreme Court's *Daubert* decision itself.[c]

End Notes

[a.] For example: In the Latent Friction Ridge Comparison discipline, verification of the results obtained by one examiner's individualization is required in some circumstances and recommended in others. See the Scientific Working Group of Friction Ridge Analysis, Study and Technology (SWGFAST), in its guidelines and standards at www.swgfast.org. Several other forensic disciplines use the ACE-V methodology in the comparison sciences, among them forensic document examiners, firearm and toolmark examiners.

[b.] The ACE-V process is described in **Friction Ridge Skin: Comparison and Identification**.

[c.] In *Mitchell, supra* [6] at 244, the court explained: "*Daubert* does not require that a party who proffers expert testimony carry the burden of proving to the judge that the expert's assessment of the situation is correct. As long as the expert's scientific testimony rests on 'good grounds, based on what is known,'" the testimony should be admitted and tested by the adversary system.

Pharmacogenomics

Introduction

In 1865, Gregor Mendel discovered the basis of inheritance and genetics. Pharmacogenetics and its related science pharmacogenomics emerged as our understanding of genetics advanced, in particular, that certain enzymes coded by the genetic blueprint process both endogenous and exogenous substances (such as drugs). This understanding is likely to develop further in years to come and may even allow personalization of drug treatment – personalized medicine, based on a person's genetic profile [1, 2]. Thus, pharmacogenomics is likely to increasingly contribute to clinical and forensic practices in the future.

Pharmacogenomics has already been useful to optimize treatment of lung cancer by identifying genotypes likely to predispose to toxicity and poor outcome [3]. Patients with homozygous *UGT1A1*28* are more likely to develop neutropenia, whereas patients with *GSTP1 1105 G/A* or *G/G* genotypes may show partial response. Another study identified the combination of five-gene biomarkers (*DUSP6, MMD, STAT1, ER BB3*, and *LCK*) as an independent predictor of relapse-free and overall survival [4].

Pharmacogenomics and pharmacogenetics are currently used interchangeably; however, pharmacogenetics is readily defined as the study of the genetic effect, e.g., single-nucleotide polymorphism (SNP), on an individual's ability to metabolize a drug or other substance, pharmacgenomics is concerned with the whole-genome effect on drug metabolism and efficacy.

The emerging clinical applications of pharmacogenetics/pharmacogenomics may be directly verified by the use (and approval by various regulatory agencies) of genotyping methodologies/platforms, the frequent inclusion of this topic in scientific and clinical meetings, and the availability (in 2007) of a pharmacogenomic survey program offered by the College of American Pathologists.

Pharmacogenomics serves as an "adjunct" to other tests and scientific practices. For example, genotyping can be conducted as an adjunct to the autopsy (molecular autopsy) and complements the current forensic applications such as DNA fingerprinting.

Thus, this article presents pharmacogenomics as a complementing discipline to enhance drug therapy and serve as an adjunct to forensic pathology/toxicology. Forensic applications include an algorithm for the use of pharmacogenomics in forensic pathology/toxicology, with emphasis on interrelationships to circumstances and drug use/abuse history, scene investigation, and autopsy findings.

On the opposite end of the spectrum, the use of molecular/genetic testing in postmortem forensic science has included DNA fingerprinting for identity testing. Recently, pharmacogenomics as molecular autopsy has been used for the assessment of genetic contribution to drug toxicity in postmortem forensic toxicology. In common with the other applications

of clinical and scientific findings in forensic science, the findings might add to the understanding of disease mechanisms and optimization of treatment including drug therapy. Thus, the use of pharmacogenomics in forensic toxicology may add to the understanding of drug toxicity due to genetically predisposed impaired drug metabolism, and in so doing thus provide better interpretation and indirectly enabling the emerging personalized medicine.

Principles of Pharmacogenetics/Pharmacogenomics

According to the central dogma of molecular biology, the genetic code of DNA is passed, through transcription, onto *mRNA*. The information in *mRNA* is passed, through translation, in protein synthesis. These proteins may be drug-metabolizing enzymes, transporters, and receptors. As a result, DNA genetic variations (*see also* **Polymorphism: Genetic**) determine the enzyme activity, transporters, and receptor sensitivity.

For drug-metabolizing enzyme genes, the lack of and the presence of genetic variations results in normal, deficient, or higher enzyme activities. Genetic variations might include SNPs, deletion, duplications, and other variations. The polygenic determinants of drug response are illustrated by Figure 1. By comparing an individual with two wild-type alleles (normal or extensive metabolizer *see also* **Phenotype**) on the left to an individual with two variant alleles (a poor metabolizer) on the right, the genetic variations would result in lower enzymes activity and elevated plasma concentration *versus* time curve (calculated as area under curve, AUC), with corresponding increased toxicity and decreased receptor sensitivity and efficacy. The heterozygous individual in the middle with one variant allele (an

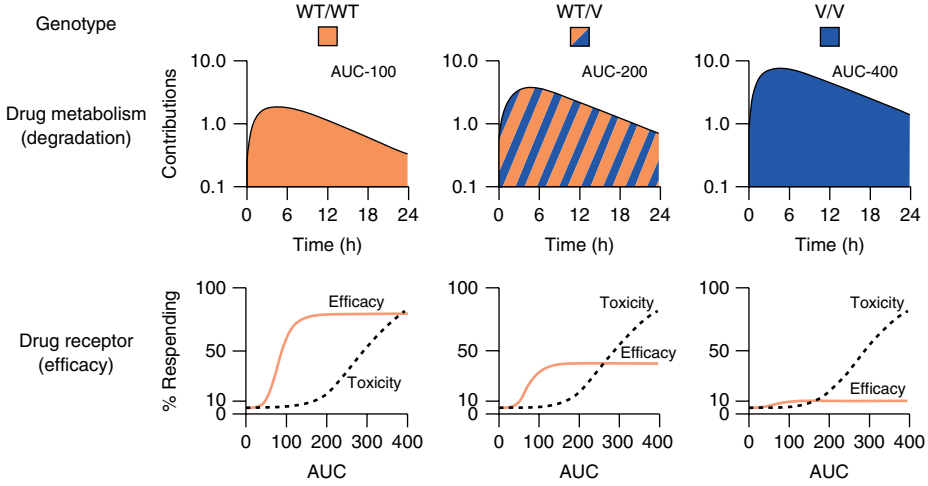

Figure 1 Polygenic determinants of drug response [With permission from publisher of Ref. 5, © Massachusetts Medical Society, 2003.]

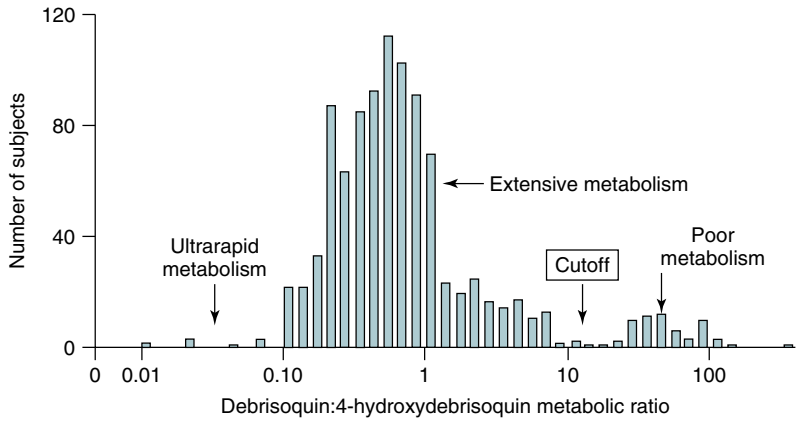

Figure 2 Pharmacogenetics of CYP 2D6 [Reprinted by permission of Macmillan Publishers Ltd: Clinical Pharmacology & Therapeutics [6], ©1992.]

intermediate metabolizer) exhibits AUC, toxicity, and efficacy intermediate between those of the extensive and poor metabolizers. With a possible combination of nine metabolism and receptor genotypes, the therapeutic index (separation of therapeutic and toxic responses) could range from 13 to 0.125.

Further, individuals with multiple copies of the genes are ultrarapid metabolizers (UMs). An example of this is shown in Figure 2, which shows the debrisoquin metabolic ratios (MRs) of these phenotypes [6].

Race and ethnicity can affect the prevalence of "poor" metabolizers, but they are usually relatively uncommon. For example, there are variations in the prevalence of one of the more common P450 enzymes, CYP2D6, in African-Americans and the Chinese. Patients who are genotypically slow metabolizers may, for example, require more tramadol (analgesic) than other "normal" subjects, possibly explaining the variable response to pain management in some patients.

Genetic variation can also make a person more susceptible to disease [7].

Tests and Methodologies

The majority of the current testing is primarily based on pharmacogenetics (PGx). The top 10 tests in 2005 as assessed by the American Association of clinical Chemists (AACC) are listed in Table 1 (in descending order).

Within the list, CYP and other phase II enzymes (conjugating enzymes) such as uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1) accounted for the majority of drug/substrate metabolism for drugs approved in the United States, about 75%

Table 1 Top 10 pharmacogenomics tests

Abbreviation	Name and function
CYP 2D6	Cytochrome P450 2D6, phase I drug-metabolizing enzyme
TPMT	Thiopurine *S*-methyltransferase, phase II drug-metabolizing enzyme
CYP 2C9	Cytochrome P450 2C9, phase I drug-metabolizing enzyme
CYP 2C19	Cytochrome P450 2C19, phase I drug-metabolizing enzyme
NAT	*N*-acetyltransferase, phase II drug-metabolizing enzyme
CYP 3A5	Cytochrome P450 3A5, phase I drug-metabolizing enzyme
UGT1A1	Uridine diphosphate glucuronosyltransferase 1A1, phase II drug-metabolizing enzyme
MDR1	Multidrug resistance (P-glycoprotein), drug protein transporter
CYP 2B6	Cytochrome P450 2B6, phase I drug-metabolizing enzyme
MTHFR	Methylenetetrahydrofolate(CH_2THF) reductase converts CH_2THF to 5-methyltetrahydrofolate

involving CYP 3A4 and cytochrome P450 2D6 (CYP 2D6) enzymes. Testing is complicated since there are more than 160 alterations for *CYP 2D6* genes alone. Assay problems can include allelic drop-out, intra-allelic recombination, the need for specific assays not affected by pseudogenes *CYP 2D7* and *CYP 2D8*, and to address gene conversion of *CYP 2D6* from *CYP 2D7*. Consequently, genetic testing is not yet widespread.

The more common pharmacogenomic tests are readily performed either by home-brew assay or a commercially available test or platform. The approaches included nonamplification, e.g., fluorescent *in situ* hybridization (FISH), target and signal amplification methods including endpoint polymerase chain reaction (PCR) detection, allele-specific primers, length analysis using restriction fragment length polymorphism (RFLP) and oligonucleotide ligation assay (OLA), real-time PCR, signal amplifications, and new methods including solid-phase microarrays and fluorescent-based bead assay (liquid mircoarray). The manufacturers and the status of FDA approvals are listed in Table 2.

Some laboratories performing genotyping have adapted the PCR liquid bead-based detection. The choice of the platform and assays seems to reflect the ease of "home-brew" assay development and the lower cost of the instrument and reagents. Nevertheless, there are relative advantages and disadvantages of the various testing kits available. These need to be understood before having a test conducted.

Clinical Applications

The clinical applications of pharmacogenomics are classified according to the drug group, specialties, and diseases and include opioids, pain management, nicotine addiction, HIV treatment, immunosuppressants, and thiopurine *S*-methyltransferase (TPMT) for acute lymphoblastic leukemia, and psychiatry. Polymorphisms of the neurotransmitter transporters (serotonin, norepinephrine (noradrenaline), dopamine and P-glycoprotein, and serotonin transporter show little effect on serotonin active antidepressants selective serotonin reuptake inhibitor (SSRI) response, suggesting that the current scientific literature showing transporter genotypes is not yet contributory to predictive therapy [9]. There was evidence to support the use of genotype-based dosing for drug transporters such as P-glycoprotein (ABCB1) and OATP-C (SLC21A6) and other CYP enzyme genes. Other important and emerging areas include cancer, cardiovascular disorders, and hematology (Table 3)

It would be important to recognize the role of therapeutic drug monitoring (TDM) and toxicology

Table 2 Methodologies for pharmacogenetics testing[a]

Method	Company	FDA cleared or approved
Sequencing[b]	Abbott (Abbott Park, IL)	Yes
Real-time PCR	Applied Biosystems (Foster City, CA)	–

Table 3 Examples of associations between drug response and genetic variants[a]

Drug	Variable clinical effect	Genes with associated variants	Possible mechanism
Azathioprine and mercaptopurine	Bone marrow aplasia	TPMT	Hypofunctional alleles
	Reduced therapeutic effect at standard doses		Wild-type alleles
Some antidepressants and β-blockers	Increase side-effect risk	CYP 2D6	Hypofunctional alleles
	Decreased efficacy		Gene duplication
Omeprazole	*Helicobacter pylori* cure rate	CYP 2C19	Hypofunctional alleles
Irinotecan	Neutropenia	UGT1A1	Decreased expression due to regulatory polymorphism
HIV protease inhibitors	Central nervous system levels	MDR1	Altered P-glycoprotein function
β-Blockers	Blood pressure lowering and heart rate slowing	ADRB1	Altered receptor function or number
Diuretics	Blood pressure lowering	ADD1	Altered cytoskeletal function by adducin variants
Warfarin	Anticoagulation	VKOrC1	Variant haplotypes in regulatory regions leading to variable expression
		CYP 2C9	Coding region variants causing reduced *S*-warfarin clearance
Abacavir	Immunologic reactions	HLA variants	Altered immunologic responses
QT-prolonging antiarrhythmics	Drug-induced arrhythmia	Ion-channel genes	Exposure of subclinical reduction in repolarizing currents by drugs
General anesthetics	Malignant hyperthermia	RYR1	Anesthetic-induced increased release of sarcoplasmic reticulum calcium by mutant channels
Inhaled steroids	Bronchodilation	CHCR1	Unknown
HMG-CoA reductase inhibitors (statins)	Low-density lipoprotein	HMGCR	Altered HMG-CoA reductase activity

[a] Reproduced with permission from Ref. 10. © ACP, 2006

more generally as global phenotypic indexes including contributing pharmacokinetic, pharmacodynamic, drug–drug interaction, and other environmental factors develop. Thus, pharmacogenomic biomarkers might be readily characterized as an adjunct to enable the practice of personalized medicine. To update on these applications, a summary of recent examples would include pharmacogenomics for alcoholism, psychiatric disorders, and opiates (opioids).

Alcohol

Alcoholism is a complex psychiatric disorder with high heritability (50–60%) and with a lifetime prevalence of alcohol dependence of 20% in men and 8% in women in the United States. Alcoholics may be categorized as follows: type 1 – later onset with feelings of anxiety, guilt, and high harm avoidance and type 2 – early age of onset, usually men, manifesting as impulsive and antisocial behavior, and associated with low levels of brain serotonin [11].

Genetic variations of alcohol metabolizing genes affect drinking behavior and hence decrease alcoholism. Genes of neurotransmitter pathways "reward pathway" (serotonin, dopamine, gamma amino-butyric acid (GABA), glutamate, and β-endorphin) and the behavioral stress response system (corticotrophin-releasing factor and neuropeptide Y) may constitute therapeutic targets. By using the type 1/2 systems, progress is being made to understand the pharmacogenomic response to current pharmacotherapy. Further, alcohol inheritability may be affected by genetic variations for a number of enzymes and other factors such as those affecting cognitive function, stress/anxiety response, and opioid function [12].

Psychiatric Disorders

There are a number of schizophrenia-associated genes associated with affective disorders.

A number of P450 enzymes are involved in metabolizing antipsychotic drugs including CYP 2D6, CYP 1A2, and CYP3A4 (Table 4). Since CYP 1A2 is inducible, individuals with *CYP1A2* variants and some SNP combinations (haplotypes), in the 5′-regulatory regions, may demonstrate variable response [13].

Genetic variability leading to clinically significant changes has been shown for a number of antidepressants and antipsychotic drugs [14–17]. This has led to a lower incidence of adverse effects and has optimized the response to the drug therapy.

Opioids

The best example of an opioid response being affected by genetic variability is codeine [18].

Table 4 CYPs with major roles n the *in vivo* clearance of antipsychotic agents[(a)]

CYP	Antipsychotic drug	Altered drug substrates and inhibitors that may be used in psychotic patients	Inducers	Numbers of allelic variants
1A2	Clozapine	Omeprazole	Omeprazole	24 plus wild-type (also 9 predicted haplotypes)
	Olanzapine		Cigarette smoke Barbecued meats	
2D6	Risperidone Chlorpromazine Thioridazine	Dextromethorphan Codeine Imipramine Nortriptyline Paroxetine	None	94 plus wild type
3A4	Ziprasidone Quetiapine Aripiprazole Haloperidol	Erythromycin Diltiazem Ciclosporine Ethinyl estradiol	Rifampicin Carbamazepine Phenytoin Dexamethasone	38 plus wild type

[(a)] Reproduced from Ref. 13. © Pharmaceutical Press, 2006

Codeine is metabolized CYP 2D6 to its active metabolite morphine. UMs may suffer exaggerated and toxic opioidergic effects and poor metabolizers may experience reduced pain relief [19]. Even though P-glycoprotein is an opioid transporter, *ABCB1* genotypes' influence on opioid pharmacodynamics and dosage requirements were highly variable [20].

Forensic Applications

Pharmacogenomics is best treated as an adjunct to forensic pathology (*see also* **Toxicology: Forensic Applications of**), complementing information including autopsy findings, case history including medication, and scene investigation. The term *molecular autopsy* has been used to represent the application of genetic testing to assist the more conventional autopsy examination.

Case review initially assesses the likelihood of a genetic factor explaining a certain event. These factors include the presence of acute or chronic toxicity, autopsy findings (*see also* **Autopsy**), sample collection sites, postmortem intervals, coadministered drugs, case/medical/medication histories, scene investigations, and possible intent. As the case review continues with developing toxicological findings, elevated drug concentrations and identification of known and unknown drug/metabolites that might have interacted are prime criteria for case selection for pharmacogenomics (*see also* **Postmortem Biochemical Examinations** and **Toxicology: Forensic Applications of**). Further, the postmortem intervals are also considered in case selection and in interpretation. Once the case is selected, whole-blood samples are then transferred (*see also* **Toxicology: Analysis**), with chain of custody, for pharmacogenomics testing by the molecular and pharmacogenomics laboratory.

Currently, the testing platform is based on Pyrosequencing™ and include the following: *CYP 2D6*2-*8, CYP 2C9*2*3, CYP 2C19*2-*4, CYP 3A4*1B*, and *CYP 3A5*3.* The forensic applications are illustrated by the opioids (*see also* **Opioids**): methadone, oxycodone, and fentanyl.

UMs will produce larger amounts of morphine from codeine, and this is more likely to cause toxicity as well as increase the likelihood of overdose to breast-feeding infants [21].

Methadone response is affected by the activity of CYP3A4 and CYP2B6 and to a lesser extent CYP 2D6. ABCB1 accounted for minor pharmacokinetic variability. Other studies showed that *CYP* genes did not affect methadone metabolism.

*Case History 1. The decedent was a 41-year-old female, 6 month in her pregnancy. She had heart murmur and rheumatoid arthritis treated with methadone. Further, amitriptyline was prescribed for her depression. She celebrated New Year' Eve with her husband. On the following morning, she was found dead in her living room. Scene investigation revealed her ingestion of nine 50-mg tablets of amitriptyline within 17 days and two to three 95-mg dose of methadone. Several years before, she had attempted suicide by drug ingestion. Toxicological analysis of iliac blood showed the following drugs and concentrations in milligrams per liter: methadone, 0.7; amitriptyline, 1.5; nortriptyline, 2.2; diazepam, 0.19; and N-desmethyl diazepam, 0.13. The elevated antidepressant concentrations of iliac, peripheral blood, would not be due to postmortem drug redistribution and more attributable to acute drug ingestion. Molecular autopsy by pharmacogenomics showed that she was homozygous for CYP 2D6*4, corresponding to a poor metabolizer phenotype. This would result in the lack of hydroxylation of methadone, amitriptyline, and nortriptyline, thus resulting in elevated parent drug concentrations. Death certification was as follows: cause, mixed drug toxicity, and manner, accident [22].*

Further, cytochrome P450 2B6 (CYP 2B6) poor metabolizers are more likely to develop QT elongation. In addition, higher doses are needed for individuals with two copies of the wild-type haplotype and lower doses for AGCTT haplotype. Thus, haplotyping may be used to individualize methadone therapy.

Together, the genetic contribution to drug metabolism impairment may be interpreted as a gene dose effect, resulting in more pronounced drug toxicity. Such an effect might be readily demonstrated as a pharmacogenomics converging continuum and is helpful to understand the effect in the living.

Similarly, oxycodone response is affected by the activity of CYP 2D6 isozyme as Case Report 2 illustrates.

*Case History 2. A 49-year-old male with a history of alcoholism and chronic lower back pain was prescribed OxyContin™ and Percocet™. He also had depression, posttraumatic stress disorder, and attempted suicide once. The scene investigation revealed only 12 of the 60 oxycodone pills that were obtained from the day before. Last seen by his roommate in the morning, the decedent was found unresponsive later that afternoon. Toxicological analysis of subclavian blood showed methadone, 0.44, mg l^{-1}. Testing showed that he was CYP 2D6*4 homozygous, corresponding to a poor metabolizer phenotype. Autopsy also showed that he had hepatic cirrhosis and atherosclerotic heart disease. Given the short postmortem interval and subclavian blood source, the elevated oxycodone was not due to postmortem drug redistribution but might be due to poor metabolizer phenotype and hepatic cirrhosis, both contributing to impaired drug metabolism. Death was certified as follows: cause of death, oxycodone overdose, and manner of death, accident [23].*

Similarly, fentanyl response is affected by the activity of a number of enzyme types as Case Report 3 illustrates.

Other Applications

Pharmacogenomics including proteomic, RNA interference, and other molecular and functional biomarkers are being increasingly used in drug discovery and development as encouraged by governmental agencies and scientific and professional organizations. Pharmacogenomics has been used to enhance patient's safety in therapies with approved drugs. Thus, the use of pharmacogenomics is regarded as an adjunct for optimizing drug therapy and, in forensic pathology/toxicology, for providing a molecular autopsy. Thus, TDM and toxicology would be helpful as global indexes. This would add to the understanding of potential genetic contribution to metabolism of approved drugs such as methadone and oxycodone, thus enabling and improving the practice of antemortem drug therapy, a tangible benefit for family members of decedents.

*Case History 3. A 44-year-old white female complained about her knee pain and was treated with Duragesic™ fentanyl patches. She appeared to be "goofy" and went to bed. She was found dead 24 h later. The decedent was a drug abuser with psychiatric history. Previously, she cut her arm to obtain drugs and also expressed suicidal ideation. Toxicological analysis of subclavian blood showed the following drugs and concentrations in milligrams per liter: fentanyl, 0.019; norfentanyl, 0.008; cyclobenzaprine, 0.16; tramadol, 0.06, diphenhydramine, 0.08; citalopram, 0.22; and olanzapine, positive. The MR of fentanyl/norfentanyl was 2.5. Molecular autopsy by pharmacogenomics showed that she was heterozygous for CYP 3A4*1B and CYP 3A5*3, different from the majority of Caucasians CYP 3A4, WT, and CYP 3A5*3 HM. In this study with limited number of fentanyl cases, the MR of this case is lower than the MRs of majority of the cases with high-fentanyl concentrations. Together, these findings suggested that for the first time, cytochrome P450 3A5 (CYP 3A5) comediated with CYP 3A4 the metabolism of fentanyl to norfentanyl. Death certification for the above case was as follows: cause of death, mixed drug toxicity, and manner of death, accident [24].*

The experience may be helpful to apply pharmacogenomics in the possible emerging practice of personalized justice. One such emerging application would be applying pharmacogenomic biomarkers for the interpretation of possible "side effect/behavior/impaired performance" of the drivers arrested in cases involving driving under the influence of drugs (*see also* **Drug-Impaired Driving** and **Behavioral Toxicology**). By using pharmacogenomics, the driver's impaired driving performance may be partially explained on the basis of genetics-predisposed impairment of drug metabolism and therefore accumulation. This might result in driving

impairment. Similar to the use of DNA fingerprinting in identity testing, applying pharmacogenomics and other molecular biomarkers in the future as adjunct biomarkers in the above context may constitute a rational approach in understanding and the deliberation of the driver's liability, thus offering the possibility of personalized justice.

Further, with the availability of proficiency survey program by the College of American Pathologists in 2007 and quality assurance/control from commercial sources, the clinical adaptations will soon be readily achieved by clinical laboratories. National Academy of Clinical Biochemistry (NACB) guidelines would certainly pave the way. Challenges remain for adequate reimbursement, clinical interpretation, ethical guidelines, and education of the patients and healthcare professionals. Thus, Gregor Mendel's "little trick – long story" would indeed continue in the form of new articles as a result of the human genome project and the rapid advances in molecular biology and pharmacogenomics.

Phenotype

Introduction

The genomics and bioinformatics era has enabled the recent development of systems and methods for the derivation of human phenotype from the genotyping of crime stain DNA evidence. This is accomplished through an empirical process of inference, either directly through genotypes for the functionally relevant genetic positions (loci) or indirectly through an appreciation of the genetic heritage of the donor. Forensic scientists are accustomed to using DNA sequence polymorphisms as identifiers. On the basis of the frequency of the identifier, we can statistically link individuals with samples associated with criminal investigations. Microsatellites, such as the short tandem repeats (STRs) employed for the Federal Bureau of Investigation (FBI's) combined DNA index system (CODIS) have been most commonly used for this purpose because they are multiallelic. That is to say, they have many alleles (varieties per location, or locus) and so relatively few loci are necessary to produce sequence signatures. Microsatellites are not chosen from the human genome based on their human ancestry or phenotype information, since this type of information would render them more or less powerful as identification tools among different human subpopulations. Thus, they are relatively useless for inferring phenotype. If we find that a suspect or a database entry matches the STR profile, we can extract probative value from the profile, otherwise, we have traditionally employed nongenetic investigative processes designed to produce the suspects necessary to achieve this objective.

For many cases, the investigative process begins with an attempt to ascribe characteristics or features to the perpetrator that can lead to identification. If a human eyewitness were available, we would query the witness about physical appearance – what the suspect was wearing, the suspects "race" and, more

specifically, we would obtain estimates and ranges for the basic anthropometric phenotypes such as skin color, eye color, height, etc. In the best-case scenario, we might obtain the basic physical descriptors or features such as those that might be present on a work identification card for the suspect, and, in a suboptimal scenario, we might obtain descriptors that are inaccurate or misleading. Unfortunately, the best-case scenario with human eyewitnesses is rarely achieved; unreliable information is sometimes provided by design (perhaps the witness has a motive to deceive) or by circumstance such as might be the case if the witness observed from afar on a darkly lit street. Assuming that the integrity of the witness is intact, and the witness had a clear view of a suspect, we are still left with fundamental problems created by the subjective nature of the human experience. Human testimony is generally not objective, almost always unstandardized, and never formally quantitative. Physical descriptions provided by one witness may or may not comport with those from another – not necessarily because one is wrong, but because one witness' opinion on what it is to look "dark" or "Asian", for example, may be different from the other. These basic problems translate into a fundamental defect associated with the extraction of phenotype data from human eyewitnesses – namely, that the testimony is not falsifiable, meaning that an investigator cannot verify its accuracy through independent examination. Nonetheless, there is a reason investigators consider themselves lucky to have access to eyewitness testimony. An investigation is much like a classification problem, where one attempts to make the most specific classification possible (the ascription of identity). Given the number of variables, and the fact that the number of incorrect classifications far outnumbers those that are correct (one) the classification problem is complex and we need classification features in order to delimit the likely possibilities. Here, data from witness testimony is analogous to a classification feature, and information theory (e.g., Bayes theorem) teaches us that even suboptimally informative (as opposed to uninformative or misleading) "features" are better than no features at all [1, 2]. Clearly, it would be far better to extract physical information on the donor using empirical techniques that lend themselves to the scientific method – techniques based on the observations of unperturbed nature, producing objective, quantitative and falsifiable data that can be communicated logically to others using standardized terms. It happens that if DNA is available from a crime scene, we now have access to new methods meeting these criteria for the inference of certain aspects of physical appearance (human traits or phenotypes).

The recent completion of the first human genome draft has provided a foundation for the development of empirical processes by which a partial physical portrait of a DNA donor can be constructed. In this article, we discuss certain overt phenotypes that are highly heritable, which are required if we hope to draw connections between DNA sequences and trait values. For example, parents with dark skin tend to have children with similarly dark skin and blue-eyed parents tend not to have brown-eyed offspring, suggesting that if we knew which and how genetic regions controlled or were informative for skin and eye color, we could predict these phenotypes simply through genetic observation. In fact, since most anthropometric (comparative human) phenotypes are determined by inherited gene sequences, much of a crime-scene DNA donor's physical information is imbedded in their DNA – we have only to figure out how to extract it. The inheritance of some phenotypes is relatively simple, and this information can be extracted with the investment of time and money. For others of more complex inheritance, the information is not currently extractable and may never be with existing technology.

There are two basic methods for inferring phenotypes from DNA. If we desire to infer phenotype from DNA using *direct methods*, we need to understand at least the major elements of the genetic architecture of the phenotype – that is, which genes and gene variants (as well as environmental factors) underlie variable expression of the phenotype. These genes are called *phenotypically active loci*, and their variants *phenotypically active variants*. With the direct method, we relate genotypes to specific phenotypes through our understanding of the genetic architecture, or if we do not fully understand the genetic architecture, through an empirical process based on prior experience and the use of databases. Of course, at least some of the genetic architecture must be understood or captured by our databases for the direct method to be possible. Even for "relatively simple" phenotypes, the expression tends to be extraordinarily complex, involving multiple variants per gene, sometimes more than one gene and sometimes even environmental factors. As basic genetics research

powered to identify these genes and factors must involve many hundreds, even thousands or tens of thousands of subjects (depending on the phenotype, the number of loci, and their frequency in the relevant populations), arriving at the requisite level of understanding is very expensive and time consuming. As a result, we can so far only use direct methods with a couple of the overt human phenotypes that have so far proven amenable – hair color, iris color and, possibly soon, skin color as well (at least within some human populations).

Another method of inferring phenotype from DNA is based not on any understanding of the genetic architecture of the phenotype, but based on the recognition that expression of the phenotype is correlated with certain elements of human population structure. This is called the *indirect method* of DNA-based phenotype inference. Indirect methods are based on an appreciation of individual genomic ancestry in terms of admixture. We choose the term *admixture*, rather than mixture, because the distribution of ancestry within populations and individuals tends toward amalgamation and the preservation of structure rather than dilutive blending and homogenization (by analogy, the colors yellow and red combining to produce an amalgamation of yellow and red, rather than orange). The correlation between elements of ancestry and phenotype within populations of individuals allow for an inference of the latter on an individual-by-individual basis. If skin color, for example, is systematically and quantitatively darker among individuals with increasing levels of African genetic ancestry, and if we have a good database of individuals of varying African ancestry and their skin color measurements, we can infer the skin color of a crime-scene donor from a precise genomic ancestry estimate of the donor's African admixture. The use of databases makes the process both objective and empirical in that the inference is based strictly on observation (as opposed to based on a model such as a model of the genetic architecture). As we describe, in this article, depending on the phenotype and its distribution among the world's various populations, we can employ the empirical method with reference databases to not only infer trait value but also to do so quantitatively and with predefined levels of confidence (based on the likelihood that the inference is correct). In what follows, we first describe the currently available methods for indirectly inferring phenotype from DNA, then those for direct inference. We then discuss some of the first cases that have employed these methods with success and close with a brief discussion on the issues associated with the penetration of these new methods into the modern forensics investigative process. Most of our discussion here is necessarily brief and significantly more details can be found in [3] which represents the first text to discuss this topic in depth.

Indirect Method of Phenotype Inference

The indirect method of phenotype inference relies on the empirical process, which itself is driven by observation. With this method, we rely on observations of correlations between phenotypes and ancestry, rather than direct relationships with gene sequences. This focuses our attention to certain phenotypes unevenly distributed among the world's various populations, which arose either because they conferred selective advantage among our ancestors in certain geographical regions or through sampling and genetic drift. Reproductive barriers such as oceans, geographical extremes, and assortative mating helped to solidify a global amalgamation of populations as and after our ancestors expanded out of Africa some 200 000 years ago (reviewed in [4, 5]).

The main phenotypes distributed as a function of genetic ancestry and of interest to the forensic investigator are those that are overt, such as skin color, certain facial features, hair/iris color, stature, etc. To infer them accurately, we thus need an accurate tool with which to measure an individual's ancestry, and we need to measure this ancestry (and phenotype) among large population of individuals. Polymorphism of the Y and mtDNA chromosomes are the gold standard for reconstructing human population histories and measuring the apportionment of genetic diversity among the world's populations (Figure 1), but these chromosomes are uniparental (e.g., the Y is inherited by males from their father, who inherited it from his father, and his father, etc.) and as such, they are of little use to the forensic scientist. For example, from measures of Y chromosome mixes among various worldwide populations, we might note that the distribution of higher eumelanin index values (darker skin colors, Figure 2) is correlated with certain Y-haplogroups such as E that dominates in present-day Africa, or the L of South Asia and that lighter eumelanin index values correlated with those

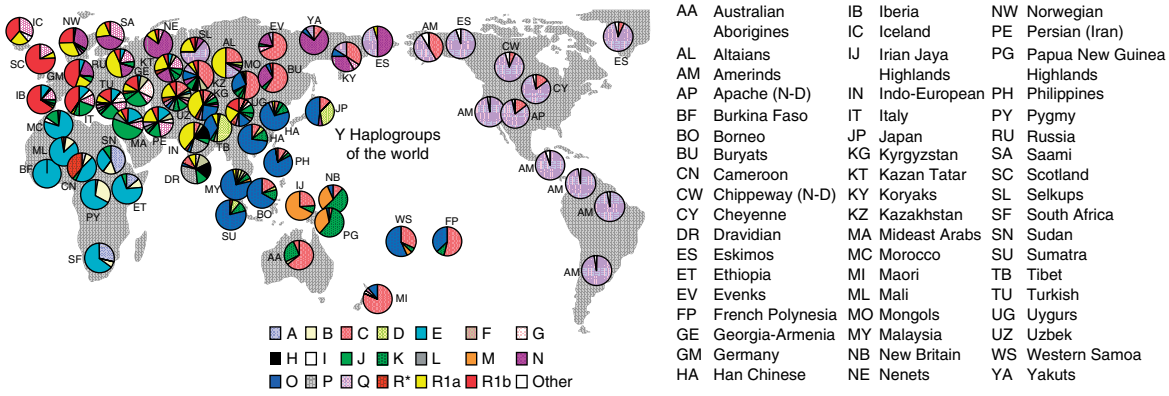

Figure 1 Global apportionment of Y haplogroup diversity. Pie charts illustrate the proportion of haplogroups as identified in the legend at the bottom. Populations are identified with a two-letter code/defined by the legend to the right [Reproduced with permission from J. D. McDonald. © 2004.]

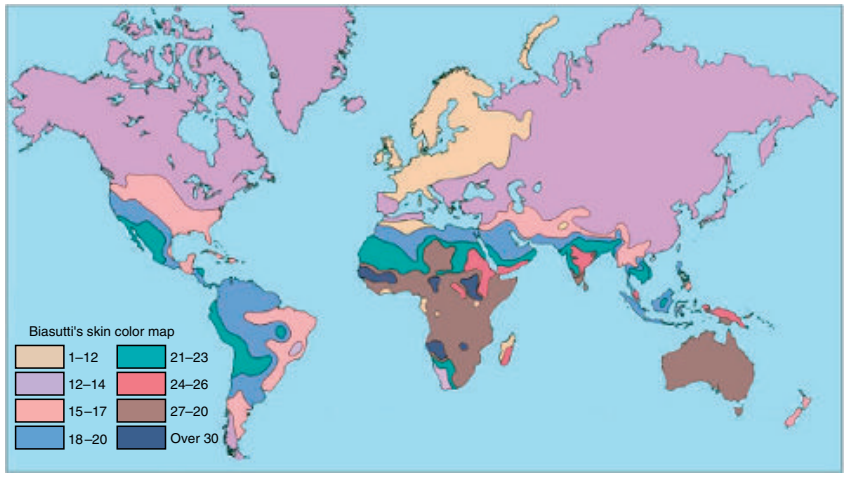

Figure 2 Geographical distribution of skin melanin levels. Higher values correspond to darker colors [Reproduced with permission from Cengage Learning © 2000.]

such as R or I shared among Europeans (compare Figures 1 and 2). Armed with this data, we might predict light European-like skin color for 28% of African Americans based on Y haplogroup sequence alone because no fewer than 28% of African Americans in the United States have a European Y chromosome as a result of recent admixture [6]; [7]; [3]. Indeed, the history of many other populations involves the admixture of those parental populations within which our anthropometric phenotype differences evolved and the ancestry for any one individual is best considered as a unique point along a sliding scale of admixture among these populations. In the field, we call this "sliding scale" a multidimensional continuum of admixture, based on the graphical methods we use to display the results (Figure 3). Uniparental chromosome polymorphisms are not useful for predicting phenotype because they do not tell us enough about the ancestry of any given individual, which is a complex function of all of the ancestors not just their patrilineal or matrilineal lines.

To indirectly infer a phenotype from the DNA of an individual, we must first have a method by which to quantitatively estimate individual genetic

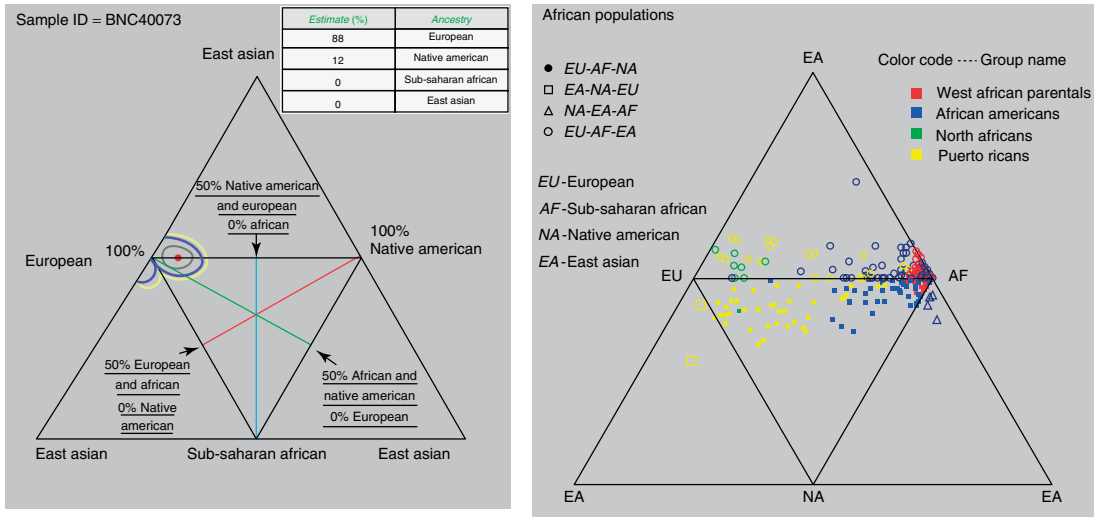

Figure 3 Individual genomic ancestry estimates portrayed with a tetrahedron plot. (a) The most likely estimate (MLE) for an individual is shown with a spot (red) which corresponds to specific percentages shown in the upper right-hand box. The percentages are obtained in four-dimensional space with an algorithm, but can be displayed on a two-dimensional piece of paper using this plot diagram; projecting the MLE spot perpendicularly on the each of the three axes within any of the four subtriangles (arrows) gives the corresponding percentage. The closer the spot is to the triangle vertices (labeled European, sub-Saharan African, East Asian, or Native American), the higher the percentage admixture corresponding to that type of ancestry. (b) Plot of numerous MLEs for individuals of color-coded self-described ancestry (legend upper right) obtained using the 176 AIM panel described in the text. Though continental Africans show predominantly African admixture, this African-American sample shows considerable European admixture and the Puerto Rican sample shows even more

ancestry admixture, contributed by all the ancestors of an individual (e.g., an individual might register with 80% "European" and 20% "African" admixture or some other mix). To do this, we measure ancestry informative markers (AIMs) on all 23 chromosomes of an individual. Secondly, we need to derive our understanding of the relationship between phenotype and ancestry from the same type of data – individual phenotype measurements and individual genomic ancestry admixture estimates. Note that we are therefore working on the level of the individual (within and/or between populations) rather than on the level of the population and so rather than using uniparental polymorphisms we must use AIMs distributed among all 23 chromosomes. Though binning or assigning an individual to a single population (such as "Caucasian") is conceptually easier than estimating the admixture of ancestry, it is not suitable for this purpose for the same reason we cannot use inferences of ancestry from uniparental chromosome polymorphisms. Specifically, we need to know what percentage of an individual's karyotype is derived from the ancestors of a given population, if we hope to compute the probability that the individual expresses a phenotype that is highly characteristic of that population.

AIMs are polymorphisms showing significant allele frequency differences between human populations. For example, an AIM may come in two "flavors" – a G allele and an A allele, with G rarely found in European or Eurasian populations but commonly found among various African populations. Most AIMs are single nucleotide polymorphisms (SNPs) such as this, with only two alleles, and SNP–AIMs constitute about 0.04% of the 2 million or so SNPs in the human genome. To construct an admixture panel, the most informative AIMs are selected from those that have been databased via the human genome (or similar other) project and the allele frequencies/frequency differentials among our founding parental populations is inferred through analysis of modern-day representative descendants. Using the AIM genotypes of any one individual, we invert the frequency of these alleles in various

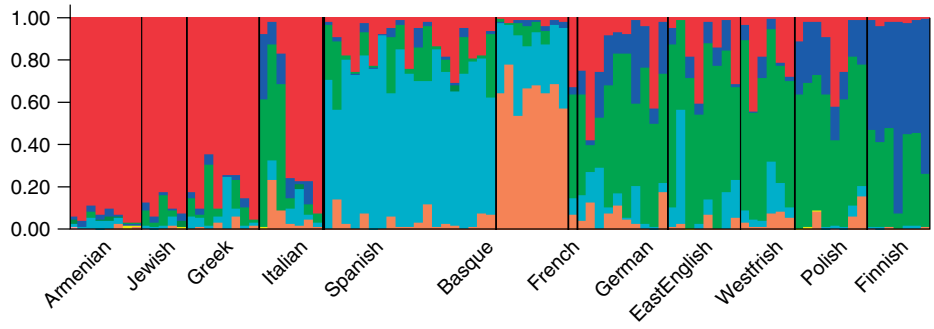

Figure 4 Individual genomic ancestry admixture estimates among Europeans with respect to a five-population European model. The 1346 European AIM panel described in the text was used to generate the data. For each individual, the proportional ancestry derived from these five parental European populations is represented with a bar, using colors coding for each ancestry type and the scaling on the left. Markers and genotype data were derived from the work published by [11] [Reproduced from Ref. 11. © Elsevier, 2007.]

populations in order to calculate the likelihood that the individual's ancestry was derived proportionally from these populations. The likelihood for all possible proportions is calculated, we select the best as the most likely estimate (MLE), and select those within two–tenfold likelihood values fall within the confidence intervals for the MLE (Figure 3a). If the admixture panel is to address the global population, worldwide population models are usually chosen on the basis of hypothesis-free clustering results (e.g., see [9]). One panel that has been well characterized incorporates a four-population model; this panel (developed in the laboratory of the author) was the first to be extensively characterized and applied for forensic cases ([3, 10]; discussed further below). Since individuals derived mainly from the Eurasian continent share one element of ancestry, we can arbitrarily name this element "European" or "Eurasian", and so on for the other three elements. Other more complex global models are possible but whatever the model, the choice of nomenclature is arbitrary, and usually based on either the modern-day origin of the parental representatives or geographical origin of the parental population (estimated from paleoarcheological, linguistics, and/or uniparental chromosome analyses). Mathematical methods allow for an accommodation of uncertainty with regard to the estimation of parental allele frequencies from modern-day representatives, as well as other pertinent variables, and the reader can refer to [3] for more details. For this discussion, here, suffice it to say that whatever the chosen population model, as long as it is based on hypothesis-free clustering results, an individual's admixture proportions are a function of genetic distance and thus potentially relevant for indirectly predicting phenotype. As of this article, three panels are available to forensic professionals through a company located in Sarasota Florida (DNAPrint genomics, Inc., see www.dnaprint.net or www.ancestrybydna.com) – the aforementioned 176-AIM continental panel (European, African, Indigenous American, and East Asian; [3, 10]), a 320-AIM Eurasian panel (Northern European, Southeastern European, Middle Eastern, and South Asian; [3]) and a 1476-AIM European panel (Figure 4; [3]).

Discerning whether particular elements of individual ancestry are correlated with certain phenotypes is accomplished through databases and regression analyses, where we plot one variable (such as a trait value) against another (such as percent admixture for a given ancestry type) and note whether or not there is a statistical dependence of the former on the latter. Regression analyses have shown correlations for skin eumelanin content and individual African ancestry levels using a 30-AIM ([12], African-American population) and the aforementioned 176-AIM panels ([10], Puerto Rican Afro-Caribbean population; Figure 5). For example, we could conclude from the regression analyses in Figure 5 that an individual with >75% African admixture determined using the 176-AIM panel is most likely to have an M (eumelanin content) value above 40 and an individual with less than 50% African ancestry is most likely to have an M value less than 40. With larger databases, we could provide not only an expected M value by

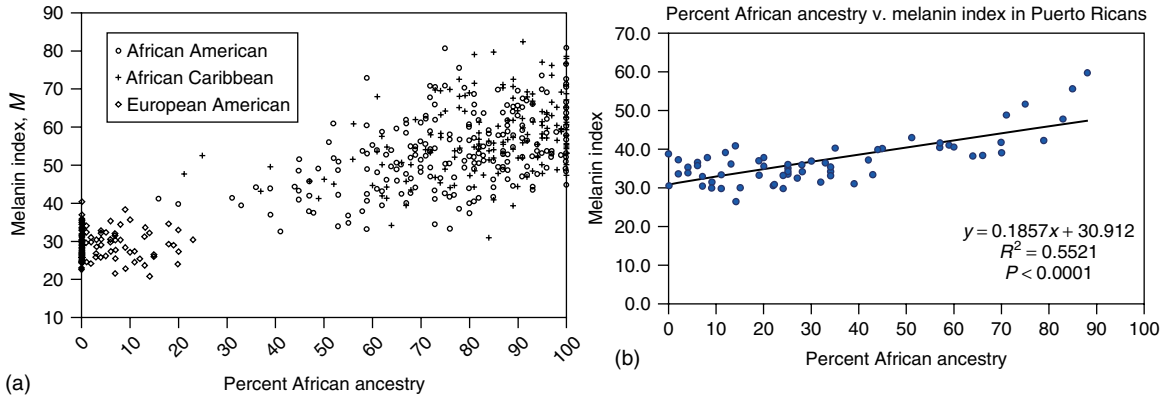

Figure 5 Regression of eumelanin value (M) from skin measurement on African individual genomic ancestry estimates in a population of (a) African Americans, European Americans, and Afro-Caribbean samples, obtained using a 30-AIM panel [12] and (b) Puerto Ricans, obtained using the 176-AIM panel described in the text [3, 10]. Each spot represents the point estimate of African admixture for an individual. Higher M values correspond to darker skin colors (higher concentration of eumelanin per unit skin area)

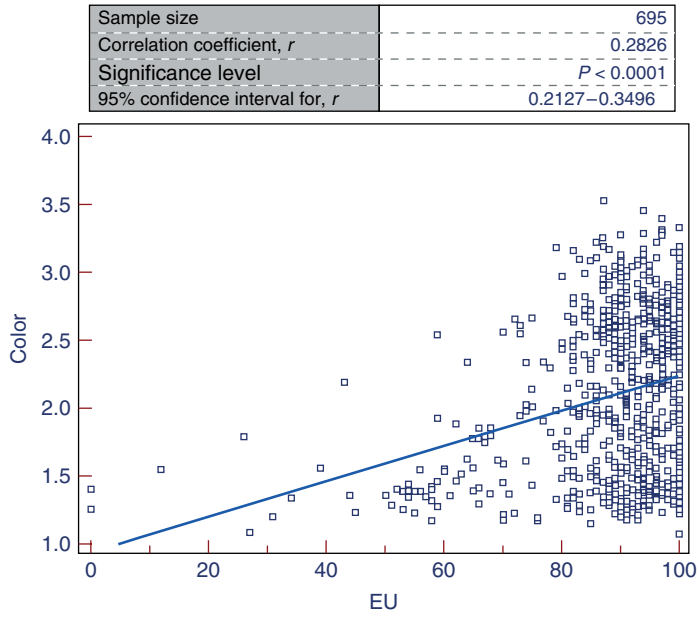

Figure 6 Regression of iris eumelanin scores from digital photographs on European individual genomic ancestry estimates in a population predominantly of self-described "Caucasians". Each spot represents a point estimate of European admixture for an individual. Higher color scores correspond to lighter colors (less eumelanin)

taking an average but we could also quantify the reliability of this value with confidence intervals. A correlation has also been demonstrated between iris color and European ancestry [13]; we can see from Figure 6 that while individuals with high "European" admixture have light (color $>$ 2.2) and darker iris color (color $<$ 2.2), individuals with substantial non-European admixture (20% or greater) almost always have darker iris colors. Thus, a crime-scene DNA sample determined to have been deposited by an

individual with 40% East Asian and 60% European admixture, or 50% African and 50% European admixture can be inferred to have an iris color on the darker end of the range observed in the human population. With larger databases, we could even quantify the likelihood that this type of conclusion is wrong. For example, if we see that the conclusion is true for 999 of 1000 individuals, we could estimate that the conclusion is correct with 99.9% certainty and that only 1 in 1000 such conclusions would be wrong. As of this article, the indirect method can only be used for these two phenotypes but through the construction and use of admixture databases, we may soon learn of others. For example, if we construct an admixture database of individuals, which included the self-described "ethnicity" and a digital photograph for each entry, and then query the database with a particular admixture profile (± a reasonable range), we might get a return of several entries like that shown in Figure 7. From these returns, we could discern whether the individuals are more likely to refer to themselves as belonging to one particular population than another, and how reliable such an inference can be expected to be. Using software biometric tools, we might learn that the average distance between the eyes (for example) is significantly different from that of a random collection of individuals, or a group of individuals with a different type of admixture profile. Some investigators may be able to use collections of digital photographs corresponding to an admixture profile to mentally compile a composite sketch, though the future promises to provide software for identifying all of the phenotypes statistically characteristic of the profile (compared to randomly specified samples) as well as the ranges of trait values, we can expect algorithms to construct an *in silico* "rendering" of the suspect similar to that provided by a human eyewitness.

A very important point that needs to be highlighted is that if our admixture methods are insensitive or inaccurate, if there are problems with the population model or parental representatives we have built our test on, or if there are glitches with the database software, there will be error. However, assuming that the size of the database is adequate, this error is expected to result in an increase rather than a decrease in entropy of the system [3]. The increase in entropy leads to a loss of information and an inability to recognize correlations in regression analyses (false negatives) rather than an ability to recognize false correlations (false positives). For example, an admixture assay based on only a few AIMs covering only

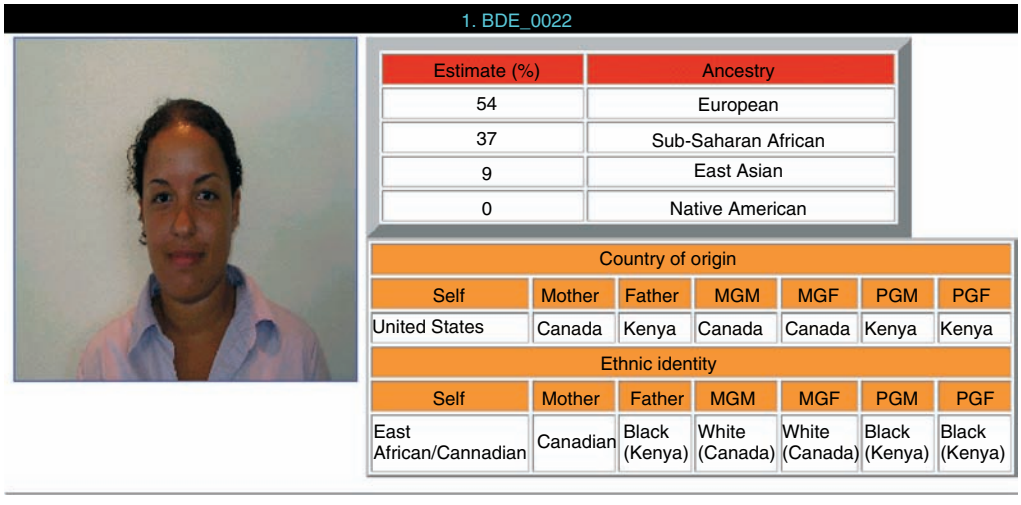

Figure 7 Example of an admixture database entry. Entries in this particular database (www.dnawitness.net) included a digital photograph taken under standardized conditions, country of origin, that of their mother, father, and their maternal grandmother (MGM) and paternal grandmother (PGM) as well as maternal grandfather (MGF) and paternal grandfather (PGF). Similarly, the self-reported "ethnic identity" is provided by each subject. The laboratory that administers this database took the photograph and determined the admixture profile with respect to a global four-population model using the 176-AIM panel discussed in the text. The database had 4700 entries as of August 2007

one chromosome would produce a large standard error in admixture estimates and the imprecise estimates may be so scattered about their true values in a regression plot that the relationship between trait value and ancestry is concealed (e.g., in Figure 5b, imagine the spots so far scattered above and below the line at low as well as high African admixture values that the sum of squared distance to a line indicating no correlation is similar to that for one indicating a good correlation). False positives can only obtain if false positive correlations are produced between phenotypes and elements of ancestry, which equates to the creation of false pattern, but random error that we would expect from a poorly performing assay would, by definition, obfuscate pattern and increase the entropy. It is possible to create false pattern from an assay that produces estimates with biased error, but with admixture/phenotype databases even these tend to result in a decrease rather than an increase in entropy. For example, consider an assay that has a tendency to erroneously estimate low levels of African admixture for South Asians (but not for other "European" populations such as Middle Eastern or Continental Europeans). It might seem that this error could lead to the mistaken conclusion that low levels of African admixture for individuals of primarily European ancestry is correlated with very dark skin color, even though most Continental Europeans with low levels of African admixture exhibit lighter skin colors (e.g., Figure 5). However, note that all of the Europeans would be present in the database, and using the high European/low African profile to query the database would result in a jumble of various light and dark skin color phenotypes rather than the shade that would be observed, were the error not present. Thus, we have an increase in entropy over which we would expect without the error, leading to an inability to make an accurate inference and false negative (type I) error rather than the creation of a false positive. Nonetheless, admixture panels that produce biased estimates are easily identified if they are properly validated and characterized [3]. A properly constructed and validated admixture panel should exhibit single-digit percentage accuracy (total error from statistical imprecision and bias combined). The laboratory of the author operates such a validated admixture/phenotype database ($n = 4700$ samples as of August 2007) and has used it in several homicide cases, but as we discuss later, so far only to indirectly infer skin color and iris color. Finding other phenotypes for which the indirect method will be useful in the future and the development of more advanced data mining and composite sketch software tools will require significantly greater investment.

Direct Method

Though they can be correlated with phenotypes, ancestry and markers of ancestry do not cause phenotypes – genes do. In contrast with the indirect method, the direct method relies on measurements of the actual genes underlying the phenotype of interest. Though far more satisfying in a theoretical sense, since we expect to be able to do a better job of predicting trait value (more accuracy and tighter confidence intervals), the direct method is rarely practicable because it requires an understanding of the dominant aspects of the genetic architecture of a phenotype, and acquiring this understanding is a very expensive and time-consuming endeavor. To date, research on the genetic basis for only human iris color and one aspect of hair color has been productive enough to enable direct phenotyping from DNA. The objective with the direct method is to define polymorphisms associated strongly enough with the phenotype that they are predictive for that phenotype with good sensitivity and specificity. Note that hundreds of good gene/phenotype associations have been described in the literature over the past decade or so (mostly for clinical phenotypes), but few of them are sufficiently strong or detailed enough within each gene to enable "genetic classification". Given the complexity of human phenotypes, useful polymorphisms are likely to be found for phenotypes where expression is controlled by one to a few genes at most, and will almost always be useful in the context of diplotypes (diploid pairs of haplotypes, where a haplotype is a chromosomal string of SNP alleles). Which diplotypes are associated with which trait values would be best determined through an empirical process of database construction and query, as with the indirect method, except we query with diplotypes rather than admixture profiles.

Iris Color

The best example of an effective direct system for inferring a human phenotype is human iris color. Linkage screens and association scans have shown

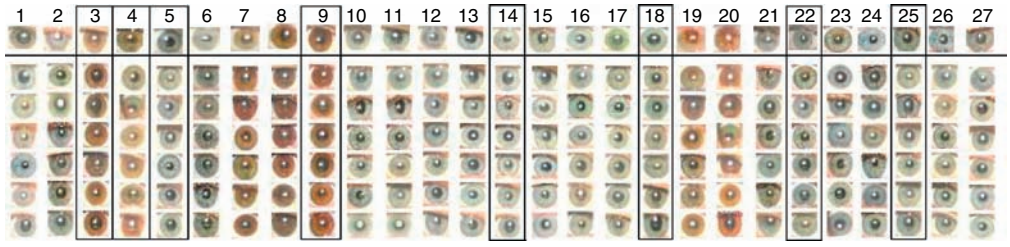

Figure 8 Examples of iris color inference enabled with the 33 marker/iris color database described in the text. Iris color is inferred using the average color exhibited by samples in the database with matching diplotypes and an interval is provided around this point estimate using the range of colors exhibited or a default range, whichever is larger. This inferred range is then used to query the database and all of the irides falling within the range are presented. This typically produces tens or hundreds of irides of similar overall color from a distance (determined by eumelanin content) though of different pattern, depending on the color and database size. Shown here are returns for 27 test subjects. Six representatives of the inferred iris color score range are provided for each of the 27 test irides below the line and the actual color of the test iris is shown above the line
