Radioimmunoassay (RIA) was one of the first heterogeneous immunoassays, but problems associated with the disposal of radioactive waste and rapid decaying of the radioactive isotopes have seen it being replaced with nonisotopic EIAs [7, 8, 13, 14]. The most common type is the antibody-coated tube utilizing γ-emitting I^{125}-labeled antigen. Separation of the bound and free antigen is accomplished by simply decanting the liquid leaving the bound fraction coated to the tube. The technique is extremely sensitive and specific and tends to be less susceptible to matrix effects, especially for analysis of whole blood samples, but when radioactive substances are involved it requires special precautions and sophisticated apparatus (γ-radiation counter). The technique has been largely replaced by the ELISA method.

Cloned Enzyme Donor Immunoassay (CEDIA)

Cloned enzyme donor immunoassay (CEDIA) is a more recent homogeneous immunoassay that uses

Table 3 Common commercial ELISA drug screening kits

Propoxyphene	Haloperidol	Phencyclidine
Tramadol	Tricyclic antidepressants	Hydromorphone
Amphetamine/ methylenedioxyamphetamine (MDA)	Methamphetamine/ methylenedioxymethamphetamine (MDMA)	Cannabinoids (tetrahydrocannabinol/carboxy-THC)

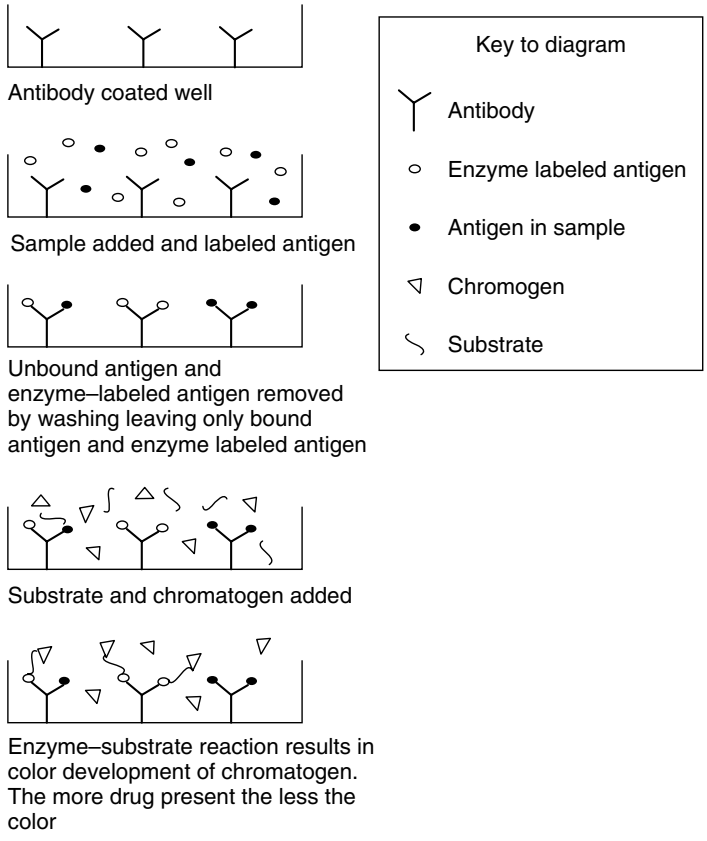

Figure 4 Competitive immunoassay process

the binding of an antibody to change the activity of an enzyme [7, 8, 15–18]. CEDIA uses genetically engineered fragments of β-galactosidase from *Escherichia coli* as the enzyme label. The enzyme is present as two inactive fragments known as the *enzyme acceptor* (*EA*) and *enzyme donor* (*ED*). The ED contains the small portion of enzyme missing from the larger EA fragment. Antibodies that bind to the hapten that is conjugated to the ED fragment prevent the reassociation of the enzyme and therefore the enzyme activity. As the amount of drug in the sample increases, the amount of bound antibody to the ED fragment decreases, resulting in an increased enzyme activity due to the reassociation of EA and ED. The enzyme hydrolyzes chlorophenolred-β-galactoside (CPGR) to chlorophenolred (CPR) and galactoside and the enzyme activity can be measured spectrophotometrically.

Fluorescence Polarization Immunoassay (FPIA)

Fluorescence polarization immunoassay (FPIA) is also a heterogeneous immunoassay technique that uses fluorescein-labeled antigen [8, 19]. The labeled antigen can rotate freely when not bound to an antibody; however, when it is bound, its ability to rotate is markedly reduced. Light at the excitation wavelength of fluorescein is passed through a polarized filter. The amount of polarized light emitted is reduced by freely rotating fluorescein but there is little loss of polarization by the relatively stationary antibody bound fluorescein. As any drug present in the sample competes with the fluorescein-labeled antigen for the antibody, there is a reduction in the amount of fluorescein bound and therefore a reduction in the amount of fluorescence through the polarized filter.

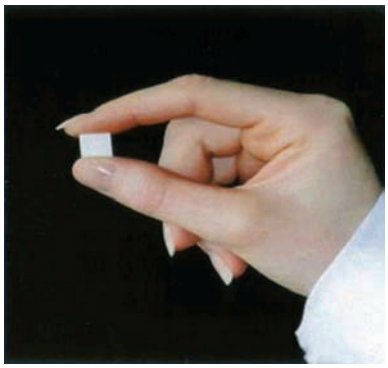

Figure 5 Biochip – actual size (Photograph courtesy of Randox) [Reproduced with permission from Randox.]

Chemiluminescence Immunoassay

The principle used in this immunoassay technique is similar to other heterogeneous assays but offers greater sensitivity using chemiluminescence. The signal produced by chemiluminescence immunoassays is generated by the emission of light during a chemical reaction. The glow of light over a short period is captured by a charged coupled device (CCD) camera, which also enables detection of separate assays. This technique has been developed to assay up to 10 different drugs, 8 drug classes, in the 1 sample analysis using Randox evidence Biochip Array Technology. This is achieved by attaching specific drug antibodies to discrete test regions on the biochip. The CCD will simultaneously record the light emission from each of the biochips and the image is processed to quantify and validate the signal. Figure 5 shows the actual size of a biochip and Figure 6 the discrete test regions on the chip.

Kinetic Interaction of Microparticles in Solution (KIMS)

Kinetic interaction of microparticles in solution (KIMS) is a homogeneous immunoassay in which the labeled compound is a microparticle with several drug molecules attached [8, 17, 20, 21]. If the sample being analyzed is drug free, then the microparticle with drug molecules attached conjugates with several antibody molecules and aggregates to form a larger particle. This aggregate will scatter transmitted light and as the reaction proceeds the abundance will increase. If drug molecules are present in the sample, they will compete with the conjugates bound to antibodies and result in a decrease in the rate of absorbance increase in proportion to the concentration of drug present.

Sample Extraction

There are two major methods for sample extraction:

Solvent Extraction (Liquid–Liquid Extraction)

This is the most frequently used separation technique employed in toxicology laboratories worldwide. Most

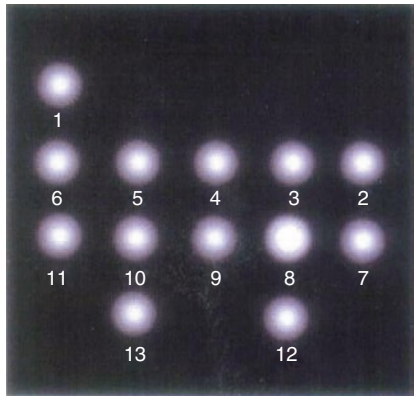

Figure 6 Magnified image showing luminescing discrete test regions of the processed drugs of abuse biochip (Randox evidence) (Photographs courtesy of Randox) [Reproduced with permission from Randox.]

drugs have some degree of polarity so it is important to select a solvent that will maximize the extraction of the target drugs but minimize the extraction of endogenous compounds. By adjusting the pH of the specimen drugs can be separated into basic and acidic drugs.

Making the specimen basic (pH 9) by the addition of ammonia or sodium borate buffer will favor the extraction of weakly basic drugs. Buffering the specimen to pH 4 by the addition of an acidic buffer (potassium dihydrogen phosphate) will allow the extraction of acidic and neutral drugs.

Basic drugs comprise the majority of drugs found in forensic cases and are often present at low concentrations in blood. To improve the detection of these drugs, it may be necessary to incorporate a clean-up step (or back extraction) in the extraction scheme to remove more of the endogenous compounds and still retain the drugs of interest. This can be particularly important when analyzing postmortem blood specimens that can often contain a multitude of endogenous compounds formed postmortem. Once the specimen has been extracted at basic pH into an appropriate solvent (such as butyl chloride), it is back-extracted into aqueous acid solution (usually 0.1 M sulfuric acid), the acidic and neutral compounds will remain in the organic layer. The acidic layer is separated from the organic layer and is then made alkaline (sodium hydroxide) and re-extracted into organic solvent, which is then separated from the aqueous layer and concentrated, usually under a stream of nitrogen. Care should be exercised in the evaporation step, as some of the more volatile compounds can be lost if subjected to heat; amphetamine and methylamphetamine are prime examples.

The concentrated extract can now be analyzed using the appropriate chromatographic technique. A typical basic/neutral drug extraction scheme is shown in Figure 7 and a back-extraction for basic drugs in Figure 8.

Acidic drugs of forensic interest tend to be present in much higher concentrations than basic drugs and

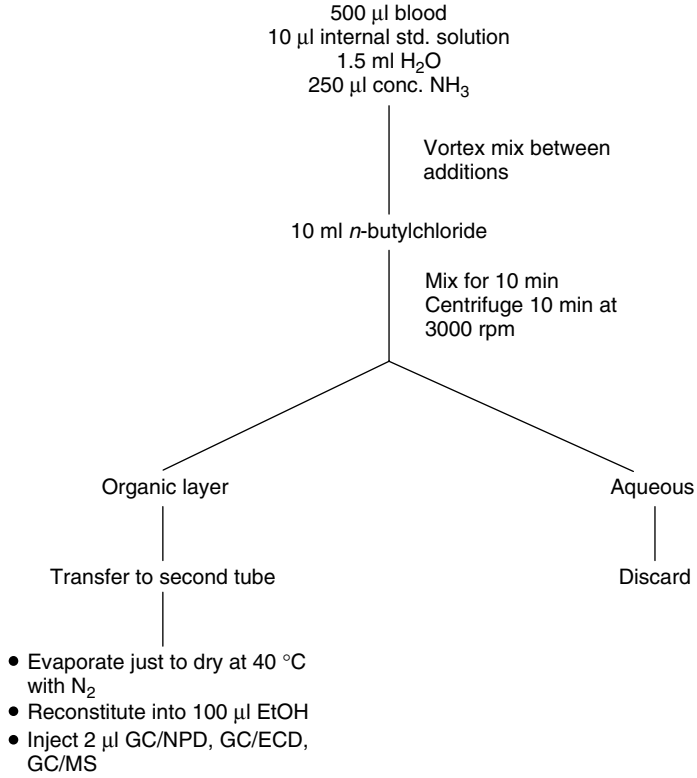

Figure 7 Extraction scheme for basic and neutral drugs

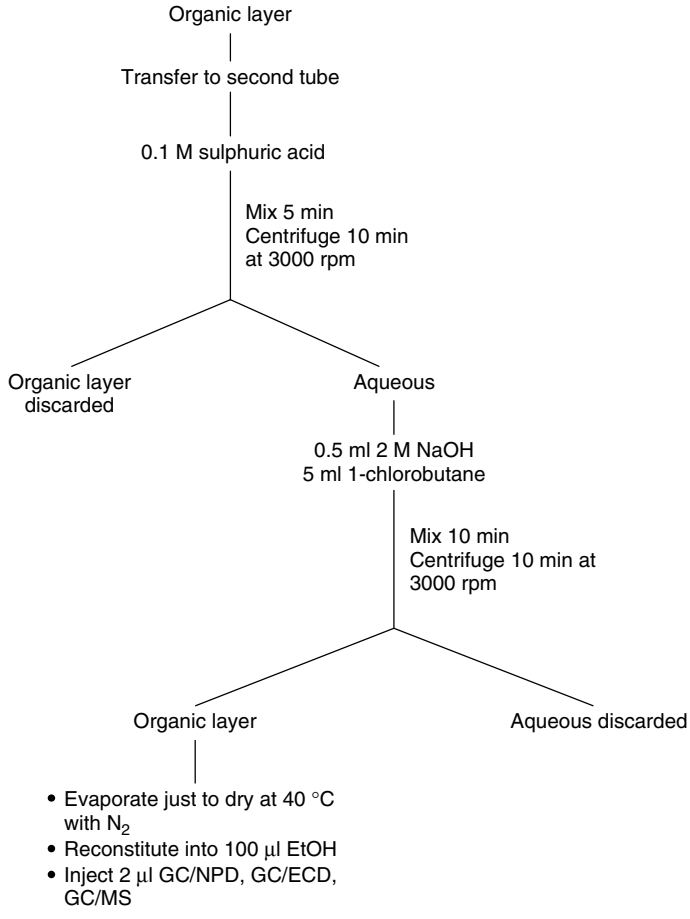

Figure 8 Back-extraction scheme for basic drugs

the need for a cleanup step in the extraction is generally not required. If a cleanup step is required it can be achieved by the partitioning between immiscible solvents of differing polarities. The more lipid soluble endogenous compounds (sterols and fatty acids) will partition into the less polar solvent (e.g., petroleum ether), whereas the more polar drugs will partition into the more polar solvent (e.g., acetonitrile). A typical extraction scheme for acidic and neutral drugs is shown in Figure 9.

Solid Phase Extraction (SPE)

Solid phase extraction (SPE) techniques are becoming more popular in forensic toxicology laboratories because of their better extraction efficiencies, particularly with more polar drugs, and the ability to automate the extraction using liquid handling systems. Initial difficulties with postmortem samples, which often contain large amounts of particulate material and are often clotted, which in the past could easily plug the fine SPE absorbent packing, have now been overcome by better sample preparation techniques (sample dilution and centrifugation) and improved SPE column technology. There are several SPE column manufacturers and many published screening techniques in the literature [22–26]. Most commonly used sorbents are porous silica particles with octadecyl (C_{18}) or other hydrophobic alkyl groups surface bonded. SPE sorbents have evolved from liquid chromatography phases and have developed over time to include a number of different functionalities e.g., $-C_2$, –CH, –phenyl, –CN, –diol, and mixed-mode bonded phases.

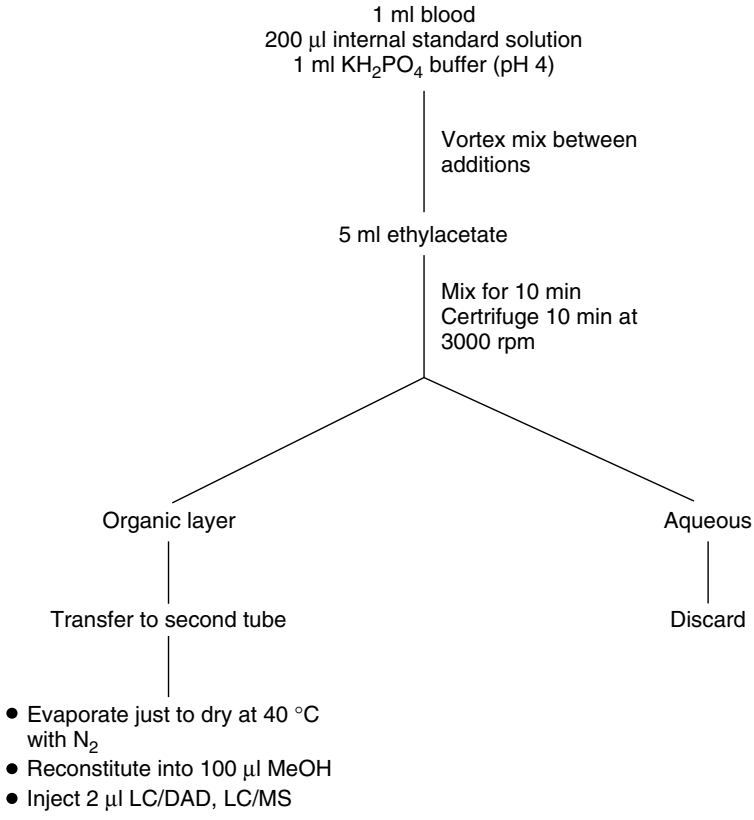

Figure 9 Extraction scheme for acidic/neutral drugs

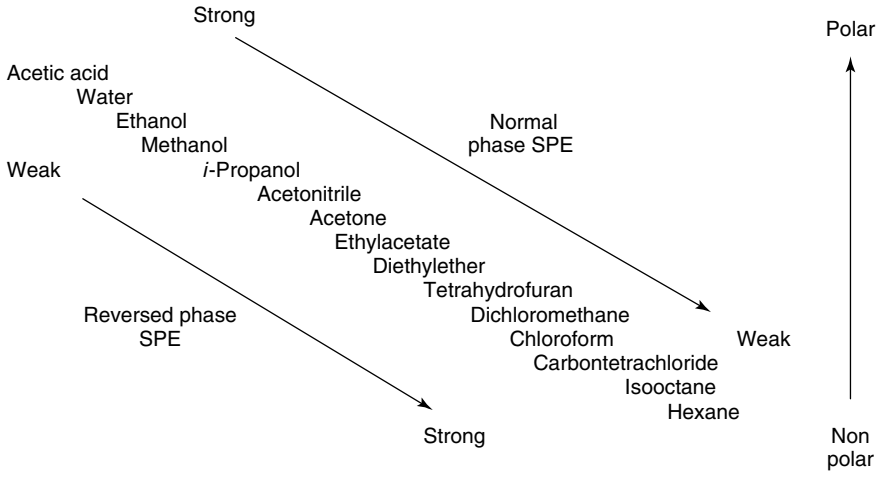
There are predominantly three different mechanisms for the retention of compounds by the sorbent:



1. Reverse phase (polar liquid phase and nonpolar solid phase): Compounds are retained by hydrophobic interactions (nonpolar–nonpolar interactions and dispersion forces).
2. Normal phase (nonpolar liquid phase and polar solid phase): Compounds are retained by hydrophilic interactions (polar–polar interactions and hydrogen bonding).
3. Ion exchange: It is electrostatic attraction of charged group on compound and charged group on the sorbent.

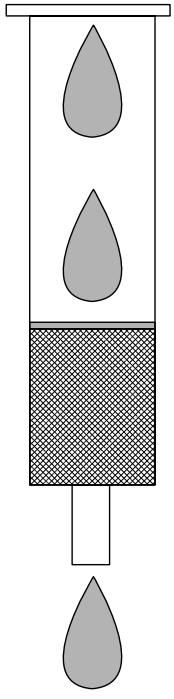


Table 4 shows the characteristics of solvents commonly used in SPE.

The basic procedure for SPE is a five-step process as shown in Figure 10, and a typical SPE using a combination of a strong cation exchange and a C8 sorbent (UCT XTRACT®, 200 mg 3 ml^{-1} P/N XRDAH203) for the analysis of opiates in blood is shown in Figure 11.

An alternative technique to liquid–liquid extraction and SPE is solid phase micro extraction (SPME) that has been developed for the analysis of volatile and some nonvolatile compounds [27–32]. This technique incorporates sample extraction, concentration, and sample introduction in one step and is fast, requires no solvents, is reusable, and can be adapted to any GC. The apparatus consists of a fused silica fiber coated with a stationary phase that is attached to a stainless steel plunger. After inserting the plunger through a septum into a vial containing the sample the fiber is exposed to either the headspace or the liquid for 20–30 min. The equilibration time can be reduced by increasing the ionic strength of the sample, stirring, or by heating the sample. After equilibration, the fiber is retracted back

Table 4 Characteristics of solvents commonly used in SPE

1. Select the appropriate SPE cartridge – capacity, bed weight, and sorbent type
2. Condition the cartridge. Use an appropriate solvent or aqueous buffer to wet the sorbent material and allow the sample to come into contact with the packing. Do not allow the SPE packing to dry between conditioning and sample addition as there will be uneven contact between sample and packing resulting in non-reproducible efficiency and drug recoveries.
3. Add the sample. Pass the sample solution slowly through the column using either vacuum or positive pressure at a flow rate of ~2 ml min^{-1}.
4. Wash the column. Remove unretained and unwanted compounds from the column using the same solution that the sample was dissolved in or solvents of sufficient polarity that they will not remove the compound(s) of interest.
5. Elute the compound(s). The compound(s) of interest are eluted using a solvent of sufficient polarity to recover the analyte(s) but leave any unwanted compounds that have not been removed by the wash step

Figure 10 Solid phase extraction sequence

into the plunger and inserted into the GC injection port where it is desorbed by exposing the fiber again (Figure 12). This also serves to recondition the fiber, which can be reused for up to 100 further analyses. The fiber may also be re-extracted into an organic solvent and analyzed by HPLC. There are number of different stationary phases available to suit the type of analysis. For less polar compounds, a poly-dimethoxysiloxane phase is used and depending upon the molecular weights (mw) of the compounds of interest the film thickness will vary. Generally, as the thickness of the film increases the lower the

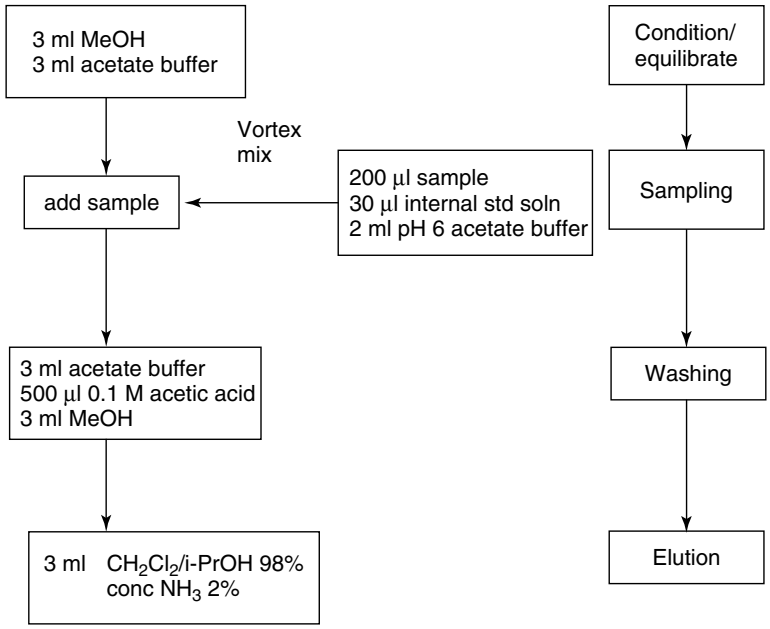

Figure 11 Analysis of opiates using mixed-mode SPE

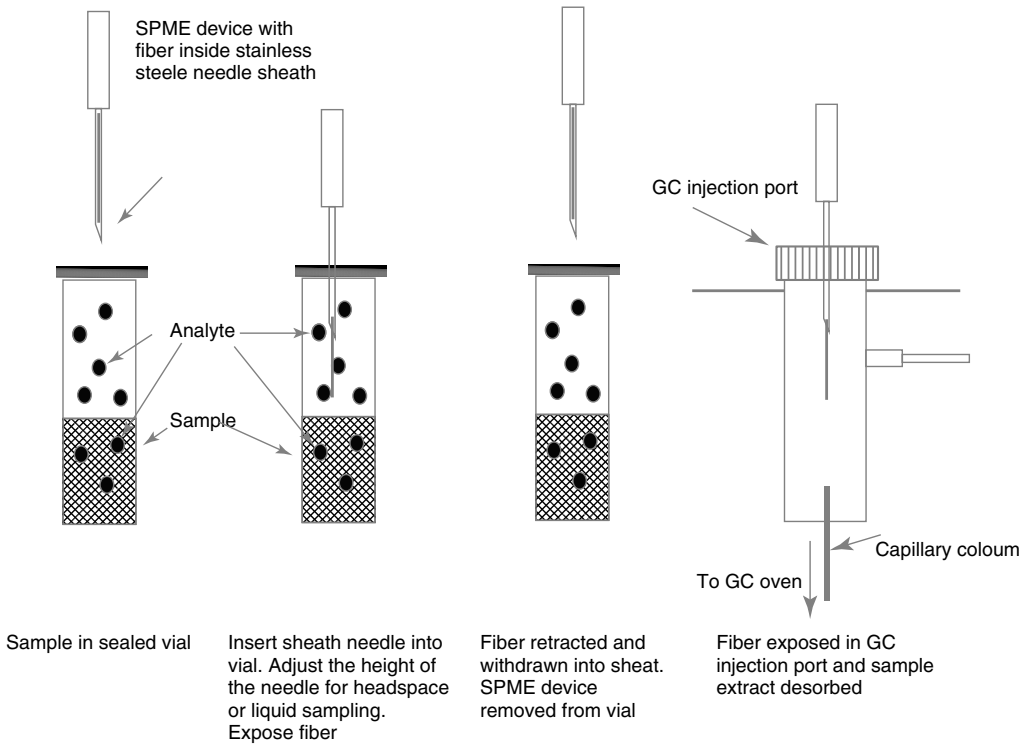

Figure 12 SPME sample headspace adsorption and GC desorption process

molecular weight (MW) of the compounds retained. Polyacrylate films are used for polar compounds (*see also* **Postmortem Toxicology: Laboratory Analysis**).

Screening by Gas Chromatography

GC has been the technique most widely used in forensic toxicology laboratories. If a drug has sufficient volatility for it to exist in the vapor phase at temperatures up to 350 °C and does not decompose at these temperatures, then there is a high probability that it can be analyzed by GC. Compounds in a specimen extract can be separated by introducing an aliquot of the specimen extract (sample injection) into a column that contains a stationary phase that has a continuous flow of an inert gas (e.g., helium) through it. The column is contained in an oven with controlled temperature. The components within the extraction mixture will spend differing periods of time in the stationary phase, depending upon their affinity for it and the time for the molecules to reach the end of the column will vary (retention time). The greater the affinity of the molecule to the stationary phase the longer they will be retained on the column and hence the greater the retention time. At the end of the column, there is a detector that produces a signal that is proportional to the amount of the compound passing through it. This signal will be processed and recorded. Each compound that elutes from the column will have a characteristic retention time, which can be defined, as the time interval between sample injection and detector response.

Stationary Phases and Column Supports

Few solid stationary phases are used for screening in forensic toxicology; however, blood–alcohol analysis is an exception. The majority of forensic laboratories analyze blood and other liquid biological specimens for alcohol concentration using either graphitized carbon black or polymer conventional packed columns. These phases are extremely good at separating low molecular weight hydrocarbons (C1–C10). Some examples of these are Carbopak C with 0.2% Carbowax 20M, Chromosorb 101–108, Porapak, and Tenax. Blood–alcohol analysis can be achieved by dilution of the specimen with in internal standard (e.g., *n*-propanol) and direct injection of an aliquot of the aqueous mix (Figure 13).

To prolong the life of the column and reduce the frequency of changing injection port liners, tungstic acid can be added and the diluted solution centrifuged to precipitate any protein in the sample. Another technique is to add an internal standard to an aliquot of the sample and seal the vial. After heating the sample in the vial to ~60 °C, the headspace is then

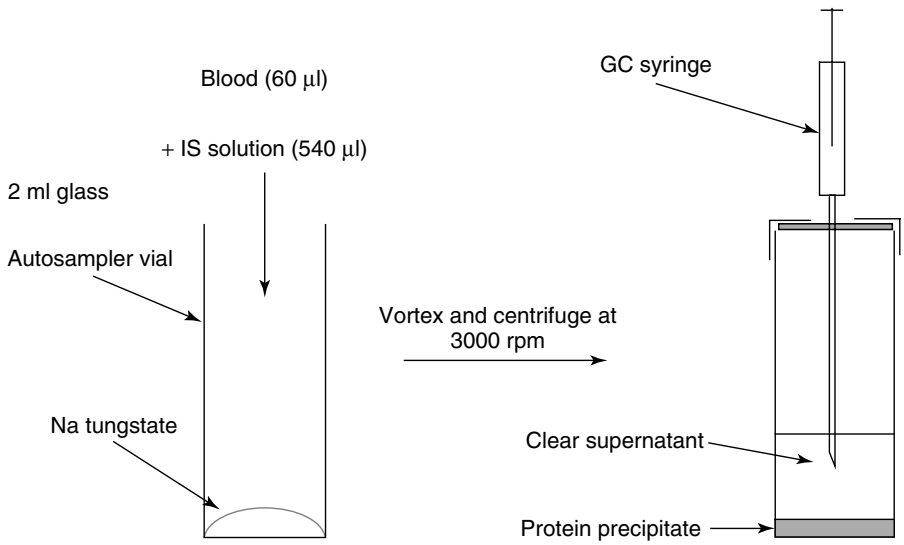

Figure 13 Blood–alcohol analysis – sample preparation for direct injection technique

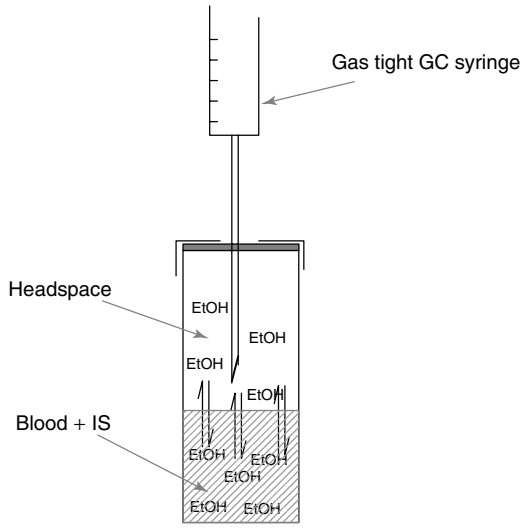

Figure 14 Blood–alcohol analysis: headspace technique

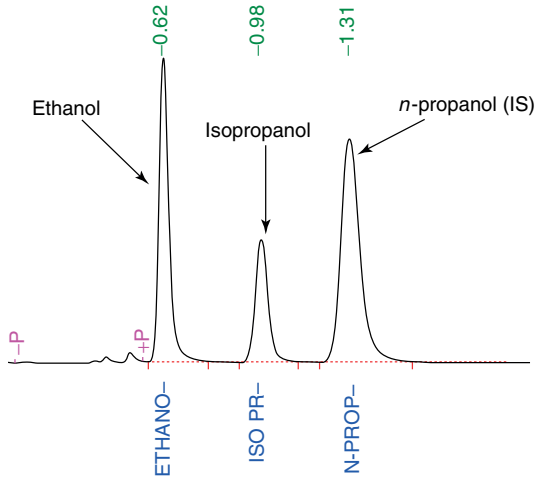

Figure 15 Chromatogram of ethanol analysis in blood: 2 m × 2 mm i.d. glass column packed with Carbopak C with 0.2% Carbowax 20 M. Oven 100 °C, injection port 220 °C, FID 220 °C, and He carrier gas flow 30 ml min^{-1}

injected onto the GC column via the heated injection port (Figure 14).

A chromatogram of ethanol analysis using a 2 m × 2 mm internal diameter (i.d.) glass column packed with Carbopak C with 0.2% Carbowax 20 M is shown in Figure 15.

The most commonly used stationary phases for drug screening are the liquid stationary phases comprising polysiloxanes. These stationary phases are liquids coated to the inside of a fused silica capillary column. The dimensions of the capillary column can vary between 0.1 and 0.32 mm i.d. and can be from 10 to 60 m long.

Polysiloxanes are characterized by a repeating siloxane backbone and each silicon (Si) atom can have two functional groups attached to it. The type and number of these functional groups will distinguish the properties of the stationary phase. The least polar polysiloxane is when it is 100% substituted with methyl groups, and this is generally designated as *XX-1* (where XX is usually the manufacturers identifier e.g., DB-1 and HP-1). By substituting more polar functional groups such as phenyl and cyano groups the polarity of the column can be changed (Figure 16). If 5% of the Si atoms contain two phenyl groups this will be known as *XX-5*; if 50% contain phenyl groups this is known as *XX-17*. Some polysiloxanes have two different functional groups present on the same Si atom, e.g., cyanopropyl and phenyl to increase the polarity, an example of this is the XX-1701 column (14% cyanopropyl-phenyl-methylpolysiloxane).

In total, 100% methyl-substituted polysiloxanes have been used extensively in producing retention time databases and are commonly used for screening purposes. In more recent times, columns that have up to 5% of the methyl groups substituted with phenyl

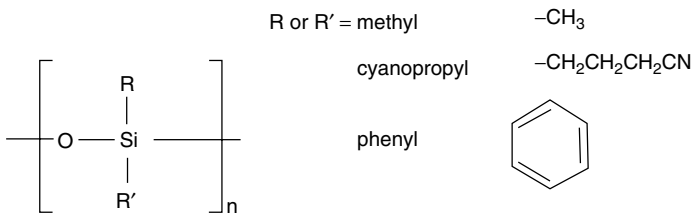

Figure 16 Polysiloxane backbone with differing functional groups

have produced essentially a nonpolar stationary phase that have improved thermal stability and as a result produce much less column bleed, which is especially useful in systems that use MS as the method of detection.

Split/Splitless Injectors

An inlet splitter allows a high flow of carrier gas into the injector, while still allowing a low flow ($1-2\,\mathrm{ml\,min^{-1}}$) through the capillary column. The excess carrier gas is vented via a split line to the atmosphere. The ratio of the inlet splitter flow and the column flow is known as the *split ratio* and determines what proportion of the injected sample passes on to the column. The lower the split ratio, the more sample is introduced onto the column.

When the injector is operated in the splitless mode it allows the entire injected sample to pass onto the column. This is particularly useful for extracts that contain very low concentrations of drugs. After a fixed time, the split vent is opened to allow a larger flow of carrier to flow through the injector, which will purge any remaining sample from the injection port. By keeping the temperature of the column oven below the boiling point of the solvent, the sample can be focused into a narrow band and reduce any peak broadening. Auto injectors allow the analysis of large numbers of samples, usually overnight when the laboratory is unattended.

Headspace Analysis

The headspace sampling technique can be used to screen biological samples for the presence of volatile hydrocarbons (e.g., petroleum products, propane, and butane) [33]. To increase the sensitivity of this technique, it is usual to sample a large volume of headspace (50 ml) and pass it through an adsorbent (e.g., Porapak Q) to trap the volatiles, which are then thermally desorbed onto a GC column. For complex mixtures, it is usual to analyze the headspace by capillary GC/MS. Figure 17 shows a typical total ion trace for a headspace sample of petrol in blood.

Detectors

For example, some detectors like the flame ionization detectors (FID) are nonspecific in nature and will respond to almost all compounds that pass through the GC column, while there are others that will specifically respond to compounds that contain particular atoms. For example, the NPD will detect compounds that contain nitrogen or phosphorus and ECD will detect compounds that have electron capturing atoms or functional groups (e.g., halogens, nitro groups and carbonyl groups). The NPD is extremely useful in drug screening since most drugs contain nitrogen while extraction solvents and many of the coextracted endogenous compounds in biological samples do not (e.g., fatty acids, lipids, and sterols). There are a number of relative retention databases that use standard capillary columns that are available for compound identification [34]. The ECD is a highly sensitive selective detector particularly useful to detect benzodiazepines and halogenated pesticides and herbicides. These detectors also offer greater sensitivity and selectivity over nonspecific detectors. This greater sensitivity can be utilized by derivatizing the

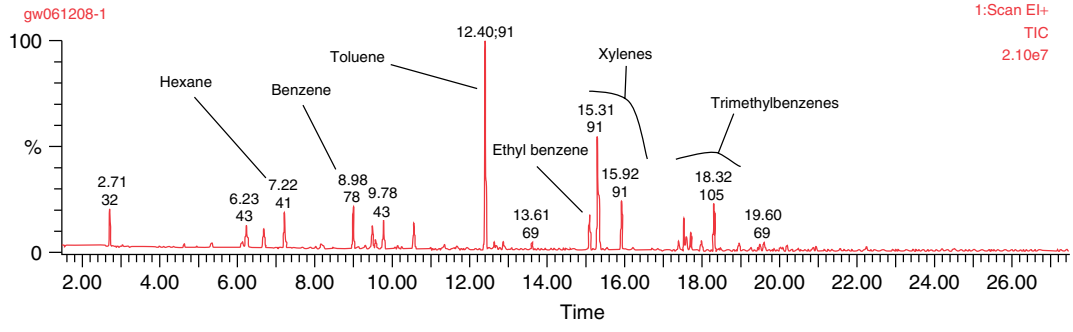

Figure 17 Total ion chromatogram of a headspace sample: 60 m × 0.25 mm i.d. BP-1 capillary (film thickness 1 μm), oven temperature 45 °C (6 min) to 260 °C at 10 °C min^{-1}

compounds with functional groups containing halogen, e.g., trifluoroacetic, pentafluoropropionic, and heptafluorobutyric anhydrides.

MS detectors have become increasingly popular as they provide the opportunity for unique identification of compounds. The most commonly used MS detector uses an electron impact technique to ionize the compounds eluting from the capillary column, which then fragment in a characteristic and reproducible way. These fragments are focused and accelerated into a mass filter (quadrupole or ion-trap), which rapidly scans for masses usually in the range up to about 1000 amu. The abundance of each mass at a given scan time is measured and results in a mass spectrum. This characteristic mass spectrum can be searched against a number of commercial mass spectral libraries (e.g., PMW (Pfleger, Maurer, and Weber), NIST, and Wiley libraries). The advances in computer technology allow the searching of vast library data extremely fast.

For added sensitivity, the quadrupole MS can be operated in the selected ion mode (SIM) where only preselected masses for the compounds of interest are collected. This is a useful technique for targeted screening of drugs but is limited for general unknown screening.

The ion-trap detector offers similar sensitivity when operated in either the full scan or SIM mode due to its longer ion collection period. Mass spectra produced by the two different mass detectors are sometimes quite different as they are characterized by the conditions under which they are run, this can make comparison between different instruments difficult.

Dual Detector Systems

It is not uncommon in forensic toxicology laboratories to use a dual detector screening system. There are several different combinations that can be used and the sample can be split at the injection port and two columns of differing polarity used to separate the drugs in the extract (Figure 18) or the effluent from the column can be split between two different detectors (Figure 19).

When using the single injection dual column approach the effluent from both the columns will be detected by the same type of detector (usually NPD or ECD) and a relative retention time (RRT) database can be set up for both the columns (e.g., DB-1 and DB-17). Searching the RRT of unknown peaks in the two chromatograms will provide better discrimination

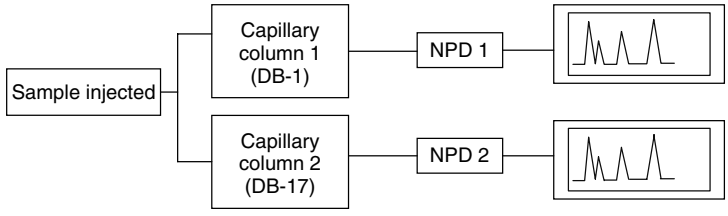

Figure 18 Sample injection split between two different columns

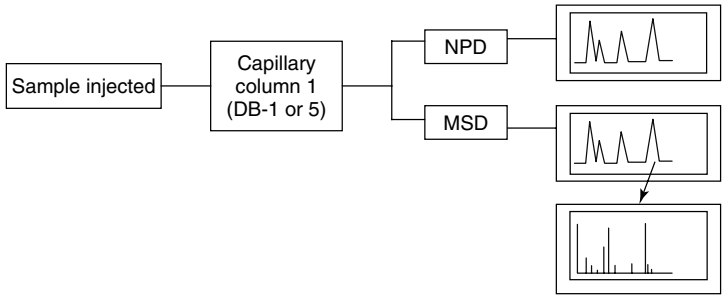

Figure 19 Column effluent split between two detectors

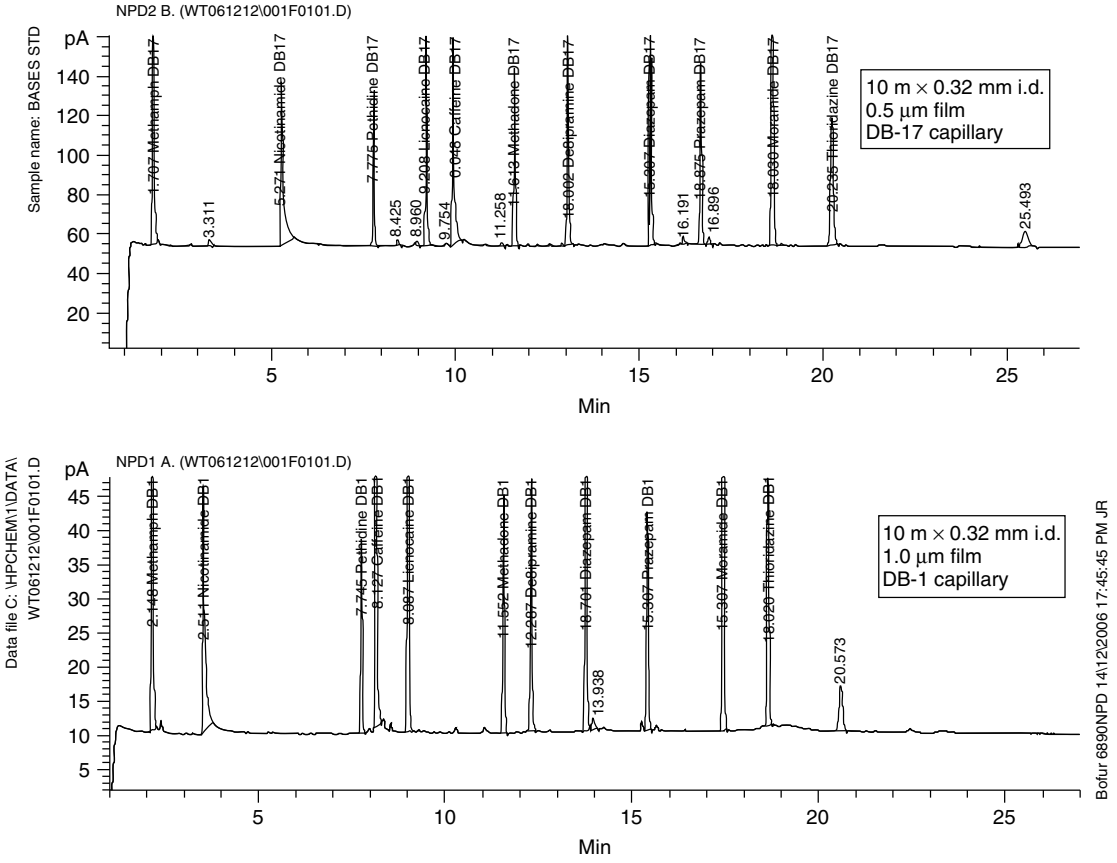

Figure 20 Dual column NPD chromatogram. Column oven 100 °C (0.5 min) to 280 °C (8 min) at 10 °C/min, injection port 250 °C, detector 325 °C, He carrier 4.9 ml min^{-1}, and splitless injection

as to the identity of the unknown than if data from a single chromatogram was used (Figure 20).

A much more common configuration is to split the effluent from the end of the column to two detectors, one being an NPD and the other an MSD. By using the NPD chromatogram to identify peaks of interest (many endogenous peaks will not produce a NPD response) the mass spectrum of the peak at the corresponding retention time can be obtained from the MS total ion chromatogram (Figure 21).

Gas Chromatography–Mass Spectrometry (GC–MS)

The use of GC–MS to screen biological samples for drugs is also a popular technique [26, 35–37]. However, because extracts from biological samples often contain many endogenous compounds the technique requires extensive sample preparation before GC–MS analysis if a general drug screen is required. Total ion chromatograms (TIC) containing endogenous compounds can often mask low concentrations of drugs. An alternative technique is to use selected ion extraction for characteristic ions of drugs of interest, these extracted ion chromatograms can show the presence of drugs even if the TIC does not. Unfortunately, this technique can limit the number of drugs that can be screened for, but is very good for selective drug screening. Figure 22 shows a TIC and extracted ion chromatogram of a blood extract.

High-Performance Liquid Chromatography (HPLC)

At one point of time HPLC was only used for the analysis of compounds that could not be analyzed

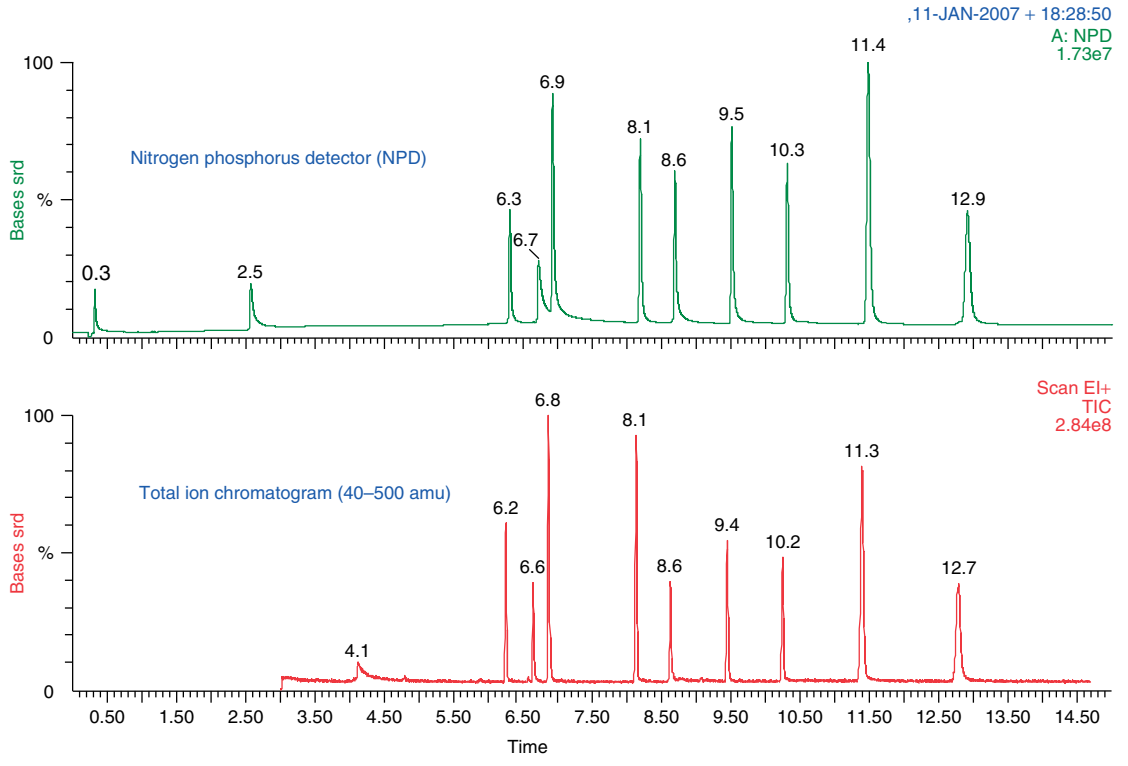

Figure 21 Dual detector (MSD and NPD). Column: 15 m × 0.32 mm id DB-5 ms 0.5-μm film thickness: 70 °C (0 min) to 280 °C (4.5 min) at 20 °C min^{-1}, He carrier 4 ml min^{-1}, injection port 250 °C, NPD 250 °C, and MSD transfer line 260 °C

by GC (nonvolatile thermally unstable compounds). Since the introduction of the DAD in the mid-1980s the ability to produce a UV spectrum has dramatically increased the use of HPLC systems for routine drug screening [38–41]. The identification of drugs is based on the combination of retention time and UV spectrum. Figure 23 shows the HPLC-DAD trace from an acid drug extract.

HPLC is the separation of components in a mixture based on the selective partitioning of compounds between a liquid-mobile phase and a stationary phase. The sample is introduced through an injection port into the mobile phase stream, delivered by the high-pressure pump, and moves through the column where the separation takes place. As the compounds are separated they are detected at the column outlet with a flow through detector or are transferred into the MS.

The selection of the stationary phase and mobile phase is important as alterations to one or the other can lead to improved compound separation particularly when there are endogenous compounds present.

Columns and Mobile Phases

Typical HPLC columns are 10–30 cm long with internal diameters of 2–4.6 mm. The columns are filled with small diameter particles (3–10 μm in diameter). For drug screening, the most common type of packing is based on bonded organic polymers; examples of these are styrene–divinylbenzene copolymers, used in reversed phase LC and octadecylsilane silica columns. Polymeric materials have an advantage over silica-based ones as they are more stable over a larger pH range.

Adsorption is the major mechanism in silica normal phase column/nonpolar mobile phase where the separation is achieved by the competition between analyte molecules and mobile phase molecules for the adsorption sites on the silica. Polar groups are retained more strongly than nonpolar ones and

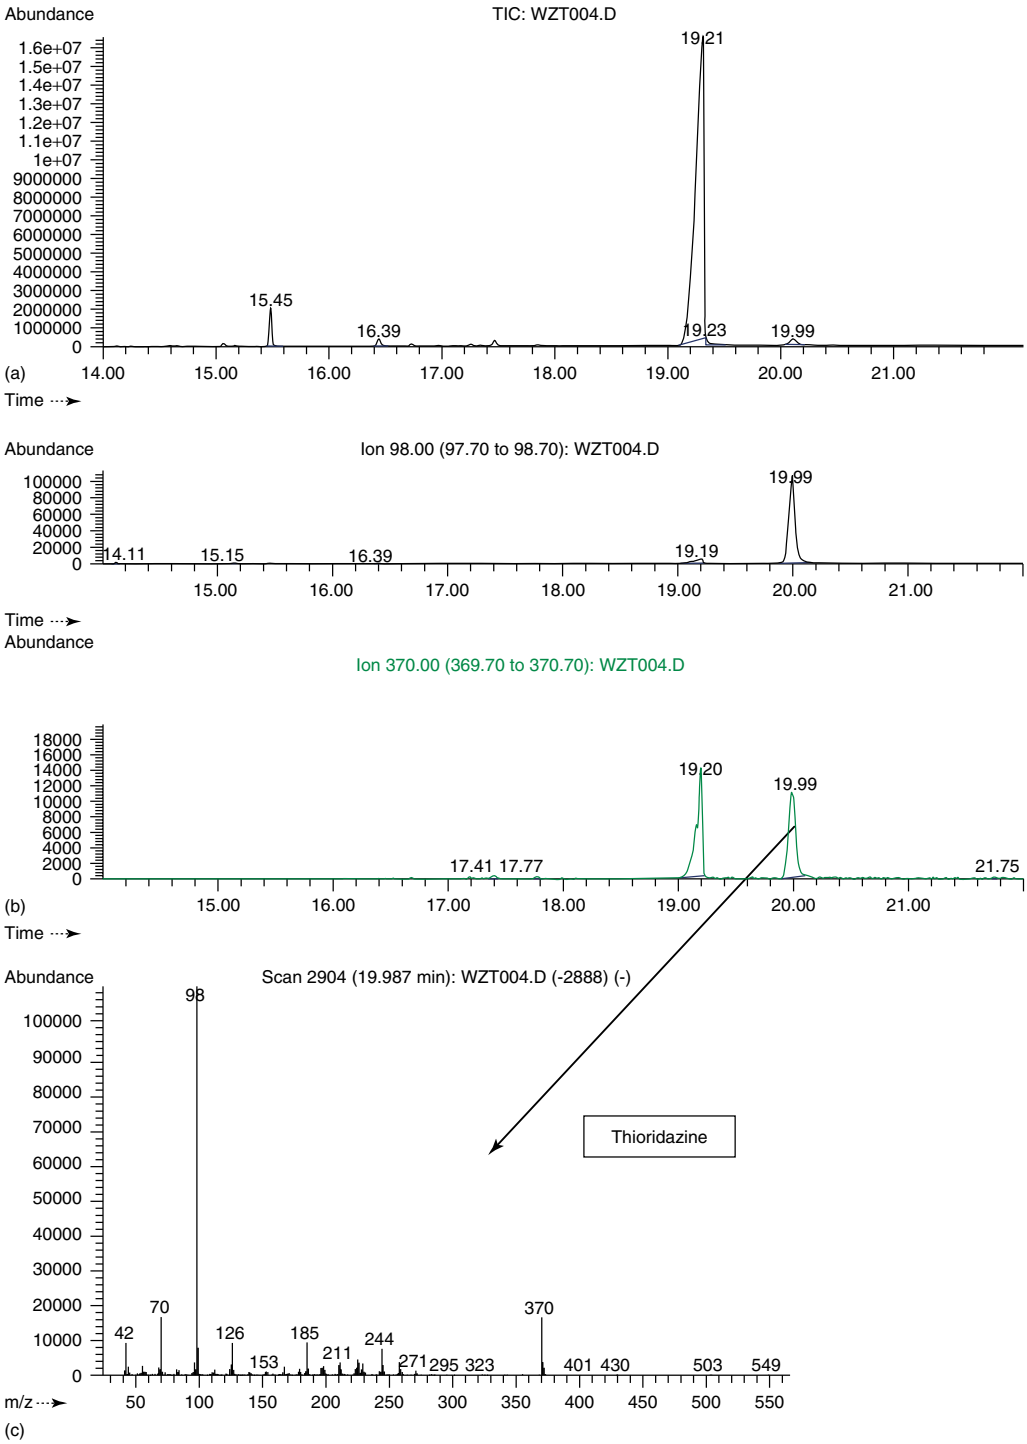

Figure 22 (a) Total ion chromatogram of blood extract. (b) extracted ion (m/z 98 and 370), and (c) mass spectrum – thioridazine

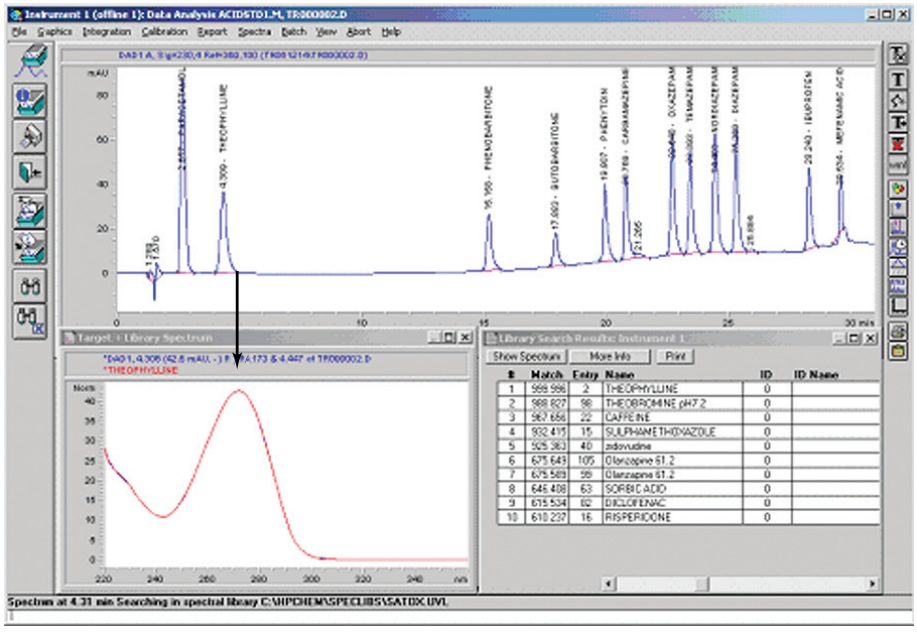

Figure 23 HPLC-DAD chromatogram of a drug mix showing the UV spectra and library search of theophylline. Agilent Zorbax SB-C18 (5 µm, 2.1 × 150 mm) with XDBC8 guard column (5 µm, 4.6 × 12.5 mm)

hence retention times increase as the polarity of the compound increases. Water is very strongly bound to silica and care should be taken to minimize the amount of water in the eluent solvent. The elution strength of the mobile phase can be varied by changing the proportion of miscible solvents of differing polarity.

By increasing the polarity of the elution solvent, the adsorption mechanism ceases to be the major mechanism, leading to difficulties in predicting retention behaviors. Often mobile phases consist of predominantly methanol modified with an aqueous buffer (sodium hydrogen phosphate or ammonium nitrate) and retention of the compounds can be controlled by pH, ionic strength, or methanol: aqueous ratio.

With reversed phase systems, the retention of compounds is controlled by the hydrophobic interactions between the drugs and alkyl groups bonded to the packing material. As the polarity of the analyte increases the retention will decrease. Polar mobile phases (usually acetonitrile or methanol) are modified with an aqueous buffer. Increasing the polarity of the mobile phase will result in an increase in retention time. The chain length of the alkyl group bonded to the packing will also affect the retention of compounds with an increase in retention and an increase in chain length ($C_{18} > C_8 > C_2$).

Liquid Chromatography–Mass Spectrometry (LC–MS) and Liquid Chromatography Tandem Mass Spectrometry (LC-MS/MS)

In recent years, the use of liquid chromatography–mass spectrometry (LC–MS) [42–48] and liquid chromatography–tandem mass spectrometry (LC–MS/MS) [49–53] in drug screening has developed rapidly. There are two main interfaces that allow the introduction of a liquid effluent from the HPLC column at atmospheric pressure into the high-vacuum MS system: electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI). In ESI, the column effluent is formed into charged droplets using a strong electrical field with ions produced from evaporating solution droplets. In APCI, the effluent is first nebulized and then heated with ions produced by gas-phase ion–molecule reactions. A series of low-pressure chambers and ion focusing lenses is used to optimally transport the ions into the MS. Both the ESI and APCI produce limited spectral information compared to electron impact mass spectra and

for identification purposes it is often necessary to perform secondary fragmentation. Figure 24 shows the separation of benzodiazepines and metabolites in blood using LC-APCI/MS/MS. Table 5 shows the selected precursor ions $[M + H]^+$ and the resultant product ions used for the identification of the compound.

One problem that is commonly encountered in ESI LC-MS is ion suppression. This results from a reduction of ionization due to the presence of coeluting compounds. These compounds can effect the formation of the charged ions in the liquid phase. If there is sufficient ion suppression of the drug(s) in the extract then they would not be detected and

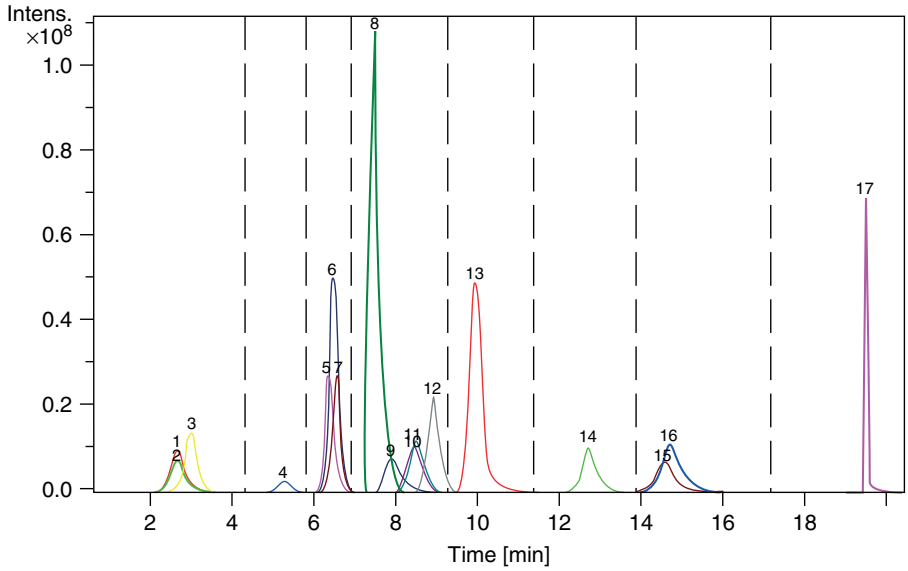

Figure 24 APCI product ion chromatogram for separation and detection of benzodiazepines: Agilent Zorbax XDB C8 column (4.6 × 150 mm, 5 µm particle size). See Table 5 for details of drugs

Table 5 Precursor ions and major product ions for each of the benzodiazepines and metabolites in Figure 24

Peak number	Drug/metabolite	Pseudo-molecular ion $[M + H]^+$	Product ion (m/z)
1	7-Aminonitrazepam	252	224
2	7-Aminoclonazepam	286	250
3	7-Aminoflunitrazepam	284	264
4	Bromazepam	316	288
5	Clonazepam	316	270
6	Nitrazepam	282	236
7	Flunitrazepam	314	268
8	Clobazam	301	259
9	Triazolam	343	308
10	Alprazolam	309	281
11	Lorazepam	321	275
12	Oxazepam	287	241
13	Temazepam	301	255
14	Nordiazepam	271	243
15	Diazepam	285	257
16	Midazolam	326	291
17	Prazepam	325	271

this could lead to incorrect results being reported [46, 54]. For this reason, the sample preparation should reduce the amount of endogenous compounds in the matrix extract that can lead to ion suppression and the effect of other compounds used in the analysis (salts, drugs, metabolites, and deuterated internal standards) should be evaluated before using this technique routinely.

Trace Evidence: Transfer, Persistence, and Value

Introduction

A list of the types of material that might be classed as trace evidences would be endless as the material encountered could range from the classical items such as glass and fibers to more obscure examples such as pollen, cosmetics, and dust. While the range of material is broad, the mechanics of transfer and persistence is generally the same.

Transfer of material from one item (donor) to another (recipient) is generally associated with contact between the two items. It may also be associated with proximity between the two items, such as glass transfer close to a breaking window or paint transfer by splashing. Direct contact on its own may not be sufficient for transfer to occur. There must also usually be some sort of action or force.

Factors that affect the degree of transfer of material include

- the duration of contact;
- physical strength of the contact;
- the nature and condition of the donor material; and
- the nature and condition of the recipient material.

Persistence over time of the transferred material on the recipient item is vital if forensic science makes any contribution in a criminal case. Rarely, the suspect in a crime is apprehended at time zero (immediately). Even if this happens, still there would be a time lag between the apprehension of the suspect and the seizure of the relevant items for laboratory examination. Normally, a suspect is apprehended minutes, hours, or days after the crime. The amount of transferred material remaining i.e., persistence, depends on a number of factors including

- the amount of material transferred initially;
- the time between the initial transfer and the recovery of transferred material;
- the nature of the transferred material; and
- the activities of the recipient item subsequent to transfer.

Transfer and persistence studies have been important to forensic science for many decades beginning with the writings of Dr. Edmond Locard in France in 1929 [1–3]. Initially, the interest stemmed from a need to understand the mechanism by which evidence may be generated and our need to understand the science behind the concept of "every contact leaves a trace". It soon became apparent that the results of such studies feed our expectations in the approach to casework. The emphasis in forensic science on the interpretation of results in the context of the background circumstances of the case in question took on a different angle through the use of a Bayesian approach [4–6]. Transfer and persistence studies have been valuable sources of data, which the forensic scientist can use to estimate probabilities and likelihood ratios. Information gained from such studies is also valuable to determine whether or not it is appropriate to seize certain material from a crime scene or to conduct certain laboratory examinations.

The underlying principles of transfer and persistence outlined above are applicable across the full spectrum of cases in forensic science; however, in light of the fact that the nature of the material in question affects both transfer and persistence, it is appropriate to examine the various evidence types individually. There is more published data on the individual commonly encountered types of trace than on the overall concept.

Fibers

One of the most important studies on the transfer of fibers was undertaken by Pounds and Smalldon [7] Ụsing wool and acrylic as donor items, a number of recipient items were examined. Their general conclusions were that the number of fibers transferred increased with the area of contact and pressure of contact, but decreased with consecutive contact passes and considerably varied depending on the recipient garment. The mechanism for the transfer was considered by the same authors [8] (*see also* **Examination of Fibers and Textiles**). They suggested that there were a number of mechanical processes taking place including

- transfer of loose fibers that are already on the surface of the fabric;
- loosely bound fibers are easily pulled out by friction; and

- new fiber fragments are created by the contact and are transferred.

Other studies confirmed the conclusions of the earlier studies and examined the transfer of various fiber types to different fabric types and to different surfaces [9–11]. Where a mixture of fibers exists in the donor garment, preferential shedding is frequently encountered and the minor component may be recovered disproportionably to its amount in the donor garment [12, 13].

The persistence of fibers was also studied by Pounds and Smalldon [14]. Further, the fibers being studied were wool and acrylic and the authors found no significant difference in persistence between the two fibers. The most significant factor was the time of wear of the recipient garment after transfer of fibers. Fiber loss is initially rapid with approximately 80% of fibers being lost after only 4 h. However, they recovered transferred fibers up to 34 h after initial contact. Subsequent studies [15–19] confirmed their results and posed other reasons for loss of transferred fibers, including other garments being worn over recipient garment, contact of recipient garment with other garments/objects, and the surface features of the recipient garment. Shorter fibers (<2.5 mm) persisted longer than longer fibers but that finding was not supported by a further study, which found no difference in persistence between short and long fibers. In addition to the loss of transferred fibers from the recipient garment, transferred fibers may be redistributed on the recipient garment. This can cause problems if significance is attached to the specific location of the recovered fibers.

The persistence of fibers in head hair was studied [20, 21]. Wool and acrylic ski masks were used as the donors. Initial rapid loss of transferred fibers was again a feature of the decay pattern. Fibers were recovered from the hair up to 6 days, provided the hair was not washed. No significant difference was observed between wool and acrylic. Differences in hair type did affect the number of fibers transferred and their persistence, fibers persisted more readily in "short coarse" hair than in "long fine"/"straight" hair.

Hair

Irrespective of the significance that scientists place on the evidential value of hair, it is a commonly encountered evidence type and it is important to understand the factors affecting the transfer and persistence of hair. Hair is lost from the scalp naturally each day. Hair transfer from the donor would normally occur by direct contact with the donor's head or by contact with the donor's clothing, which has shed hairs on the surface. The persistence of hair on clothing was examined [22] and found to display the same decay pattern as fibers with only a small number of hairs surviving a day's wearing of the garment. Other studies [23, 24] showed that the rate of loss of hair from the fabric differed depending on the fabric. Hair persisted longer on garments made from wool than on nonwoollen garments. It is suggested that the scales on hair and wool facilitate the hair to "hold on" to the woolen fibers (*see also* **Hair: Microscopic Analysis**).

Glass

Glass is a material that is frequently encountered in forensic science laboratories in the course of normal casework. In contrast with fibers and hair transfer, which normally involve contact, glass transfer will not occur if fabric comes in contact with a nonbroken glass surface. Particles of glass are not lost from the surface of the glass. The normal transfer situation is where the person actually breaks the glass (kicks, uses elbow, etc.) or is standing nearby when the glass is broken. Standing nearby could refer to that person using an object to break the glass, throwing an object to break the glass, or being an innocent observer to any of the other activities, which lead to the glass being broken. Pounds and Smalldon [25] examined the distribution of glass fragments on the floor and on individuals in front of a breaking window. They showed that the number of particles (>1 mm) per unit area falls off extremely rapidly with distance, decreasing by half for each 20 cm increase in distance. The effect was less marked for smaller glass fragments. For individuals standing nearby, the results were in line with expectations, most fragments were found on the individual who stood closest to the window. Very few large fragments (>1 mm) were found on clothing even when there were significant numbers on the ground surrounding the person. This suggested that the larger particles are not retained on clothing even for relatively short periods. One of the problems associated with transfer experiments using glass is the fact that the number

of fragments produced and the distance travelled will be affected by how the window is broken and with what force. Several studies [26–28] employed a pendulum to standardise the impact. Glass fragments were projected as far as 3.3 m. Another factor, which affects the transfer mechanism, is the window type and size. In practice, the exact circumstances of how a given window is broken in casework cannot be known and it may be impossible to estimate the number of fragments likely to have been transferred. It is suggested that it is possible to estimate the distance between the offender and the window (*see also* **Glass**). This is based on three likely positions of the offender:

- breaking the window with body (shoulder/elbow), distance would be 0.0 m;
- breaking by striking with tool or foot, distance would be 0.6–0.9 m;
- breaking by throwing an object, distance would exceed 1.5 m.

Glass fragments may also be transferred to the hair or headwear of the person who is suspected of breaking the window [29].

The persistence of glass has also been studied. An early study [30] used an air rifle to project glass particles of known size onto two fabric types, wool/acrylic and cotton (denim). The persistence of transferred glass was determined at time intervals from 30 min to 6 h. The results show that the size of the particles influence the percentage retained on the fabric. Particles of the order of 1 mm are retained longest. Particles less than 0.5 mm were lost earlier and it was found that cotton retained them better than wool/acrylic. In one experiment, the persistence after 5 days was examined and a small number of particles were found even after this time gap. Further studies on glass persistence were done by breaking a window and observing how many fragments were retained after a certain period of time [31–33]. Initial rapid loss was further seen and then a slowed loss over a period of time. Even 8 h after the breakage, as many as seven fragments of glass were recovered from clothing.

Apart from time, the main factors influencing persistence of glass are post transfer activity, nature of recipient garment, and the condition of the garment. Damp or wet would appear to be more retentive than dry.

Paint

The most frequently encountered mechanism of paint transfer in the context of forensic science is, contact together with some degree of force. This can be caused by impact or abrasion and the amount of material transferred will depend on the degree of force applied. In traffic accident situations, it is not unusual to have multiplayer transfer from one vehicle to the other and vice versa. In some cases, the paint is loosely attached to the substrate and contact with little or no force may be required for transfer to occur. This is more frequently encountered in household paint transfer, which is common in burglary cases. In most cases, however, the paint is firmly attached to the substrate and force is required for transfer to take place (*see also* **Paint**).

In the case of wet paint, transfer can occur by means of simple contact. In some instances, paint will transfer through the air by splashing or dripping.

The persistence of paint flakes on clothes has received little attention in the literature, but some surveys were conducted on paint flakes found on clothing [34, 35]. It has been suggested [36] that the persistence of paint particles would resemble that of glass, but the number of paint fragments likely to transfer to clothing would be very small in comparison to glass. When wet paint is transferred and dried, then this will persist indefinitely until the item is washed and even then may not be removed depending on the nature of the paint.

Gunshot residue

Gunshot residue or firearm residue is produced when a firearm is discharged. The mechanism consists of a number of chemical reactions and decompositions produced at the second the firing pin strikes the primer of the cartridge. The metal vapors from the projectile mix with the decomposition products and the resultant vapor ejects from all possible openings in the firearm and condense/deposit on items nearby, including the hands and clothing of the person discharging the firearm (*see also* **Firearm Discharge Residue: Analysis of**).

Once deposited, the gunshot residue will be lost continuously, depending on the activity of the individual. Laboratory tests indicate that gunshot residue will remain on the hands only for a short time period

[37, 38] but in casework detectable amounts were detected several hours later. It is suggested that the probability of finding gunshot residue on hands more than 3 h after firing is very low.

Hydrocarbon Fire Accelerants

Hydrocarbon fire accelerants such as petrol can be important when crimes such as arson and petrol bombings are being investigated. Hydrocarbon fire accelerants are volatile liquids and will transfer to clothing and skin by direct contact with the liquid or the vapor. Unlike the other materials referred to earlier, hydrocarbon fire accelerants will naturally decay because of their volatile nature; therefore, persistence is less dependent on post transfer activity but is highly dependent on time and environmental conditions, especially temperature. Little or no study has been done on the persistence of hydrocarbon fire accelerants. One study examined the persistence of petrol on clothing and shoes after pouring petrol around a room [39]. Evaporation rates from shoes, clothing, wood, and carpet material were studied [40]. They found that petrol could still be detected on carpet even after 7 days. The transfer and persistence of petrol to car carpets was studied [41]. The study showed that petrol can transfer from the soles of shoes to carpet and can be detected for up to 24 h. In the same study, petrol was deposited directly onto carpet and depending on the amount deposited, petrol could be detected after 7 days (*see also* **Fire Debris: Laboratory Analysis of**).

Recent studies on persistence on hands suggest that petrol can be detected for longer periods than was traditionally considered. This may be associated with improved detection as well as improved recovery.

Other Materials

Other materials, which can be transferred, include pollen, soil, vegetation, dust, and other particles. Few of these have received attention. Pollen transfer and persistence was examined [42], and the distance-decay pattern previously observed for glass was further observed for pollen in a room containing cut flowers. The greatest number of grains was found in close proximity to the flowers. Once pollen is transferred to clothing, the persistence depends on the level of activity after transfer.

Metal particles on clothing in forensic casework can arise in crimes such as safe breaking or burglary. Metal particles will be deposited by the stream of particles produced by the action of the abrasive disc of the angle – grinder on the metal in question. One study [43] showed that after transfer, larger metal particles are lost more easily than smaller particles and that particles could be detected on the recipient garment even after 17 h.

Biological Traces

Body fluids are a powerful source of information to the forensic scientist because of DNA (*see also* **DNA**). Increasingly, the key questions with the detection of a DNA profile on an item are, how did the DNA reach there (transfer) and how long was the DNA there (persistence)? For saliva, the method of transfer may be direct, by licking or indirect, by spitting. Blood transfer mechanisms have become an important part of the work of the forensic biologist because of bloodstain pattern analysis. Generally, transfer will be by contact or by airborne transfer. Semen is normally transferred by sexual intercourse or external ejaculation onto clothing.

The persistence of saliva on skin and clothing has had limited attention [44, 45]. A recent study shows that saliva will be detected up to 4 days on the skin of living persons [46]. Saliva has been detected on clothes up to 28 days [47].

The persistence of semen on vaginal and other swabs has been studied [48] and semen has been detected on vaginal swabs up to 7 days after intercourse. It is believed that if semen is deposited on clothing it will survive indefinitely providing the conditions are not such as to encourage biodegradation. Washing of clothing will not necessarily remove the semen but will render the detection difficult.

Once blood is deposited on a surface, it will remain there indefinitely unless removed by cleaning or washing. If the conditions are damp or musty, then degradation can occur. The question of aging of blood is occasionally encountered, but there are difficulties in addressing the issue and generally it is not considered to be possible.

Problems with Transfer and Persistence

Transfer and persistence studies can be beneficial to forensic science in trying to understand how

something may have entered into an item originally and how long it is likely to remain on the item. There are dangers associated with drawing conclusions based on these studies. In most cases, we do not know the exact circumstances of the action, which lead to the transfer. How long exactly were the two people struggling? Was it a strong/very strong interaction? What was the exact surface area of the contact? How far away exactly was the person standing who threw the brick at the window? What exact force was used to throw the brick? What exactly has the suspect been doing since the crime that could have lead to loss of material from his/her clothing?

In the absence of answers to the above questions, we are in a difficult situation in estimating expected amounts of material persisting after a given time period as we do not know the amount transferred at time zero. The presence of CCTV footage and some eyewitness accounts can help inform our decision making in the area. It does not mean that we cannot make a reasonable estimate and especially if we have done some reconstruction experiments.

Another complicating factor is the phenomenon of secondary (or higher order) transfer. This arises where there is transfer from the primary donor to recipient number 1 and recipient number 1 subsequently transfers to recipient 2. The first recipient may be a person or some object such as a chair/car seat.

Secondary transfer of fibers has been studied [49, 50]. In general, the likelihood of secondary transfer of fibers is higher if the initial recipient is a chair/car seat rather than items of clothing. If the number of fibers initially transferred is high then this provides a large pool of fibers with the possibility of further transfer. When small numbers of fibers are recovered, the interpretation may be difficult and the scientist must examine the background circumstances to establish if primary or secondary transfer is in operation. Secondary transfer may also be beneficial to the investigation of crime. One study examined the secondary transfer of fibers from ski masks via head hair to pillowcases [50]. While the fibers from the ski mask would be lost from the head hair relatively quickly, a link between a suspect and the ski mask could be established indirectly via the fibers recovered from the pillowcase. Secondary transfer may also lead to a redistribution of fibers once transferred, and this phenomenon was recently examined using ski masks [51]. Fibers, which were seeded onto the inside, were recovered from the outside and *vice versa*.

Secondary transfer of hair has also been examined and this is a common occurrence, as the head hair is frequently shed to the persons' clothing as the initial transfer and subsequently transferred to recipient number 2. Some of the factors which favor secondary transfer of hair were also examined [22].

Secondary transfer of glass has also been studied [52, 53]. The studies examined scenarios where a person has broken a window and then travels in a car with another individual. Very little secondary transfer was observed. If a person carries an item, which has broken glass on the surface, then the conditions favor secondary transfer.

In most cases, secondary transfer of paint does not occur. A vehicle colliding with one vehicle and subsequently colliding with another vehicle could give rise to secondary transfer. A tool used to cause damage to a painted surface could transfer paint from that surface to the scene of the next burglary. This could in fact be used to link both scenes.

Secondary transfer can occur in relation to DNA evidence also. Transfer of DNA from one individual to another and subsequently to an object is possible under specific laboratory conditions [54, 55].

Secondary transfer is essentially the mechanism whereby contamination of items can take place. Whether it is the crime scene examiner or forensic scientist, anti-contamination measures must be established to ensure that they are not the intermediaries that facilitate unwanted transfers.

Conclusion

There are essentially two methods of transfer of trace material, by direct contact such as with paint and fibers or by a contactless transfer such as with breaking glass or gunshot residue vapor. Persistence studies are generally influenced by the same factors where time since transfer has a major effect on the amount of material recovered. Decay patterns over time for most materials will have a similar profile.

Transfer and persistence studies help to increase our knowledge on the basic mechanics involved in trace evidence exchanges. The information gained can help decide whether trace evidence is likely to

be present on a suspect's clothing after a certain time lapse. In addition the results can be used to inform our expectations on how much of a certain type of evidence we would expect to find based on the background circumstances of the case. These expectations can then be used in our case assessment and interpretation framework.

Persistence studies invariably depend on our ability to detect small amounts of trace evidence, and advances in searching and analytical processes will push out the boundaries of detection.

Much of the work on transfer and persistence was carried some time ago and there is scope for the area to be revisited specifically with respect to epithelial cells/touch DNA.

Traffic Fatalities

Introduction

Globally, the annual number of traffic deaths has risen to more than 1 million after 2000. The rate of traffic fatality during the last decades has decreased in high-income countries but increased in low-income countries. For all countries, the annual cost of road injuries in terms of medical care, disability, and property damage has been estimated to exceed USD 50 billion [1].

To enable the application of the best available preventive measures, better knowledge of the causes of fatal traffic crashes is desired. In the following, we present some data regarding different types of traffic deaths, followed by a section regarding different preventive measures.

Intentional Deaths

Although traffic homicides probably represent an extremely small fraction of all traffic deaths, suicides are estimated to be constitute a few percent of all motor vehicle crash fatalities [2–4]. For obvious reasons, suicides in traffic may, however, be underestimated [5]. Suicide by motor vehicle crash typically involves a single vehicle, single occupant crashes, or a head-on collision of a single occupant vehicle with a heavy goods truck. Many of the victims have attempted suicide on at least one previous occasion and about half of the traffic suicide victims have a mental insufficiency. Inebriation of alcohol is also frequently described in these crashes. For obvious reasons, these characteristics are typical of the cases we recognize as suicides, and the characteristics described may thus be biased. One must also consider the possibility of "hidden suicides" when the victim makes the suicide look like a unintentional traffic crash, e.g., for insurance benefits. It is, however, impossible to have a reasonably safe opinion regarding what the victim actually intended during the seconds before crash, and consequently the circumstances and the previous history of the victim are crucial factors in the classification process. But, even in a "typical" case of head-on collision of a single occupant vehicle with a heavy goods truck, there is still the possibility that the driver fell asleep and did not intend the collision, and the case will be even more difficult to classify if the victim was inebriated. In some cases, the autopsy findings may be indicative in themselves, e.g., when other signs of self-destructive behavior are revealed.

It should be noted that "traffic suicides" are not necessarily restricted to those killed in vehicle crashes, but include also the people who use the traffic environment to commit the suicide, and that also such suicides are subject to preventive measures. For example, suicide by jumping from a bridge represents a method where the potential of prevention is great [6].

Unintentional/Accidental Deaths

These cases form the vast majority of road traffic deaths, and represent probably more than 80% of all traffic deaths. The remaining deaths are distributed as follows: 2–3% suicides, ~2% undetermined manner of death, and some 10% natural deaths at the wheel [4]. Although some preventive strategies such as deformation zones may apply to all types of traffic incidents (cf. [7]), railway, watercraft, and aircraft fatalities will not be further discussed here.

The majority of accidental traffic deaths occur in road traffic, involving passenger cars and/or trucks, and where other traffic elements are more seldomly involved. In rural areas, however, off-road traffic fatalities form a significant percent of all traffic deaths. For example, in Northern Sweden, snowmobile-related deaths form the third most common group of all traffic-related deaths, and the number of deaths involving ATVs (all-terrain vehicles) is increasing (cf. [8]). Both these types of off-road traffic deaths involve mostly younger males, and are significantly related to high speeds and drunken driving [9, 10].

Natural Deaths

Deaths in the traffic environment due to natural causes are estimated to represent a minority of all traffic deaths. Several factors, among others a low autopsy rate and other biases in the statistics might, however, underestimate these types of events. In addition, in severe traffic trauma, natural death might go undetected since the injuries are expected to cause the fatality or, occasionally, since the body is severely mutilated and not allowing the pathologist

to correctly examine crucial inner organs such as the heart. It is clear though, that many natural deaths of passenger car drivers are associated with no or only minor injury and property damage. This indicates that the driver experiences some warning symptoms and consequently reduces the speed or even brings the vehicle to a stop before he becomes unconscious [11]. In the medico-legal investigation, the main findings in these cases are absence of severe injuries and presence of more or less severe pathological findings of disease, most often some form of ischemic heart disease [11].

A closely-related issue is to what extent an (acute) disease can be considered to have "caused" an accident where traumatic injuries have caused the death. In a study of 480 traumatic traffic deaths, disease processes was judged to "probably" have caused the crash in 6% of all deaths, of which in 1.3% the causal relationship was considered "very probable" [12].

Undetermined Manner of Death

In a few percent of traffic deaths, there are some – but not enough – indications of a suicide, and in these cases the forensic pathologist classifies the manner of death as "undetermined". The same is the case in even fewer cases, where there are signs – but not enough – of a natural death, or a homicide.

Prevention – Precollision Phase

During the last decades, vast improvements have been made regarding the traffic environment, including improvements and/or introduction of traffic lights, signs, flyovers, highways, speed reduction, game fences, etc. The vehicle itself is of course also under constant development, and reformed driver's education, information campaigns toward high risk groups, differentiated insurance rates, police surveillance and so forth, has also aided in reducing the risk and effects of crashes. More recently, the importance of separating passenger cars from heavy vehicles has been emphasized [13].

Disease. Preventing people with different diseases to drive a car is a very controversial issue. Also from a medical standpoint, it is in many cases hard to argue in favor of restrictions, since we do not have the instruments to identify the individuals 'at risk'. Of course, in individuals with loss of hearing, loss of eye sight, advanced dementia, etc., this decision is easily made. But it must at present be considered impossible to identify for example, which individuals have a coronary heart disease of such an advanced stage that continued driving must be prohibited because of the danger posed to the driver himself or others. To do this with presently available methods, large sums must be spent on advanced medical examinations, and a large population of drivers must be stopped from driving. In an autopsy study of 480 consecutive traffic deaths, 85% of the drivers over 70 years of age had medical factors that could lead to sudden incapacitation of driving ability [12], but only a small proportion of the victims had sought medical care for the disease.

Drunken Driving. Alcohol is a well-known risk factor in traffic accidents, and as the first country, Sweden passed in 1941 a law prohibiting drunken driving. Mainly, ethanol has a hypnotic and anesthetic effect on the central nervous system, and the seemingly stimulating effect is the result of a primary depression of higher centers in the brain, resulting in an unchecked behavior. Already in low concentration, ethanol has a negative effect upon judgment and motor functions. It has been estimated that at a blood alcohol concentration of $1.5\,g\,l^{-1}$, the risk of a car driver to be involved in a crash causing personal injury has been estimated to be about 300–600 times higher than when driving sober (cf. [14]).

Owing to the measures taken to reduce the number of alcohol-related deaths and injuries in traffic, the percent of alcohol-related crashes has decreased in many high-income countries. The percent of alcohol-related crashes resulting in a fatality is, however, still very high – in the United States, the percent is around 40% [15]. In Sweden, a country with a very restrictive view on drunken driving – both legally and according to the public opinion – the percent is still high, around 20% of traffic deaths, and exceeding 50% in fatal single vehicle crashes (but around 10% in multi vehicle crashes) [16]. Obviously, it seems very difficult to further reduce the percent of alcohol-related incidents. Although inebriation of vehicle drivers is most dangerous, the negative effect of alcohol is also obvious in cyclists, pedestrians, etc. [17, 18]. Another aspect is that fighting against drunken driving might displace this problem to other categories of road users [18].

One explanation for this is most certainly that a considerable proportion, may be 60% or more, of the drunken drivers are chronic alcoholics, who do not care about the legal implications of drunken driving. Autopsy findings in support of chronic alcoholism are, mainly, a high or very high ethanol concentration (on average often around $1.7\,g\,l^{-1}$ in fatally injured drivers) and the finding of liver steatosis without any other medical explanation.

As a consequence of the findings presented above, effective treatment of alcohol abuse would certainly have a beneficial effect. Another measure would be the introduction of a so called alcolock, a device which allows the driver to start the engine only if his breath is free from ethanol. In recent years, alcolock devices have become mandatory in commercial vehicles in some countries.

Drugged Driving. Whereas alcohol has been known for a very long time period to cause or contribute to traffic crashes, other drugs have attracted interest only in more recent times. Legislation regarding driving under the influence of drugs is, however, tricky, since many people are taking prescription drugs which may have an effect on the ability to drive. The drugs used may differ between different countries, but benzodiazepines and central stimulants are two of the most common according to the literature [19].

Young and Old Drivers. The risk of fatal or severe injury is six times greater among 18- to 19-year-old drivers than among 45- to 54-year olds, mostly because of higher speed and lesser driving experience. Also elderly persons are subjected to higher risks of injury and death; the risk is twice as high in the ages 65–74, and six times higher in the ages 75–84 [20, 21]. With an aging population, and successively older vehicle drivers, age-related health problems are expected to play an increasing role in the prevention strategies, e.g., regarding dementia (cf. [22]).

Prevention – Collision Phase

This is the true phase of injury, when the kinetic energy ($mv^2/2$) transforms to heat and energy-consuming deformation of the vehicle and the human body. To reduce the deleterious effects of this energy transformation, which are generally associated with rapid deceleration, it is important to reduce the pressure (i.e., the amount of force per unit area) when the body hits the interior of the vehicle, or reduce the rate of deceleration. This can be achieved by decreasing the speed of deformation by distributing it over a larger area and over a longer time period. Airbags provide one example where the design is such as to provide a large surface area which spreads the force applied to the body over a wider area.

Similar principles may be applied to the vehicle itself by constructing deformation zones. Irrespective of the protection measures taken, forces and consequent risk of injury is proportional to the deceleration.

Safety belts increase deceleration time in the collision phase, distribute the deceleration forces to the pelvis and over the chest, decrease or derate the effect of head injury, and decrease the risk of ejection from the car. The safety belt has a high protective effect and has been reported to decrease the risk of lethal injury by 40% and to reduce personal injuries by 50%.

Air bags represent a passive safety system which at a rapid deceleration will inflate and form a protective balloon between the person and the interior of the car. Air bags were primarily constructed to reduce the risk of serious head injury in frontal collisions, but also have a protective effect regarding neck injuries, and have been reported to reduce both these types of injury by approximately 40%. Air bags should always be used in combination with safety belts.

A variety of *protective devices for children* have been introduced during the last decades. These include a number of different child seats, designed for different ages (body sizes), where the forces are distributed over a larger body area, and where the intergroup movements of torso and head are minimized. Persons with a body height of less than 140 cm are not recommended to sit in front of an air bag since this may increase the risk of head and neck injury.

Rear end collision may cause disabling neck injuries, so called whiplash injuries, and *head-rests* have been shown to significantly reduce this type of injury.

It has been calculated that the use of *helmets* may reduce fatal injuries among bicyclists by 40%, and severe injuries by approximately 70% [23], and similar figures are also applicable to motorcycles. Helmets have, however, probably not a similar protective effect in snowmobile crashes [24].

Prevention – Postcollision Phase

After the crash, effective medical care and rehabilitation are most important to reduce the long-term effects of traffic injuries. Alarm and ambulance systems and highly specialized trauma care have gone through a rapid development in high-income countries, including the use of helicopter transports, especially in remote areas [25] to minimize delay. The potential to save lives and to reduce long-term effects of injury through optimized medical care is significant [26, 27].

The Postmortem Examination in Traffic Deaths

In many countries, fatally injured traffic victims are subjected to a medico-legal autopsy, following a police investigation of the crash. The reasons for such an approach is in part to investigate whether further legal actions are motivated from the law enforcement, but also to give a basis for in depth investigations, as already for a long time have been applied in aviation crashes. In this way, data from the traffic environment, the vehicles involved, and the injured victims are gathered and processed by a multi-disciplinary team. To optimize the quality of data from the victims, medicolegal autopsies are routinely performed in many countries. In the postmortem examination, the determination of the cause and manner of death is of great importance, but additional questions to the traffic investigation might also be answered, for example the use of seat belts, position in the vehicle, and time of survival. The medico–legal investigation includes a careful external and internal examination of the body including histopathological investigations in order to document injuries and signs of disease. Toxicological analyses including alcohol and drugs are also of paramount importance for the understanding of the fatal crash.

The following are the main tasks of the forensic pathologist in the investigation of traffic deaths:

- To reveal the cause and manner of death – for the cause-of-death statistics, for the next-of-kin, and for accident preventive work.
- To assist in any reconstruction of the event after analysis of the case, including autopsy findings and the results of toxicological analyses.
- To diagnose any disease – including also previously unknown disease – which may have initiated the crash, or contributed to death.
- To reveal if any medical treatment before (and after) the crash has been effective and relevant, since imperfections in these respects may have caused the crash and/or have influenced upon the chances of survival.
- To act as a "whistle blower" in cases where extraordinary findings are made, e.g., new drugs, changes in drug panorama, and new injury patterns (cf. [28]).

The final aim is of course to find and introduce preventive measures, in order to reduce the traffic fatalities and injuries.

ANDERS F. ERIKSSON AND MATS G. ÖSTRÖM

Training and Certification (in Criminalistics)

Introduction

Criminalistics is composed of many different sciences and covers a large spectrum of disciplines. As a result, training[a] in criminalistics must be strongly based on natural sciences (physics, chemistry, and biology) as well as emphasize topics specific to criminalistics and the criminal justice field. To obtain his/her basic training, the future criminalist can choose to attend one of the rare university programs offering a comprehensive coverage of forensic sciences, to attend a university offering a natural science degree with an emphasis in forensic sciences, or to pursue a regular natural science degree [1, 2]. Well-known university degrees in forensic sciences (or with a forensic emphasis) include the ones offered by the School of Criminal Sciences of the University of Lausanne in Switzerland, the Centre for Forensic Science of the University of Strathclyde in Scotland, and the Centre for Forensic Science of the University of Technology Sydney in Australia. When attending universities offering a natural science degree with an emphasis on forensic sciences, one must be careful in choosing a program. Owing to a recent global interest generated by the production of idealized TV shows, a plethora of university programs have been developed with the claim of forming forensic scientists. Extreme caution is required with some programs that offer no more than a curriculum that merely includes a few criminal justice and forensic classes taught by professors who have little or no experience in forensic sciences.

Another problem is the existence of "broad brush" courses taught by people with previous forensic experience but who rely solely on their experiences and do not include a robust underpinning science component. As a result, students graduating from such programs may falsely expect to become forensic scientists; however, they have acquired little if no notion of the basic principles of forensic sciences and are no more prepared to work in the forensic science field than a regular chemist, biologist, or physicist. Overall, a balance must be struck.

In the United States, where this problem is prominent, the Technical Working Group on Education and Training in Forensic Science (TWGED) issued a document defining the minimum requirements for the core curriculum of a forensic sciences degree [3]. Another very interesting and more informal approach was developed by the National Institute of Forensic Science (NIFS) in Australia: a list of questions that a prospective student, or parents, can ask about a university program was defined, along with desirable answers from the forensic science industry perspective [4]. This allows the student to carry out a relatively good assessment of the seriousness of the university program and to evaluate its content vis-à-vis the intended career.

Table 1 shows the requirements set forth by TWGED for some specific forensic scientists [3]. Generally, it is often recognized that a minimum of a bachelor's degree in a natural science, criminalistics, or a closely related field is necessary to work as a forensic scientist [5, 6]. However, academic education is not a criterion sufficient to start working in a crime laboratory on real cases, although it is a solid and necessary starting point.

Figure 1 shows the path followed by a forensic scientist during his/her career. After academic education, the forensic scientist must undergo a period of training, which will lead to his/her full operability at the crime laboratory and at crime scenes. After this induction training, a continuing education program is also devised to ensure that the criminalist is up-to-date with evolving science and that the most appropriate and valid science is applied in casework.

Induction Training Programs

A newly hired, inexperienced criminalist cannot immediately work on real cases, but spends a certain amount of time getting field-specific education by learning from his/her colleagues and working on mock cases. Before they perform casework, all newly hired forensic scientists will have to follow an initial training program, also known as an *induction training program*, which can vary significantly in length based on the person's previous education and on the operational institution's resources, sometimes up to two years. This initial training can be defined as [3] "the formal, structured process through which a forensic scientist reaches a level of scientific knowledge and expertise required to conduct specific forensic analyses." If the university degree conferred did not include a major forensic component, the training will likely be extensive and must include the basic principles of forensic sciences. By contrast, the student who followed a valid forensic program will typically require less training before he/she can work on real cases.

The program includes on-the-job training as well as specialized education. Even when the candidate has a comprehensive forensic degree, a certain level of specialization may be required when working in some particular domains. This training may be obtained through designated courses or university programs, or from the laboratory where he/she works in the form of on-the-job training. Responsibility is gradually increased as the criminalist starts working on real cases under the very close supervision of more experienced colleagues or supervisors. After the induction training period, which may conclude with successfully completing an examination, the forensic scientist may undertake his/her own casework independently.

Continuing Training

The training of a forensic scientist does not stop at the end of the initial training period. Forensic scientists face a constantly evolving criminal element combined with ongoing technological advances and, as a result, have to develop new techniques and methods. Keeping current with modern criminalistics is a necessary process referred to as *continuing training*, and can be defined as [3] "the mechanism through which a forensic scientist remains current or advances to a higher level of expertise, specialization, or responsibility". This can be achieved through continuing education as well as practical experience.

Table 1 Sample curriculum for undergraduate forensic sciences degree proposed by TWGED [3]. These examples are based on a minimum of 120 semester hours to obtain a degree. Credit hours as described above are meant to indicate semester credit hours[(a)]

	Firearms Impression evidence Questioned documents Prints	Chemistry evidence Controlled substances	Biology
University general education (36–40 h)	Courses required by the university, which may include language, humanities, social sciences, technical writing, mathematics, computer science, and public speaking. Credit hours required will vary from one university to another. Some forensic degree coursework may count toward fulfilling these requirements		
Natural science core (34–38 h)	Biology I	Biology I	Biology I, II
	Calculus	Calculus	Calculus
	General chemistry I, II	General chemistry I, II	General chemistry I, II
	Organic chemistry I, II	Organic chemistry I, II	Organic chemistry I, II
	Physics I, II	Physics I, II	Physics I, II
	Statistics	Statistics	Statistics
Specialized core (12 h)	Inorganic chemistry	Analytic chemistry quantitative	Biochemistry
	Instrumental analysis	Inorganic chemistry	Genetics
	Optics/lasers	Instrumental analysis	Instrumental analysis
	Physical chemistry	Physical chemistry	Molecular biology
Forensic science core (6 h)		Forensic science survey	
		Forensic professional practice	
Forensic laboratory science (9 h)	Internship	Forensic chemistry internship	Forensic biology internship
	Microscopy	Microscopy	Microscopy
	Physical methods	Physical methods	Physical methods
Additional courses (19 h)	Crime scene	Advanced instrumental analysis	Cell biology
	Image analysis	Drugs	Introduction to criminal justice
	Introduction to criminal justice	Introduction to criminal justice	Legal evidence
	Legal evidence	Legal evidence	Microbiology
	Materials science	Analytical toxicology	Population genetics
		Materials science	Immunology
		Pharmacology	Public speaking
		Public speaking	

[(a)] Reproduced from Ref. 4. US Department of Justice, 2004

Continuing education may be obtained through two main categories: scientific literature (autodidactic manner) and attendance at courses and conferences.

Scientific literature: The forensic scientist should regularly peruse scientific periodicals, such as *Forensic Science International, Science & Justice, Journal of Forensic Sciences*, the *Canadian Society for Forensic Science Journal*, and the *AFTE Journal*. Articles relevant to his/her domain of competency should be carefully and thoroughly read and understood. The criminalist should also be acquainted with additional scientific journals more focused on some specific topics of a natural science or other relevant disciplines that publish articles pertinent to forensic sciences on a regular basis. Most crime laboratories have subscriptions to some of the most important journals addressing forensic sciences topics.

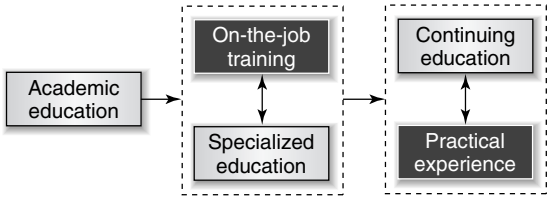

Figure 1 The career path of a forensic scientist

Courses and conferences: Attending conferences is also extremely important. The scientific value of the presentations is a serious asset to continuing education, as is the possibility of sharing information with other practicing colleagues. Many professional organizations conduct conferences on a regular basis, such as the triennial meeting of the European Academy of Forensic Sciences, the annual meeting of the American Academy of Forensic Sciences, the biennial symposium of the Australian & New Zealand Forensic Science Society, and the triennial meeting of the International Association of Forensic Sciences.
Different associations around the world also offer topic-specific courses. These classes usually provide excellent continuing education. The basic and advanced fire debris analysis courses organized by the Bureau of Alcohol, Tobacco, Firearms and Explosives with the National Center for Forensic Sciences (USA) are some examples.

Furthermore, the experience gained from handling practical casework is also a valuable addition to the constant evolution of the criminalist's skills. This is particularly useful when combined with other activities, such as scientific research and teaching. Although teaching is a valuable asset to continuing education, criminalists also must keep learning from others and reevaluating themselves from time to time.

Certification

The goal of certification for personnel is to provide a formal and objective guarantee that a candidate has a minimal level of knowledge, skills, and abilities (KSA) in a given discipline. The KSA constitute the (defined) competency of a person. This competency is formally recognized through the delivery of a certificate and, in many instances, becomes visible with the addition of initials after the person's name. The process of certification should be voluntary and must include an objective peer review of one's education and experience as well as the successful completion of a series of examinations.

Criminalistics encompasses a wide variety of different areas, and thus personnel must meet a large number of skills and competencies. This renders the certification process quite complex and, as a result, it may be quite difficult for a small organization to have its personnel certified (and/or to maintain certifications) in all different areas.

Program Development

In order to set up a certification program, the following three conditions must be met [7]:

1. The KSA of the criminalist must be clearly defined.
2. An efficient manner of evaluating the criminalist's competency must be developed.
3. The certification must be recognized by professionals in the field (both providers and clients) as proof that the criminalist reached the level of competency defined under (1).

The definition of the level of competency of forensic practitioners is the responsibility of professional organizations. As such, it is one of the goals of the California Association of Criminalistics (CAC) and the Forensic Science Society (FSS) [8]. As professional organizations are constituted of members active in the forensic community, they are the decision makers that will act in the best interests of the profession.

Although it is obvious that there should be a minimum level of competency common to all forensic scientists – fundamental forensic concepts, principles of identification and individualization, chain of custody, ethical constraint – each discipline's certification will have its own definition of KSA. The European Network of Forensic Science Institutes (ENFSI) published a comprehensive document defining the baseline competency for forensic practitioners [9]. This document exposes the general concepts that all forensic scientists should acquire, and may be used as a baseline to develop other certification programs in different specialties. Nevertheless, other professional organizations have defined competency levels for the certification in different specialties. For example, the Scientific Working Group for Fire and Explosives (SWGFEX) produced the *Training guidelines*

for the fire debris analyst, which defines the minimum KSA for a person to become a fire debris analyst [10] (*see also* **Fire Investigator: Standardization, Accreditation, and Certification**), just as the Scientific Working Group for the Analysis of Seized Drugs (SWGDRUG) produced a *Training and Education* document defining the minimum KSA criterion for a drug analyst working in a forensic laboratory [11]. Other organizations have published documents in their respective disciplines [12–14].

Once the KSA is defined, it is necessary to develop a method of evaluating a candidate and determining whether or not the competency level has been reached. There are several possibilities to test a candidate's competency. In general, an efficient certification program will include a written examination, an oral examination, and a practical examination or a proficiency test. It is only through the combination of these three exams that the criminalist's competency can be comprehensively tested. A written examination tests the entirety of the knowledge of the discipline. Such an examination should not be exclusively constituted of multiple-choice questions, but should also include some development questions. An oral examination tests one's capacity to reason with the acquired knowledge on a particular topic. As an alternative to a regular oral examination, the candidate could be asked to defend a certain number of case reports. This tests one's aptitude to justify one's actions and to reason through a particular scenario, a very important quality. Finally, a practical examination, while expensive and cumbersome to organize, is the best manner of observing a forensic practitioner in his/her everyday medium and evaluating his/her ability to apply his/her knowledge in practice. For example, a fingerprint examiner would be asked to make a few fingerprint comparisons and identifications or a drug analyst would be required to analyze several unknown samples. Alternatively, a proficiency test can be used *in lieu of* a practical examination. In this case, it is important to understand that there will be no direct control over how the test is performed.

All of this effort would be useless if the professional community did not recognize the certification program. This goal is automatically (but not instantaneously) achieved when the first two conditions are irreproachably fulfilled. However, the reputation of a certification program takes a long time to be established and is highly influenced by the behavior of its members. Also, the independence of the certification organization is highly influential to the well being of the program. For example, an organization should not offer both the certification program and the training to take the certification. Thus, a university can offer training, but should not certify its graduates. This lack of independence would damage the professional community's recognition of the certification. When a particular discipline benefits from several organizations, it may not be wise for each organization to develop its own certification program(s). Besides the obvious redundancy, this contributes to a dilution of the programs and a diminished recognition of the value of the certification. As a good example, the American Board of Criminalistics offers several certifications; however, they do not offer any training.

Certification Process

Each certification organization has its own process. However, a generic process is described here (Figure 2). The process can be divided into three main steps: application, evaluation, and recertification.

First, the criminalist who desires to obtain certification must complete an application, for which a certain number of criterion or prerequisites must be met. These prerequisites usually concern education (and possibly training) and experience. Other requirements, such as citizenship in the country in which the certification organization is registered, a minimum age, or no criminal records, also may be necessary. In some rare circumstances, the organization may require a particular training. This is the case with the National Association of Fire Investigators (NAFI), which requires each candidate for the vehicle fire investigator certificate to attend their four-day *NAFI/CVFI vehicle fire investigation course* [15]. A more elegant solution would be for an organization to require that the candidate follow a class or course provided by a third-party organization.

Once the application is received by the organization and all requirements are successfully met, the candidate may be evaluated through examinations. The registration fee for the examination is usually a couple of hundred US dollars. Whenever the candidate successfully passes all examinations, a certificate is issued for a given period of time.

Since the validity of the certification is limited in time, a recertification process ensues. In general, most

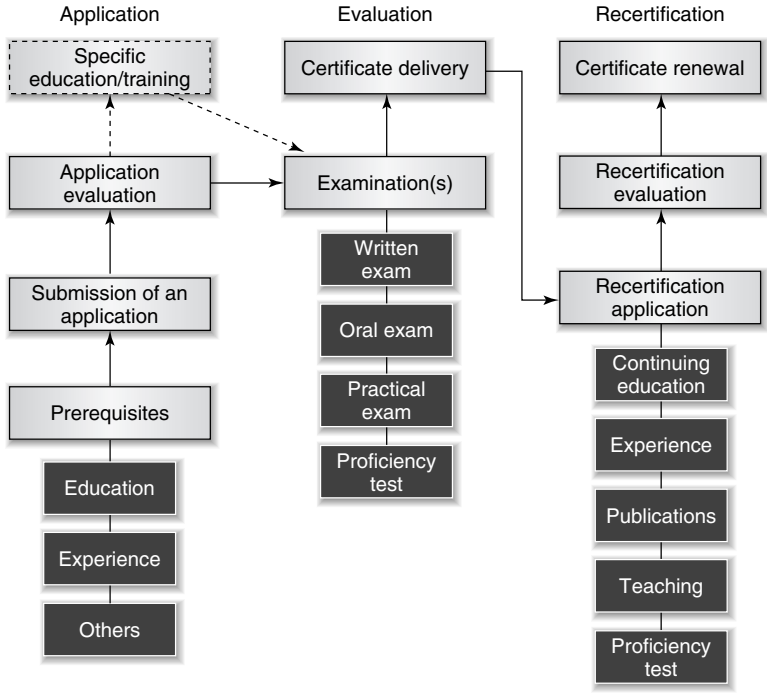

Figure 2 The generic process of certification

certificates are valid for a period ranging from two to five years. The recertification process usually consists in completing paperwork and demonstrating that the requirements necessary to maintain certification were fulfilled. These requirements typically consist of continuing training – practical experience and attendance at courses or conferences – as well as the publication of scientific articles and successful completion of proficiency tests. A system with points for each category is developed and, upon the acquisition of a given number of points, the certificate is renewed for a new period of validity.

Advantages and Drawbacks

It is important to understand the limitations of a certification program. A perfect certification program defines rigorous competency criteria and guarantees an infallible evaluation of a criminalist, and, as a result, certification should be a synonym of competency. This is the idea behind a certification program: To certify the criminalist's competency with full guarantee. Unfortunately, in practice, it is not possible to consider all certificates as proof of competency [7]. The reasons behind the gap between competency and certification are multiple; however, the main one lies in the evaluation of candidates. To date, there are no flawless examination processes that will guarantee the competency of the successful candidate. This problem has been recognized by the American Board of Criminalistics, which states that [16] "No single examination is a total measure of an individual's ability to do the work. Examinations measure knowledge and reasoning" and that "knowledge measured on an examination only reflects the understanding at that point in time. Continuing professional education is needed."

Another fundamental question also comes into play. In the adversary system, an expert witness can be called to testify and must first qualify to do so. During this procedure, referred to as *voir dire* in the United States, the certified criminalist will use his/her certifications as credentials to qualify as an expert witness. As such, if the certification is simply obtained through the payment of a fee, it should not allow someone to qualify as an expert. This will lead to a system in which the certified incompetent is recognized while the noncertified

Table 2 Some certification programs with some of their characteristics

Organization	Name	Education	Prerequisite	Required experience	Examination type
American Board of Criminalistics (ABC)[a]	Diplomate (D-ABC)	Bachelor, or equivalent, in a natural science or an appropriately related field from an accredited institution	Two letters of recommendation	Two years full-time experience[b]	Written (MCQ)
	General criminalistics Fellow (F-ABC)	Bachelor, or equivalent, in a natural science or an appropriately related field from an accredited institution	D-ABC certification – proficiency test – two letters of recommendation	Two years experience in the specialty[b]	Written (MCQ)
	Forensic biology Drug analysis Fire debris analysis Trace evidence				
	Technical specialist (S-ABC)	Bachelor, or equivalent, in a natural science or an appropriately related field from an accredited institution	Proficiency test – two letters of recommendation	Two years experience in the specialty[b]	Written (MCQ)
	Drug analysis Forensic molecular biology				
International Association for Identification (IAI)	Certified crime scene investigator (CCSI)	None	Two courses in crime scene investigation – two letters of recommendation	One year	Written (MCQ)
	Certified crime scene analyst (CCSA)	None	Four courses in crime scene investigation – two letters of recommendation	Three years	Written (MCQ)
	Certified senior crime scene analyst (CSCSA)	None	Six courses in crime scene investigation – two letters of recommendation	Three years	Written (MCQ)

(*continued overleaf*)

Table 2 (*continued*)

Organization	Name	Education	Prerequisite	Required experience	Examination type
	Certified footwear examiner	High school diploma	Education specific to the discipline – two letters of recommendation	Three to eight years[b,c]	Written (MCQ)
	Bloodstain pattern examiner	None	240 h of discipline-specific education – two letters of recommendation	Three years following the 40-h basic training	Written
	Forensic art certification[d]	None	80 h of discipline-specific education – submission of two drawings, which led to the identification of a suspect – two letters of recommendation	One year and 25 drawings	Written (MCQ) and practical (1 drawing)
	Forensic photography certification	None	40 h of discipline-specific education – two letters of recommendation	Three years[b]	Written (MCQ) and practical (10 photographs)
	Certified latent-print examiner (CPLE)	None	80 h of discipline-specific education – two letters of recommendation	Two to four years[c]	Written, practical (50 fingerprints), and oral defense
	Tenprint fingerprint certification	None	96 h of discipline-specific education – two letters of recommendation	Two to four years[c]	Written, practical, and oral defense
Association of Firearm and Tool Mark Examiners (AFTE)	Firearm evidence examination and identification	None	Membership in the association	Three years experience in the discipline	Written and practical
	Toolmark evidence examination and identification	None	Membership in the association	Three years experience in the discipline	Written and practical
	Gunshot residue evidence examination and identification	None	Membership in the association	Three years experience in the discipline	Written and practical

The Forensic Science Society (FSS)	Crime scene investigation	None	Three referees	Three years experience in the discipline	Written, practical, and oral
	Document examination	None	Three referees	Five years experience in the discipline	Written, practical, and oral
	Fire investigation	None	Three referees – case files submission	Five years experience in the discipline	Written and oral
	Firearms examination	None	Three referees	Five years experience in the discipline	Written, practical, and oral
	Forensic imaging	None	Three referees – case files submission	Five years experience in the discipline	Written, practical, and oral
	Document examination	None	Three referees	Five years experience in the discipline	Written, practical, and oral
	Fire investigation	None	Three referees – case files submission	Five years experience in the discipline	Written and oral
	Firearms examination	None	Three referees	Five years experience in the discipline	Written, practical, and oral
	Forensic imaging	None	Three referees – case files submission	Five years experience in the discipline	Written, practical, and oral

MCQ, multiple-choice questions

[(a)] At the time of writing of this article, ABC was changing their certification programs. Please refer to their website http://www.criminalistics.com for the most current information

[(b)] In these cases, the candidate must also be actively working in the discipline of certification

[(c)] The required experience varies according to the candidate's education

[(d)] This certification is under revision and the new one will include more stringent training and experience requirements

competent criminalist is not. Thus, it is necessary to ensure that the gap between certification and competency is as small as possible.

The advantages of certification lie at the level of the employer, the employee, and clients. For the employer, it is a first step toward a quality management system. By paying particular attention to the qualification of criminalists, the employer places the criminalist's competency before the techniques used, an important characteristic too often neglected. For the practitioner, it provides a formal recognition of one's achievements, a particularly important fact since criminalistics is not a professional activity ruled by a special law, such as with professional engineers. Finally, for the clients of a crime laboratory, it provides a certain assurance that the personnel are qualified. This confidence is quite important and should not be undermined.

From a critical point of view, the certification may provide a false impression of permanent quality coming from a laboratory. One must remember that certification only concerns personnel and neither equipment nor procedures (*see* **Accreditation: Organizational**; **Accreditation: Laboratory**). As such, it does not attest to the quality of the work performed in a crime laboratory.

Certification Programs

There are several certification programs available in forensic sciences in general and a few that concern criminalistics. Table 2 presents some of the most reputable programs closely connected to criminalistics, along with some of their characteristics.

End Notes

[a.] There is a distinction between education – which refers more broadly to cognitive development, such as the formal one obtained through school studies – and training – which refers more to a vocationally oriented approach providing specific information regarding a particular task [17]. While attending a university program is education rather than training, some training can be provided during such a curriculum, particularly if practical laboratories are taught. In the scope of this article, the term training is to be understood as encompassing education.

ERIC STAUFFER AND BEATRICE SCHIFFER

Transfer: DNA

DNA is skin cells and in other cells contained in body fluids, such as blood, saliva, urine, and semen. Each of us has about 10^{14} cells in our body (100 000 000 000 000), almost all with a full DNA profile packed inside them. We lose a number of these cells every minute of every day. A typical fingerprint contains many dozens of cells and one should expect to leave one's DNA everywhere that one goes. This is one of the main differences between DNA and fingerprints; DNA can be transferred from one person to another and from that other person to some other place where the first person may have never been. Most contacts between people and objects are expected to result in the transfer of cells, and hence DNA, from one to the other and vice versa.

A large number of parameters (such as, but not limited to moisture levels, texture of the surfaces involved, strength, and duration of contact) need to be considered when evaluating the potential for DNA transfer in any given situation. Consequently, the amount of DNA transferred, and the ability for subsequent transfer to other people and objects, has not yet been thoroughly explored in research studies. Most of the limited research that has been conducted has used small numbers of individuals (about 4–10) in a very limited range of scenarios. In summary, no clear picture has emerged that could enable a confident interpretation of the mechanism that caused DNA to be present when the finding of DNA is not associated with any particular body fluid (e.g., blood or semen) on an object.

This discussion highlights some of the comments and conclusions that feature in the published work. Operational scientists may attempt to make reference to their casework and experience as a source of informed data on these points, but it should be obvious that it is impossible to use this as a substitute for controlled experiments or to draw confident conclusions, no matter how many profiles are observed or objects examined, without knowledge of what *actually* caused the DNA to be present. Within this limited context, it can be reported simply how many objects submitted for such testing can yield profiles; even then, this is a biased sample of objects, since objects are unlikely to have been submitted unless there was an initial expectation that someone's DNA would be associated with them.

The presence of a DNA profile matching that found on an item does not necessarily show that a particular person ever had direct contact with the item. "It has also been shown that a full profile can be recovered from secondary transfer of epithelial cells (from one individual to another and subsequently to an object) at 28 cycles" [1].

"The full DNA profile of one individual was recovered from an item that they had not touched while the profile of the person having contact with that item was not observed. This profile was also detected using standard 28-cycle amplification" [2].

These statements were reporting experimental results performed in controlled conditions and so the extrapolation to casework is difficult other than to establish that such transfer is possible.

The authors state, "When 30 min and 1 h delays were incorporated between human contact and contact with the object, profiles from both individuals were detected. This suggests that for most casework situations where secondary transfer is concerned, mixed DNA profiles can be expected" [2].

This remains speculation.

They also state, "In the context of other cases or scenarios where the conditions are different to those tested within this work, specific experimentation would be required to generate the appropriate data on secondary transfer. It would be important to hear what the 'suspect' says in the context of each case."

One author concludes, "a detectable secondary transfer is very unlikely" [3] although there is no

quantitation of "unlikely", the level at which detection can be reliably accomplished, nor supportive evidence from controlled trials. While this paper asserts that "case experience has found that the handled object bears the profile of the most recent handler", several other works contradict this claim. While the DNA of the last person to touch the item may, or may not, be on the item, the DNA of others who may or who may not have touched the item may also be present. There is no reliable way of ascribing a particular profile to a particular time.

The factors affecting transfer of DNA are not fully known, but there is work to suggest that, *inter alia*; the duration of contact (longer – more transfer), force (higher – more), friction (more – more), and movement (more – more) are important factors. None of these are unexpected.

The results obtained in some of the papers discussed so far did not replicate (agree) the work of another group who had published in 1999 [4]. The improving sensitivity of current techniques may explain this discrepancy. Another may be the variable influence of personal factors in the ability of the participants, of which there are usually few (less than 10), to shed DNA.

There is work that has discovered that people vary greatly in their ability to shed DNA:

> "The observation made by other authors that individuals differ in their tendency to deposit DNA when in contact with an object has been confirmed through specific experimentation ... The reason for this difference in shedding ability is as yet unknown."
>
> "It is well known that there are significant differences among individuals in terms of the amount of DNA that they deposit upon touching an object. The reasons for these differences remain unclear and need further investigation" [5].

> "We have also determined that the quantity and quality of DNA profiles recovered is dependent upon the particular individuals involved in the transfer process. The findings reported here are preliminary and further investigations are underway in order to further add to understanding of the issues of DNA transfer and persistence" [2].

The literature contains preliminary studies or case histories on the possibility of recovering DNA from fingerprints left on the skin or in rope, cord, wire, etc., used for strangling, gloves, knives, solid parts of cars, and other objects, and on the interference of substances used to highlight fingerprints during later genetic analysis.

These works report on isolated experiments, dictated by the need to resolve definite cases, but "*systematic studies on recovery techniques, interference by contaminants, the influence of individual and exogenous factors in the number of cells left ... , and the percentage of success in PCR analysis of the genetic impression from nuclear DNA, have not been exhaustively carried out*" [6] (the quoted text has been italicized here).

Hence, there is a lack of definitive work on the transfer of DNA, but there are, nevertheless, studies that show that DNA can persist for some time after contact.

The highly variable results obtained by experimenters in this area merely add to the uncertainty about *any* conclusion based on the finding of low amounts of DNA on an object.

All of the work cited refers to person to person, person to object, or person to person to object transfers. We can find no work referring to object to object transfer, although this is clearly a possibility; given the precautions taken by laboratories and other agencies in avoiding such, there is one study, undertaken as part of a court case, that has demonstrated tertiary transfer [7].

Primary transfer (i.e., person A to person B or item) is always going to occur more frequently than secondary transfer (i.e., person B or item to someone or something else), and is therefore inherently more likely. It is usually impossible to quantify the actual or relative probabilities of these.

Trauma Analysis of Skeletal Remains

Introduction

The role of the forensic anthropologist, when dealing with human remains is not only to establish the biological profile, time of death, and personal identification, but also in helping the pathologist in interpreting signs and therefore possible cause of death on skeletal remains. In some ways, the forensic anthropologist is for the skeleton what the forensic pathologist is for an intact cadaver. It is frequently difficult to determine cause of death when examining skeletons – most deaths by natural causes and many accidental or violent deaths do not leave signs on the skeleton. However, when studying skeletal remains that may belong to a murder victim, the anthropologist must look for the smallest signs of trauma that may indicate the application, for example, of blunt or sharp force injury. In these cases, the experience of an expert osteologist is crucial.

Signs visible on bone are generally of those produced by mechanical injury or any biodynamic reaction to a mechanical insult. Trauma modalities are the same as for soft tissues. Therefore details of different types of lesions are not discussed (since they have been discussed elsewhere). However, forensic anthropology has studied peculiar aspects of trauma specifically on bone [1–42], which are briefly summarized in the following paragraphs.

Bone Reaction and the Issue of Aging a Lesion

In the forensic context, it is necessary to distinguish when a particular lesion was inflicted with respect to the time of death. When one is examining a well-preserved cadaver (or a living person for that matter), it is fairly easy to distinguish if the lesion was produced during life or after. If a lesion is vital, tissues around the lesion (a bruise, a cut) will be a red or purplish color, and if the person survived a good deal after a specific lesion was inflicted, one can also, according to chromatic variations of the wound, more or less determine how much time has gone by. It is common knowledge that a bruise is at first blue, becomes green, brown, and then yellow. If, for example, the wound is inflicted already on a dead body, no such vital reaction will be seen on the skin.

The situation is very different for bone, and it is frequently impossible to determine whether a bone fracture found on a skeleton was inflicted just before or just after death (for reasons that are clarified below). Therefore, forensic anthropology, when dealing with trauma, has developed a different type of nomenclature that divides skeletal trauma into three different types: antemortem trauma, perimortem trauma, and postmortem trauma.

Antemortem Trauma

Bone, when vital, can react only in two different ways to trauma (or any type of insult, for that matter: mechanical, chemical, or microbiological). The two

main responses are the lytic response, i.e., a loss of tissue or a reaction that "take away" bone tissue; or a proliferative response. Generally, in cases in which the person survives the trauma, mechanical insults give a proliferative reaction. Therefore, if a person dies immediately after a bone fracture, for example, there will be no time for the proliferative reaction to develop. If the person survives, vital reactions will be visible – this is the case, for example, of subjects that have been subjected to torture before dying. On the skeletons of these individuals one can still detect, if the survival time was long enough, signs of a vital reaction.

Bone trauma inflicted weeks or months or years before death of the individual can frequently be diagnosed on skeletal remains. When a bone is lesioned, fractured for example, a series of events takes place: Initially, in the living person, vascular damage produces a hematoma around the region involved. Within days a fibrous matrix produces a support for a successive formation of the bone callus.

These reactions occur also in the presence of bone contusions or other types of trauma, even if a fracture is not present.

However, when a fracture is present on healthy bone, the sequence of reactions is the following: (i) there is a circulatory phase that is related to the loss of blood due to the rupture of vessels, which seeps into the tissues and calls in white blood elements and platelets – this occurs between the first hours and the first two weeks after trauma; (ii) the first metabolic phase, which consists of soft callus formation. The cells called in by the inflammatory reaction become cartilage cells, which can create a soft callus that unites the two fracture edges; (iii) the second metabolic response, which implies the maturation of the initial callus with osseous apposition. At this stage, periostitis begins to become visible. Final remodeling will follow.

So initially, the callus consists of woven or young bone (an immature version with a completely different aspect from mature bone). Immature bone has the appearance of a porous "lacey" structure; mature bone looks like normal adult bone, with a very smooth surface (Figures 1 and 2).

These lesions, where a bone reaction can be seen, are called *antemortem*. However, the time necessary for signs of survival to trauma to be evident depends on many factors. These include the site of the lesion or the health status of the person, or

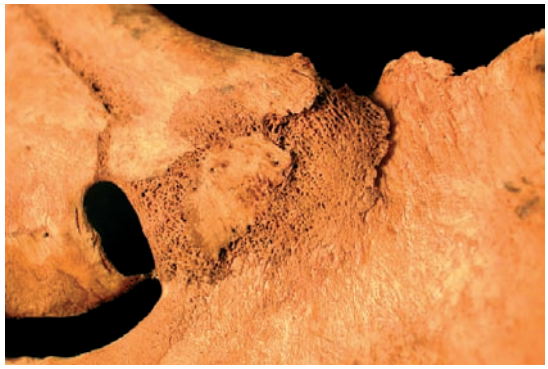

Figure 1 A close-up of the superior part of the scapula where one can notice the presence of porous, slightly darker bone between two fracture edges. This is woven bone and has been aged at around four weeks before death

Figure 2 Tibia and fibula, at the proximal end (next to the knee) of the leg. One can appreciate on the fibula (the thinner bone) a bulge that indicates the presence of callus formation. The bone of the callus is less porous and more robust – the lesion occurred one year before death

even environmental and genetic factors. Sledzik and Kelly studied 257 war victims who had survived skeletal lesions (with different times of survival). These authors found that bone remodeling appeared already after 13 days from trauma; some individuals even showed osteological bone reactions at seven days from trauma. The first appearance of woven bone can be seen as "periostitis", i.e., immature bone, deposited on the margins of the fracture and slowly closing it. Minimum time since death when periostitis is visible is one week. Other clinical sources also indicate that new bone formation after a fracture may be macroscopically visible between 4 and 10 days, but generally occurs between 10 and 14 days from

the lesion. The formation of the callus (first made of soft tissue and then of bone) occurs between 14 and 40 days, sometimes 90, while final remodeling of the callus into adult bone usually occurs between one and two years.

When a visible callus has been formed, it is convenient to perform a radiological analysis of the bone – in fact this may show the internal state of bone remodeling and help to age the lesion.

It is obvious that detection of antemortem trauma is useful for verifying trauma inflicted some time before death, which may be related to maltreatment or torture; however, it may be related to more "normal" events, such as accidents, and therefore be useful in building the biological profile.

Perimortem Trauma

All lesions called *perimortem* occur when the bone is still elastic: the margins of the fracture will therefore have an elastic aspect (green fractures) and will often be squashed. One can imagine a thin branch, when it is still green and not dry (Figures 3 and 4). If one tries to break it, it will bend and finally break, but in an "elastic" fashion. This peculiar mode of breaking can occur, however, in two different situations: when the person is alive, i.e., just before death, and therefore the trauma has something to do with the cause or moment of death; or just after death, when some sort of early postmortem trauma (maneuvers on the cadaver, geological events such as rocks falling on the body) has fractured the bone. In this last case, the macroscopic reaction of bone will be the same as when the trauma is inflicted just before death, since tissues will still be elastic. Usually, perimortem fractures show bone spicules that are slightly intro- or extroflexed. When the skeleton is buried, an indication that the trauma was perimortem also comes from the fact the fracture edges are "dirty", i.e., they have in time absorbed soil and therefore have become colored.

Thus, in forensic anthropology, the term perimortem means either shortly before or shortly after death – traditional methods cannot go further; however, the adoption of histopathology techniques may indeed solve this issue: forensic histopathology (microscopic) techniques may, in theory, be able to still find some sign of vital reaction in a specific fracture (i.e., the presence of early bone remodeling (Figure 5) or of those soft tissue factors that

Figure 3 "Green" perimortem fracture of the distal third of a femur. The elastic appearance as well as the dark edges of the fracture indicate its perimortem origin

Figure 4 The posterior spinous processes of a vertebra is broken in a perimortem fashion

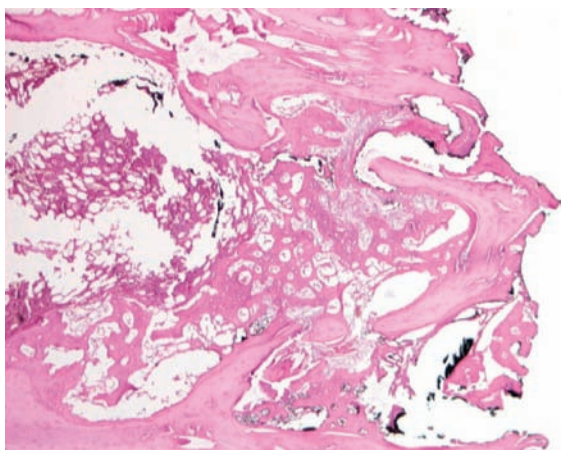

Figure 5 Microscopic analysis of the edge of a perimortem fracture of clean bone showing the microscopic presence of early bone remodeling, which indicates a brief time of survival. No signs of vital reaction were visible macroscopically in the bone

may remain microscopically visible even after most soft tissue has decomposed). Regardless of the fact that histopathology techniques could improve forensic anthropology diagnostic capabilities, no one has ever looked at the presence of vital reactions in "clean", dry or macerated bone. As mentioned above, the diagnosis of the vitality of a skin wound, for example, (whether it has been produced antemortem or postmortem) as well as determination of the time elapsed between the production of the wound and death (in other words the age of the lesion) is a crucial issue in forensic pathology. It is a well-known fact in forensic medicine that the inflammatory reaction that follows wound production will mark the vitality of a peculiar lesion. In fresh skin, in fact, the red-purplish coloration (hemorrhagic infiltration) of a cut or bruise will reveal its vitality, and therefore antemortem formation, whereas the change in coloration, from a macroscopic perspective (from blue to brown to yellow, etc.) will reveal the time of survival. In more difficult cases (e.g., when hemorrhagic infiltration is not so evident or when a more accurate time of survival is needed), microscopic analyses can be performed. A plethora of data from classical histological techniques and newer immunohistochemical techniques provides more accurate statements of survival time, although this depends on the stain used, time from death, etc., new research may shed some light in the future on this important issue and help verify if a "perimortem" lesion is actually antemortem or postmortem.

Postmortem Lesions

It is also possible to verify if the bone fracture has been inflicted on material that was already skeletonized, and therefore certainly classifiable as postmortem. In these cases, since the majority of soft and therefore elastic tissues has disappeared, fractures have a "drier" appearance. Once again one should imagine the example of a branch. In this case, the branch is dry, and it breaks in a very clean fashion (Figure 6). An elastic dry bone behaves in the same manner. These are bone lesions that are frequently determined by the actual excavation or manipulation of skeletons. Usually, they have margins that are white, or at least lighter in color than the surrounding bone, since the fracture edges, having been produced recently, have not been colored by soil pigments.

Figure 6 Example of typical postmortem trauma on a humerus. One can notice that the margin is clean cut, does not have an elastic appearance, and is lighter in color

Also, there exist what are called *taphonomic lesions*: these are due to the destiny encountered by the human remains. Environmental, geological, climatic, animal (Figure 7) or human events (Figure 8) may indeed create lesions on bone, which must be distinguished from the lesions due to the action of a weapon.

Most Commonly Found Traumatic Lesions of Forensic Interest on Bone

Blunt Trauma

Blunt trauma includes all types of impacts of the bone with a resistant surface without points or sharp

Figure 7 The distal extremity of this humerus shows a loss of the lateral part of the bone with adjacent puncture marks. These are due to fauna

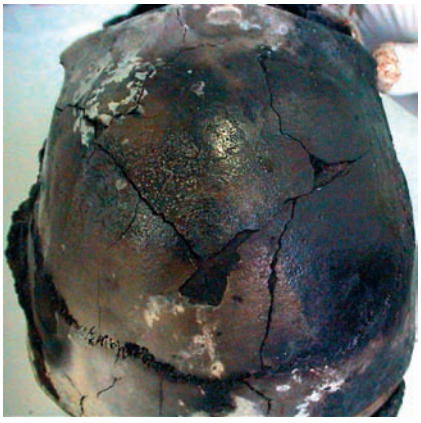

Figure 8 The top of a charred cranium. Fractures on burnt bone on the other hand are extremely difficult to interpret and at times it is impossible to distinguish fractures due to perimortem trauma from fractures caused by the effect of fire

Figure 9 Example of a formed fracture on the cranial vault where a plug of bone of similar dimensions to the weapon (a hammer) was forced inward

edges. Lesions on bone tissues are characterized mainly by fractures, presenting different patterns and therefore modes of production. In forensic pathology and anthropology, analysis of cranial fracture patterns is of utmost importance; the fracture pattern can provide information on lesion production modality and weapon characteristics. Different hypotheses have been developed in order to explain different fracture patterns.

According to the type of blunt surface area, cranial fractures can be classified into formed "impact site" fractures, when a plug of bone is forced inward (Figure 9), and linear or radiating fractures.

The cranium in fact can be considered as a plasto-elastic material; when applied forces are feeble, bone structure undergoes a transient deformation, which disappears after trauma removal. With higher forces, bone structure is permanently deformed. At highest forces, bone structure breaks, with production of fractures.

Lesions in the remaining skeletal districts can be classified into open (when there is also an interruption of skin) or closed fractures; bending, twisting, compression, or tearing fractures according to their shape and mode of production; diaphyseal, metaphyseal, or epiphyseal fractures according to the site of lesion; complete, incomplete, or comminuted in conformity with lesion severity.

In conclusion, the analysis of the bone fracture patterns on the skeleton may help reconstruct a part of the dynamics of the traumatic event.

Sharp Force Injury

These lesions are produced by pointed or sharp-edged tools. Penetrating lesions caused by tools such as needles, nails, and screw drivers can sometimes be visible on bone and a detailed study of the lesion, especially if performed with a cast, can help reproduce tool shape and size and allow at times to obtain very precise information. Cutmarks are produced by the sliding of a sharp edge on the bone surface and, once again, can give some information on the instrument used (Figures 10 and 11).

Sharp tools and saws are usually utilized in cases of body dismemberment, a peculiar modality of

Figure 10 Cutmark on the upper surface of the middle third of the left 11th rib due to the passage of the blade of a kitchen knife, while the victim was stabbed

Figure 11 Once the anthropologist has performed the osteological analysis of the lesion, it is then up to the pathologist to verify which soft tissues may have been involved and to hypothesize if and how that specific lesion may have compromised vital functions. Here is a diagram of the anatomical distribution in vivo of the viscera around the lesioned rib (circle)

corpse concealment or mutilation. As in other cases of penetrating or cutting wounds on bone, the in-depth study of the cut can give detailed information on the instrument used, particularly in the case of saws (Figure 12). As saw teeth cut bone a kerf is formed. The corners formed in the initial cut are called *initial corners of the kerf*. As the cut develops, these develop into kerf walls and kerf floor. Kerf floors frequently provide the most information about the points of each tooth and the relation of the teeth to each other in the blade.

Gunshot Lesions

Gunshot lesions are produced by the projection of a bullet by gas expansion, and are classified into single bullet lesions and multiple bullet lesions; the first type is carried out by short gunshot weapons such as revolvers and handguns, the second type by long gunshot weapons such as rifles and shotguns. The single bullet, when it hits a body, produces an entry wound, a path inside the anatomical structure it crosses, and an exit wound (if it does not impact and get trapped inside internal structures, especially

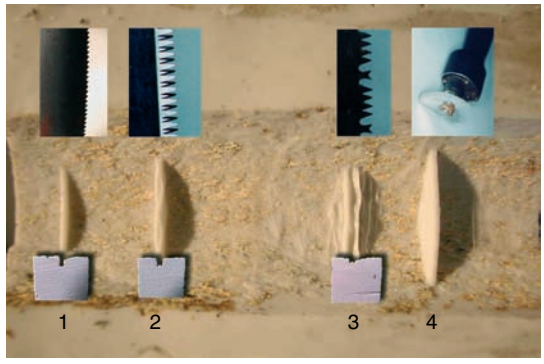

Figure 12 In the figure at the top one can see, from left to right, (1) a saw for metal with small teeth positioned on the same line; (2) a hard wood saw with multifaceted teeth; (3) a green wood saw with teeth laterally inclined with respect to the blade; and (4) a Stryker saw. These saws were used to make four incomplete cuts in the cortical bone of a femoral diaphysis. In the middle of the figure, one can notice the negative cast, made in silicone, of the lesion made by each saw. At the very bottom, the positive cast made in chalk. One can notice, particularly in the silicone negative cast, the different morphology of the kerf floor, which reflects the different characteristics of the saw blade

bone). Entrance wounds in bone, particularly the cranium, are usually (but not always) round shaped and regular; on cranial flat bones, the lesion is characterized by a typical kind of beveling. Entrance wounds are beveled with larger cratering on the interior surface (*tabula interna*) than on the *tabula externa*, probably because of the spreading of forces and lack of support within the *diploe* (Figure 13a, b).

Gunshot fractures are useful in distinguishing an entrance wound from an exit lesion; and fracture lines from an exit wound will break off on preexistent fractures originating from entrance wound.

Where gunshot reaches the cranial surface tangentially, the detachment of a bone fragment produces the typical keyhole lesion, which indicates the gunshot direction

Multiple bullet lesions have different morphological appearances according to gunshot distance; at short distance pellets tend to travel bound together; at long distance instead pellets tend to separate and spread, and each bullet will produce its own entrance lesion.

Mechanical Asphyxia and Drowning

Sometimes the forensic anthropologist may be confronted with the hypothesis of mechanical asphyxia

(a)

(b)

Figure 13 (a) An entrance wound seen from the external surface of the cranial vault: round with a relatively regular margin. (b) An exit wound seen from the external surface of the cranial vault: notice the obvious outwards beveling with cratering of the tabula externa

since suspicious signs may be present on the skeleton. Moreover, among different forms of asphyxia, three modalities may produce bone: manual and ligature strangulation, and hanging. Manual strangulation (throttling) occurs when the neck is constricted by hands. Ligature strangulation occurs by the use of a string or rope, for example, coiled around the neck. Hanging occurs when the coil(s) around the neck is/are tightened by the weight of the body. Manual and ligature strangulation and hanging may produce fracture of the lateral horns of the hyoid, which will be visible on the skeletonized remains but must be distinguished from taphonomic effects.

Death by drowning is a form of mechanical asphyxia due to penetration of water in the respiratory

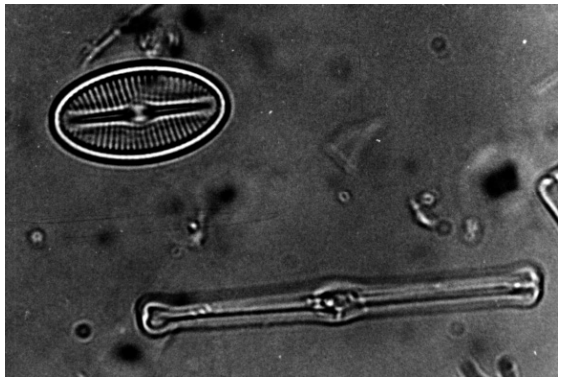

Figure 14 Example of diatoms extracted from human tissues and observed under the light microscope

airways, with replacement of alveolar air. In cases of skeletons found in or nearby lakes, rivers or the sea, the anthropologist should know of the potential of diatom analysis. Diatoms are a major group of eukaryotic algae, and are one of the most common types of phytoplankton. A characteristic feature of diatom cells is that they are encased within a unique cell wall made of silica (hydrated silicon dioxide) called a *frustule* (Figure 14). This makes them particularly resistant. During drowning, diatoms penetrate in the airways with water, enter the blood circulation, and then spread into different tissues and bone structures as well. Thus the presence of diatoms in bone may be an indication of drowning, although much caution must be adopted in the interpretation of such data, since there may be contamination from other sources.

CRISTINA CATTANEO AND DAVIDE PORTA

Trauma Causation: Analysis of Automotive

Objective and Introduction

Humans have developed refined mental activity and physical adeptness but have not evolved the capacity to withstand impacts at high speeds.

In a high-velocity incident, analysis of physical evidence on the human body may assist in identifying the cause of impact trauma. Biomedical engineering integrates engineering, biological principles, and physical evidence for forensic analysis and can therefore provide useful input for the consideration of the cause of the incident, in conjunction with other disciplines including accident reconstruction, forensic pathology, orthopaedic surgery, and neuroradiology.

What is Biomedical Engineering?

Biomedical engineering applies engineering principles to biological systems, holistically utilizing knowledge in engineering, biology, and medicine. The cross-disciplinary field integrates engineering (e.g., external force applied) with biomedical sciences (e.g., tissue tolerance) and clinical input from health care providers (e.g., medical diagnosis).

Biomedical engineering differs from other fields such as mechanical engineering, as biomedical engineers have esoteric knowledge and training about the kinematic and kinetic behavior of biological systems, while mechanical engineers have mechanical system expertise, for example. The key difference between a biomedical engineer and a medical doctor is that diagnosis, prognosis, and treatment are outside the scope of the engineer. The biomedical engineer focuses on the forensic elements or the cause of the incident or trauma on the basis of the engineering aspects. On the basis of a clinician's diagnosis, the biomedical engineer can mathematically model the system, which is often the mechanics/kinematics of the trauma sustained. The next step is to derive quantitative comparisons with the human tolerances for the specific tissues that sustained failure in the subject incident.

In forensic biomedical engineering, physical evidence on the body can be examined and interpreted relative to the body's physical interaction with the environment. The biomedical engineer applies engineering principles to better understand the effect that forces have on the body.

Biomedical engineering may have first begun more than 3000 years ago with the oldest known limb prosthesis. In the year 2000, a 3000-year-old mummy from Thebes bearing a wooden prosthetic tied to its foot, serving as a big toe, was uncovered by German archaeologists.

Historically, biomedical engineering education programs focused on prosthetic design. In the last

50 years the field has also contributed to the study of injury mechanics in accident analysis. Today, there are more than 90 university programs in Biomedical Engineering. In forensic applications, the field focuses on the kinematics and the mechanics of trauma.

Biomedical Engineering Methodological Approach to Trauma Causation

There is no single formula to assess the causation of trauma. There are, however, proven foundations for the biomedical engineering analysis of trauma.

The engineer considers multiple variables to determine the probability of each potential cause of injury. These include vehicular damage, change in velocity, the plaintiff's pre-existing medical condition, the temporal relationship to the onset of diagnosis, as well as the expertise of medical doctors, surgeons and/or forensic pathologists to provide the specific diagnosis of trauma. Insights and analysis of the accident investigator may also be used to further understand the mechanism of trauma. Because the biomedical engineering discipline involves training in biology and medicine, biomedical engineers may be called upon to evaluate how external outputs, i.e., forces and accelerations on the body, will affect the internal structures, i.e., load capacity and failure modes.

There are three categories of analytical elements that serve as a foundation for study. These elements are integrated with the available investigative facts in order to evaluate the mechanisms of trauma, and/or determine whether the trauma is consistent with the specific incident. The collective analysis is termed *Mechanical, Analytical, and Medical* (MAM) analysis.

1. Mechanical input–consideration of the static and dynamic forces acting on the body:
   (a) impetus for the trauma/accident reconstruction;
   (b) trauma characteristics;
   (c) kinematics–the study of the positions, angles, velocities, and accelerations of body segments and joints during motion; and
   (d) Preimpact position.
2. Analytical engineering–examination of available evidence in conjunction with accepted scientific principles:
   (a) tissue tolerances and susceptibilities;
   (b) testing;
   (c) computerized mathematical modeling analysis; and
   (d) crash recorder or global positioning system (GPS) data.
3. Medical facts and findings:
   (a) radiological findings;
   (b) clinical facts and findings;
      history
      diagnosis
      contact trauma (bruising, contusions, etc.);
   (c) surgical findings.

The findings of the biomedical engineer are dependent upon the quantity and quality of the available evidence and data. The analysis converges to a net result when all of the elements point clearly to the same causal factor. If the results do not fit consistently toward a single cause, then both consistent and inconsistent findings are identified and/or additional work is recommended.

The Application of Biomedical Engineering to Forensic Disciplines

Biomedical engineering can be applied to a variety of forensic analyses. Here we will focus on the vehicle: for example, use of occupant restraints, pedestrian analysis (contact specifics and injury causation), trauma causation, repetitive stress in the automobile environment, and product defects. A few examples of the types of issues that can be analyzed follow.

Occupant Restraint

The physical evidence of the seat belt condition, the occupant kinematics and trauma, and the vehicle interior may determine whether the occupants were likely restrained, and restrained properly. From this information, other elements can be determined, such as (i) the proportion of the trauma due to the plaintiff's lack of a seat belt versus the defendant's excessive speed or (ii) the likely trauma sustained had the 2-year-old been properly restrained in a child's car seat compared to seated in his mother's lap.

Pedestrian Analysis

Pedestrian analysis may reveal multifaceted data about the incident. For example, (i) the direction the

Figure 1 Pedestrian direction of travel prior to impact

pedestrian was traveling prior to impact (Figure 1), (ii) whether the brain injury occurred from the initial impact or from the subsequent impact, (iii) whether the brain trauma would/would not have been less severe had the vehicle been traveling at the speed limit, and (iv) at the time of impact, whether the boy was on his bike or walking next to his bike in the crosswalk. Had the boy been wearing a helmet, what trauma would he likely have sustained?

Trauma Causation

Biomedical engineering analysis can be utilized to determine whether the mechanics are present, or sufficient force is present, to cause the trauma diagnosed by the medical doctor: for example (i) the statistical likelihood that a brain injury was sustained in a low-force incident; (ii) whether or not the mechanics for shoulder impingement are present in the impact; (iii) whether the boy's arm in the back seat was amputated during ejection, rather than inside the vehicle; (iv) whether the front seat occupant's trauma was due to the kinematics of the unrestrained occupants of the rear seat; and (v) whether, using the principles of fracture mechanics, the plaintiff's elbow implant most likely failed from the unrestrained frontal impact rather than that same day's fall on roller blades (Figure 2).

Repetitive Stress in the Automotive Environment

For example, can the lateral femoral cutaneous nerve damage present in 52 Highway Patrol officers be

Figure 2 Condition before and after elbow implant failure. Is it due to frontal impact or from a roller blade fall?

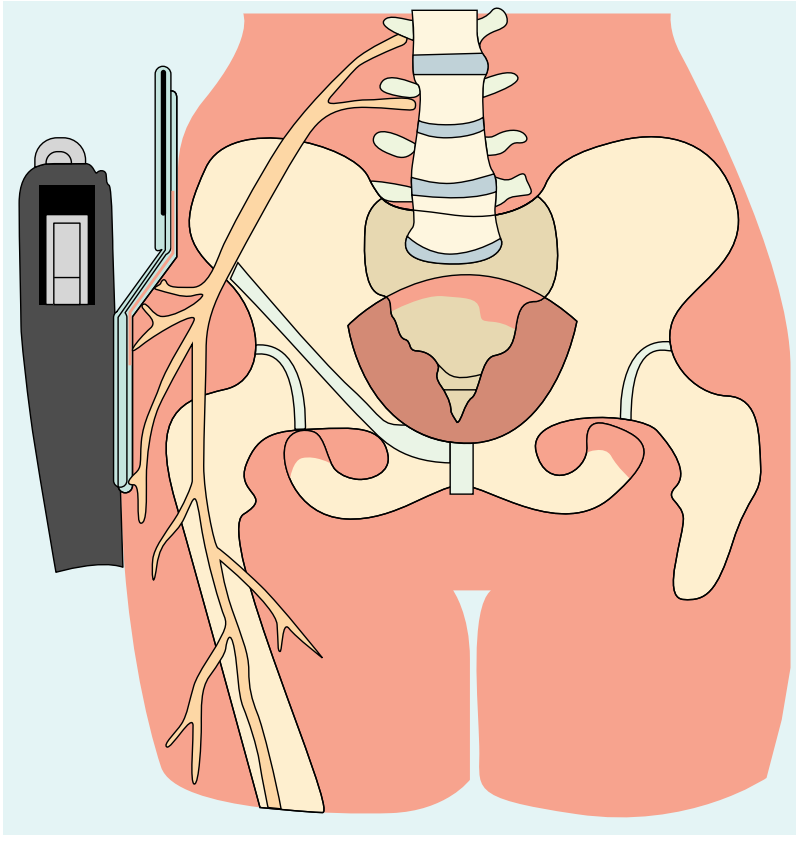

Figure 3 Holster over the pelvis and neuronal structures illustrating compression of the lateral femoral cutaneous nerve

causally traced to a change in holster design that compresses the hip over the lateral femoral cutaneous nerve (Figure 3)?

Product Analysis

Examples include (i) whether the seat anchor failure did or did not cause trauma; (ii) whether or not the injuries were caused by either the ejection or the initial impact itself; (iii) whether the roof should have withstood the force as the commercial truck rolled onto its roof, mechanically asphyxiating the occupant (Figure 4); (iv) whether the globe (eyeball) rupture was caused by the air bag rather than the occupant's diamond wedding ring; and (v) whether the small-stature woman's cervical and facial fractures were caused by the air bag rather than the non-use of seat belts.

The Design and Proper Use of Biomedical Engineering Experiments

The previous section outlined how biomedical engineering may be applied forensically. This section describes the added value of well-executed experiments to determine scientifically the most likely causal factors.

A means of determining causation is to experimentally analyze the issues. These experiments can make use of variants in the environment to compare results. Common questions that experiments may help to answer include:

- Would a seat belt have prevented specific trauma?
- If the vehicle were traveling within the speed limit, what trauma would most likely be sustained?
- Which of the ejected decedents was driving?

Figure 4 Should the roof have withstood the weight of the commercial truck?

- What would have been the probability for brain injury in the subject incident had the seat belt been worn correctly?
- Were the bilateral locked cervical spine facets caused by the first or second impact?

Engineering experimentation can be called upon to assess the biomedical engineering elements of vehicular accidents through two principal methods:

1. Interpolation using existing experiments to "bookend" a specific incident.
2. Custom experimentation, which involves designing a custom experiment to answer a specific question.

Using Existing Experiments

Exhausting the sources of existing experiments is recommended as a first step, even if custom experiments are eventually required. If the subject incident falls into a category of standardized crash tests (in the United States an example is the New Car Assessment Program's frontal impact at 35 mph), existing experiments may be sufficient and more cost/time effective. If not, customized experiments may be necessary. Internationally, there are many sources for crash tests and experimental results. In the United States the most common include the following:

- National Highway Safety Administration (NHTSA)
- Insurance Institute for Highway Safety (IIHS)
- Society of Automotive Engineers (SAE)
- American Association for Automotive Medicine (AAAM)
- Other State or National Agencies
- Automotive Manufacturers.

The Application of Standardized Crash Tests: Interpolation. The key here is how the standardized experimental results may be properly applied to a specific problem. The following short examples will illustrate the key points: *interpolation, not extrapolation*. Interpolation of engineering experiments is the means to explain the expected result or trend between two or more data points. Take the example of two crash tests, one at 10 mph and another at 15 mph. If the vehicles are substantially similar, crashes and occupants may be analyzed. The results of a 12.5 mph crash test could potentially be interpolated from the two experimental bookends of 10 and 15 mph.

Conversely, it may be inappropriate quantitatively to extrapolate, or to go outside the data, to project

30 mph results from tests at 10 and 15 mph; however, sometimes nominal data can be determined if conducted correctly. For example, an appropriate interpretation regarding the 30 mph analysis relative to the 15-mph test is that the forces and accelerations would be expected to be higher. The nominate data may prove helpful in the absence of quantitative data. How much higher, however, may not be reliably projected.

Real World Example of Crash Test Interpolation. On the basis of the forces and accelerations of a specific side impact collision, what is the likelihood that a brain injury was sustained?

A driver is side-impacted by another vehicle to the driver's side of the vehicle. Medical doctors retained by the plaintiff and defendant disagree on whether a brain injury was sustained by the driver in the incident. Is a brain injury more or less likely on the basis of the magnitudes of accelerations and forces?

Mechanical. The side impact was direct to the driver's door by another vehicle of like bumper height and weight. There was no evidence of occupant contact to the vehicle interior, such as window fracture, indentations of the body against the door, and/or blood/tissue evidence. The impact was insufficient to deploy the side air bag. Digital data within the vehicle, specifically the air bag computer and crash data recorder data, were not available since the force of the incident was insufficient to "wake up" the air bag algorithm.

The male driver was of average height and weight, so contact with the roof rail or window frame would not be expected. There were no other occupants or heavy cargo in the vehicle at the time which may have contributed to the driver's trauma.

Medical History and Clinical. The driver was middle aged and in good health with no contributory past medical history. A review of the medical records of the injured driver helps to determine whether there was:

- contact trauma sustained by the injured driver, which might yield important information regarding the motion of the occupant during the collision;
- loss of consciousness (LOC) at the scene (more specifically, Glasgow Coma Score) documented by the first responder.

The medical records are also utilized to review the history of present illness, subjective complaints, objective findings, and diagnoses from the health care providers.

A review of the trauma sustained by the other occupants in the injured driver's vehicle may assist the analysis since other occupant(s) may have experienced a similar force condition.

A biomedical engineering analysis of the medical records is not for diagnostic purposes; that is the expertise of the diagnostic clinicians. The medical records may assist in characterizing any trauma or in anatomically understanding the specific trauma sustained. The presence of contact trauma may increase the statistical likelihood of brain trauma. If there is contact trauma, what is its cutaneous character? Does the contact trauma shape, size, or depth assist in pinpointing the source? Is it consistent with a specific surface and does it rule out other surfaces? Is it consistent with a yielding or unyielding surface? (An unyielding surface has the potential to greatly increase the force experienced by the occupant as a function of the topography of the surface.) In a separate unique analysis, a piece of plastic inside the vehicle broke off and impaled an occupant, so the contact could be matched to a specific piece of plastic in the vehicle and a single unyielding point of contact.

In this analysis, there was no clinical evidence of contact documented by the health care providers or recalled by the injured person during the deposition.

Medical: Radiological. Continuing with the example, a review of the head computed tomography (CT) films taken on the date of the accident also confirmed no evidence of contact. For background, it may prove helpful to look at the actual films themselves with the assistance of a radiologist, if needed, to supplement the radiological report. This is not radiologically to diagnose the trauma, but to utilize the physical evidence in determining its cause. For example, the size and shape of a minor scalp swelling may not be clinically important and therefore not mentioned in the radiological reports. Even if it is included, external contact trauma may not be a diagnostic focus, so the precise description of the shape, size, orientation, and depth should not be assumed to be included in the report.

In this specific case, the radiological evidence of no contact trauma was consistent with the clinical and investigative evidence.

Analysis: Research of Existing Testing. A review of standardized side-impact tests identified a test at a change in velocity of slightly greater than the subject vehicle test. On the basis of a comparison of the crash profiles, the subject incident was slightly less of an impact than the published research test that utilized a similar make and model of the (year) vehicle. Therefore, the crash test would be expected to overestimate the forces sustained. The dummy (in the test) also did not contact any surfaces, as its head traveled laterally. The research test showed that the accelerations measured at the center of the dummy's head were less than required to cause a brain injury compared to human tolerance according to Federal Motor Vehicle Safety Standards. Since the actual impact was of lesser magnitude, the forces and accelerations would be expected to be of lesser magnitudes or smaller compared to the standard test. Hence, if the accelerations measured by the dummy in the standardized test at a faster impact speed did not exceed tolerance, then a similar impact at a slower speed would probably not exceed tolerance unless the trajectory or area of contact was dramatically changed.

In this example, the answer could be derived without the time and expense of customized crash testing. However, when the impact or the seating scenario is unusual, crash test results may not be available for interpolation and customized testing may be required. An example of a custom biomedical engineering experiment is given below.

Biomedical Engineering Experimental Design. The second most common categorical use of biomedical engineering forensic experiments is the development of customized experiments to investigate specific issues in a specific incident. If the analysis undertaken does not fit into common categories, such as the side, rear, or frontal impacts, a detailed review of the literature is required. If there is no similar test, then custom test directions may be considered. Test alternatives include full-scale testing (full-scale vehicle into full-scale vehicle), deceleration sled testing, and/or subsystem testing. Subsystem refers to a part of the system; an example will illustrate an experiment that helped to determine whether or not a brain injury would likely have been sustained.

An Example of Design of a Biomedical Engineering Subsystem Experiment. What is the statistical probability that a minor rear impact would cause a brain injury? This section illustrates the use of subsystem experimentation.

Mechanical Considerations. An undersized pickup truck was at complete stop when it was rear-impacted by a passenger vehicle. The accident reconstruction analysis indicated that the change in velocity was approximately 5–10 mph and the principal direction of force was directly rearward without offset (both vehicles' axes were in line). There was no structural damage to the rear of the pickup truck. The damage to plaintiff's vehicle was limited to the bumper. The defendant's vehicle sustained no damage to the front bumper.

Analysis of the Vehicular Interior Environment. The plaintiff reported to health care providers that a head injury was sustained when his head struck the rear window of the truck cab, causing the glass to crack. The vehicle seated three occupants in a front bench seat and has a configuration with a sliding glass window immediately behind the occupants. Contrary to the plaintiff's history provided to health care providers, the photos of the truck (Figure 5), and the repair estimates for the truck, there was no indication that the back window was damaged.

The plaintiff driver was the only occupant in the pickup. The plaintiff was seated normally and naturally, looking straight ahead. There was no hematoma or laceration or other evidence of contact trauma to his head. The vehicle had a head restraint although it did not fit the plaintiff optimally. The head restraint was too low for the 5'10" driver.

Medical Considerations: Review of Health Care Provider Documents. A review of the past medical history included:

- legal actions including two workers' compensation claims, one slip and fall, and one previous MVA (motor vehicle accident);
- two prior DUI (driving under the influence) arrests;

Figure 5 Damage to plaintiff's vehicle in a rear impact

- employment for five to six days in a job before quitting, stating the job "aggravated (his) hypertension";
- comment from five years earlier: "there is no etiology for (his) pains";
- comment from six months earlier: "I cannot explain his current symptoms on an organic basis";
- comment from the last health care provider 2 months prior to the incident: "wants disability extended".

The first health care provider (two days post incident) was a medical doctor who noted the following history provided by the patient:

- rear-ended at 30 mph;
- head broke glass in the pickup;
- bloody nose; and
- no LOC, no problem with memory/smells/weakness.

The diagnosis of the medical doctor was cervical muscle sprain. Further, there were no radiological findings on the cervical plain films (X-ray) or on the brain MRI conducted three weeks post incident. Post-concussion syndrome was first diagnosed one month post incident.

An independent medical examiner with specialization in neurological surgery did a review of the medical records and found: "it would be considered unlikely that any significant injury resulted from the vehicular accident. At most, he may have suffered a mild cerebral concussion and a cervical strain."

A neurologist/psychiatrist also conducted a medical record review and examination. He concluded that there was insufficient evidence to conclude that the possible mood disorder (major depressive disorder) had been caused by the MVA. Additionally, numerous inconsistencies and credibility issues were raised by the reviewer including the following:

- In the deposition, He left a job at "A" hospital for a better job at "B" hospital. Employment records at "A" hospital indicate that he was dismissed for forging a physician's signature for a medical leave excuse.

Vehicle Digital Data: Crash Data Recorder and Air bag Data. There was no crash data recorder on either the plaintiff or the defendant's vehicle. No air bags were deployed in either vehicle, so no air bag data was available.

Previously Conducted Impact Testing. There was no rear-impact testing available in a similar truck that had been conducted at a low velocity with an instrumented dummy.

Design of Biomedical Engineering Experiment to Quantify Head Acceleration. An inverted pendulum subsystem test was designed to contact the seat at the same juxtaposition and velocity as the plaintiff's head/neck might have contacted the seat in a 7.4-mph rear impact as shown in Figure 6.

The digital data was acquired at 10,000 Hz. Analysis of the data utilized the head injury criterion (HIC),

Figure 6 Experimental juxtaposition of Hybrid III Dummy Head relative to suspended rear window glass

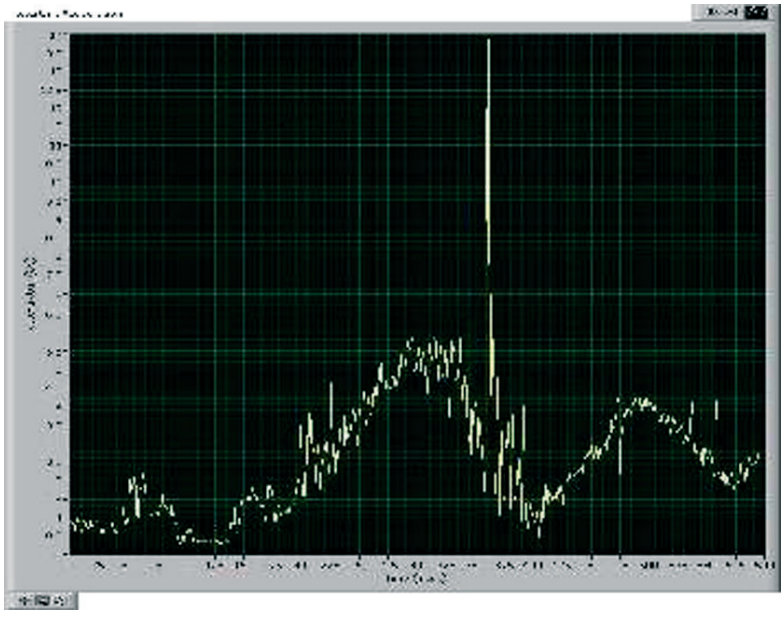

Figure 7 Graph of acceleration in G's (unit of gravity) versus time in milliseconds

or as shown below, where $(t_2 - t_1)$ represents duration of impact and a is acceleration.

$$\left\{ \frac{1}{(t_2 - t_1)} \int_{t_1}^{t_2} a \, dt \right\}^{2.5} (t_2 - t_1) < 1000 \qquad (1)$$

An example of a resultant acceleration versus time graph is shown in Figure 7. The results of the HIC analysis (Figure 8) illustrate that the values are below tolerance. Brain injury would not be likely in this incident on the basis of the HIC results of nine trials.

Findings. In this case, the work by the independent medical examiners consistently indicated that a head injury was unlikely. For example, statements included: "It would be considered unlikely that any significant injury resulted from the vehicular accident", and "At most, he may have suffered a mild cerebral concussion".

The experiments resulted in a means with which to quantify mechanically the likelihood that brain injury tolerances could have been exceeded in the incident. This contribution supplemented the expertise of the health care professionals.

Computerized Mathematical Modeling Analysis

Mathematical modeling allows a scientist to analyze the motion of a human and quantify the forces sustained in an injurious event without exposing human subjects to potential harm. The human body is represented by a number of rigid bodies linked together by springs and dashpots representing the characteristics of human joints and, collectively, the human body. Because of the body's numerous degrees of freedom, the occupant's motions during a collision can be complex. Mathematically, the human body, modeled by connected rigid bodies, can interact with the environment via system inputs or external accelerations. External accelerations include impacts with surfaces, interaction with restraint systems, and/or air bags, for example. Simple systems such as inverted pendulums can be modeled, as well as complex systems such as an unrestrained occupant hitting a complex surface at impact. Note that simulation is different from animation since simulation mathematically defines kinematics and kinetics. In contrast, animation is simply the visualization of motion that may or may not be defined by the simulation or mathematical results. Animation relies upon the quality and validity of the simulation to determine the accuracy of the result.

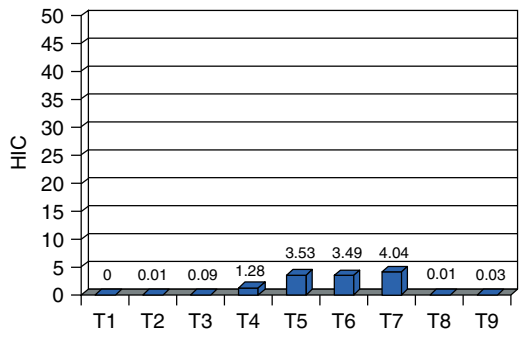

Figure 8 Results of HIC values for nine trials

As an example of this methodology, here we will review a model of a motor vehicle occupant subjected to a same-side impact. The occupant is restrained, and the goal is to study the dynamics of the head; therefore, the lumbar spine, pelvis, and lower extremities are simplified. This is separately determined to be appropriate in this case because the lower body is restrained by the seat belt. The body is modeled in four segments representing the head, neck, thorax, and lumbar spine/pelvis.

The human side-impact (restrained) model with five degrees of freedom is illustrated in Figure 9. The model can be utilized in its two- or three-dimensional (3D) form.

The variables are defined as follows: q_1, pelvic translation; q_2, rotation between the thorax and lumbar spine/pelvis (torsional spring and dashpot kT, bT); q_3, rotation between the neck and thorax (torsional spring and dashpot kN, bN); q_4, rotation between the head and the neck (torsional spring and dashpot kH, bH); q_5, head axial rotation.

Once the model is developed and verified, it can be utilized within those parameters of verification. Examples of model verification include human subjects, cadaver, and anthropometric dummy experiments at impacts that bookend the subject incident (experiments at higher and lower exposures than the subject incident). The model is considered valid as

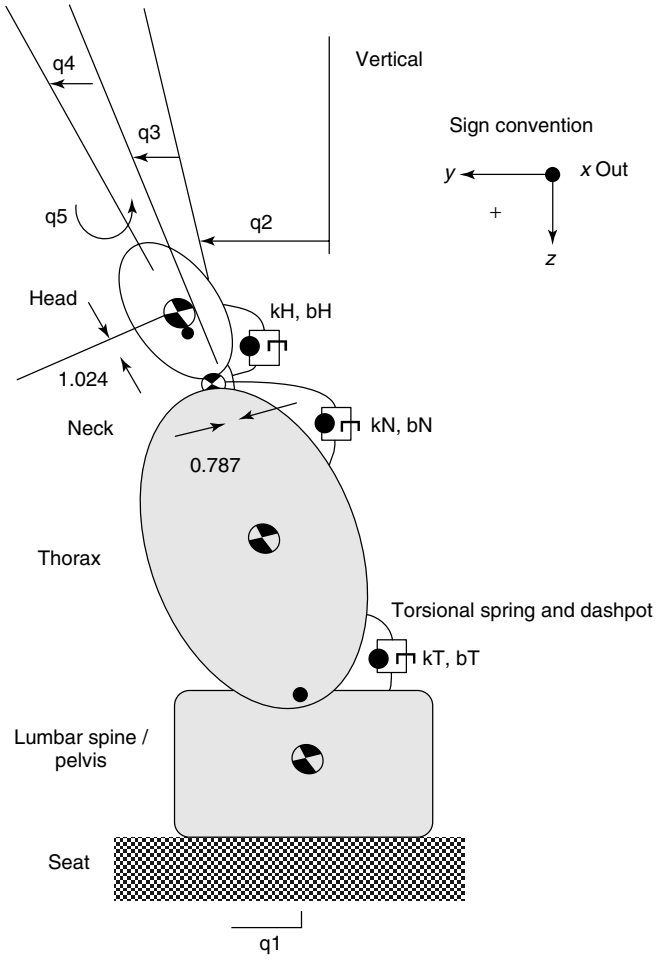

Figure 9 Occupant with five degrees of freedom in a side-impact model

long as the new variables are within the validated parameters.

Properly validated computer mathematical modeling can be an effective biomedical engineering method to quantify the kinematics and kinetics of an impact incident. The correct use of the validated model is interpolation within the experimentally validated parameters. For example, if a model is validated at fall heights of 20 and 25 ft, the model can be used between that range, especially if it is known whether the relationship is linear, or predictably nonlinear and no additional governing variables apply. Conversely, once contact occurs with the automobile dashboard, the dashboard noncontact experiments are often not proper for model validation.

Mathematical modeling can also be utilized when the input variables change. This is especially helpful, for example, when more information becomes available to the accident investigator that alters the known vehicle's change in velocity. The model could be then used to reanalyze the result cost effectively as long as the new variables are within the validated parameters.

Treatment, Mandated: Mental Health

These risks include a fourfold increase in the risk of suicide, increased risk of violence, arrest, poorer mental functioning, life satisfaction, and long-term prognosis [1]. Far from being an outdated practice, several recent developments in mental health law and treatment has brought the return of mandated treatment to the forefront of mental health law.

In recent years, mandated treatment has been expanded to domestic abusers [2], individuals with severe addictions [3], sexually violent sexual offenders [4], and individuals deemed dangerous as the result of a host of mental illnesses [5]. However, mandated treatment remains controversial given its utilization of legal leverage to accomplish its aim of outpatient community treatment. In cautioning against such incursions against liberty and individual autonomy, Justice Brandeis warned, "The greatest dangers to liberty lurk in insidious encroachment by men of zeal, well intentions, well meaning, but without understanding." However, others argue that the government has the responsibility to prevent harm and provide effective treatment, even at the expense of some individual freedom for those suffering from a severe mental illness that leaves them unable to care for themselves or leaves them disposed to dangerous behaviors within the community. Moreover, many individuals voluntarily agree to participate in treatment thus lessening loss of liberty [6].

Of course, clinicians are faced with issues related to low-base rate, false positives, and false negatives within their clinical assessment of risk. It is with these issues in the forefront that we discuss mandated treatment. This article focuses on three primary issues. First, we discuss important legal precedents concerning applications of mandated treatment. Second, we intend to delineate issues and various definitions of dangerousness, especially as they are related to civil commitment standards. Finally, we discuss recent trends in mandated treatment, with specific emphases

on various populations mandated treatment is applied to. Through exploration of these topics we hope to elucidate issues associated with mandated treatment.

Legal Foundations for Civil Commitment and Community-Based Treatment

Various courts have provided guidance and direction for procedural issues and requirements governing how commitment standards can be applied. Statutes and cases regarding mandated treatment have been wide ranging and each touch upon important constitutional questions related to individual autonomy and self-determination. Such issues include diagnoses related to the civil commitment of sex offenders, conceptualizations of dangerousness, and preserving the delicate balance between preservation of individual rights versus the global concern of protecting the public from potentially dangerous individuals who suffer from mental illnesses. The principle landmark case dealing with civil commitment was the case of Alberta Lessard. Arrested in 1971, Ms Lessard was committed to an inpatient facility on the sole basis of the presence of schizophrenia. In *Lessard v. Schmidt* [7] the Court ruled that mental illness alone was no longer sufficient to justify commitment. Instead, civil commitment was premised on both the presence of a treatable mental disorder *and* linking that disorder to likelihood of violence or aggression. Lessard was a watershed case in mental health law as it signaled a move from *parens patria* to almost exclusive use of the state's police powers in effectuating civil commitments. In voicing an alternative perspective to Lessard, a Wisconsin psychiatrist coined the term "dying with their rights on" to describe the inability to commit seriously ill patients who were in need of mental health care [8]. *Lessard* represented the enduring difficulties inherent in mental health law that often focuses on balancing the individual rights of the patients to be free from coercive treatment and society's demand for safety and treatment related to abnormal behaviors.

The Lessard case was the first in a series of cases leading to changes in civil commitment. The changes resulted in thousands of individuals once committed to hospitals being returned to the community requiring resources to be funneled into community-based treatment programs. For instance, a case management model and assertive community treatment has led the way to treating mentally ill individuals within their home communities rather than reliance on large, institutionalized-based care [9]. According to the National Alliance for the Mentally Ill, assertive community-based programming is available in approximately 19 states throughout the United States. The presence of community-based treatment to assist with mandates is even more essential in light of the recent ruling in ***Olmstead v. LC***, decided in 1999 [10]. In this case, the Supreme Court ruled that the American with Disabilities Act required that states place persons with mental illnesses in community care when deemed clinically appropriate insofar as such placement is a reasonable accommodation given the fiscal ability of the state to provide such care. When combined with the Lessard ruling, the Supreme Court of the United States, through these two decisions, ensured that mentally ill individuals have rights that must be protected, which includes the right to the least restrictive environment while being afforded protections against unlawful and unneeded commitment.

In addition to providing effective treatment, a key consideration of mandated treatment to individuals living in the community with mental disorders is to decrease violence [11]. Moreover, treating and reducing the likelihood of violent behavior is a central consideration in the creation and implementation of policy, especially regarding civil commitment [12]. The data for commitments has shown that the implementation of mandated treatment can have a beneficial effect for both individuals and the community. As noted by Monahan and colleagues [13] mandated treatment falls within the realm of social welfare, yet relies upon the judicial system in successfully monitoring and enforcing mandated treatment. It should be noted that mandated care can take several forms including, representative payeeship, the use of diversion agreements, and brief, involuntary hospitalizations for stabilization of psychiatric symptoms [14]. Not surprisingly, individuals coerced to engage in treatment often feel disenfranchised making continued involvement in treatment difficult.

Changing Conceptualizations of Dangerousness: Mandated Treatment

A recent trend in the implementation of mandated treatment revolves around how dangerousness is

defined. In highlighting this changing conceptualization one only needs to look at variations of civil commitment and increasing such definitions. In discussing specific issues we outline (i) changes to laws in standard civil commitment, (ii) mandated treatment for so-called sexually violent persons, and (iii) the insanity acquittee and community treatment.

Standard Civil Commitment

In a law review article entitled, "Beyond Overt Violence: Wisconsin's Progressive Civil Commitment Statute as a Marker of a New Era in Mental Health Law" Erickson *et al.* [6] outlined changes in many states, with an emphasis on Wisconsin, how overt violence or the threat of it is no longer the only definition considered for civil commitment. The article discussed how legislatures have expanded criteria allowing for civil commitment. This shift in commitment criteria demonstrates a growing understanding that certain individuals are so severely incapacitated by severe mental illness that they are unable to care for themselves. In considering individuals who do not present with overt violence as eligible for mandated treatment, expanded definitions of dangerousness within various state statutes acknowledge the insidious danger poised by untreated mental illnesses to both patients and the public at large. While such polices have a de facto parens patria overtone, consistent with court precedent, they are founded upon the state's police powers and require a finding of dangerousness before treatment can be initiated.

Sex Offender Commitment

One of the most contentious areas of mental health law concerns the civil commitment of sex offenders who already served their correctional time but are deemed to pose a continued risk of offending, typically related to a mental disorder. In *Kansas v. Hendricks* (1997) the Supreme Court of the United States upheld Kansas' right to civilly commit sexual offenders for additional treatment, even after completion of their incarceration [15]. In re Crane (2000), the Supreme Court provided individual states wide latitude in deciding which clinical conditions or diagnoses would warrant an individual eligible for commitment under sexual civil commitment laws [16]. This decision no longer required the presence of a major mental illness and instead provided commitment power to states on the basis of a variety of disorders, including personality disorders. In contrast to most previous decisions concerning criteria for civil commitment, the court expanded upon what could lead to loss of liberty. The court in Crane stated,

> "In recognizing [in *Hendricks*] that [lack of control is required], we did not give to the phrase lack of control a particularly narrow or technical meaning. And we recognize that in cases where lack of control is at issue, inability to control behavior will not be demonstrable with mathematical precision. It is enough to say that there must be proof of serious difficulty in controlling behavior. And this, when viewed in light of such features of the case as the nature of the psychiatric diagnosis, and the severity of the mental abnormality itself, must be sufficient to distinguish the dangerous sexual offender whose serious mental illness, abnormality, or disorder subjects him to civil commitment from the dangerous but typical recidivist convicted in an ordinary criminal case." (p. 413)

This decision has led one scholar [17] to suggest that relying on personality disorders and paraphilia as mental disorders represents a weak link in mental health diagnoses and should not be used as a basis for commitment. Despite substantial criticism these laws have continued to expand throughout many jurisdictions in the United States.

Since the beginning of laws authorizing the civil commitment of sex offenders, 17 states have enacted legislation with the subsequent commitment of over 2500 sex offenders [18]. These laws are based upon the state's responsibility to protect its citizenry from undo harm. In committing sex offenders, it has been argued that the state's rights for safety outweigh the loss of liberty for sex offenders who are likely to commit future sexual crimes. Nonetheless, there have been substantial criticisms, beyond diagnostic issues, leveled against laws authorizing the sex offender commitment. These criticisms have been aimed at three broad aspects of sex offender laws: (i) the inaccuracy of sex offender civil commitment evaluations [19], (ii) the high cost of committing sex offenders to inpatient treatment facilities [20], and (iii) the misuse of the mental health system to commit sex offenders to indeterminate commitment in locked inpatient facilities [21].

In addressing the accuracy of sex offender evaluations, Jackson and colleagues [19] used case studies

with actuarial information to assess if 392 individuals attending a professional conference in psychology and law could accurately predict sexual violence. The results were discouraging in several ways. First, the results found that seasoned clinicians were no more accurate than graduate students at predicting which offenders would be reconvicted of a sex offense. In fact, these "experts" were "accurate in their predictions of future sexual violence approximately one-half of the time" (p. 124).

Another criticism that has gained momentum is considering the cost-benefits for civilly committing sex offenders for indefinite periods of time. The high cost of committing sex offenders has recently come under fire. Janus [20] discussed how the population of civilly committed sex offenders is growing in Minnesota and Wisconsin, which is taking away needed funding from more prevalent forms of violence, such as domestic abuse. Combined with the lack of studies demonstrating accuracy of commitment procedures, this could lead to large amounts of money being allocated to committing individuals to secure facilities who, in reality, pose little risk of sexual reoffense.

Lastly, using mental health laws to commit sex offenders has drawn additional criticisms. Appelbaum [21] paralleled the civil commitment of sex offenders to new legislation being introduced in England to confine dangerous offenders. He stated, "Identification of person's who are likely to commit violent acts in the future is a fraught process. . . . " (p. 398). His concerns could readily be applicable to sexual commitment evaluations, especially in light of recent research [18] questioning the potential issues with the accuracy of such evaluations. The problems with the commitment of sex offenders have led some legal scholars [22, 23] to question the construct of sexual civil commitment laws. Such concerns continue to fuel the controversy associated with the mandated treatment of sexual offenders beyond their prison terms.

Mandated Treatment of Insanity Acquittees

A concept in the treatment of individual found not guilty by reason of insanity (NGRI) is treating individuals in the community. Often, these individuals are released from locked inpatient hospitals and transitioned into the community [24]. However, these individuals, to minimize dangerousness and reduce mental health symptoms, are typically released with conditions. These conditions typically include those associated with probation and parole (e.g., abstinence from alcohol and drug, no firearms); however, conditions often include mandated treatment, including but not limited to medication compliance and treatment designed to decrease violence (e.g., anger management) [25].

Vitacco *et al.* recently studied the efficacy of a statewide program for conditionally released NGRI acquittees [26]. Results demonstrated a low rate of both general and violence recidivism with the largest number of NGRI acquittees being returned to the hospital for rule violations. Several other research studies [27–29] demonstrated similarly low rates of violence and aggression through the use of community-based mandated treatment. Although mandated treatment for NGRI acquittees has been implemented for a long time, recent advancements in how programs are administered and implemented have paved the way for fiscal responsibility and successful treatment.

Conclusions and the Promise of Mandated Treatment

The use of mandated treatment always presents a delicate balancing act between public safety and ensuring the rights of mentally ill individuals. That balance is made more difficult through changing conceptualizations of dangerousness and expansion of mandated treatment to sex offenders and insanity acquittees in communities. However, mandated treatment is an important tool that when used properly can decrease dangerousness and protect the public. With continued advances in neuroscience, mandated treatment may prove effective in keeping mentally ill individuals in the least restrictive environment and ultimately saving lives.

Treatment, Right to: Mental Health

Right to Treatment

The right to treatment and its antithesis the right to refuse treatment are cornerstones of therapeutic jurisprudence (TJ). As noted by Perlin, legal decisions regarding treatment rights should be considered from a TJ perspective because they maximize constitutional protections for the mentally disabled [1].

According to David Wexler, TJ is the focus and examination of law on human and emotional factors and transforming the legal system toward a therapeutic benefit [2]. Thus, instead of law for law's sake, TJ places the therapeutic goal ahead of all others, including efficiency, *starie decisis*, and legal formalism. In considering the right to treatment within the framework of TJ, there are several landmark cases harmonious with this point of view.

In reviewing these legal precedents, no case is as important for the right to treatment as *Wyatt v. Stickney* [3]. The court in the Wyatt case was unwavering in declaring that patients "unquestionably have a constitutional right to receive such individual treatment as it will give each of them a realistic opportunity to be cured or to improve his or her mental condition". This decision had a dual impact: on one level, it required the state of Alabama to provide treatment beyond the historical asylum model that often led to lifelong institutionalized care; at a broader level, it hastened the deinstitutionalization of thousands of mentally ill individuals, returning them back to the community. Since the right to treatment announced in *Wyatt* amounted to a judicial mandate to massively increase fiscal spending on an already overburdened public mental health system, the stage was set to end the decades long monolithic asylum model.

Unfortunately, for mental health clinicians, later judicial decisions further muddied the water with mixed rulings which obfuscated long held principles asserting the state's right to care for disabled and mentally ill persons. Much of the confusion was borne by the addition of numerous constitutional protections by the courts that dramatically changed the procedures used to provide institutionalized care. One such example is the decision in *O'Connor v. Donaldson* [4], where the Supreme Court tackled the issue of liberty for the mentally ill. In brief, the uncontested facts were that Mr Donaldson was delusional and believed he was being poisoned. Similar to many persons with severe mental illnesses, he possessed little insight into his illness and denied any need for mental health treatment. However, there were no evidence of manifest dangerousness and Mr Donaldson appeared to be capable of residing outside the state institution with little danger to self or others. The Court agreed with Mr Donaldson, which resulted in a simple and straightforward ruling: The key paragraph in the decision reads: "A finding of 'mental illness' alone cannot justify a State's locking a person up against his will and keeping him indefinitely in simple custodial confinement" and "In short, a state cannot constitutionally confine without more a nondangerous individual who is capable of safely surviving in freedom by himself or with the help of willing and responsible family members or friends." The *Donaldson* decision struck down many involuntary civil commitment laws in favor of expanded procedural protections transposing an informal process to one with most of the rigors of the adversarial process. Nonetheless, this ruling has been roundly criticized by mental health scholars [5, 6] on the bases that the O'Connor decision does not (i) provide adequate guidance regarding treatment and dangerousness, (ii) lacks empirical support, and (iii) provides little to no right for treatment for nondangerous individuals.

Despite the obvious ideological shift of the right to treatment movement from state paternalism to an emphasis on individual autonomy, this movement led to other notable outcomes. Indeed, right to treatment laws have indelibility influenced the public mental health system by ensuring that patients receive less coercive and effective treatment. The benefits often noted include improved quality of care and recognition of valuable constitutional rights among a frequently disfranchised group. However, frequent criticisms of this modern shift observed include increased risks of suicide, substance abuse, and involvement with the criminal justice system. Such issues highlight the need for effective treatment of the mentally ill, even in the absence of manifest dangerousness [7]. Within this framework, this article is designed to discuss issues and complications surrounding the right to treatment and how to navigate right to treatment from within the broader context of TJ. Once we discuss the issues related to the right to treatment, we further focus on three specific populations: adolescents, prisoners, and not guilty by reason of insanity (NGRI) acquittees. These populations have been instrumental in fueling discussions on treatment rights within medical and mental health contexts.

Navigating the Right to Treatment: Setting the Stage

The literature is replete with examples informing clinicians how to deal with right to treatment issues.

In correctional settings, there has been recent case law dictating that a constitutional right to treatment exists [8]. However, in other settings all practitioners too frequently left to their own judgment to navigate how to ensure that rights to treatment are upheld. Of course, difficult issues are prevalent in those decisions. For instance, the right to treatment does not denote which type of treatment patients are legally entitled. For example, what a therapist should do if a patient requests treatment that is less effective than a more empirically based one, yet the client is more comfortable with? This scenario is played out across the county often leaving clinicians to discuss the pros and cons of less effective treatment.

In the case of *Osheroff v Chestnut Lodge* [9], a physician sued Chestnut Lodge in Washington, DC for failing to provide appropriate treatment for his depression as he experienced intense despair during his entire seven-month stay. Instead of medication they offered one to one therapy. During the seven months, Dr Osheroff was declared incompetent, lost his medical practice, and his wife divorced him and took custody of their children. After seven months, he was transferred to another hospital, placed on antidepressant medications, and never needed to be rehospitalized for mental health symptoms. He eventually remarried and continued practicing medicine in New York. The case was eventually settled; however, its influence remains as it alerted mental health clinicians that they have the responsibility to ensure that a selected treatment, even if wanted by their patients, is not provided *in lieu* of treatment that is likely more effective (e.g., medications for depression) and to make sure that the record reflects they presented the client with several known benefits and liabilities of all known treatments.

In considering the right to treatment, Perlin [10] discussed considerations related to the availability of appropriate resources to ensure proper treatment decisions are made. As discussed above, clinicians have an ethical and potentially legal obligation to inform client of alternative, more effective treatments. In extrapolating TJ to issues of treatment in clinical practice, clinicians have a wide variety of issues to consider. Such issues include autonomy, decision-making capabilities, and providing an environment where informed treatment decisions can be made by clients who know their legal rights regarding treatment.

Juvenile Offenders and the Right to Treatment

Adolescents are no longer considered as parental properties incapable of decision making regarding their own treatment; instead, they are allowed autonomy regarding treatment decision. A recent public policy report highlighted the ever increasing practice of allowing adolescents to be responsible for many treatment-related decisions [11]. In many jurisdictions, adolescents are allowed to enter therapy without parental consent. This expansion of rights for adolescents is a recent development showing improved understanding of the capabilities and insight of adolescents regarding their best interests. This understanding is evidenced by changes in philosophy concerning the treatment of adolescents, including those incarcerated.

The right to treatment in adolescents in correctional settings is salient for another reason. If we view the right to treatment from a TJ perspective and we acknowledge that treatment is designed to improve quality of life, then it is a logical step to guarantee incarcerated adolescents with mental health issues treatment aimed at decreasing recidivism and promoting community tenure. Although these theoretical assumptions are laudable, achieving these goals remains elusive in practice. However, as we discuss in the forthcoming paragraph, a balance between incarceration and treatment can be obtained when using cost-effective, empirically based strategies.

In a study of young offenders, Shelton [12] discovered that only 23% of any youth diagnosed with a mental disorder residing in a juvenile detention facility received treatment. Such results are discouraging in light of recent evidence demonstrating that therapeutic interventions are cost-effective over the long term and serve to reduce violent and criminal recidivism [13]. These statistics underscore the need for effective treatment with adolescent offenders and provide a logical foundation for goals of treatment – simply, to minimize the likelihood of future criminal behavior while allowing the greatest opportunity for an incarcerated free life.

Nonetheless, programs for young offenders will continue to face challenges in the future. From a policy perspective, "get tough" programs for adolescent offenders have recently gained partial support due to several highly publicized horrific crimes of violence committed by some young offenders.

Thus, incorporating new treatment approaches often entails overcoming public skepticism, which favors traditional juvenile justice interventions that mirror approaches within the adult corrections system. Practitioners must find ways to integrate right to treatment within this complex system. One such way is to find empirically supported treatment that demonstrates recidivism reduction and long-term cost savings [13, 14].

Adults and the Right to Treatment

Like adolescents, challenges abound in the treatment of adult offenders within the criminal justice system are underscored by recent changes in policy. One such example is the formation of "super max" prisons where the focus is solely on management of offenders exhibiting behavioral problems in other correctional facilities or whose crimes are considered to be so horrendous that rehabilitation is not considered as an appropriate option. Such prisons primarily rely on isolation with the goal of protecting society and other prisoners from a selected group of intractable offenders. The creation of such facilities, which are vastly expensive, is borne from the popular notions that such offenders are untreatable, and thus, incapacitation is the only legitimate aim for this subgroup. Yet, the empirical evidence is mixed as to find whether such predictions are true.

Moreover, in regards to mentally ill offenders, court precedents consistently evince a right to treatment. Such rights are buttressed by significant case law decisions. A prime example is *Estelle v. Gamble* [15] where the US Supreme Court ruled that the Eighth Amendment of the Constitution guaranteed prisoners the right to medical care. Likewise, in ***Vitek v. Jones*** [16] 445 U.S. 480 (1980), the Supreme Court held that a mentally ill inmate was entitled to procedural protections given his impending transfer to a psychiatric facility. The court noted that the enduring stigmatizing effect inmates suffer when they are labeled and segregated based on their mental illnesses.

Not surprisingly, state institutions have been mandated to provide a basic level of services to individuals under their care. In ***Youngberg v. Romeo*** [17] the Supreme Court ruled that a mentally disabled child residing in a state institution in Pennsylvania had a right to several basic necessities including safe conditions within the institution, freedom from restraint, and adequate living conditions.

The right to treatment in insanity acquittees was underscored in *Rouse v. Cameron* [18]. Charles Rouse was committed to St Elizabeth's Hospital as NGRI on weapon charges, for which he was held indefinitely and significantly longer than if he was incarcerated in prison. The Circuit Court of Appeals for the District of Columbia reiterated that commitment is not used *in lieu* of incarceration and that individuals committed under NGRI standards have a right to treatment. As Judge Bazelton alluded to in the Rouse case, mental health practitioners must treat individuals, improve their functioning, and return them to the community when they are no longer ill. This perspective is wholly consistent with TJ, as it affirms the desire to place the person in the least restrictive environment and uses the law as a tool to do so.

Current insanity laws and requirements for continued commitment reflect this model of treatment. In *Foucha v. Louisiana* [19] the US Supreme Court held that continued confinement of Foucha would be unconstitutional as his mental illness was in remission and continued commitment required both the diagnosis of mental illness and dangerousness.

Foucha represented a step forward in the conceptualization of commitment and unlike other standards, it was clearly defined, even if the concepts of mental illness and dangerousness are not.

Conclusions

The right to treatment is a relatively new movement in mental health law. Although it is fairly new, the movement has gained momentum through court cases and its consistency with the concept of TJ. By using treatment to secure earlier release from inpatient facilities and improve overall functioning, the foundations for right to treatment are rooted in a person's rights of autonomy, which underlie the constitution. Yet this right to treatment lies in tandem with the right to effective treatment and release if treatment proves ineffective. The right to treatment presupposes that the individual is able to be treated and that practitioners have some treatment (e.g., medications or therapy) that would benefit the patient. Ultimately, the right to treatment would be most aptly construed as a right to effective treatment.

Treatment, Right to Refuse: Mental Health

Consequently, courts have decreed that mentally competent adults may refuse treatment even if such treatment is considered in their best interests. While many constitutional scholars point out that the word privacy is never mentioned in the federal constitution others maintain that privacy, and hence, autonomy is imbued within American legal traditions. As early as 1891, the United States Supreme Court held, "No right is held more sacred, or is more carefully guarded, by the common law, than the right of every individual to the possession and control of his or her own person, free from all restraint or interference of others, unless by clear and unquestioned authority of law [1]." This entry is going to discuss issues, with a specific emphasis on court cases, related to the right to refuse treatment.

The right to refuse treatment enjoys wide international support concurrent with the emergence of the modern privacy rights during the 1960s. The Canadian Supreme Court ruled in 2006 that the "right to refuse unwanted medical treatment is fundamental to a person's dignity and autonomy." This statement provides the ethical backdrop many cite in support of the right to refuse treatment. As noted by psychiatrist and Harvard law professor Stone [2] the right to refuse treatment has assisted in the development of informed consent documents, which have gained general acceptance in the mental health field and serve to inform patients of the benefits and risk of treatments. While mental health practitioners often view informed consent as a means of mitigating liability, their existence is borne from the notion that patients should understand risks entailed by medical procedures being performed on their body.

The increasing use of the right to refuse treatment has been roundly criticized by many groups who argue that the doctrine directly harms patients who are often unable to accurately assess the benefits of treatment because of the cognitive impairments inherent with their mental illnesses. Additionally, some argue that due process invariably requires lengthy procedural matters before courts that are ill equipped in discerning the potential harm patients risk when allowed to forego treatment. Such harm includes an increased risk of suicide, incarceration, homelessness,

victimization, and rehospitalization [3]. To describe cases where patients waited for treatment, a popular Wisconsin psychiatrist coined the phrase "dying with their rights on" to describe the well-intentioned, but problematic quagmire inherent when mentally compromised adults refuse treatment.

The right to refuse treatment has also permeated aspects of criminal procedure leading to incompetent defendants being allowed to refuse treatment to restore their competency [4]. While criminal defendants enjoy this right under a different rubric of the privacy doctrine, the courts have nonetheless recognized a limited right of defendants to refuse treatment when there does not exist a compelling state interest for involuntary treatment. Although complications are numerous when trying to balance the best interests of patients with their right to refuse treatment, practitioners must be cognizant of how the right to refuse treatment can influence the manner in which they practice. To improve our understanding of the right to refuse treatment, we will evaluate court cases and discuss their influence on clinical practice.

Influential Court Cases and the Right to Refuse Treatment

There are wide ranging cases that have been decided at the state and federal level that provide guidance on the right to refuse treatment. A close review of these cases demonstrates wide jurisdictional differences in the refusal of treatment and how such refusal can be overcome by the state. In the following section, we will explore many of the influential cases from the last 50 years and their application to the right to refuse treatment.

In the "Application of the President and Directors of Georgetown College, Inc." [5] the rights of individuals and the medical establishment conflicted and court guidance was sought regarding the potential death of a patient who refused medical treatment. In this instance the discussion of the right to die after a suicide attempt was at the forefront. In this case, the court ruled, "where attempted suicide is illegal by the common law or statute, a person may not be allowed to refuse necessary medical assistance when death is likely to ensure without it." Since suicide has long been considered illegal in most jurisdictions, courts will refuse to recognize a right to an essentially illegal act. However, in cases where death is imminent because of disease, such as cancer, the decision to end life may ultimately rest with the circumstances of the case, although the recent trend has been a broadening recognition of the "right to die" (see generally *Cruzan v. Director* [6]).

The ability to refuse medical treatment has also been extended to mental health patients and incarcerated individuals. The case of *Rennie v. Klein* [7, 8] was a landmark decision in mental health law and began setting parameters for when an individual could refuse mental health treatment. In this case, Mr Rennie was involuntarily hospitalized because of schizophrenia and decompensation after his brother's death; however, he refused to take his prescribed antipsychotic medication. The hospital, believing the treatment was in his best interests and Mr Rennie incompetent to decide the matter, applied in the court for permission to involuntarily treat Mr Rennie. The United States District Court of New Jersey ruled that (i) Mr Rennie could not be forced psychotropic medications in the absence of an emergency situation and (ii) medications might not be forced without offering the patient due process. The importance of this decision is that it required a finding of dangerousness and entitled patients to basic due process rights prior to involuntary administration of treatment.

The Rennie decision set the stage for new refusal rights for mentally ill individuals. Subsequent decisions continued to expand on those newly acquired rights. Notably, in *Rogers v. Orkin* [9], the Massachusetts Superior Court ruled that even individuals deemed appropriate for involuntary commitment had a right to refuse medications. The court in Rogers differentiated the need for commitment versus a finding of incompetence to refuse medications. The bottom line was that a justification for committing an individual to a hospital could not be substituted for the due process necessary to mandate medication. In the absence of due process, the continued right to privacy regarding control over one's body was viewed as superseding the right of the state to medicate without further due process.

Another Massachusetts case *Rogers v. Commissioner* [10] established that a judicial hearing is required for overriding an individual's unwillingness to take medications and competent patients have the right to refuse medication. Such a model is found in a recent decision in the state of Alaska [11]. In *Myers v. Alaska Psychiatric Institute* [11], the Supreme Court of Alaska ruled, "In the absence of emergency, a

court may not authorize the state to administer psychotropic drugs to a nonconsenting medical patient unless the court determines that the medication is of the best interests of the patient and no less intrusive alternative means is available (p. 239)." Formal judicial hearings have become the cornerstone of right to refuse treatment in addition to informed consent.

A patient's consent to treatment has long been considered fundamental to American jurisprudence [12]. Nowhere was this fundamental right more evident than in the case of *Zinermon v. Burch* [13]. In 1981, Mr Darrell Burch was found wandering incoherently and bloodied along a Florida highway and was brought to a private hospital. Once there, Burch was clearly delusional (e.g., reported being in heaven) and appeared confused. He agreed to be admitted to the hospital and signed consent forms to be admitted. Eventually he was transferred to Florida State Hospital (again, he signed informed consent to be admitted) and was successfully discharged after five months at Florida State Hospital.

Three years later, Burch sued his doctor, Marlus Zinermon and the state of Florida alleging civil rights violations that he was subjected to during involuntary confinement, which included treatment. The Supreme Court sided with Burch and ruled that a violation of rights occurs when an incompetent individual is allowed to voluntarily enter a mental health hospital because the person is incapable of providing consent. In these cases, the hospital bears the responsibility of applying for an order of commitment in a court of law within a certain designated period of time, usually 72 h.

The decision in *Burch* raised the bar for hospitals higher in ensuring that an individual they suspect as incompetent be provided a judicial hearing on the matter to protect patients' rights. As noted by the court in an earlier decision [14], involuntary treatment for the mentally ill is unconstitutional if the mentally ill individual can survive safely with the help of friends or family.

As evident by the above cases, the issue of consent and the right to refuse treatment have been clear with individuals with mental illness. Further, the court has also ruled on prisoners. The case of *Washington v. Harper* [15] exemplifies the complex issues involved in right to refuse treatment cases. Harper was a mentally ill inmate whose violence was reduced through compliance with antipsychotic medications. Nonetheless, Harper refused his medications and sued the prison. The United States Supreme Court ruled that the decision to medicate Harper should be left to medical professionals and that in doing so Harper's interests in liberty must be weighed and balanced with the interests of the government to provide a safe and orderly penal institution. In this case, the Supreme Court ruled that an administrative act was sufficient and no formal judicial hearing was constitutionally required to ensure that Harper's rights were protected.

Pretrial issues related to mental state are also influenced by right to refuse treatment decisions. A question that may be posed by a defendant is whether the jury has a right to view the defendant in an unmedicated state when a mental health issue might be the crux of the case. The case of *Commonwealth v. Louraine* [16] grappled with this issue. Mr Louraine was on trial for first-degree murder after stabbing a man 21 times in a halfway house for individuals with mental illness. In this case, the Supreme Court of Massachusetts ruled that the trier of fact is entitled to see the defendant in the unmedicated state, especially as it relates to mental health issues (e.g., mental state at the time of the offense). Allowing the right to refuse treatment to apply to pretrial defendants simply means that the defendant's demeanor is as important as verbal testimony when considering certain mental health issues. Certainly, viewing a defendant in a nonmedicated state when the person is more disorganized and symptomatic may improve the likelihood of a jury accepting a mental health defense.

Right to Refuse Treatment and Therapeutic Jurisprudence

Like its counterpart, the right to treatment, the right to refuse treatment has been viewed from the perspective of therapeutic jurisprudence. As Winick [17] discussed, refusing treatment is controversial, yet remains sanctioned by the law of the United States, even in life threatening situations. Viewing the right to refuse treatment through the lens of therapeutic jurisprudence maximizes constitutional rights to individuals with mental disorders and those experiencing significant medical issues [18]. Relatedly, competent individuals have wide latitude to choose

tailored treatment or refuse treatment altogether and consider a wide range of factors including religious and cultural beliefs. Moreover, as noted in the landmark cases of *Rogers* and *Rennie*, the presence of a mental illness did not equate to incompetence and required separate due process; no longer were incompetence and mental illness equated in the eyes of the court.

Conclusions

In a broad analysis, practitioners and hospitals must consider several factors regarding the right of an individual to refuse treatment. In our conclusion, we provide several key considerations regarding the right to refuse treatment relevant to both practitioners and legal advocates.

1. The right to refuse treatment is fundamentally linked to privacy.
2. The fundamental right to refuse treatment is not absolute and can be overturned if the individual wishing to refuse treatment is either incompetent to refuse treatment or considered dangerous.
3. Be aware of jurisdictional issues regarding the right to refuse treatment. Often, laws vary widely from jurisdiction to jurisdiction concerning how issues related to right to refuse treatment are handled.
4. Informed consent is a critical component of both the right to treatment and the right to refuse treatment; however, informed consent is only valid when completed by a competent individual.
5. The right to refuse treatment has been considered through a lens of therapeutic jurisprudence where the constitutional rights of the disabled are afforded maximal protections.

Considering the right to refuse treatment with these in mind will improve quality of care and allow for the rights of the ill to be cared for while remaining mindful of the responsibilities of practitioners.

Ultimate Issue Evidence by Experts

A recognized axiom of the common law is that the finder of the facts is the sole authority on what happened during events that gave rise to litigation. Witnesses were traditionally not permitted to speculate on the "ultimate issue" of guilt or innocence, or on whether the defendant was negligent or careful, or whether necessary facts had really occurred. It was also a general rule that an expert testifying as (*see* **Expert Opinion: United States**) to cause and effect from an analysis had to state his conclusion as a matter of expert opinion, and not as "fact". Cases later extended the rule to exclude opinions which embraced the issue that was to be the final resolution of the events on which the litigation was based. The rule came to be known as the *ultimate issue doctrine* [1].

Over the years the rule's prohibition was gradually relaxed because many expert findings unavoidably border on what might be considered the ultimate issue questions. Legal scholars, also, had strongly criticized the barring of experts' ultimate issue opinions. Thus, in recent times, the prohibition all but disappeared and experts are, today, permitted to state opinions based on most though not all facts that relate to the ultimate issue to be resolved.

In the US federal courts, the common law prohibition was abolished when the Federal Rules of Evidence (FRE) (*see* **Federal Rule of Evidence 702**) were adopted in 1975. Rule 704 specifically provides that expert opinions or inferences are not objectionable solely because they embrace the ultimate issue to be decided. However, the rule retains a prohibition against certain behavioral expert witnesses' opinions.[a]

While a clear modern trend of state courts has been to follow the federal model and abolish the ultimate issue rule, that movement is by no means unanimous. Some courts have specifically rejected the relaxation of the prohibition on ultimate issue opinions. Thus, one court stated:

> We are not prepared to reject the ultimate issue prohibition . . . in a criminal case . . . where life or liberty often turns upon inferences raised by circumstantial evidence The process of resolving conflicting inferences, affected as it is by the credibility of the witnesses who supply such evidence, is the historical function of a jury. . . . We are unwilling to entrust that function to experts in the witness box [2].

End Notes

[a.] FRE 704 on opinions relating to the ultimate issue to be decided provides the following:

(i) Except as provided in subdivision (ii), testimony in the form of an opinion or inference otherwise admissible is not objectionable because it embraces the ultimate issue to be decided by the court.

(ii) No expert witness testifying with respect to the mental state or condition of a defendant in a criminal case may state an opinion or inference as to whether the defendant did or did not have the mental state or condition constituting an element

of the crime charge or of a defense thereto. Such ultimate issues are matters for the trier of fact alone.

Subdivision (ii) was added by Congress in 1984, as a result of a celebrated trial wherein multiple psychiatric experts for the government testified that the defendant was sane, and equal number testified for the defense, asserting the defendant's insanity. A behavioral science expert can, of course, testify to a diagnosis with regard to defendant's mental state and motivation, as long as these findings are expressed in clinical terms, rather than as ultimate legal conclusions.

Use of Knowledge-Based Systems in Forensic Science

Introduction

A knowledge-based system (KBS) is a computer system that is programed to imitate human problem solving by means of artificial intelligence and reference to a database of knowledge on a particular subject [1]. KBSs exist in various guises and specialties in forensic science, but they generally have one common goal – consistency. Many forensic scientists concern themselves with the idea of consistency. This means that if a piece of evidence is measured or evaluated using the same technique, then two scientists should independently arrive at the same result. Inherent in the goal of consistency is the idea that the user of a KBS can draw on and add to the knowledge and information contained within a system. For example, programs such as Computerised Assistance for Glass Evidence (CAGE) use information from previous scientific studies on transfer and persistence of glass, and allow users to see the probability distributions used by other analysts in similar glass cases.

KBSs have become increasingly important to forensic scientists. They allow new scientists to use the results of previous research and casework, and, at the same time, add to the repository of information contained therein. Such systems can reduce errors and improve the quality of casework. At the heart of many KBSs lies a graphical model or Bayesian network [2]. Bayes nets allow scientists to formalize the conditional dependencies that exist between variables in a complex process without necessarily concentrating on the statistical detail that may be defined or refined at "run time". Such systems will become increasingly more commonplace in the forensic community in the future.

The remainder of this article attempts to briefly review the KBSs that are in active use in the forensic community. The list of systems is by no means exhaustive.

The Statistical Evaluation of Forensic Glass Evidence

The evidential value of forensic glass evidence has been heavily statistical since the early 1970s [3, 4]. One of the first problems that scientists in this field encountered was calculating the required quantities from Student's t distribution. Previously, this had been done with published tables, an approach that is slow and error prone. Because they cannot be exhaustive, tables are also subject to rounding and interpolation errors. To counter this problem, and to aid in the process of grouping recovered glass, Evett and Lambert [5, 6] designed the program RUNG [7]. This program evolved with the input of John

Buckleton and Richard Pinchin into a commercial product called Fragment Data System (FDS). This program incorporated the work of Evett, Lambert, Buckleton, and others. RUNG was not a KBS as such because it incorporated no prior knowledge from either the literature or from other casework. However, RUNG is regarded as an important precursor to later work. FDS took a small step toward being a KBS in that it allowed the user to calculate part of a likelihood ratio by using a refractive index (RI) frequency table. CAGE, produced by Richard Pinchin and John Buckleton, was the first real KBS for the evaluation of likelihood ratios with glass evidence. CAGE allowed nonspecialists to evaluate the likelihood ratios espoused in the revolutionary work of Evett and Buckleton [8, 9]. CAGE was revised and altered by Hicks and Wyss and rereleased as CAGE 2000. The aim of CAGE 2000 was to develop user documentation and make the program accessible from the internet. The purpose of the latter was to include as much expertise as possible from the global community into the system [10].

Curran, in his PhD work, produced two programs for glass evaluation. The first was Statistical Analysis of Glass (StAG), which implemented the work of Walsh *et al.* [11] on a continuous approach for glass evidence, and the work of Triggs *et al.* [12] on divisive grouping. The second program produced by Curran is called TRANSFER [13], and it allows the expert to input case details from scene examination in order to estimate the transfer probabilities. TRANSFER (also known as TFER) was one of the early users of a graphical model or Bayes Net, and the first program that allowed the user to alter the model graphically, albeit in a limited way.

RUNG, FDS, and StAG are systems that allow the comparison of RI measurements, and, in the case of the latter two, calculation of the continuous part of the likelihood ratio. TRANSFER is a KBS explicitly for the evaluation of transfer probabilities that are part of the likelihood ratio (LR) calculations for glass. CAGE and CAGE2000, on the other hand, attempt to encompass all of these tasks as a true KBS should.

None of the systems deal with the evaluation of elemental concentration information arising from glass evidence. Curran *et al.* [14], Aitken and Lucy [15], and Aitken *et al.* [16] present likelihood ratio calculations for multivariate evidence that rely on the user having a database of measurements of elemental concentrations from other samples of glass not related to the case at hand.

The Evaluation of DNA Evidence

The evaluation of forensic DNA evidence is a complex, multistage task and can be aided by KBSs at each stage. KBSs exist for the postamplification stages of DNA evidence handling. The first stage is automated allele designation. Modern DNA typing equipment produces a "trace" corresponding to each of the three to five marker dyes that are used to tag different groups of loci. This set of traces is called an electropherogram (or epg), and information about the alleles present in the epg is given by "peaks" on the traces measured in the relative fluorescence units (rfus). The height of the peaks corresponds roughly to the basic amount of DNA present. The location of the peaks along the horizontal axis (size in base pairs) is matched to an allelic ladder, and it is here that the allele is designated. Software that automates this designation process must take into account knowledge of the multiplex in use, the performance of the machine in the particular run in which that evidence was measured, and information about the stochastic behavior of the systems. On the basis of this information, a KBS makes allele designations and usually allows the expert to override those designations. The next stage of the process depends on the circumstances of the case. It may be that no suspect exists, and matching profiles are searched for in a database of known offenders. Similarly, one may look for "matching" relatives of the true offenders. Alternatively, if there are suspect profiles, then an assessment of the relative strength of the evidence, given the purported facts of the case, may be carried out. KBSs can aid in all of these tasks.

The Forensic Science Service (FSS), driven by Ian Evett, Richard Pinchin, John Buckleton, and Peter Gill were early proponents of producing specialist software for the interpretation of DNA evidence. The software produced by the FSS covers a raft of tasks. First, for automated allelic designation, there is STRess and it's predecessor STRipe. Familial provides computer-aided search of DNA databases for profiles of potentially related individuals. Kwikmix I, II and III (Curran, Healy, and Young) provide implementations of traditional nonquantitative DNA mixture interpretation [17, 18]. Kwikmix III may be used

in conjunction with Pendulum (Buckleton, Pinchin, Curran, Healy, and Young) [19, 20] (now known as i-Stream) to provide a computer aided implementation of the binary approach to DNA mixture interpretation. In the binary approach certain allelic combinations may be ruled as infeasible given the quantitative information available from modern genotyping systems. The FSS-i^3 suite of tools (i-STRess, i-STReam and i-ntegrity) are heavily validated and in current use in the United Kingdom and around the world. Kwikmix III is validated and in internal use in the FSS. LoComatioN (Curran and Healy) is a system that allows the nonexpert to statistically evaluate Low Copy Number (LCN, also called low template DNA) evidence, using an extension to the methods of Gill and Buckleton [21, 22]. The program FINEX (also known as HyperDue) written by Robert Cowell [23] allows the evaluation of likelihood ratios for complex pedigree problems. Although heavily validated, LoComatioN [24] and HyperDue are not currently used in casework.

There are also several programs that are not produced by the FSS that are in common use. DNAMIX I, II (John Storey) and III (Gary Beecham) is a package for traditional interpretation of DNA mixtures based on the work of Weir *et al.* [18], Curran *et al.* [17], and Beecham and Weir [25]. Charles Brenner produces a package called DNA-VIEW, which allows, amongst other things, the user to interpret DNA mixtures as well as do paternity and kinship analysis (http://dna-view.com/dnaview.htm). Mark Perlin and Beata Szabady [26] developed a method for the deconvolution of mixtures based on linear analysis that is implemented in the software Trueallele®.

In conjunction with a recent book on the statistical interpretation of DNA evidence [27], and following a series of dedicated papers by Fung and Hu, a software suit is now available to handle computation of mixed DNA profiles and kinship cases (http://www.hku.hk/statistics/EasyDNA/).

The Institute of Environmental Science Research Limited (ESR) has several products for DNA evidence. The program FaSTR is designed to do automated allele designation [28], and SPURS (Curran) estimates the sampling error in DNA mixture calculations using the Bayesian highest posterior density (HPD) method described in Curran *et al.* [29, 30]. SPURS III (Curran, Delme Thomas, Tony Ellis) also evaluates DNA mixtures both symbolically and numerically.

Outlook

KBSs are expected to be developed in the future on other evidence types as well, as they allow for consistency, storage, and transmission of expert knowledge. KBSs on other evidence types are being developed: The FSS produces a system for a Bayesian interpretation of fingerprint evidence. This system implements the work of Neumann *et al.* [31, 32]. DNA will remain an area with strong needs that will be met either through academic research (see e.g., http://people.math.aau.dk/~tvede/dna/) or commercial development (such as GeneMapper® ID-X from Applied Biosystems, the FSS-i^3 suite from the FSS, or TrueAllele® from Cybergenetics).

Variable Number Tandem Repeats

Introduction

There are a range of polymorphisms available for scientific analysis, many of which are capable of assisting the assessment of identity in a forensic inquiry. One major variety of polymorphism applied for this purpose are a particular type of repetitive sequence known as *minisatellites*, or variable number of tandem repeats (VNTRs). VNTRs are large fragments of DNA that are composed of sequentially aligned units, each of which has a high degree of sequence homology. Individual units are typically between 20 and 100 bp in length and are repeated consecutively up to 100 times. The overall molecular weight (MW) of a VNTR locus is determined by the number of times that the units are repeated. This is the polymorphic feature of these loci. VNTR loci are highly polymorphic and for that reason are powerful identification markers.

VNTRs were the first loci ever targeted in mainstream forensic DNA techniques. In the technique developed by Sir Alec Jeffreys [1, 2] VNTRs were analyzed using restriction fragment length polymorphism (RFLP) and following electrophoresis were visualized on an autoradiograph via Southern blotting [3]. These methods, originally referred to as "DNA fingerprinting", produced highly discriminating results in criminal [4] and noncriminal [5] cases. Restriction enzymes were specifically chosen to correspond with sites that flanked minisatellite loci. This meant that the minisatellite was excised and the inherent length variation of the loci was assessed (Figure 1). If a single DNA probe was utilized, the method was known as *single locus profiling* (*SLP*) whereas if a collection of probes were used this was termed *multilocus profiling* (MLP).

While the RFLP-VNTR approach was valid and reliable from a forensic perspective, the technique had significant limitations. A large volume (greater than 50 ng) of high-molecular-weight (HMW) high-quality DNA was required for RFLP analysis [6]. The technique was laborious and time consuming and radioactive materials were required for detection. The technique was unable to unequivocally resolve all the alleles of most VNTR loci and as such was criticized for the level of subjectivity required to interpret results [7–9].

A profound extension of forensic capabilities came through the emergence of the technique known as the *polymerase chain reaction* (*PCR*) [10, 11]. Essentially a sample preparation step, the PCR amplifies subanalytical quantities of DNA to a concentration that allows genotyping to be performed by routine analytical methods that vary according to the polymorphism being analyzed. Early PCR-based methods targeted smaller VNTR loci such as the D1S80 locus [12, 13]. These approaches were available in commercially produced DNA profiling kits and proved to be robust and effective forensic tools, providing an average random match probability (RMP) of approximately 10^{-4}, and requiring a template DNA concentration of only 2–5 ng (10–25

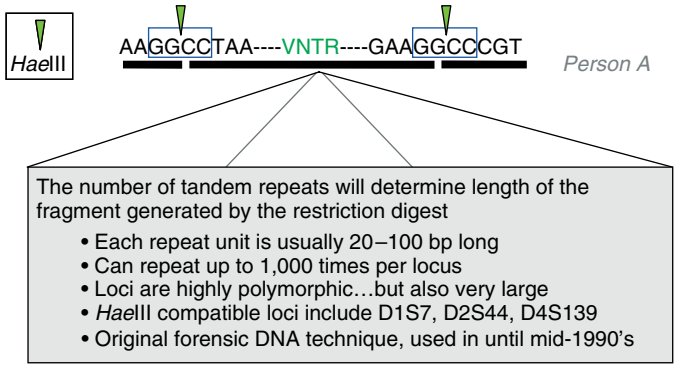

Figure 1 Diagrammatic representation of RFLP-typing of VNTR loci using a commonly applied restriction enzyme, *Hae*III

times less than required for RFLP-based VNTR typing).

Violence Risk Assessment for Mental Health Professionals

A Bureau of Justice National Crime Victimization Survey found the annual rate of violent victimization to be 12.6 per 1000 for all workers. In comparison, the annual rate of violent victimization for mental health professionals was 68.2 per 1000 [1]. Compared to the rest of the healthcare field, the rate of violent victimization for mental health professionals was found to be approximately three times higher. Approximately 32.4–56% of psychiatric trainees reported being assaulted sometime during their training [2–5]. The subject of violence committed by patients both in the community and against mental health professionals has become a pressing issue for mental health professionals. When fatalities occur and are highly publicized, both public and professional concerns are raised about the adequacy of mental health assessment and treatment of potentially violent individuals [6]. Additional concerns about risk assessment and prevention have arisen as a result of changes in the public mental health system over the past several decades. The public mental health system is now servicing an increasing number of patients with serious mental illness who have been transferred from correctional institutions or other forensic services [7, 8]. It is understandable that this trend might increase clinician anxiety; however, its actual effects on risk management are still unclear.

The causes and treatment of pathological aggression and violence remain poorly understood despite their substantial costs to society [9]. It is believed that the vast majority of persons suffering from mental illness are not violent; rather, certain untreated symptoms appear to increase the risk of violent behavior [10]. The paucity of evidence-based research on

assessing and managing violence in clinical practice is striking, and has left clinicians with little guidance on which approaches may be best in the acute setting. In particular, there is a major gap in the research addressing how the clinician should approach even basic procedures such as interviewing for violence risk, or responding to a patient's aggressive behavior.

To date, most studies of patient violence have recommended implementing staff training that includes (i) didactic lectures on the biopsychosocial causes of violence, (ii) identifying high risk clients, (iii) training concerning the use of seclusion and restraints, (iv) regular patient risk conferences, (v) conflict management training, (vi) simulated training exercises, and (vii) required reporting of incidents [11, 12]. Clinical risk assessment and management involves identifying patient factors that affect violence risk (both aggravating and protective factors), organizing one's reasoning in the context of the patient's circumstances, and coming up with a risk management plan [12]. (*see also* **Risk Assessment: Patient and Detainee**; **Duty to Warn**).

General Principles

It is possible to conceptualize risk factors as falling into two broad categories – dynamic or static [13]. "Dynamic risk factors" are fluid and potentially modifiable. The clinical importance of dynamic risk factors lies in the clinician's potential ability to target them with interventions. "Static risk factors" do not change (e.g., gender, past violence), and have shown a statistical relationship with violence risk.

The following points are basic, yet important principles of clinical risk assessments:

1. Risk assessments should be contemporaneous (i.e., done immediately after the clinical encounter).
2. Risk assessments should consider both risk enhancing and protective factors.
3. Risk assessments should consider dynamic and situational variables.
4. Risk assessments should be done at clinically relevant or critical times (e.g., removal of restrictions, level changes, clinical worsening/improvement, discharge, etc.).
5. Whenever possible, relevant collateral data should be gathered (e.g., mental health records, police or probation records, etc.). Some clinical scenarios may warrant contacting family or social contacts, which may require the patient's documented consent. In the case of a psychiatric emergency, consent is waived.
6. Documentation of risk assessments should include decisions and reasons for choosing, or not choosing a particular intervention. This serves as a proof that you used careful, thoughtful reasoning consistent with the standard of care – or, what the courts refer to as "reasonable professional judgment".

Risk documentation should include some form of analysis of risk factors, and a general estimate of overall risk level (low, moderate, or high). Some experts believe that due to significant inter-rater reliability problems in the clinical setting with ratings in the "moderate" range, only ratings of low or high can be reasonably considered. This is the reasoning adopted by the Classification of Violence Risk (COVR) software program, designed to assist clinicians with decisions about discharge planning for acutely hospitalized civil patients [14]. The risk level should be followed by a treatment plan that directly addresses each relevant dynamic risk factor, and the clinician's reasoning for choosing or rejecting options.

In the forensic risk assessment literature, numerous actuarial risk assessment instruments (ARIs) have been developed. ARIs attempt to make predictions based on empirically demonstrated relationships between risk factors and outcomes [15]. These tools can be helpful guides for the clinician, but using them alone to determine patient management may run the risk of missing important clinical factors. Most authorities believe that they are best used to "structure" clinical judgment insofar as they remind the clinician to inquire about certain risk factors. Thus, at the present time, the standard of care *does not require* their use in clinical treatment settings [16, 17].

The standard of care requires mental health clinicians to "exercise the skill, knowledge, and care normally possessed and exercised by other members of their profession" [18]. Documentation showing that the clinician (i) performed a reasonable assessment of risk and then (ii) provided some rationale for implementing a reasonable management plan will be

very likely to meet the standard of care. The documentation need not be extensive, but should include the basic elements discussed in the following section on documentation.

The use of an ARI, or an ARI-derived checklist, to help "structure" the clinician's assessment may ultimately represent an "ideal" (above standard) practice. In the forensic mental health field, two of the most commonly used ARIs are the HCR-20 and Violence Risk Assessment Guide (VRAG), which have been shown to significantly predict violence in the community [19, 20]. These tools have enhanced validity when combined with a knowledge of "dynamic" risk factors derived from structured professional judgment [20]. These methods of approaching violence risk assessment are seldom taught to general clinicians and trainees who might benefit from them [21].

Summary of Clinical Violence Risk Factors

A *clinical violence risk assessment* quantifies the level of risk at a particular time using known risk factors, important clinical nuances, and professional judgment. Because violence risk is dynamic and influenced by many variables, periodic assessments over time are often necessary. The following list of risk factors has been culled from the above ARIs, the general literature on clinical violence risk [22–28], and consultation with forensic mental health experts in the field of violence risk assessment. The risk factors below are intended to assist the clinician in structured assessment of risk:

Historical factors

- past violence – must consider the pattern (egosyntonic, affective, and predatory);
- severe or frequent past violence;
- use of weapons during violent acts;
- age – late teens, early 20s
- male gender;
- low IQ;
- unemployed;
- major mental illness;
- criminal record;
- combat training;
- access to and familiarity with weapons;
- juvenile delinquency – especially first arrest before age 18;
- cruelty to animals, fire setting;
- childhood abuse.

Clinical factors

- homicidal or violent thoughts;
- substance use;
- impulsivity;
- poor insight into mental illness or past violent behaviors;
- noncompliance with treatment;
- psychosis: especially command hallucinations of familiar voices, and hallucination-related delusions;
- delusions: especially persecutory, systematized, misidentification syndrome, history of acting on delusions;
- depression – with suicidal ideas, or ideas about committing a homicide-suicide;
- mania (acutely symptomatic);
- organic brain dysfunction: especially traumatic brain injury, frontal lobe syndrome, and intermittent explosive disorder;
- posttraumatic stress disorder (PTSD) (acutely symptomatic);
- lack of empathy, antisocial or psychopathic traits;
- paranoid personality traits;
- accepting or condoning attitudes toward violence.

Acute factors

- homicidal or violent intent or plans;
- intoxication or recent substance use;
- actions taken on plans/threats;
- unconcerned with consequences;
- no alternatives to violence seen;
- intense fear or anger;
- specified victim – consider proximity, likelihood of provocation.

In addition, Table 1 outlines other important factors to consider after a patient has made a threat.

The Risk Management Plan

A risk management plan should be crafted immediately after the clinical risk assessment has been completed. Recall that risk assessments should be done at clinically relevant or critical times, such

Table 1 Factors to consider in assessing threat and risk [29][(a)]

A – *Attitudes that support or facilitate violence*: What is the nature/strength of the patient's attitude toward the behavior? Condoning or accepting? The stronger the perceived justification, the greater the likelihood of action. It may be helpful to assess the patient's appraisals of provocation from others, violent fantasies, and expectations of outcome.
C – *Capacity or means to carry out the violence*: Does the patient have the physical or intellectual capability, access to means, access to the victim, or opportunity to commit the act? How well does the patient know the victim's routines, whereabouts, etc.?
T – *Thresholds crossed*: Has the patient already engaged in behaviors to further the plan? Acts committed in violation of the law suggest a willingness/ability to engage in the ultimate act.
I – *Intent*: Does the patient have mere ideas/fantasies or solid intention? Level of intent may be inferred from the specificity of the plans and thresholds crossed. How committed is the patient to carrying out the act? Does he believe he has "nothing to lose"?
O – *Others' reactions and responses*: What reactions does the patient anticipate from others? Does the social network reduce or enhance the risk? Do social contacts believe the patient is serious?
N – *Noncompliance with risk reduction*: Is the patient willing to participate in risk management interventions? What is the patient's history of compliance/adherence to previous plans? How much insight into the situation does the patient have?

[(a)] Adapted from Borum and Reddy, 2001

as when the patient experiences a significant clinical worsening, significant stressor or upon admission and discharge. At such times, it may be necessary to obtain collateral data from mental health records, family members, or other social contacts. It should be noted that in the case of a psychiatric emergency (e.g., risk of suicide or violence) the need to preserve life supersedes the need to obtain consent. In most circumstances, this means that obtaining the patient's consent to contact family is not necessary.

The basic principle behind the "risk management plan" is to identify all those risk factors that are amenable to treatment interventions (dynamic risk factors), and target them with reasonable treatment interventions.

Documentation

The importance of good documentation cannot be overstated. It is the central piece of evidence in every malpractice trial, and good documentation has stopped many malpractice cases from proceeding. Courts do not expect clinicians to predict the future, prevent all tragedies, and render continuously flawless care. Rather, there is a general expectation that clinicians will use "reasonable professional judgment" based on a thorough consideration of the clinical data.

When clinicians do not document their reasoning, there is no evidence to show that they used thoughtful and reasonable professional judgment. Documenting information received, clinical decisions, and actions taken is an essential exposure-limitation technique [30]. The rule of austerity should be considered when documenting. In other words, the clinician should document the important facts and conclusions in an objective tone. The clinician should avoid waging battles of professional disagreement in the progress notes. Venting emotions into the progress notes rarely serves a useful purpose, yet is often harmful to the clinician who is a defendant in a malpractice case.

Risk assessment documentation should include some form of analysis of risk factors, and a general estimate of the overall level of risk. This should be followed by a treatment plan that directly addresses relevant dynamic risk factors, and the clinician's reasoning for choosing or rejecting options. In the event that instructions and information is given to the patient and the family, this too should be documented, along with whether or not they agree with the treatment decisions. In the event of a Tarasoff type situation, unrecorded warnings to a patient's family member that he or she has been threatened run the risk of being perceived as less credible by a jury.

When documenting interventions as part of the risk management plan (e.g., hospitalization versus intensive outpatient treatment, warning versus not warning a third party), it is advisable to include a statement explaining the rationale for the decision. For example, the clinician should document

that the option of hospitalization was considered, the clinical basis for rejecting that option, and the clinical basis for proceeding with a different option.

General Documentation Principles

First, the clinician should keep in mind at all times during actual documentation the fact that if a lawsuit occurs, the records may be read out loud in court [31]. In some cases, entire sections of the record are photographed, enlarged, and displayed on a poster board for the jury's inspection. Therefore, it is important that the documentation be clear and legible. To provide evidence of competent clinical care, the record should contain objective findings, patient statements, clinical judgments, and clinical decision-making. The most credible documentation is recorded, dated, and timed just after service is rendered. Documentation occurring after an adverse event is likely to be seen as self-serving and vulnerable to accusations of fabrication. After a tragedy has occurred, hindsight bias will often cause others to regard the event as more probable than it really was. Because many aspects of mental health treatment are less than "certain", it is helpful to document what seems tentative along with the reasoning for the clinical decisions. This helps emphasize the reality of the uncertainties inherent in clinical practice.

To counteract erroneous lay perceptions that all psychiatric patients are incompetent, at the relevant times the documentation should reflect the patient's capacity for decision making and ability to understand responsibilities such as reporting side effects, seeking emergency care, or notifying caregivers about changes in thought or mood. Quotations from the patient or family members are often viewed as highly credible evidences. For example, documentation that the patient stated, "I would never kill myself because I love my children too much", will provide important data for clinical decision making, as well as powerful evidence for a jury's consideration. Finally, even the most experienced clinicians regularly consider consultation with colleagues in difficult circumstances. Seeking an outside, objective opinion is the mark of a competent, caring clinician. In addition, documentation of the consultation will make it rather difficult for a plaintiff's attorney to claim that no other reasonably prudent clinician would have made the decision in question when both clinician and consultant have come to the same conclusion.

Visitation Rights

Approximately half of the marriages in the United States end in divorce, affecting more than one million children a year. Since about 10% of divorces involve litigation over custody or visitation, ∼100 000 children a year are the subject of legal battles. Mental health professionals (usually a psychologist, psychiatrist, or social worker with child training) aid the courts by providing recommendations for custody and visitation. The methodology for a custody evaluation, the topic of this chapter, has been described by the American Psychological Association [1], the American Academy of Child and Adolescent Psychiatry [2], the National Interdisciplinary Colloquium on Child Custody [3], and Bernet [4].

Brief History of Divorce and Child Custody

Public policy and legal practice in the United States have passed through several stages [5]. Through most of recorded history it was understood that the children of a marriage were the property of the father and he routinely took custody of the children when divorce occurred. During the latter part of the nineteenth century, both the English and American legal systems started to act on behalf of the child and consider the relative moral fitness of the competing parents. The "tender years" doctrine, which was introduced in the late nineteenth century, presumed that young children should be raised by the mother because she had a stronger attachment and would provide better care. Since the 1920s, lawmakers and courts have placed emphasis on "what is best for the interest of the child," as expressed by Justice Benjamin Cardozo in *Finlay v. Finlay* [6]. The concept of best interests

of the child is broad and somewhat elusive, but significant because it implies that the needs of the child are more powerful than the rights of either parent. Starting in the 1970s, our society emphasized equality between the sexes – for example, many women objected that they seemed to have lower status in the workplace and many men objected that they seemed to have lower status in child rearing. As part of this broad social phenomenon, fathers challenged the assumption that the mother should routinely be the custodial parent and the father the noncustodial parent. In 1981, the landmark case of *Ex parte Devine* [7] established that the tender years presumption violated the Fourteenth Amendment to the US Constitution. Thereafter, the courts increasing ordered fathers joint and primary custody.

Reasons for Custody Evaluation

The vast majority of parents who separate and divorce do not need an elaborate and expensive custody evaluation conducted by mental health professionals. In most instances of divorce, parents work these issues out between themselves. In other instances, a mediator helps the parents agree on plans for the child or a judge simply takes the available information and makes the decision for the parents.

A formal custody evaluation by a mental health professional may be helpful to the child, the parents, and the court in circumstances, such as the following:

- one or both of the parents have a mental disorder that may impair the person's parenting skills;
- the child may have mental health needs that the parents and court should consider in developing the custody arrangements or parenting plan;
- the divorce has been unusually hostile and the custody evaluation may be a less adversarial approach to make decisions involving the children;
- the child's relative attachment to the mother and father appears to be an important issue;
- it is suspected that one of the parents has tried to alienate the child from the other parent through suggestion or indoctrination; and
- a parent has been accused of physical or sexual abuse.

Format for the Evaluation

Although practitioners may vary in the details of their evaluation procedures, the following are common components of custody and visitation evaluations.

Initial Conference

It is sometimes helpful at the outset to have a meeting with the mother and father together in order to clarify the purpose and the format of the custody and visitation evaluation that is about to occur. This initial conference can be used to collect basic information and resolve all of the administrative aspects of the evaluation, such as the following:

- the chronology of the marriage, including the births of the children, the separation(s), and the divorce;
- the legal status of the case, such as pending court dates;
- the court order authorizing the evaluation;
- the names and addresses of the attorneys; and
- the current situation, including the current visitation schedule.

The initial conference can be used to schedule all of the testing and interviews that constitute the evaluation. It is also an opportunity to obtain the written authorizations from both parents to obtain additional information from the pediatrician, teachers, therapists, and other pertinent individuals. The evaluator should obtain written permission from both parents to release clinical information at the end of the evaluation to: both of the parents' attorneys; the guardian *ad litem* or attorney for the child, if there is one; and the court. The arrangements for payment should also be established at the initial meeting.

At the outset of the custody evaluation, it is wise to clarify ethical issues such as confidentiality and role definition. Both children and parents need to be aware that this forensic evaluation does not provide total confidentiality. Ultimately, much of this information will be presented in the written report (to be read by a judge, attorneys, and other persons) and perhaps in the testimony of the evaluator. Before accepting this document, the practitioner should clearly explain that any material that she reads in conducting the evaluation might, and in some jurisdictions must, be produced to the opposing parent and attorney.

Regarding role definition, it is important for the parties to understand the difference between a forensic evaluation and psychotherapy. That is, the forensic evaluation is not therapy, although it may be therapeutic in the general sense. Also, practitioners who are already involved with some member of the family as a therapist should not undertake to perform a custody evaluation. Those are mutually exclusive roles that should be performed by different professionals. Throughout the initial meeting, the evaluator observes how the parents speak and cooperate with each other, aiding the evaluator's formation of an opinion on legal custody.

Parent Meetings

The evaluator meets with each parent individually in order to complete a clinical evaluation and to assess that person's parenting attitudes and skills. This may require one long meeting of 2 or 3 h or several shorter meetings. Although evaluators have different priorities as far as what information to collect from each parent, a sample agenda could include the following:

- a brief history of the marriage;
- a brief history of the period of separation and divorce;
- information about each child, such as the parent's opinion of the child's strengths, weaknesses, and reactions to the divorce;
- the past history of the parent, including education, work history, and legal problems, such as arrests;
- the psychiatric history of the parent, including symptoms, episodes of treatment, and how it might have affected that parent's relationship with the child;
- the medical history of the parent, including use of drugs and alcohol;
- the parent's proposal for the child's custody and visitation; and
- the parent's feelings toward the other parent.

In order to assess parenting attitudes, the evaluator may decide to present several hypothetical situations for the parent to assess and resolve. For example, "If you are granted custody of the child, how would you help the child maintain a good relationship with the other parent?" and "If you lose custody, how would you maintain a good relationship with the child?" As with any psychiatric or psychological interview, the evaluator is interested not only in the content of the answers but also in the way the parent approaches the task of the interview and the parent's style of relating to the interviewer.

Child Meetings

The meetings with the child should be used to accomplish these tasks: complete a clinical evaluation of the child; assess the child's attachment to each parent; determine how the parents' separation or divorce has affected the child; and assess whether the child has been indoctrinated in some way. In most circumstances, the evaluator should determine the child's preferences regarding custody and visitation and his reasons for that preference. In some instances, it may not be appropriate or useful to elicit the child's conscious preferences. There should be at least two interviews with the child, so that each parent brings the child for one appointment. The content and format of the interviews depend on the age of the child.

Preschool Children. With preschool children, the evaluator may want to start the interview with the parent and the child together. The evaluator could invite the parent and child to engage in some play activity together, such as drawing pictures or building with blocks, and could ask them to plan a weekend outing together. It should be possible to make observations about how both the child and the parent deal with such an assignment. About halfway through the meeting, the evaluator should ask the parent to leave and explain to the child that the parent will be waiting outside the interview room. The evaluator would have explained this procedure to the parent prior to the interview. When the parent leaves the room, the evaluator should observe how the child and parent deal with separation. During the remainder of the meeting, the evaluator can use play, drawing, or other techniques that are customarily used in assessing young children. At the end of the meeting, the evaluator should observe how the child and parent deal with reunification.

School Age Children. With latency children, the evaluator can use a semistructured interview commonly used in clinical evaluations of children. She can introduce topics or tasks that pertain to school, peers, recreational activities, and family relationships.

Simple projective questions can be helpful, such as the baby bird story; the evaluator may say, "A baby bird that lived in nest with its mother and father. One day there was so much wind that the baby bird was blown out of the nest. The baby bird, could fly, but only a little bit. Tell me what happens next in the story."

The child might express himself through drawings, such as draw-a-person, drawing his family doing something exciting, or drawing a picture of something happy/fun and something that is not so nice. One approach is to make a list of the parents and step-parents and ask the child what he likes and what he does not like about each person. The child's dislikes might turn out to include information about child maltreatment or parental behavior such as alcohol and drug abuse. The evaluator might ask the child to describe the current custody and visitation arrangements and ask whether the child would want them changed in any way. If the evaluator chooses to elicit the child's preferences, it should be done in a way that minimizes the importance of the question. It is useful to mention that it is the judge who is going to decide this issue, not the child or the interviewer. Because of the possibility of parental indoctrination, the interviewer should explore what each parent told the child to say to the evaluator and what the parents say about each other.

Adolescents. With an adolescent, the evaluator may take the approach of asking the youngster to express his opinions about the current situation at home. For instance, an adolescent might relate his perception of the relationship between the parents, what he knows about the reasons for the divorce, and the effects of the divorce on his own life. Most adolescents can discuss the advantages and disadvantages of life with each parent, the merits of particular visitation arrangements, and how to keep their own lives from becoming entangled with their parents' issues. The adolescent may have definite opinions about where he wants to live and what he wants to say to the judge. The evaluator should explore in detail the reasons for the youngster's preference and also other aspects of the case, such as how the adolescent intends to maintain a good relationship with both parents.

Home Visits

Many custody evaluations include home visits at each parents' residences. A home visit could include checking for the following: safety (e.g., "baby proofing"); age-appropriate toys and educational material; adequate sleeping arrangements; suitable food supply; and first aid supplies. Many evaluators interview the child and parent during the home visit, instead of interviewing the child with the parent at the office.

Outside Information

In conducting a custody and visitation evaluation, the evaluator should collect information from certain outside sources after obtaining permission from one or both parents, as appropriate. It is usually helpful to interview the other people who live in the mother's or father's home, such as step-parents, grandparents, nannies, and other siblings who are not directly involved in the custody dispute. In some cases, it is appropriate to speak on the phone with the family's pediatrician, since she may provide unbiased observations about both parents' skills and attitudes. It is often important to speak to previous and current psychotherapists of the child and the parents. When speaking with collaterals, including teachers and therapists, the evaluator must be mindful that they may already be allied with one of the parents and weigh their opinions accordingly. Treating therapists should not make custody recommendations to the court; however, they can discuss their observations of the parties with the individual who is conducting the independent forensic evaluation.

Psychological Testing

Psychological testing can be very useful in many custody and visitation evaluations. Comprehensive personality inventories such as the Minnesota Multiphasic Personality Inventory-2 and the Personality Assessment Inventory can be used to screen for unidentified parental psychopathology and to determine each parent's overall psychological adjustment. Both of these tests also contain scales that indicate the person's openness to providing sensitive information.

In some circumstances, it may be helpful to conduct formal intellectual testing (if there is a question about a parent's cognitive abilities) or a battery of

projective tests (if there is a question about the diagnosis of a parent's mental illness). Projective psychological tests constitute an opportunity to observe the parent's efforts to cope with an unstructured and stressful situation, as well as providing information about psychological resources and characteristics. Other psychological tests, such as the Parenting Stress Index, can provide information about a parent's level of attachment to the child, perceived problem areas in the child, and the perceived helpfulness of the spouse. The Ackerman–Schoendorf Parent Evaluation of Custody Test is designed to assess the fitness of parents for custody. Of course, if psychological testing is used, the same tests should be administered to both parents.

Psychological testing of the child can also provide useful information. Behavior rating scales such as the Achenbach Child Behavior Checklist and the Personality Inventory for Children can identify problem areas and clinical syndromes. The Family Relations Test, although it is not standardized, provides a nonthreatening means of assessing a child's feelings toward each parent, as well as the child's overall style of dealing with unpleasant feelings.

There are several standardized psychological tests that are specifically intended for custody evaluations, including the Bricklin Perceptual Scales (BPS), the perception-of-relationships test (PORT), and the Parent Awareness Skills Survey [8].

Conference with Attorneys and Parents

At the end of a custody and visitation evaluation some practitioners schedule a conference with the attorneys and parents together. This face-to-face conference gives the evaluator an opportunity to explain her conclusions and recommendations and to explain why certain factors were considered more important and other issues less significant. This wrap-up conference gives the parents and attorneys an opportunity to ask questions and for both parties to have access to the evaluator's answers.

Critical Factors

It is understood that, in contested cases, decisions regarding custody and visitation are guided by seeking the best interests of the child. However, parents and attorneys may disagree and argue about exactly what constitutes the best interests of the child in their particular set of circumstances.

There is no standard set of guidelines for what factors should be taken into consideration and what weight should be given to each factor. Each state has its own laws and precedents that spell out the issues for judges to consider in that jurisdiction. It is likely that evaluators and judges are influenced by their personal values when they make recommendations and hand down decisions in these cases. Many legislatures, courts, and mental health professionals consider the following issues important in child custody and visitation determinations.

Factors Associated with the Parents

- **Parental Attitudes and Parenting Skills.**

The evaluator should be able to assess whether the parent truly tunes to the child's emotional and physical needs *or* simply considers the child a narcissistic extension of himself or herself *or* is extremely anxious, passive, and helpless in common childcare situations.

- **History of caretaking.**

An evaluator should assess the level of involvement of each parent in the day-to-day childrearing activities. That is, to what degree has each parent fed and bathed the children, supervised their homework, organized their birthday parties, and taken them to the pediatrician? Being an active parent favors that person to be the custodial parent, although the evaluator must also consider a parent's unavailability due to work obligations.

- **Continuity of placement.**

It is usually presumed preferable to continue the current custody arrangement unless there is a good reason to change it. Usually a parent cannot file for a change in custody unless there has been a change in circumstance since the last time the court decided the issue.

- **Parental alienation.**

The presence of alienation must be assessed. The reader is referred to the section in this encyclopedia for a review of parental alienation phenomena.

- **Physical health.**

It is important to assess whether one of the parents has a serious or chronic illness which would compromise that person's ability to nurture the child.

- **Mental health.**

The clinical evaluation should reveal any serious psychiatric condition or any significant drug or alcohol abuse. The evaluator should comment on whether the psychiatric condition will impair parenting skills. For example, a history of repeated bouts of paranoid schizophrenia would be ominous. The specific diagnosis may not be as important as an assessment of the person's parenting skills in the present and in the future.

- **The households.**

The evaluator should consider the other people that are in the child's life, while in the home of each parent. The evaluator should note the people who are not appropriate for the child to be around, as well as people who are positive influences.

- **Financial considerations.**

This generally is not a factor, since ideally payment of child support tends to equalize financial differences. However, an evaluator might consider finances to be meaningful if it results in a large difference between the households – for instance, if one parent cannot afford an appropriate sleeping arrangement for the child.

- **Allegations of abuse.**

Sometimes one parent alleges that somebody in the other household, either the parent or step-parent or perhaps a boyfriend, has physically, emotionally, or sexually abused the child. If these allegations are substantiated, it would have a bearing on the child's custody and visitation.

- **Parental morals.**

The evaluator should assess whether a parent is exposing the child to immoral conduct. Obvious examples include exposing the child to criminal behavior, pornography, or parental drug use.

Factors Associated with the Child

Child's Attachment to the Parents. An evaluator should assess and consider the level of attachment between the child and each parent. Many children have a solid, positive attachment to both the mother and the father, which is certainly the most desirable circumstance. However, some children have a much stronger and healthier attachment to one of the parents.

Child's Preference. Many children understand that their parents are fighting over their custody, but really do not have a strong opinion or preference as to their living arrangements as long as they continue to spend time with both parents. Other children are able to express a definite preference and can explain their reasons for that preference. For instance, the child might express that one parent is warm and nurturing and the other is cold and aloof. The evaluator should determine whether the child's stated preferences are substantive and consistent with her own observations (e.g., "My stepdad is really mean!"); based on trivialities ("Mommy lets me stay up late on the weekend."); or misinformed ("Daddy told me that Mommy is stupid."). Whether the judge considers the child's preference depends on the child's age and varies from state to state. In general, a court is likely to give more serious consideration to the preference expressed by an adolescent than that of a child. In some states, the court is required by statute to consider the child's preference once the child reaches a particular age.

Outcome: Common Scenarios

Two Competent Parents

After conducting a custody evaluation, perhaps, the most common result is to find two parents who are both competent and nurturing in their own ways. That is, either of the parents would be a more-than-adequate custodial parent. If that is the case, the evaluator can list the various factors mentioned above – and others that might be relevant – and indicate which ones favor the mother and which ones favor the father. The evaluator can also indicate the significance or weight attached to each factor. By presenting the data in this way, both the evaluator and the judge can add up the list and determine whether one parent is preferred over the other.

One Competent, One Deficient Parent

Arriving at a conclusion in this kind of situation seems easier, since the evaluator can recommend

that the competent parent should have custody of the child. In addition, however, the evaluator can make specific suggestions designed to help the noncustodial parent become more capable. The evaluator would also want to discuss whether it is important for the child to continue to have a good relationship with both parents or whether one of the parents is so disturbed that he or she should not have contact with the child.

Two Deficient Parents

In some custody disputes, the evaluator may find that neither parent has the skills and attitudes to be fully satisfactory. The evaluator must be satisfied with the least detrimental alternative. If the evaluator is concerned about the parents' abilities, it may also be an opportunity to be creative and offer additional suggestions that might benefit the children. For example, supportive therapy or parenting classes or ongoing mediation between the parents might be helpful. The evaluator might recommend some continuing involvement by a capable relative or continuing supervision by a social service agency.

Outcome: Less Common Scenarios

Disputes Over Relocation

Americans are very mobile and frequently one or the other of divorced parents moves some distance from their original home, which may create a problem for the noncustodial parent to exercise visitation. These cases involve conflict among three competing interests – the right of the custodial parent to move, the right of the noncustodial parent to have visitation, and the right of the child to have a good relationship with both parents, as well as stability in his life. Because this is a changing area of law, an evaluator must know the current law in his practicing area. The current trend is for state legislatures and courts to make it somewhat easier for the custodial parent to move to another location, especially if it is done because of better job opportunities or a significant change in the family. Needless to say, there are times when it is in the child's interests switch custody to the parent who stays in the original community, because of the child's deep ties to friends, relatives, or school in that community.

Parent Versus Step-parent

When the dispute is between a biological parent and some other individual, such as a step-parent, grandparent, or foster parent, it is generally held that the biological parent has a greater right to the child as long as he or she is considered "fit." At times, this principle seems to contradict the principle of pursuing the best interests of the child, since a child might be removed from a wonderful step-parent or foster home and returned to biological parents who are barely adequate.

Grandparent Visitation

In recent years courts have considered whether grandparents have the right to visit their grandchildren, even without the agreement of the children's parents. Mental health professionals may be asked to make recommendations regarding grandparent visitation after considering the potential pros and cons, i.e., the possible benefit to the child on the one hand and the possible aggravation of family conflict on the other. Typically, that issue would arise in cases that have already come to the attention of the court, such as a custody or visitation dispute between the parents. In a recent ruling, *Troxel v. Granville* [9], the US Supreme Court concluded that the Constitution protects the right of parents to "establish a home and bring up their children". That means that in an intact family, grandparents will not be able to ask the court to override the parents' refusal to allow visitation.

Dispute over Religious Upbringing

Strictly speaking, each parent has the legal right to take his or her child to whatever religious activity the parent desires when the child is in that parent's household. In some cases, both parents want to enroll the child in religious education and to promote actively and assertively their respective religious beliefs. Since some religious beliefs profoundly contradict each other (one religion versus another, one sect versus another, and religious belief versus atheism), the child may become mentally confused by incompatible dogmas and emotionally disturbed by intense loyalty conflicts. Also, the issue of religion might be a consideration if the child has already formed an attachment to a particular faith and it

would be confusing or disruptive to interrupt that attachment. If the parents cannot negotiate a reasonable compromise, the evaluator may recommend that a particular parent be in charge of the child's religious upbringing. Also, an evaluator may be asked to comment on whether a person's religious beliefs has reached the point of becoming fanatical or even delusional, which could affect one's style of parenting.

Parental Kidnapping

One of the tragic outcomes of child custody disputes is that one of the parents may kidnap the child. This may occur if one of the parents concludes that his own circumstances are above the law or if he believes the child may be in danger if allowed to visit the other parent. A parent's intent on abducting a child may be assisted by an underground network. Parents desiring to bring back an abducted child have been known to hire private commando units. Federal laws (the Uniform Child Custody Jurisdiction Act and the Parental Kidnapping Prevention Act) and an international agreement (the International Child Abduction Remedies Act) provide procedures and sanctions to address some aspects of this issue. These laws provide that the ensuing custody trial should take place in the location where the child habitually resided prior to the abduction.

Homosexuality

In some states – for instance, California and New York – it is common for male homosexuals and lesbians to have custody of their children, but it is less usual in other parts of the country. A custody evaluation involving a homosexual parent should be based on objective data and not on stereotypes. The professional literature regarding this issue indicates that homosexuals can provide healthy, nurturing homes, although the children may be affected by social stigmatization in the community.

Possible Recommendations

By the end of the evaluation, the evaluator will be expected to provide the court an opinion regarding physical custody and legal custody. The two recommendations are not dependent on each other. That is, if the evaluator recommends sole physical custody, he may recommend joint legal custody. Alternatively, if the evaluator recommends joint physical custody, he may recommend sole legal custody.

Primary or Sole Physical Custody

With primary or sole physical custody, the child lives primarily with the custodial parent and has visitation with the noncustodial parent. In most instances, the child has regular, predictable visitation with the noncustodial parent. In some cases, the visitation is limited or supervised if the court finds that the noncustodial parent may be irresponsible (such as drinking and driving) or dangerous to the child. Sole physical custody would be appropriate if one parent is clearly competent and the second parent is significantly impaired and would not be reliable in caretaking activities.

Joint Physical Custody

In joint physical custody, the children live about equal time with each parent. For instance, the children might live one week at the mother's household and the next week at the father's household.

Split Custody

Split custody means that the children are divided between the parents rather than primarily living in the same household. It is generally considered advantageous to keep siblings together, mainly because children of divorce feel threatened and insecure and they derive support and consistency from each other. If the brothers and sisters are living together, they have the sense that at least part of the family is still in one piece. The evaluator would need to provide a strong reason for recommending that siblings should live in different households. However, when siblings will be living in different households, visitation can be arranged so that they are together much of the time. Every-other-weekend visitation, for example, can be scheduled in such a way that the siblings are always together every weekend.

Primary or Sole Legal Custody

When one parent has primary or sole legal custody of the child, that parent makes the decisions regarding

the child's education, medical care, and religious upbringing.

Joint Legal Custody

In joint legal custody, neither parent's rights are superior. In this arrangement, both parents have equal rights and responsibilities regarding issues such as the child's education, medical care, and religious upbringing. The joint custody order may include language to the effect that if the parties cannot agree on any particular issue, one party (usually the parent with actual physical custody) will have the final and exclusive decision on that issue. The evaluator may recommend joint legal custody if the parents are able to communicate with each other and are willing to take each other's opinions into consideration. Joint legal custody would not be an appropriate recommendation if the parents seem incapable of cooperating with each other.

Parenting Time

Some states do not use the terminology of "custody" and "visitation," but refer to the "primary residential parent" and the "non-primary residential parent." Instead of having conclusions regarding custody and visitation, the evaluator may make recommendations regarding the duration of the mother's and the father's "parenting time." The evaluator may make recommendations as to whether a particular parent should be responsible for major decisions (regarding education, health, and religion) or that the responsibility should be shared.

The Written Report

The evaluator should be aware that the written report will be seen by several people, including readers who may attach undue significance to isolated sentences and phrases. The best approach is to make the report detailed enough so that the reader fully understands the methodology that was followed and the basis for the conclusions and recommendations, but not so detailed as to include every datum that was collected. Although each evaluator writes reports in widely different ways, a report may include the following headings.

Identifying Information

This includes names and birth dates of the child(ren) and the contesting parties, who are usually the parents.

Referral Information

This usually includes a brief chronology of the marriage; a statement of the current status of the child(ren)'s custody and visitation; and an excerpt from the court order authorizing the evaluation. There should be a statement about the circumstances of the referral and the specific purpose of the evaluation.

Procedure for the Evaluation

This consists of a list of the various meetings that were held, the psychological tests utilized, and the outside information that was collected.

Observations

This part includes a separate section for each family member. Each parent is discussed individually, with a summary of that person's strengths, weaknesses, personality traits, significant medical and psychiatric problems, and whether these factors have a bearing on the person's ability to be a good parent. Each child is also discussed individually, with a summary of his strengths and weaknesses, identification of any psychiatric disorder, and a comment about how the child is coping with the parents' divorce. In addition, the report should address the following: the child's attachment to each parent; whether the child has a preference regarding custody and the reasons for the preference; and whether the child seemed unduly influenced by one of the parents.

Conclusions

This part consists of a list of specific statements that the evaluator believes are supported by her data, i.e., the observations discussed above. For instance, the evaluator might conclude that one parent has had a major mental illness in the past, that is, likely to be a problem again in the future;

or, that a parent has personality traits or a personality disorder that affects his or her parenting abilities; or, that the children are uniformly attached and bonded to one parent more than the other.

Recommendations

This section should follow logically from the conclusions. The evaluator may make recommendations regarding the custody of the children, the visitation schedule, whether the visitation should be supervised, whether any member of the family should be in psychotherapy, whether the parents should attend parenting classes, and other issues that are important in this particular evaluation.

Visual Recognition Systems in Identification

There has been a significant rise all over the world in police-reported crime figures particularly due to thefts, assaults, and robberies; consequently, the use of video-surveillance cameras has increased to face and deter this sort of crime. Thus, identification by video-surveillance systems is more frequently becoming the object of forensic investigation; such an investigation must be based on the physiognomic comparison of two persons: the suspect and the person represented in the photographs or film.

The issue of the identification of living criminals was first tackled in Europe at the end of the nineteenth century by Bertillon, who introduced a method of personal identification of the living based on anthropology, i.e., on the study of body measurements for anthropological comparison and classification. This approach has since been used in identification procedures.

With the increasing diffusion of video recording systems as deterring crime devices, it has become a routine procedure to compare images of a suspect with those obtained from surveillance films, paying special attention to the morphological characteristics of some peculiar anatomical parts (such as eye, nose, mouth, and ear) of the head, which are the most discriminant. These methodologies often meet limits of a practical nature: the subject may resort to disguises in order to hide identity and to prevent identification; on the other hand, in many cases, the initial images available have an informative content, which is too poor for applying the procedure in a reliable manner. Nonetheless, sometimes the images are of satisfactory quality and forensic examination can be performed.

Anthropologists are therefore getting more and more involved in the identification of the living [1–20]. Since the 1990s, anthropologists have, in fact, noticed an increase in the number of cases they are called upon as expert witnesses concerning the identification of living individuals from photographs. Nowadays, judges are constantly asking for "anthropometric" or photometric (though the term

is inaccurate) expertise with the request of verifying if a person seen on a specific video or photograph is the same person as the suspect. This is a completely different aspect of forensic anthropology, which deals with human diversity and strives to verify morphological and metric characteristics that make the physiognomy of one person distinct from that of another.

Facial recognition is one of the most common tasks performed in these instances, and one of the most difficult. In the previous articles, we have mentioned the difficulty in identification or individualization, the lack of common standards, and the intrinsic problems in identifying human remains by bone morphology during the comparison of postmortem and antemortem morphology. It may seem paradoxical but the comparison of faces is even more difficult. What our brain automatically does every day (i.e., the recognition of individuals by their face) is extremely difficult to analyze and replicate by scientific procedure. Thus, something that seems intuitive may be difficult to support in court. No common protocols exist at the moment and most experts still use "their own method". Furthermore, at present, perhaps because of the lack of science and of a clear methodology (the old methods are being severely questioned by recent research [7]), "identification" in these cases is frequently performed by nonbiological experts such as video analysts or even police staff, i.e., by experts who are not trained in anthropology or human diversity. Although there are, at the moment, no clear evaluations of how unexpert and expert opinions compare, and satisfactory algorithms still do not exist, the authors' experience has shown that the specialist in biology/anthropology/human diversity, which has a forensic formation, will tend to focus on the errors, difficulties, and pitfalls of this sort of comparison and be more cautious, whereas an "unscientific" eye may be led by instinct supported by pseudoscientific data (measurements, for example), which usually can be made to fit any hypothesis provided one does not consider the innumerous sources of error intrinsic to the method and to biological variability. Thus, it is the authors' opinion that this kind of expertise should be performed by experts trained in human diversity and forensic analysis. Another false impression is that computer experts may be sufficient as appropriate experts. Again, computer sciences may provide excellent instruments with which to perform a comparison and properly deal with and correct images; however, only disciplines such as human biology and anthropology can properly tackle the problems of variation and the study of human morphological traits – for example, of how and why they may change within the same person or be similar in two different persons. What is important for facial identification is still in part a mystery. We do know that human brains identify known faces more accurately and with a different method with respect to unknown faces, and that automated face recognition software has been seen to function almost as well; nonetheless, as in all situations, machines cannot be held the only ones responsible for such an important task.

Traditionally, there are three main approaches to facial identification. The first and perhaps most ancient is that of morphological analysis. Several classifications of forms of facial regions or types exist (from the Interpol schemas to other authors [1, 9]). As can be seen in Figure 1, these systems provide several variants of a facial character (such as face, mouth, and nose – some classifications envisaging up to 40 characters). They aim at meticulously classifying facial traits, for example, facial outline shapes, hairline shapes, mouth, nose, etc. Combinations vary among two different faces as among different populations. These tables are usually "designed to promote a consistent, systematic, and scientifically comparable evaluation of facial features as well as … making individual variation and population differences emerge from a seemingly unremarkable visage and can guide the expert in making a decision about the final match" [1]. Nonetheless, if it is true that verification of similar shapes among two faces can be a first step in the forensic analysis, it must be said that it cannot, however, be the only basis for forensic identification or individualization, i.e., even if two individuals share the classification of all 40 characters in the classification form, one cannot base identification only on this. A main problem is that the appearance of facial figures can be altered by expression, age, photographic angle, lighting, etc. Furthermore, high intra and interobserver error has been reported.

Then the anthropometric approach. Photoanthropometry can be defined as the analysis of anthropometric landmarks, dimensions, ratios, and angles to quantify facial characteristics and proportions from a photograph. Once again, the dangers in comparing faces on 2D images are only too well known: slight, imperceptible differences in orientation, facial

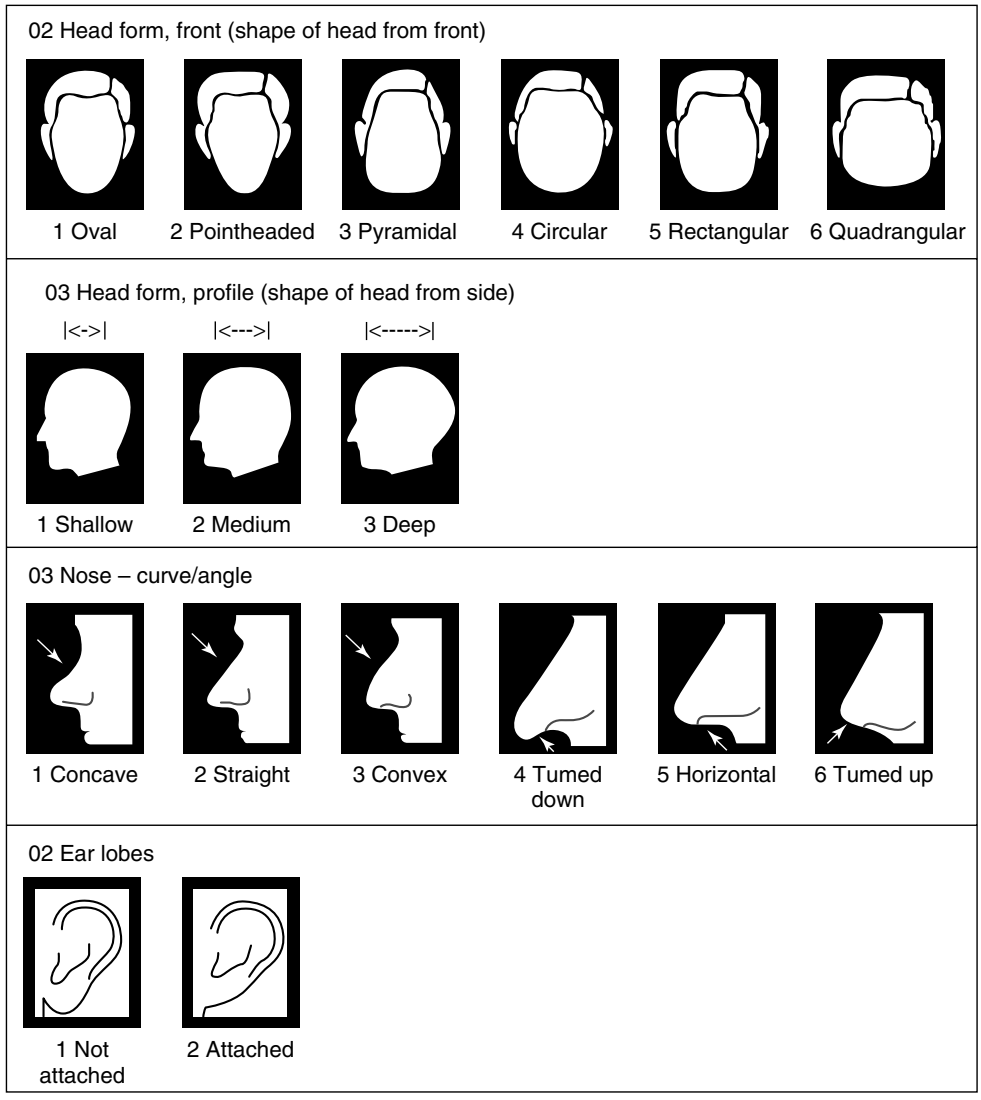

Figure 1 Example of part of the Interpol classification form concerning facial morphology

expression as well as interobserver differences in setting facial landmarks may cause drastic errors in the study of indices. Recent research has proven that the study of facial landmarks and measurements does not give consistent results. In a recent study, in particular [7], specific anthropometric landmarks were chosen and proportions and angle values between these landmarks were measured to compare target with test photos. The method did not generate the consistent results necessary for use as evidence in court.

Finally, "photographic superimposition" was introduced. The aim of this technique was to determine if facial features could be correctly superimposed on one another. Pictures with various degrees of transparency were initially superimposed; then videos and more elaborate computer systems began a novel era of superimposition. For example, one of the more common methods of recognition was (and unfortunately still is) performed by bringing the suspect to the scene of crime, having him take on the same position as the robber,

for example, and taking pictures or a video of the suspect with the closest possible head orientation as the criminal, and then performing a comparison of the facial characteristics of the two subjects by facial superimposition or through a numerical analysis of the two images. This solution, however, is full of pitfalls and requires the same recording conditions (the same camera, with the same focusing, shutter, positioning and orientation, magnification, etc.), which presumes that both camera and camera settings are not changed, usually impractical in actual situations, especially if a long time has elapsed between the criminal event and the expertise.

Furthermore, the problem that still remains and needs to be solved concerns the evaluation of the goodness of fit, whether it is possible to quantify it, as well as the usual problems that need to be corrected concerning image distortion, fuzziness, etc.

If we break free of traditional nomenclature, and focus on more modern technology, one can think in terms of comparison in 2D or 3D. More recently, advances in systems have encouraged attempts toward objective and automated identification approaches. Quantitative identification procedures can be split into two main categories: 2D–2D methods, based on the comparison between the photos of the subject to be identified (the "guilty") and the ones of the subject under investigation (the "suspect") (as mentioned above), and the so-called 3D–2D techniques, where a photo of the criminal and a 3D model of the suspect's face are matched. 3D–3D comparison techniques are more reliable because they overcome some limitations typical of the other two methodologies but they cannot be applied in actual situations until traditional 2D recording systems are substituted with 3D recording devices (such as stereoscopic systems and 3D scanners).

The 2D–2D techniques involve methodologies interested in "facial features" extraction, "geometrical features" extrapolation (eyes, eyebrows, mouth, etc.), or "jets" synthesis (referred to as *facial fiducial points* and texture around them): recognition is derived from the "similarity" degree between such facial elements in the original image and the corresponding ones belonging to the suspect's photo. Two commonly adopted approaches to perform face recognition of a person from a database are principal component analysis (PCA) and linear discriminant analysis (LDA). Both techniques try to simplify the original information content of the original images, by pointing out only the information useful for identification. The advantage is a reduction of computational costs, but they can be applied only to "one-to-many" matches (specifically to find the best match of a subject in a gallery) and not to "one-to-one" matches, that are the most common situations, when a comparison between the filmed subject and only one suspect is demanded. Moreover, all 2D–2D procedures show some intrinsic limitations, since recognition efficiency strongly depends on different environment conditions, (such as illumination, face positioning, and orientation). A number of image preprocessing techniques are requested in order to reduce the environment influence on recognition reliability, such as illumination compensation or pose estimation.

An enhancement in personal identification can be achieved through the use of 3D–2D techniques. Some authors have introduced an identification procedure based on a function, which computes the similarity between an unknown image pair and the 2D projection of a 3D face model of a stored subject. The stored 3D model is obtained starting from a stereoscopic system and extracting some facial fiducial points from the image pair.

More novel computer-aided recognition techniques can be envisaged, as independent as possible of recording conditions (illumination, face positioning, and orientation); for example, the application of the concept of "geometrically compatible images", as a tool capable of synthesizing a virtual camera, with the same optical and geometrical characteristics of the camera that filmed the original scene. The idea is to use the virtual camera to film a 3D facial model of a suspect and so to obtain a 2D image, which has the same size, position, and orientation of the original frame extracted from the video-surveillance sequence. The superimposition between the original 2D facial image and the 3D one is accomplished in correspondence of anthropometrical landmarks, distinctive for the person. The recognition is performed by superimposing the 2D facial image and the 3D one in correspondence of anthropometrical landmarks and an identification judgment is formulated on the basis of the measurements between corresponding landmarks positioned

both on the original photo and on the 2D facial model projection.

The more novel methods therefore strive to project a 3D model of the person under examination (produced with a laser scanner or with two stereoscopic cameras) (Figure 2) to the 2D image of the person to identify, in order to check matching of facial landmarks and contours. This is indeed a very rich area of research and facial identification methods may, once finely tuned, change the type and methods used for surveillance systems in terrorist attacks, bank robberies, and other crimes.

Although much research is being done, this particular field still needs to grow as regards methodology, and, from a forensic point of view, is full of pitfalls. As in the case of personal identification of the dead, the issue of "how much correspondence one needs to perform an individualization" is still an urgent matter to solve. Identification of faces still remains one of the most difficult and challenging tasks for the forensic anthropologist.

A similar type of reasoning can be applied to identification by ear morphology, limited by the same pitfalls as for the face, in general [10–14]. Sometimes, however, it is not possible to study these areas. In such cases, height and gait analysis can be the only elements which will at least allow the expert to exclude a suspect or to verify a mere compatibility.

At present, there is a growing interest for "at a distance" identification systems, such as systems of analysis and recognition of gait and/or the estimation of stature of the person on images. These systems do not require participation of the suspect and one can work on images of poorer quality with respect to that required by an identification system based on the face (which needs images with greater resolution).

The systems based on gait recognition quantify some typical biometric parameters such as the length of "stride" and gait [19, 20], typical of each person, and analyze the way the "silhouette" of a subject taped while walking, changes with time. These systems show some intrinsic limits, such as dependence on the angle of shooting, variations of the environmental conditions, the presence of persisting shades, and everything that can obstruct a correct extraction of the silhouette. Besides being systems that base the recognition on the periodical nature of gait, they entail problems when the subject is moving at varying speeds or on a route other than a straight line. Finally, these systems presuppose the existence of a reference sample of the person's gait, a factor which makes their application difficult as these are rarely available.

Figure 2 To the left, one can appreciate the face of the "perpetrator" with next to it the 3D image produced with a laser scanner from the suspect. To the right, superimposition of the face and 3D model, to check for matching points and profiles

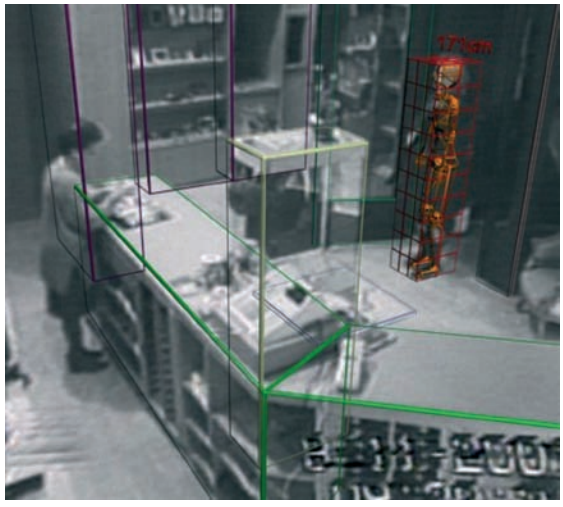

Figure 3 According to some authors, the determination of height is easily obtained by developing a virtual telecamera having the same characteristics of the video-surveillance system with which the images have been shot. The estimate of the height is done by comparison with a probe whose height can be varied in such a way as to be adjusted to that of the subject under investigation. The figure shows the criminal within a colored "box" (which includes the probe)

Height appears to also be an effective parameter (Figure 3), at least in proving the compatibility between the subject on tape and the suspect, or in excluding the suspect as the perpetrator [15–18].

Some have proposed the use of a stereoscopic camera surveillance system mounted on the ceiling. The head, shot by two telecameras, is extracted with a procedure called *head pattern matching*, which models the head on a sphere. The correspondence of the head seen in the two images allows one to estimate the distance between the head and the camera and therefore to deduct the height of the person.

Others demonstrate an increase in the probability of individualization when by including an estimate of height along with quantification of the biometric parameters of gait. Such parameters, however, must be intended as an aid to the individualization as they are not sufficient by themselves to ensure identification, but useful as an additional discriminating factor.

Regardless of the technological advances and applications, identification or individualization of the living by physiognomic traits still remains one of the most difficult and dangerous tasks for forensic anthropology.

Web Resources

Introduction

Researchers generally turn to the Internet in their quests for information, and those researching forensic topics are no exception. Some interesting and useful sources for forensic-related research can be found online. This article describes some of the best resources for forensic researchers.

General Forensic Resources

The Forensic Sciences webpages of the *National Institute of Justice (NIJ)* (http://www.ojp.usdoj.gov/nij/topics/forensics) provide the full text of many NIJ publications related to forensic sciences, as well as descriptions of related NIJ programs and funding sources. One of the essential works for forensics is the s *Handbook of Forensic Services* of the Federal Bureau of Investigation (FBI), the text of which can be found online at the FBI website (http://www.fbi.gov/hq/lab/handbook/forensis.pdf). It provides "guidance and procedures for safe and efficient methods of collecting, preserving, packaging, and shipping evidence" and describes "the forensic examinations performed by the FBI's Laboratory Division and Investigative Technology Division." This online version is divided into four major sections: Submitting Evidence, Evidence Examinations, Crime-Scene Search, and Crime-Scene Safety. The Handbook is also available in print from the FBI.

While the full text of the *Handbook of Forensic Services* is available online free of cost, it is generally true that the full texts of most books are not readily accessible online. However, a database of books from *FORENSICnetBASE/LawENFORCEMENTnet BASE* (http://www.forensicnetbase.com) provides the texts of dozens of forensic science and criminal justice books that are available in full text on the website. The database is available from CRCnetBASE for an annual subscription fee.

The *National Clearinghouse for Science, Technology and the Law* (*NCSTL*) at Stetson University College of Law provides a website (http://ncstl.org) that brings a wide variety of forensic-related information together in one place, freely available to public users. It offers a database of bibliographic information for a wide variety of resources, including books, scientific and legal journal articles, newspaper and magazine articles, seminars and conference sessions, dissertations and organizations. Books and journals that are indexed in the NCSTL database are available through interlibrary loan from the Stetson Law Library. The Related Links portion of the website provides a directory of hundreds of scientific and law-related links that are useful for forensic researchers. The section Education provides handouts created for professional development presentations by NCSTL staff, as well

as transcripts, podcasts, and webcasts of lectures on forensic science and technology.

There are several useful forensic-related websites providing either research pathfinders or a categorized directory of web links, or both. *Gelman Library's Forensic Sciences* pathfinder (http://libguides.gwu.edu/content.php?pid=9061) is an excellent resource for those performing research in topics related to forensic sciences. Provided by the George Washington University, this site provides information about forensic-related resources in both print and online formats. Additionally, *Science and Technology Resources on the Internet* (http://www.istl.org/03-spring/internet.html) by science and engineering librarian Cynthia Holt, is an online article from 2003 that describes and links to the best forensic resources on the Internet. Ms Holt updated this article in her 2005 book, *Guide to Information Sources in the Forensic Sciences*, published by Libraries Unlimited.

Zeno's Forensic Site (http://forensic.to/forensic.html) is a web directory of hundreds of forensic-related sites on the Internet, which are topically categorized. An interesting feature of the site is that users can rate the links, thus providing useful feedback to future researchers visiting the site. Zeno also provides a page of links to those sites he finds particularly interesting, and provides the opportunity to be informed by e-mail when new links are added. *Kruglick's Forensic Resource and Criminal Law Search Site* (http://www.bioforensics.com/kruglaw) is a web resource sponsored by Forensic Bioinformatics that lists links to over 1500 sites related to forensics or law. Informational articles on the site include Kim Kruglick's "A Beginner's Primer on the Investigation of Forensic Evidence," Donald E. Riley's "DNA Testing: An Introduction for Non-Scientists – An Illustrated Explanation," Frederic Douglas' "GC/MS Analysis," and Paul C. Giannelli's "Expert Qualifications & Testimony". Forensic researchers can also use *Reddy's Forensic Page* (http://www.forensicpage.com), which is a web directory of dozens of links related to forensic science and law. It is organized into topical categories.

The library at Johnson & Wales, a member of the Higher Education Library Information Network (HELIN), maintains several sites that describe and link to various – and often eclectic – research resources, including public and government criminal justice resources. The *Criminal Justice: General Resources* webpage (http://library.jwu.edu/research/websites/criminal.htm) points users to gateways, directories, academic sites, clearinghouses, think tanks, and professional associations/organizations. These resources do not include government agencies, which are located and described by the library's *Criminal Justice: Official Resources* webpage (http://library.jwu.edu/research/websites/criminal_official.htm). This site describes the Internet resources supporting the criminal justice activities of official federal, state, and local government agencies. Some of these links provide gateways to government agencies, international organizations, law enforcement directories, clearinghouses, and sites that maintain criminal justice statistical data.

Some unique forensic-related sites can be found online. These include *Crime and Clues: The Art and Science of Criminal Investigation* (http://www.crimeandclues.com), a site that pulls together articles about various aspects of criminal investigation. It not only provides links to new articles on its home page but also has archives of older articles categorized by topics, including different types of scientific evidence, crime-scene and death investigation, and testimony and ethics. The links are annotated, giving the reader the time-saving capability of narrowing down possibilities before following a link. Additionally, the Forensics and Investigations pages of *TruTV's Crime Library: Criminal Minds and Methods* (http://www.trutv.com/library/crime/criminal_mind/forensics/index.html) provide background reports on some of the most notorious or unusual investigations.

To make sure that forensic scientists from various countries are all on the same page, the Multilingua Group within the European Network of Forensic Science Institutes has created a *glossary of forensic-related terms* that are immediately translated into several European languages (http://www.enfsi.org/standingcommittees/eafs/multilingua).

Keeping up to date in any discipline can be a challenge. The *Crime Lab Project Forum* (http://crimelabproject.blogspot.com) is a blog that reports on the latest news about crime labs and other forensic-related stories. The webpage–based blog is frequently updated; however, readers who wish to follow the updates can opt to have them delivered to their e-mail addresses by means of a Yahoo! group. Additionally, *Daubert Tracker* (http://www.

dauberttracker.com) is a database that tracks US federal and state court decisions and supporting documents about "evidentiary gatekeeping". It provides a database of all reported decisions and many unreported decisions dating back to 1993. It also supplies information regarding the expert's name, discipline, area of expertise challenged, and results of the challenge. The Daubert Tracker is a fee-based service, with a subscription available.

Finding Forensic-Related Articles

Searching for an article related to forensic science is easy when using *Forensic Science Abstracts* (http://www.elsevier.com/wps/find/journaldescription. cws_home/506012/description#description). This index can be found in hard copies in many libraries, but is also part of the online collection of database called *EMBASE*, a biomedical and pharmacological database available from Elsevier (http://www.info.embase.com/embase_suite/about). *EMBASE* is available for a subscription fee.

The *FORS Forensic Bibliographic Database* (http://www.forensic.gov.uk/forensic_t/inside/products/fors/fors.htm) indexes articles about drugs and toxicology, forensic biology, DNA, forensic chemistry, forensic medicine and pathology, digital evidence, computer crime, documents and firearms examination, arson investigation, image processing, fingerprints, safety, quality and management aspects of running a forensic science service. It routinely covers 150 worldwide journals, but indexes from over 1900 sources. This index dates back to 1976. *FORS* is available for a subscription fee.

PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi) is a free service from the National Library of Medicine, National Institutes of Health. It includes over 16 million citations to life-science and biomedical articles dating back to the 1950s. It includes links to online sources of the full text of indexed articles, as well as a list of libraries that hold the individual article.

When searching for dissertations, researchers can use *ProQuest Digital Dissertations* (http://www.il.proquest.com/products_umi/dissertations), which indexesand abstracts dissertations and theses in all disciplines. Online guest users can search the most recent two years of the index and abstracts database. Full subscribers can access the entire database of over two million records.

The *National Criminal Justice Reference Service* (*NCJRS*) is sponsored by several offices within the United States Department of Justice and Executive Office of the President. *NCJRS* provides one of the largest criminal and juvenile justice libraries and databases in the world, the *NCJRS* Abstracts Database (http://www.ncjrs.gov/library.html). The *NCJRS* collection contains more than 185 000 publications, reports, articles, and audiovisual products from the US and around the world. These resources include statistics, research findings, program descriptions, congressional hearing transcripts, and training materials. The collection dates back to the 1970s. The Abstracts Database is available online for free, and links to the full text of documents whenever available.

The database at the *National Clearinghouse for Science, Technology and the Law* (http://ncstl.org) indexes forensic-related articles whose focus is science, technology, law or criminal justice, thus pulling together a variety of forensic-related disciplines into one place. The NCSTL database is available for free, and links to freely available full text of articles where they exist, or the webpage where such articles can be purchased if necessary.

Most journal articles can be accessed in full text online for a fee, but there are some journals that provide their full text for free. Some of these are American Journal of Pathology (from the American Society for Investigative Pathology) (http://ajp.amjpathol.org), Archives of Pathology & Laboratory Medicine (from the College of American Pathologists) (http://arpa.allenpress.com/arpaonline/?request=index-html), Crime Lab Minute (from the American Society of Crime Laboratory Directors (ASCLD)) (http://www.ascld.org), The Forensic Echo (http://echo.forensicpanel.com), Forensic Magazine (http://www.forensicmag.com), Forensic Nurse archives (http://www.forensicnursemag.com/archives.html), Forensic Science Communica tions (http://www.fbi.gov/hq/lab/fsc/current/index.htm), INTERfaces (newsletter of the Forensic Science Society) (http://www.forensic-science-society.org.uk/publications/interfaces.html), Journal of Clinical Pathology (http://jcp.bmj.com), Laboratory Investigation (from the United States and Canadian Academy of Pathology) (http://www.nature.com/labinvest/index.html), Microgram Journal (http://www.dea.gov/programs/forensicsci/microgram/journals_index.html), NIJ Journal (http://www.ojp.usdoj.gov/nij/journals/welcome.htm), Science and Technology

Review (http://www.llnl.gov/str/str.html), and TechBeat (http://www.nlectc.org/techbeat/justnet.html).

Forensic Associations

Most forensic associations and societies maintain an online presence through their websites, which generally provide information about the organizations and their membership. The *American Academy of Forensic Sciences* (*AAFS*) (http://www.aafs.org) is a professional society dedicated to the application of science to the law and is "committed to the promotion of education and the elevation of accuracy, precision, and specificity in the forensic sciences". AAFS was founded in 1948 and has nearly 6000 members, including physicians, attorneys, dentists, toxicologists, physical anthropologists, document examiners, psychiatrists, physicists, engineers, criminalists, educators, and others. AAFS publishes the *Journal of Forensic Sciences*. Current abstracts are available to the public at http://www.blackwellpublishing.com/journal.asp?ref=0022-1198, while abstracts for volumes 1–50 can be found online at http://journalsip.astm.org/JOURNALS/FORENSIC/jofs_home.html. The AAFS website also provides a wealth of information about education and career planning for forensic scientists, as well as links to other valuable forensic science resources.

The *ASCLD* (http://www.ascld.org) is a nonprofit professional society of crime laboratory directors and forensic science managers. It is "dedicated to providing excellence in forensic science through leadership and innovation." The website offers information about forensic science education and careers, as well as the society's official newsletter, the *Crime Lab Minute*, and links to other online articles focusing on forensic science in the news.

The *Canadian Society of Forensic Science* (*CSFS*) (http://www.csfs.ca) is a nonprofit organization of professionals with an active interest in forensic science. It is open to an international membership, and incorporated to maintain professional standards and to promote the study and enhance the stature of forensic science. Abstracts of the *CSFS Journal* are available on the CSFS website. Website visitors can link from the home page to the Population Studies Data Centre, which provides raw DNA data and frequency tables from the Royal Canadian Mounted Police and the Centre of Forensic Sciences in Toronto, Ontario. Visitors can also find information about forensic science education and careers.

Formed in 1915, the *International Association for Identification* (*IAI*) (http://www.theiai.org) is the oldest and largest forensic science/forensic identification organization in the world, with over 6400 members from many different forensic disciplines. Its website provides information about the association and its many divisions, publications, and professional opportunities.

Websites of other forensic-related associations or societies include: American Chemical Society (http://www.acs.org), American Society of Forensic Odontology (http://www.newasfo.org), American Society of Questioned Document Examiners (http://www.asqde.org), Armed Forces Institute of Pathology (http://www.afip.org), Association for Crime Scene Reconstruction (http://www.acsr.org), Association of Firearms and Tool Mark Examiners (http://www.afte.org), Association of Forensic DNA Analysts and Administrators (http://www.afdaa.org), Entomological Society of America (http://www.entsoc.org), Evidence Photographers International Council (http://www.epic-photo.org), Forensic Science Society (http://www.forensic-science-society.org.uk), International Association of Bloodstain Pattern Analysts (http://www.iabpa.org), International Association of Crime Analysts (http://www.iaca.net), International Association of Forensic Toxicologists (http://www.tiaft.org), International Institute of Forensic Engineering Sciences (http://www.iifes.org), Microscopy Society of America (http://www.microscopy.org), National Association of Medical Examiners (http://www.thename.org), and Society of Forensic Toxicologists (SOFT) (http://www.soft-tox.org).

Additionally, some scientific working groups or technical working groups related to forensics have their own websites. The Federal Bureau of Investigation has a general website for scientific working groups at http://www.fbi.gov/hq/lab/fsc/backissu/july2000/swgroups.htm. Other specific working group sites include SWGDAM – Scientific Working Group on DNA Analysis Methods (http://www.fbi.gov/hq/lab/fsc/backissu/april2003/swgdambylaws.htm), SWGDE – Scientific Working Group on Digital Evidence (http://www.swgde.org), SWGDOC – Scientific Working Group for Forensic Document Examination (http://www.fbi.gov/hq/lab/fsc/

backissu/april2000/swgdoc1.htm), SWGDOG – Scientific Working Group on Dog and Orthogonal Detector Guidelines (http://www.fiu.edu/~ifri/SWGDOG.htm), SWGDRUG – Scientific Working Group for the Analysis of Seized Drugs (http://www.swgdrug.org), SWGFACT – Scientific Working Group on Forensic Analysis of Chemical Terrorism (http://www.fbi.gov/hq/lab/fsc/backissu/april2004/standards/2004_02_standards01.htm), SWGFAST – Scientific Working Group on Friction Ridge Analysis, Study, and Technology (http://www.swgfast.org), SWGGUN – Scientific Working Group for Firearms and Toolmarks (http://www.swggun.org), SWGIT – Scientific Working Group on Imaging Technology (http://www.theiai.org/guidelines/swgit/index.php), SWGMAT – Scientific Working Group on Materials Analysis (http://www.fbi.gov/hq/lab/fsc/backissu/oct1999/trace.htm), SWGMGF – Scientific Working Group on Microbial Genetics and Forensics (http://www.fbi.gov/hq/lab/fsc/backissu/oct2003/2003_10_guide01.htm), SWGSTAIN – Scientific Working Group on Bloodstain Pattern Analysis (http://www.swgstain.org), SWGTREAD – Scientific Working Group on Shoeprint and Tire Tread Evidence (http://www.theiai.org/guidelines/swgtread/index.php), TWGFEX – Technical Working Group for Fire and Explosives (http://ncfs.ucf.edu/twgfex/home.html).

Web Resources Related to Specific Forensic Topics

Forensic Pathology

Visible Proofs: Forensic Views of the Body (http://www.nlm.nih.gov/visibleproofs) is an exhibition at the National Library of Medicine, National Institutes of Health, in Maryland. An online exhibit complements the exhibition in Maryland. The website features information about the history of forensic medicine, galleries of famous forensic cases throughout history, libraries of images and video files, and other educational resources.

Forensic Anthropology

Established in 1988 and reformed in 1992 as the *International Association for Craniofacial Identification* (*IACI*) (http://www.forensicartist.com/IACI/index.html), this association focusing on craniofacial identification is composed primarily of medical and scientific professionals from all over the world. Members also specialize in the related fields of forensic odontology, forensic anthropology, two and three-dimensional skull reconstruction techniques, computer-based skull reconstruction, facial aging for law enforcement, facial mapping and composite sketching. The organization offers educational opportunities that include classes ranging from "How to be a forensic artist" and "Understanding the human face" to both basic and advanced classes such as "Facial reconstruction sculpture". The site includes links to selected historical exhumation projects as well as nearly 30 related craniofacial identification sites and publications.

Wesley Neville, an IACI member and forensic artist for the Florence County Sheriff's Office in South Carolina, maintains *Forensic Art* (http://www.forensicartist.com), a website providing a brief description of the various facets of forensic art as well as links to several additional resources.

The *Central Identification Laboratory* (CIL) at the Joint POW/MIA Accounting Command (JPAC) in Hawaii is the world's largest forensic anthropology laboratory in operation. JPAC's mission is to account for missing Americans lost during military conflicts. The material evidence – personal effects, uniform items, weapons, tools, and more – collected throughout the world to identify the missing individuals is curated in the CIL and retained items are shared with museum partners. The website of the CIL (http://www.jpac.pacom.mil) provides an interesting presentation in describing how the staff of more than 30 civilian forensic anthropologists employs the related sciences of archaeology, odontology, odontosearch, and optosearch (which allows the investigator to determine the frequency of an eyeglass prescription in a population and therefore, determine the strength of match between an unknown and a known sample) to accomplish its identification missions. The site also includes general scientific information about forensic anthropology and related fields, news releases regarding its forensic work including its project to collect family reference samples (mtDNA) to aid in identification of missing service men and women, recounts of historical missions, and career opportunities.

The *American Association of Physical Anthropology* (*AAPA*) (http://www.physanth.org) is a

professional organization formed in 1930, whose members include more than 1700 professionals, scientists, and physical anthropology students who have demonstrated qualification for membership through publication or professional activities. The AAPA site provides information such as funding opportunities, the location of graduate programs, position statements by the organization, job postings, and access to its official journal, the *American Journal of Physical Anthropology*. Other pages include information about careers in physical anthropology, the organization's annual meeting, and links to other related scientific associations.

Biometrics

A trilogy of sites developed to foster greater collaboration and sharing of information related to biometrics among federal and state government agencies, commercial entities, and the public starts at *Biometrics.gov* (www.biometrics.gov). This site is the authoritative source for all biometrics-related activities within the federal government and is divided into three main areas. First, the Biometrics Reference Room tab leads to general information about biometrics technology, provides a synopsis of biometrics programs hosted by various federal agencies like the Department of Defense, Department of Commerce, Department of Homeland Security, or the Department of Justice, and offers *Privacy & Biometrics: Building a Conceptual Foundation*, a publication that presents the government's perspective on privacy with respect to biometrics. Next, the site provides information on the National Science and Technology Council's (NSTC) subcommittee on biometrics, including presentations, publications, and additional technical information. Third, a Media tab provides press releases, graphics and 'fast facts' geared for use among members of the press.

From *Biometrics.gov*, users can link to the two partner sites: *Biometrics Catalog* (http://www.biometricscatalog.org) and *The Biometric Consortium* (http://www.biometrics.org). Each of the partner sites contains general, introductory information on biometrics and the government's privacy policy, similar to the information found on Biometrics.gov, but each site also contains additional and distinct information.

Biometrics Catalog is a free, public repository of biometrics information sponsored by the federal government but kept current by its public users – both the biometrics scientific and commercial communities – who add information as it becomes available. Postings include news releases, related government documents as well as private and scholarly, peer-reviewed reports. The government documents and private-sector reports are maintained in a searchable database (through a combination of Boolean operators and/or date ranges). The database includes more than one hundred government reports published since 1991, as well as thousands of research papers, reports, conference presentations, publications and analysis across all fields of biometrics (fingerprints, voiceprints, facial recognition, ID cards, and iris recognition to name only a few topics). Examples of article titles include "Compound Stochastic Models for Fingerprint Individuality" and "3D Face Recognition Across Pose and Expression". While most of the publications referenced on the site are recent, it also includes the Bertillon Documents in French from 1881 and a 1919 study published by the Carnegie Institution of Washington on the basal metabolism in man.

Several additional databases maintained on the site allow users to search for information such as government-authored or government-sponsored evaluations of specific biometrics technologies (examples: *Independent Testing of Iris Recognition Technology* (May 2005); *Studies of Plain-to-Rolled Fingerprint Matching Using the NIST Algorithmic Test Bed (ATB)* (April 2004)). Federal solicitations for biometrics research and development or services and reports on biometrics-related legislative or governmental agency activity are also available. The remaining databases consist of postings listing conferences and educational courses, commercial products and their companies, and biometrics consultants and analysts.

The *Biometric Consortium* (http://biometrics.org) is described as a "focal point for research, development, testing, evaluation, and application of biometric-based personal identification/verification technology". The organization has hosted annual conferences since 1992 and provides links to conference material from the later conferences as well as information on upcoming conferences. Links to other meetings or educational events and materials are also available. Additionally, the site provides links to universities researching biometric technology and their specific programs, links to selected periodicals and research publications arranged by

year of publication from 1994 through 2003, and provides an extensive biometrics glossary.

Forensic Botany

The *Internet Directory of Botany*, compiled by Anthony R. Brach, Harvard University Herbarium, and others (http://www.botany.net/IDB), is an extensive, award-winning alphabetical index of links to online botanical information. Users may peruse the lists of links to specific databases, articles, and other resources or search terms or keywords found within the titles. For example, "A Mini-Course in Medical Botany Syllabus by James A. Duke" is listed under the "A" index and will not be found if searching the "M" index (for "mini-course" or "medical botany"). However, a keyword search for "medical botany" or "James Duke" will locate the article.

Toxicology

TIAFT.org (http://www.tiaft.org) is the official website of The International Association of Forensic Toxicologists and offers direct links to additional resources from both public and members-only areas. For example, the public section maintains a user-contributed collection of reference analytical data to assist in the identification of unknown toxic substances, an *Observatory* section composed of links and a large directory of all genres of toxicology-related websites arranged by forensic specialty, and a *Powersearch* area to search for and access various scientific and medical literature and technological information.

Membership to TIAFT is $40 annually and allows access to the organization's *therapeutic and toxic drug concentrations list* developed by toxicology and medical specialists and from information obtained through the field's literature, pharmaceutical industries and by comparison with established drug data lists. Members may also access the complete text of the organization's quarterly journal, retrieve previously published journal *case notes*, read *online reviews* of various articles focused on state-of-the-art forensic and analytical toxicology topics, and tap into a collection of nearly 1500 papers presented at TIAFT meetings spanning three decades.

Soft-tox.org is the website of the SOFT, an organization of practicing forensic toxicologists and others who share an interest in the discipline. The site provides brief and general information introducing forensic toxicology and allows public users to download guidelines for the practice of forensic toxicology in the two defined areas of postmortem forensic toxicology and human-performance forensic toxicology. Additional downloads include the organization's *Drug Facilitated Sexual Assault Survey* and *Drug Facilitated Sexual Assault Drug List and Cutoffs* and the new *American Academy of Forensic Sciences (AAFS) Toxicology Section Mass Spectrometry Database*, a comprehensive drug library of the spectra for more than several hundred substances including a mini library of the mass spectra of newer drugs, metabolites, and some breakdown products.

The *California Association of Toxicologists* maintains a website (http://www.cal-tox.org) that provides an online toxicology-related exchange and discussion forum ("CAT Forum") interlinked with the Southwestern Association of Toxicologists. In addition to its links page, the site also features an extensive searchable database of online literature reviews by Dr Rodger Foltz with particular emphasis on analysis of new drugs, newer chromatographic and mass spectrometric techniques, and, in general, their application for the identification and quantitation of drugs and metabolites in physiological specimens.

Fingerprints

The FBI maintains a webpage (http://www.fbi.gov/hq/cjisd/cjis.htm) from which users may access general and historical information on fingerprint identification (*All About Fingerprints* tab), become familiar with the federal integrated automated fingerprint identification system (IAFIS), learn the proper method for taking legible fingerprints, and discover training opportunities.

Latent Print Examination: Fingerprints, Palmprints and Footprints (http://www.onin.com/fp/index.htm) is possibly the best of several solid online resources dedicated to latent-print examination, and is useful for both the novice and the experienced. The website, maintained by Ed German, a recognized expert in latent-print examination, is an extensive repository of relevant latent fingerprint, handprint, and footprint technology, history, news, case law, and links. Topics from challenges to reliability of fingerprint evidence to the latest technologies for crime-scene processing and evidence collection are explored in depth; online discussion forums and opportunities

to "ask an expert" are also available to seek additional answers and information.

Ridges and Furrows at (http://www.ridgesandfurrows.homestead.com) focuses on the enhancement of latent prints and latent-print identification through the use of advances in digital technology. The history of latent-print examination and court challenges to fingerprint science, particularly as they relate to the advancements in digital technology, are offered, in addition to links to relevant the newsletter, discussion forums, and other online learning opportunities. The website is maintained by Mary Beeton, a Canadian fingerprint technician with the Durham Regional Police Service in Ontario.

DNA

MITOMAP: A Human Mitochondrial Genome Database (http://www.mitomap.org) offers a comprehensive and searchable "compendium of polymorphisms and mutations of the human mitochondrial DNA". The database can be searched by gene, disease, or enzymes, for example, and keywords may be abbreviated or truncated. Alternatively, the user may use subsections divided into areas including "mtDNA Polymorphisms" and "mtDNA Mutations with Reports of Disease-Associations" and organized by mtDNA location or phenotype. The website is supplemented by several illustrations and tables, a "Mitomap Quick Reference" section that includes an extensive bibliography of mitochondrial references, and links to additional databases and related sites.

DNA● VIEW (http://dna-view.com) is the website maintained by forensic DNA identification consultant Charles Brenner, and presents a comprehensive look at forensic DNA analysis particularly as it relates to mathematics. The site provides topical news, articles, archived discussions on DNA identification including recent identifications after mass disasters, information on DNA identification software, and data tables organized by subject (for example, "Allele Frequencies for US Populations" provided by Cellmark Diagnostics). Topic areas such as "Discussions" are enhanced with photos, PowerPoint® presentations, news, and other articles provided by the participants.

Firearms

FirearmsID (http://www.firearmsid.com), privately maintained by Jeffrey Scott Doyle, a firearm and tool-mark examiner with the Kentucky State Police Regional Forensic Lab, provides extensive educational and investigative information including firearm safety, topical articles, expert testimony, firearms testing, and an introduction to firearms and ballistics; it is arranged by categories like the *History of Firearm ID* and *Case Profiles*. The website offers a discussion area, *Forensic Forum*, and a *resource area* provides such subtopics as *Ballistics Picture Book* and *Virtual Comparison Microscope*, while another area leads the user to databases containing rifling data and a bullet and shotshell component search.

Odontology

Forensic odontologist Mike Bowers created the website *Issues in Human and Animal Bite mark (Bitemark) Analysis* (http://www.forensic.to/webhome/bitemarks), which provides an extensive overview of the subject, supplemented by hyperlinks to several case studies (for example, serial killer Ted Bundy and the crash of Alaska Airlines Flight 261 in 2000), photos of bitemark evidence, journal articles, and links to similar websites.

Forensic Dentistry Online (http://forensicdentistryonline.com) is the International Organisation for Forensic Odontostomotology (IOFOS)'s contribution to forensic dentistry. The website includes information on bitemarks and bitemark identification, including new resources using DNA from teeth and saliva, as well as information covering the legal aspects of bitemark evidence admissibility. Also included are sections posting news items and commentaries from users, book reviews on the subject, and links to continuing education courses and odontologists.

Questioned Documents

The website, maintained by certified questioned document examiner Emily J. Will (http://www.qdewill.com), offers an overview of the subject through areas exploring the theories and applications of questioned-document examination, the external tools used in examination and a presentation of famous cases. At *Identifont* (http://www.identifont.com/index.html), users can use the largest independent directory of online typefaces to search for

type and picture or symbol fonts by font appearance, name, or similarity. Users can also download a wide selection of fonts for free. *Identifont* was developed by Human–Computer Interface, an information design and documentation company specializing in high-tech products. Similarly, *Omniglot* (http://www.omniglot.com) provides details of alphabets and writing systems, both current and ancient. Each writing system is illustrated, with information provided about its origin, usage, notable features, and the languages written with it.

DIANA BOTLUK AND ELIZABETH FITTERMAN

Weisgram v. Marley

Facts, Issues, and Interest of Forensic Scientists Summarized

Plaintiff Weisgram, in this product liability case, brought suit for the wrongful death of his mother who was killed during a fire. The fatal conflagration was allegedly caused by a defective baseboard heater manufactured by the defendant Marley Company. Plaintiff sought to prove his case by the testimony of three witnesses, proffered as experts, in his attempt to causally connect the heater defect to the fire. Defendant objected to the testimony on the ground that it was unreliable under *Daubert*. The trial court overruled the objections and permitted the witnesses to testify. The trial resulted in a verdict for the plaintiff. Defendant requested judgment in his favor as a matter of law, urging that the court erred in admitting the expert opinion testimony. The trial court denied the request and entered judgment for plaintiff.

On appeal to the intermediate reviewing tribunal – the Court of Appeals for the Eighth Circuit – the court held that Marley's motion for judgment as a matter of law should have been granted. Weisgram's expert testimony was found to be too speculative and not shown to be scientifically sound. Without this testimony, Weisgram failed to prove his case. The reviewing court decided it was not required to reverse and remand for a new trial where the evidence was not even close.

The issue was one on which different Courts of Appeal had arrived at conflicting decisions. The Supreme Court agreed to resolve the conflict. In doing so, it affirmed the Eighth Circuit court's decision and approved its reasoning. The Court simply adhered to its pre-*Daubert* 1967 opinion in *Neely* [1] and held that pursuant to procedural rules courts have the power to enter a judgment as a matter of law against a party if there is no legally sufficient evidentiary basis which a reasonable jury could find for that party.

The case addresses the scenario where an expert witness's testimony is challenged at trial, but the court, applying *Daubert* criteria, allows the expert to testify. This ruling is the lastest of three decisions further explaining the meaning of Daubert v. Merrell Dow Pharamaceuticals. See endnotes below for more information on these rulings.[a.] On appeal, however, the reviewing court concludes that the basis for the expert's opinion was not validated and therefore not "reliable" under *Daubert*.

While *Weisgram* is technically applicable only to federal courts of the United States, it has applicability in many jurisdictions that have similar procedural statutes or rulings.

Forensic scientists should note the authority of courts in the United States to enter, under certain circumstances, a judgment as a matter of law when they rule expert evidence inadmissible. They should also pay heed to the Court's words in Weisgram:

> Since *Daubert,* . . ., parties relying on expert evidence have had notice of the exacting standards of reliability such evidence must meet. It is implausible to suggest, post-*Daubert*, that parties will initially present less than their best expert evidence in the expectation of a second chance should their first try fail [2].

Be aware of the admonition that "[l] itigatgors must prepare their cases with an understanding that heightened scrutiny of all but the most noncontroversial expert testimony is likely" [3] in jurisdictions that are steeped in the adversary system.

End Notes

[a.] For summaries and importance of the other two decisions, see the separate entries: *General Electric v. Joiner* (***General Electric v. Joiner***), *Kumho Tire*

v. Carmichael (***Kumho Tire v. Carmichael***) and *Daubert v. Merrell Dow Pharmaceuticals* (***Daubert v. Merrell Dow Pharmaceuticals***).

ANN C. SMITH

Whole Genome Amplification

Introduction

DNA typing has revolutionized forensic biology and has resulted in a dramatic increase in the ability to obtain probative information from crimes involving biological material [1–8]. The adoption of PCR-based methods resulted in a significant enhancement in the capacity for successful typing of biological crime scene samples [9–13]. However, there are still situations where it is extremely challenging to obtain a standard autosomal short tandem repeat (STR) DNA profile, although cellular material is present in the evidence. Some of these situations involve low copy number (LCN) samples that contain <100 pg of template DNA, equivalent to 15 diploid or 30 haploid cells [14]. The presence of such LCN samples could be due to several factors including damaged or degraded DNA, oligospermic or aspermic perpetrators, or from extended interval postcoital samples, where sperm have been lost over time due to the effects of drainage or host cell metabolism [15–17]. Other trace biological evidence also contains small quantities of cells, including fingerprints, particulate matter, and aerosols [18, 19]. Standard typing protocols permit the detection of as little as 100 pg of DNA and therefore may not be able to accommodate LCN samples frequently encountered in forensic casework.

In an attempt to increase the recovery of DNA profiles from LCN samples, the use of increased cycle number (ICN) has been suggested to permit the formation of sufficient amounts for analysis. A critical assumption of the ICN approach is that any expected stochastic effects can be dealt with by appropriate interpretation algorithms [20, 21]. However, this method may not always be efficient, with additional cycles at high temperatures leading to a decrease in efficiency of Taq DNA polymerase [22]. This results in less amplified product being produced per cycle, unless the process is halted for fresh enzyme to be added before the additional cycles. Similarly, nested polymerase chain reaction (PCR) using two sets of locus specific primers has been suggested for LCN samples, but it is difficult to envision its use with forensic specimens due to primer compatibility problems with multiple multiplex PCR systems [23, 24].

Another approach to the analysis of LCN samples utilizes whole genome amplification (WGA) strategies. WGA methods employ various random-sequence primers and low-stringency annealing conditions to amplify large tracts of the genome in an attempt to increase the effective number of starting genomic templates prior to any downstream analysis. Theoretically, by preamplifying the limited amount of genetic material in the sample, sufficient quantities of template can be produced to overcome stochastic effects resulting from LCN templates. Several WGA methods have been developed and reported in the forensic literature, including primer extension preamplification (PEP) [25], degenerate oligonucleotide primed PCR (DOP-PCR) [26–29], long fragments from low quantities DOP-PCR (LL-DOP-PCR) [30], improved primer extension preamplification PCR (IPEP-PCR) [31], and multiple displacement amplification (MDA) [32–38].

PCR-Based Primer Extension Methods

DOP-PCR is a WGA method first described in 1992 (Figure 1) [29]. This method involves the use of a primer with three distinct regions: a 3′ end with a specified sequence, a middle region with a stretch of six degenerate bases, and a 5′ end with a longer specified sequence. Using a small number of low-annealing temperature cycles, the short specified sequence on the 3′ end hybridizes to multiple sites of the template DNA and complementary sequences are generated. The low-annealing temperature used

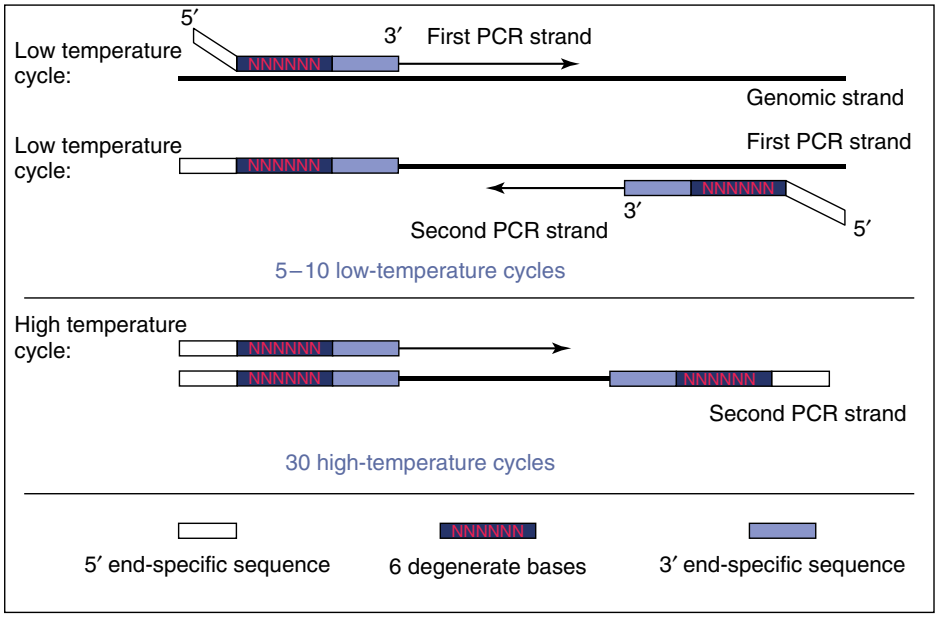

Figure 1 Schematic diagram of the degenerate oligonucleotide primed PCR process. Using a small number of low-annealing temperature cycles, the short specified sequence on the 3′ end of the primer hybridizes to multiple sites of the template DNA and complementary sequences are generated. Annealing of the 3′ end is then stabilized by the stretch of six degenerate bases adjacent to this region of the primer. The newly synthesized strands generated during the low-annealing temperature cycles serve as primer binding sites for subsequent cycles [Reproduced from Ref. 29. © Elsevier, 1992.]

in these initial cycles facilitates less stringent binding. Annealing of the 3′ end is then stabilized by the stretch of six degenerate bases adjacent to this region of the primer. The newly synthesized strands generated during the low-annealing temperature cycles serve as primer binding sites for subsequent cycles. These subsequent cycles utilize a higher annealing temperature to restrict nonspecific hybridization and allow for more specific binding based on the more stringent amplification conditions.

LL-DOP, or long products from low DNA quantities DOP, was developed to improve upon the original DOP method and provide better coverage [30]. The first modification was the use of a mixture of Taq DNA polymerase and Tgo polymerase, which was available commercially as the Expand High Fidelity Enzyme Mix (Roche Applied Sciences). It is reported that this mixture of enzymes has a threefold greater accuracy than Taq polymerase alone ($\sim 2 \times 10^{-4}$ misincorporation rate [22]). The 3–5′ exonuclease proofreading ability of the Tgo polymerase (later replaced with two polymerase) results in less sequence errors, which leads to a reduction in the number of truncated amplification products. It is reported that fragments up to 10 kb in length can be produced using this method. The LL-DOP method also incorporates increased annealing and extension times as well as increased annealing temperatures.

PEP was first described in 1992 and utilizes a mixture of random 15-base oligonucleotide primers to bind to various locations throughout the genome (Figure 2) [25]. Theoretically, 1×10^9 ($\sim 4^{15}$) primer sequences are possible using this length of primer, allowing for a plethora of sites within the genome to serve as primer binding sites. Extension from these primers then occurs with a large number of low-annealing temperature amplification cycles.

A modified version of the PEP method, IPEP, was described in 1999 and included two key changes [31]. The first modification was the addition of an elongation step prior to the denaturation step within each amplification cycle. Additionally, the mixture of Taq polymerase and a proofreading enzyme, the High Fidelity Enzyme mix, as described previously, was

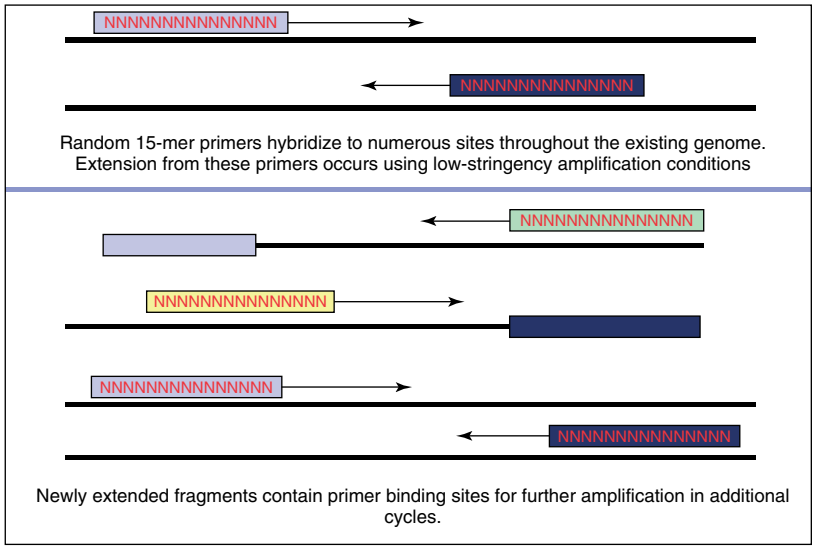

Figure 2 Schematic diagram of the primer extension preamplification process. Random 15-base oligonucleotide primers to bind to various locations throughout the genome. Extension from these primers then occurs with a large number of low-annealing temperature amplification cycles [Reproduced with permission from Ref. 25. © National Academy of Sciences, 1992.]

also utilized in the IPEP method. Further modifications to the IPEP method were made in 2005 [39]. A significant increase in the concentration of the Taq/Tgo enzyme mix and in the random 15-mer primer concentration resulted in the development of "modified improved primer extension preamplification (mIPEP)", which led to an improvement in the sensitivity of the IPEP method. The mIPEP method was also specifically designed for use with forensic casework samples.

Isothermal Amplification Reactions

An alternative WGA method is MDA, which uses the highly processive bacteriophage ϕ29 DNA polymerase [32]. Owing to the high processivity of this polymerase, primer extension from random hexamers allows products greater than 70 kb to be generated in an isothermal reaction. During this amplification process, ϕ29 DNA polymerase displaces the 5′ end of a newly synthesized DNA strand, thereby introducing a single-stranded product for further priming and extension (Figure 3). The MDA reaction is able to amplify DNA samples up to 100 000 fold and is reported to generate microgram quantities of DNA from picogram amounts of starting template.

Several amplification kits utilizing an MDA approach have been developed and are commercially available. The GenomiPhi™ v2 and the GenomiPhi™ HY Amplification kits are reported to result in the production of 4–7 μg or up to 50 μg of template DNA, respectively, in <2 h. The Repli-g Mini, Midi, and Ultrafast Mini Kit are available from Qiagen and are capable of producing 10 μg (Mini) to 40 μg (Midi). An isothermal-based reaction is also the basis for the GenomePlex® WGA products (Sigma-Aldrich). The GenomePlex® kits begin with a fragmentation of the input templates into a series of shorter, overlapping fragments. These fragments are then used to generate a library of DNA fragments, which is then amplified using a linear, isothermal amplification in the initial stages, followed by a limited round of geometric (PCR) amplifications using a universal primer to generate sufficient amounts of templates for downstream applications. Several GenomePlex® kits are available including the GenomePlex® Complete WGA kit (allows for amplification of a variety of starting materials), the GenomePlex® Single Cell WGA kit (reported to result in a millionfold amplification capable of producing microgram quantities of DNA from a single lysed

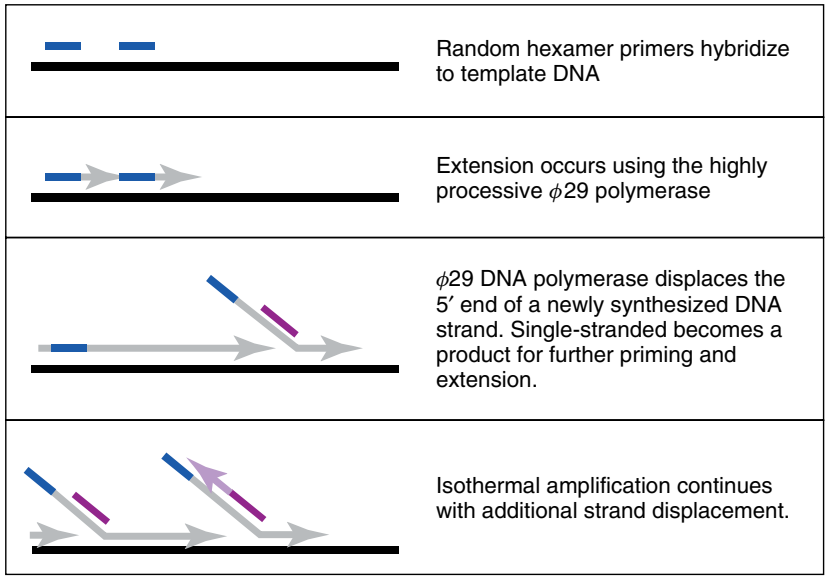

Figure 3 Schematic diagram of the multiple displacement amplification process. ϕ29 DNA polymerase displaces the 5′ end of a newly synthesized DNA strand, thereby introducing a single-stranded product for further priming and extension

cell), the GenomePlex® Tissue WGA kit (allows for amplification from fresh or frozen tissue), and also the GenomePlex® WGA Reamplification kit (allows for subsequent reamplification of the initial WGA product to produce large quantities of the product).

Genome Coverage

One of the main concerns regarding any WGA method is the successful amplification coverage of the genome present in the original sample with little amplification bias between or within commonly used genetic loci. The random nature of primers and the low stringency of amplification conditions utilized in most amplification strategies should theoretically allow for hybridization throughout the genome. Lower bias rates are typically reported for MDA (as low as sixfold between loci [32, 40]) compared to other PCR-based WGA methods (as high as $10^3 - 10^5$ [32, 41, 42]); however, individual reports vary widely, depending on the amount of input DNA used. Greater MDA bias is typically observed with smaller amounts of input DNA.

Many attempts have been made to use MDA to amplify low DNA quantity forensic samples. However, owing to the observed increase in amplification bias with smaller input amounts, attempts have been made to modify the MDA protocol to reduce this associated bias and increase the success of STR genotyping. It has been suggested that eliminating denaturation of the template DNA prior to MDA may result in a significant reduction in amplification bias [32, 43]. In a study conducted using the GenomiPhi™ amplification kit and subsequent autosomal STR typing, elimination of the template denaturation resulted in an increase in the allelic bias for those loci that were previously not showing a large amount of bias and resulted in a decrease in the allelic bias for those loci that were previously affected by amplification bias [43]. As a result, it was suggested that a pooling of template-denatured and template-nondenatured samples could be used in order to balance the effects at each of the included STR loci. In a separate study, again using the GenomiPhi™ amplification kit, the affects of molecular crowding (introducing additional sources of DNA into a single source DNA samples) on subsequent STR genotyping were investigated [44]. It was demonstrated that the incorporation of a larger amount of human DNA, animal DNA, or even glycol 400 as molecular crowding agents into low template samples resulted in an increase in the number of alleles detected.

Applications

WGA methods have aided in the development of LCN analysis of samples in the clinical research arena, although the impact of WGA in forensics has so far been relatively minor. However, recently, a few studies have been published involving the application of WGA methods to forensic samples, specifically the mIPEP and MDA methods.

PEP/IPEP/mIPEP

Early studies demonstrated the ability to obtain genetic profiles from several blood grouping loci (ABO, Lewis, and Pm) from PEP products [45, 46]. These studies were limited to relatively pristine samples using relatively large sample sizes (1–3 ng). More recent studies involving a broader range of forensic casework type samples evaluated the sensitivity and specificity of the modified PEP methods (IPEP and mIPEP). Autosomal STR and single nucleotide polymorphism (SNP) genotypes were obtained from genomic DNA samples preamplified using the IPEP method [47]. However, other studies have claimed that IPEP performed poorly with forensic samples including aged bloodstains, hair shafts, and bone samples [48]. mIPEP was successfully used to obtain autosomal and Y-chromosome STR profiles from forensically relevant samples, including buccal epithelial cells, vaginal epithelial cells, and sperm cells using only 5 pg of input DNA (~equivalent to 1 diploid or 2 haploid cells) [39]. STR profiles were also obtained from contact DNA samples (single dermal ridge fingerprints) that had been preamplified with the mIPEP method [39]. Additionally, partial Y- and autosomal STR profiles were obtained from mIPEP-treated DNA recovered from bloodstains exposed to the outside environment for one year, whereas non-mIPEP-treated samples did not produce profiles [39].

MDA

Significant effort has been extended in evaluating applications of the MDA method. With a reported ability to obtain microgram quantities of DNA from picogram amounts of input template DNA, the MDA method could have a significant impact on the analysis of forensic LCN samples. Additionally, several commercial kits are available that provide standardized protocols and optimized reagents. Successful MDA of various sample types including buccal cells, fresh and aged bloodstains, semen, hair shafts, and bone samples has been demonstrated using MDA [34, 36, 43, 47, 49]. Two commercially available MDA kits were used to determine if MDA could be used to improve the number of STR alleles recovered from degraded DNA samples [43]. While there was a difference between the two kits, both demonstrated the ability to recover additional alleles that were not obtained with non-MDA samples. The usefulness of this method in the analysis of forensic LCN samples has been demonstrated by the ability to amplify extracts from contact DNA samples such as fingerprints [34]. Recently, numerous studies have also reported the ability to analyze single cells after amplification with MDA [33, 50–53].

While reports of the ability to analyze single cells using the MDA method are encouraging for future forensic applications, there appears to be a large variation in the minimum amount of input template DNA required to obtain successful results in downstream analyses. There are numerous studies that provide evidence of problems with downstream analysis of MDA-amplified samples, even when greater input DNA amounts are used. Using 4–5 ng of input genomic DNA, a significant reduction in the ability to recover STR and SNP genotype data from MDA-amplified samples was obtained compared to the original DNA sample as a result of allelic loss and amplification bias [49]. Another study reported that the use of a minimum of 10 ng of template DNA is required to overcome the effects of the amplification bias associated with MDA [54]. Other studies have demonstrated that, even though the MDA method results in the production of microgram quantities of DNA (increased quantity compared to the sample samples when amplified with IPEP), there was no significant improvement in the downstream analysis of MDA-amplified forensic and artificially degraded samples, and oftentimes this resulted in the production of extraneous amplification products [48].

Selective Genomic Enrichment

Recently, a novel technology has been developed that allows for the selective amplification of human mitochondrial DNA (REPLI-g Mitochondrial DNA kit, http://www1.qiagen.com/Products/

GenomicDnaStabilizationPurification/replig/REPLIgMitochondrialDNAKit.aspx?ShowInfo=1) using an MDA-based approach. All of the previously developed WGA methods and commercially available kits are designed to amplify nuclear genomic DNA. However, this kit is reported to effect an enrichment of human mitochondrial DNA in total DNA samples with minimal contamination from nuclear DNA in a simple one-tube procedure. This eliminates the need for additional isolation or purification steps required for some downstream applications. This WGA-based selective enrichment technology has other promising applications with admixed forensic samples such as selective enrichment of Y-chromosome sequences in sexual assault cases.

Generation of Large Quantities of Starting DNA Template for Multiple Analyses

A potential application of WGA is to produce enough original starting template to permit multiple, including replicate, testing. The efficacy of such an approach assumes that the WGA treatment results in accurate replication of the starting templates. It is likely that the accuracy rates vary between different WGA methods and different starting template quantity and quality. Forensic samples are often limited in terms of quantity, and this limits the amount of DNA testing possible with these specimens. The fidelity of starting template replication caveat notwithstanding, more DNA tests could be carried out on the same specimen. For example, mixed samples that possess minor components showing stochastic variation in allelic signal intensity could be rerun multiple times after WGA pretreatment and a consensus profile of the minor contributor deduced. MDA was reported to provide enough starting DNA template to conduct 100 separate amplifications of distinct Alu elements in an attempt to predict the ethnoancestry of the DNA donor [55].

Summary

In an attempt to increase the recovery of profiles from LCN samples, WGA strategies have been developed. WGA methods attempt to increase the effective number of starting genomic templates prior to any downstream analysis. Although WGA methods have yet to demonstrate their utility for routine forensic analysis, selective genomic enrichment and the production of sufficient sample for multiple repeat analyses are possible novel applications.

Wildlife

Prior to July 1, 1975, it was a rare event for a forensic scientist to apply the resources of a crime laboratory to wildlife- or animal-related evidence. When these applications did occur, it was mostly in an effort to determine the "family", "genus", or (ideally) "species" sources of bloodstains and loose hairs collected at human crime scenes. These identifications were generally based upon immunodiffusion tests using relatively nonspecific antisera, and microscopic comparisons utilizing small collections of known hairs from local museums or zoos. And the results were often more useful in eliminating a suspect (i.e., the blood on the suspect's shirt is not of human origin) than in trying to link suspect and victim to a specific crime scene.

During this time period, a few forensic scientists did apply their forensic protocols and tools to evidence seized by wildlife law enforcement officers; but their resources (lab space, instrumentation, databases, and "standards" collections) were extremely limited. And their efforts were mostly limited to the identification of blood, meat, and hair from locally hunted species, utilizing the same immunodiffusion and microscopic comparison techniques.

July 1, 1975 was a significant date for wildlife forensics in that 80 nations formally agreed to work together to enforce each other's endangered species laws via the establishment of CITES (The Convention

on International Trade in Endangered Species Fauna and Flora) (www.cites.org). This international agreement encouraged the member countries to enforce uniform import and export laws related to agreed-upon lists of endangered, threatened, and protected species. In doing so, the establishment of CITES brought forth an underlying forensic issue: the reality that illegal trafficking of regulated species would occur mostly in the form of parts and products, rather than whole animals; and that species-specific identifications of questioned items would be needed to enforce the CITES regulations in courts of law. Thus, the need for wildlife forensics on an international scale was born.

In 1986, in response to this need, and in an effort to support CITES, the United States established the National Fish and Wildlife Forensics Laboratory (NFWFL) in Ashland, Oregon (www.lab.fws.gov). The primary mission of this new laboratory was – and still is – to develop reliable wildlife forensic procedures and to provide forensic support to state, federal, and international wildlife law enforcement officers.

In 1993, at a meeting of the Environmental Crimes Group of Interpol in Lyon, France, the role of the NFWFL in assisting CITES and Interpol was documented in the form of signed letters of agreement. As a result of those treaties, the laboratory now works with scientists and law enforcement officers from the CITES and the Wildlife Subgroup of Interpol to continually develop and refine reliable methods of identifying wildlife parts and products and to link suspects and their animal victims to specific crime scenes.

Today, a wide range of protocols are available for the identification and comparison of wildlife related evidence. These protocols are typically divided into the following categories:

- morphology;
- molecular biology (Genetics);
- criminalistics;
- analytical chemistry;
- pathology; and
- digital evidence.

Morphology

Morphology is the study of structure and shape. In wildlife forensic science, morphological examinations of submitted evidence items are normally conducted by eye, and with the use of simple, compound, or scanning electron microscopes. These are often the simplest examinations performed in a wildlife crime lab; but at the same time, they address some of the most complex and difficult identification problems.

A protocol for a method of morphological identification would be difficult to write: the lack of standard definitions for individuals, and the fact that no two individuals (even genetic twins) are exactly alike. Two animals (e.g., two whitetail deer that are genetic twins) may start out looking very much alike, but the normal wear and tear that a young whitetail deer experiences literally from the moment of birth creates individual characteristics (a healed cut, a chipped hoof, or broken antler) that quickly separate those twins into distinct individuals.

Thus, the immediate problem for a wildlife forensic scientist is to come up with, in a manner similar to other forensic morphological identifications such as footmarks, "class characteristics" that distinguish and identify family, genus, and species of animals that are separate and distinct from population and individual characteristics. This is not a problem with whole animals; but it is very much a problem in the case of wildlife parts and products wherein the commonly occurring species-defining characteristics of the animal-source may not be present.

These identification characteristics typically fall within one of the following morphological categories:

- hair and fur;
- leather and hides;
- bones and skulls;
- teeth, claws, and beaks;
- hooves, horns, and antlers;
- feathers and down; and
- other miscellaneous parts.

Molecular Biology (Genetics)

Molecular biology involves the study of genetic information encoded in the DNA molecule, and the expression of that coding into proteins and related biological structures. Given the incredible diversity of biological structures present in the known plant and animal kingdoms, molecular biology offers the wildlife forensic scientist an extremely powerful tool to

1. determine family, genus, and species;
2. determine gender; and
3. individualize blood and tissue samples.

Family/Genus/Species ID

Prior to 1996, the forensic process of determining the species origin of an unknown tissue normally began with a series of screening (immunological) tests designed to narrow the possibilities down to the species comprising a single family (e.g., bears – family Ursidae or deer – Family Cervidae). Once the family source of the specimen is determined, the examiners went forward with either protein or DNA/PCR analysis (along with the necessary and comprehensive databases) to determine the actual genus and species involved.

In 1996, scientists at the National Fish and Wildlife Forensics Lab in Ashland, OR, utilized a Matrix-assisted laser desorption/ionization (MALDI) Mass Spectrograph to conduct research on a procedure whereby the species of a blood or meat sample is determined by the analysis of the isolated hemoglobin structure. The development and verification of this protocol made it possible to determine the species source of a blood or meat sample in a few minutes as opposed to hours or days. And the ability of the MALDI instrument to work with extremely small samples, along with the habit of hunters and poachers not to wash their hunting clothes during an entire hunting season (in the belief that the animals will smell – and be scared off by – the scent of soap) now enables a wildlife forensic scientist to sample perhaps a hundred blood spots at random from a set of hunting clothes, and shortly thereafter provide the game warden with a list of all the species the hunter "engaged with" during that hunting season; a very powerful investigative tool, indeed.

Gender ID

There are a number of nuclear DNA-based gender-determining tests available for blood and tissue samples from mammalian species. The tests generally use the polymerase chain reaction (PCR) to amplify specific sequences of the zinc finger-containing protein Y (ZFY) and the sex determining region Y (SRY) genes, both of which are located on the mammalian Y chromosome.

Individualization of Blood and Tissue

Early work on individualizing animal blood and tissue samples involved multilocus DNA probe hybridization techniques. However, new PCR methods for detecting single-locus short tandem repeat (STR) markers have been developed and applied in human forensic casework, demonstrating the technical feasibility of similar applications to animal species. Pending the arrival of new technologies, wildlife research and forensic laboratories focus a considerable amount of effort on the development of STR markers for determining the individual origins of wildlife evidence tissues.

Criminalistics

Wildlife forensic scientists frequently process evidence from an illegal hunt much in the same way that a police scientist works evidence from a homicide scene. In fact, the events associated with a typical illegal hunt often involve the following categories of "criminalistics" (or police forensic science) evidence:

- trace evidence;
- firearms;
- other weapons;
- impression marks;
- latent-prints; and
- questioned documents.

Trace Evidence

Trace evidence in an animal case can involve a wide range of materials. A classic example is a case in which a mountain lion was held captive for a period of time and then killed in an illegal "canned" hunt. As it turned out, the mountain lion tried to chew his way loose from the synthetic fiber ropes (two types were used by the suspects to secure the lion), and a forensic scientist was able to link the fibers from the lion's stomach back to the chewed ropes found at the crime scene.

Firearms

The typical circumstances in which an animal is killed with a firearm vary greatly from those of a homicide case. The most significant differences include the following:

- the distance from the suspect to the victim;
- the choice of firearm;
- the ability of the suspect to "clean up" the scene;
- the tendency of the suspect to take the victim from the scene; and
- the tendency of the suspect to frequently reuse the same firearm.

Unlike human crime situations in which the victim is most commonly killed with a pistol at short – "contact" to 25 yard – distances, the typical animal kill involves a high-powered (and large caliber) rifle or a shotgun at relatively long distances (50–300 yards).

Given the nature of the typical hunting area (brush, trees, and ground cover), it is often difficult for an illicit hunter to retrieve his expended casings; however, the long shooting distances and the fact that the shot could have come from any 360° vector point makes it extremely difficult for a crime scene investigator to locate the shooting point, much less the expended casings. However, all of these advantages (to the illicit hunter) tend to be negated by two simple facts:

1. The point of the illicit hunting is for the suspect to take the victim (as a trophy or meat) back to his residence. Thus, the bullet is likely to either be in the carcass of the animal, or in the "gut pile" left at the scene (which can be matched to the trophy head or meat with DNA techniques).
2. The typical illicit hunter spends a lot of money on his rifle or shotgun, and rarely willing to discard his weapon after a single illicit kill. Thus, it is very likely that a succession of illegal kills can be linked to a single poacher by matching the spent bullets or casings to his rifle or shotgun.

Other "Weapons"

Other hunting weapons typically associated with an illicit animal kill include the following:

- long bows and arrows;
- crossbows and "bolts";
- spears;
- spring traps;
- poison discharge devices; and
- nets.

Impression Marks

The fact that most illicit hunting situations occur in remote areas or "off-road" situations makes it extremely likely that the suspect leaves tire tracks and boot impressions in soil, mud, or snow. And the fact that these tires and boots are typically used in off-road situations makes it all the more likely that the tire or boot treads possess individualistic wear marks.

Latent Fingerprints

Latent fingerprints are the classical means of linking the suspected, the victim, and the crime scene through physical evidence. The following types of latent-bearing evidence are frequently submitted to a crime lab in wildlife cases:

- firearms;
- expended casings (shotgun and rifle);
- knives;
- "no trespassing" and "no hunting" signs;
- game tags; and
- import/export (CITES) permits.

Questioned Documents

Questioned documents are frequently encountered in wildlife investigations involving the import and/or export of wildlife parts and products. The question most frequently by the investigator is whether or not the seized documents (typically import/export permits) are valid. This can be an extremely difficult question to answer when the authorizing seals vary between countries, the names of individuals authorized to approve import/export documents change on a frequent basis, and the shipments must be "cleared" (the documents examined and approved) at the local port of entry.

Questioned documents typically associated with a wildlife case include the following:

- forged or altered hunting licenses;
- forged or altered game tags; and
- forged or altered import/export permits.

Analytical Chemistry

Chemical analysis techniques are most often used in a wildlife crime lab to provide toxicological information for a veterinary pathologist conducting a necropsy. As such, a scientist assigned to the chemistry section of a wildlife crime laboratory spends a great deal of time examining blood, urine, tissue,

and stomach/crop contents in a search for pesticides and poisons. Analytical chemistry procedures (that use chemical biomarkers) are also used to identify the species source of animal products such as bear bile and deer musk; and standard toxicological methods are routinely employed to identify chemical baits and poisons used to trap and kill wildlife.

Pathology

Veterinary pathologists are responsible for determining cause of death of an animal carcass submitted as evidence. This is accomplished thorough necropsy (autopsy) protocols involving a search for lethal wounds cause by bullets, arrows, spears, and traps; a comprehensive toxicological workup of blood, urine, tissue, and stomach/crop contents to eliminate or confirm a poison or contaminant cause of death; and a professional evaluation of the underlying health of the animal prior to death. In the process of conducting these examinations, the veterinary pathologist also searches for signs of disease that may indicate a natural cause of death.

Issues that often complicate a cause-of-death determination in an animal (but should not impact the results of a careful and professional necropsy examination), include the following:

- The possibility that the animal might have been struck by additional (nonlethal or crippling) bullets, pellets, or other projectiles on days, months, or years prior to the questioned incident.
- The possibility that an illicit bow-hunter has shot the animal with a firearm first (because of the difficulty in getting close to an alert animal), and then sticking an arrow into the bullet wound.
- The possibility that the animal was killed or fatally weakened by a modern pesticide or poison designed (as the result of environmental protection laws) to decompose rapidly after a few hours of exposure to air or sunlight.
- The likelihood that scavengers would have destroyed a considerable amount of useful blood, tissue or bone evidence if the carcass was not found and collected in a timely manner.

In conducting necropsies involving bullet wounds, it is often extremely important that the veterinary pathologist determine the trajectory of the bullet into or through the body. This information may resolve the question of where the accused hunter was properly defending himself against a charging animal, or illegally hunting a protected species. The information may also be used by investigators, during the interview process, in determining the veracity of suspects and witnesses.

Digital Evidence

Modern poachers add digital cameras to their lists of equipment, and take hundreds of digital photos to share (over the Internet) with their fellow violators. It is now a rare warrant search of a poacher's residence or business that does not include the seizure of at least one computer, or (often in the case of a business that the investigators are not allowed to shut down) the "mirroring" of the computer's hard drive data into the investigator's portable computer.

Wood

Geographical Extent and Distribution of Forests

According to the Food and Agriculture Organization [1], 30.3% of the land area of the earth is covered by forest. This area has been further classified into 13 temperate and boreal forest types and 15 tropical

forest types. It is estimated that there are between 80 000 and 100 000 tree species worldwide. Each species has a set of identifying features of potential forensic value. These include

ecological/genetic factors,
microscopic structure,
dendrochronology, and
external appearance of timber.

The geographical distribution of forest species is only the first stage in the understanding of the importance of our use of wood. The timber- and wood-processing industries are substantial. In 2000, the worldwide production of timber was worth US $342 billion and represented 1.6% of world gross domestic product [2]. Wood and wood products can be found everywhere. This wide availability ensures that wood can be a valuable forensic tool.

Value of Wood

The forensic value of wood ranges from wood shavings found on the gloves of a suspect [3] to sections of ladders found at the crime scene in the Lindbergh kidnapping [4]. The analysis of wood is an important part of accident investigation, engineering reports, boundary disputes, archaeology as well as traditional crime cases where the suspect may be linked to a crime scene.

Ecological/Genetic Factors

The 28 forest types are classified according to ecological conditions. Trees are adapted to a variety of site factors. These include soil type, climate, altitude, and latitude. Acid soils, for example, will preclude trees that are adapted to alkaline soils. It is very unlikely that shoes covered in alkaline soil and owned by a suspect come from a coniferous plantation with acid soil. Similarly, it would be surprising to find tropical species in a temperate climate such as that as experienced in the United Kingdom or Norway. Such an unusual occurrence may suggest that the tropical sample was taken from a specialist hothouse and did not occur naturally.

Forest types are not usually monocultures. The Scottish Caledonian Pine Forest contains Scots pine, birch, rowan, aspen, juniper, oak as well as certain ferns, mosses, insects, and mammals. Any combination of these species might suggest that the forensic samples may be indicative of a Caledonian Pine Forest.

Origin is defined as the natural genetic location of a tree species. Sometimes seed is collected from a particular origin and exported to other sites around the world. These new trees then acquire a provenance. Thus, Sitka spruce seed from *Queen Charlotte Islands*, British Columbia, has been imported into the United Kingdom. The resulting progeny has a provenance referred to as *Queen Charlotte Islands*. A provenance may have slightly different growth characteristics than either the original stock or other provenances. This is thought to be as a result of phenotypic plasticity. Such a phenomenon may be of use in identification. Thus. a provenance of *Queen Charlotte Islands* may flush later, and is more frost hardy in Britain, than a provenance of *Washington*, which comes from a more southerly latitude. In practical terms, differences in provenance will usually be identified by differences in bark appearance, stem form, branchiness, and timber quality all within the same species.

The use of ecological factors in a forensic context is likely to be circumstantial. It is possible in some cases to rule out suspects at an early stage of an investigation, but it is unlikely that definitive proof of association can be obtained. It is likely that the testing of tree DNA will be used much more in the future to protect forest reserves. It is estimated that the loss of income to governments from illegal logging is between $10 and 15 billion worldwide [5]. The use of microsatellite DNA markers is already being used to identify trees and timber that have been stolen from protected reserves [6]. It is estimated that in Great Britain alone out of some 40 000 subsidence cases 75% are mainly due to woody material such as tree stumps invading adjacent property. In 1999, this amounted to over £300 million in claims.[a]

Forensic dendrologists are appointed to investigate such things as boundary disputes where trees are either the cause of damage or are themselves damaged. Cases of subsidence caused by trees and trees as nuisance value are also considered in this category. Road accidents where it has been alleged that trees are responsible or when road signs are obscured by trees are also topical. The condition, size, and health of the trees are usually assessed and taking measurements of height and estimations of root mass

are common. The engineering value of wood can be assessed by experts to see whether the wood is fit for purpose.

The use of DNA profiling is a useful but not foolproof technique for the identification of individual wood samples. In the case of poplar, willow, or walnut clones, for example, DNA profiling may identify the clone but not the individual. Samples taken from old furniture or heavily contaminated wood may have an incomplete DNA profile. Wood is often dead and may not contain any viable DNA. DNA databases are not complete and the analysis of some examples may be difficult to justify in court. Other techniques that can be used alone or in conjunction with DNA profiling to achieve accurate identification are available.

Microscopic Structure

The microscopic investigation of wood is perhaps the most useful alternative technique available to the forensic scientist. Not only can timbers be compared and identified but also engineered timber products such as cardboard, papers, and other processed timbers can be analyzed and identified. Furthermore, the analysis can be thorough and supported by strong statistical methods.

Wood (xylem) is a natural material with predictable structural variation. The variation is determined mainly by species though the location of the sample from the original log is also relevant. Logs consist of three sections: heartwood, sapwood, and bark. The heartwood is inactive but the sapwood is used for conduction. Wood consists of bundles of cellulose tubes (cells) glued together with lignin. In conifers (softwoods), these cells are known as *tracheids* and are typically 2–4 mm long and approximately 30 μm wide. They lie parallel to the stem and are used for support as well as conduction. They are characterized by having thin cell walls and open channels. Macerated tracheids can be seen in Figure 1.

In broadleaved species (hardwoods), these cells are differentiated into fibers and vessels. Fibers are rather thick walled and closed and are normally used only for support. They are typically shorter and thinner than tracheids, which are about 1–2 mm long and 15 μm wide. Vessels, which are between 0.2 to 1.2 mm long and less than 0.5 mm in diameter, are used for storage of water and minerals. Lignin is a resin found in the cell wall of plant cells that acts as glue, which holds together the tracheids, fibers, and vessels. It strengthens the overall structure of the wood. An example of oak vessels can be seen in Figure 2.

Figure 1 Macerated tracheids

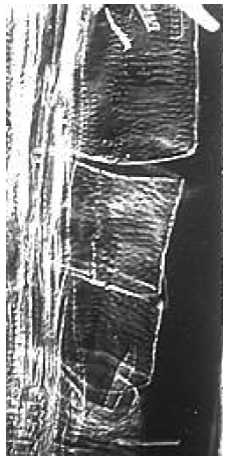

Figure 2 Oak *Quercus robur*. A decomposing vessel. The body of the long tube consists of short vessel elements that are stacked end to end

There are other structures within wood that can also be used for identification [7]. These include collenchyma and sclerenchyma, which are supporting tissues, and parenchyma, which is used mainly for storage. Medullary rays, pits, resin ducts, and pores can also be used for identification purposes. These traits vary with species.

The scientific analysis of wood has traditionally concentrated on the examination of fiber length. There is a correlation between the engineering performance of wood and the distribution of fiber length. The stiffness, hardness, durability and flexibility of timber are determined by the fiber structure. The importance of fiber length is even more evident in the wood-processing sector. The pulping process involves the extraction of the tracheids from the wood. These tracheids will later be reassembled as paper. In this context, softwood tracheids are often referred to as *fibers*. The wood is first chipped and then macerated so that the lignin can be removed and the fibers released. If the wood is rich in lignin, then the maceration process must be more active. This may include a bleaching process that is potentially hazardous to the environment. If the chosen species of tree has short fiber lengths, the resulting paper will tear easily. Long fiber lengths are associated with stronger papers. Manufacturers are concerned with producing an homogeneous product. This requires close monitoring of fiber length, which is one of the main quality procedures. Research into fiber length is therefore highly advanced. The examination of fiber length in papers, cardboard, liner paper, fiber board, and wood wool can be a useful form of identification.

Wood maceration consists of dissolving the lignin that cements wood fibers together. Various methods of wood maceration have been reviewed [8]. Various laboratory techniques have been used. They include Schulze's method [8], which consists of mixing nitric acid with potassium chlorate. This solution is often aggressive, especially when heated, so that some of the fibers are actually destroyed. An alternative milder treatment method known as *Jeffrey's method* [8] is used to mix equal portions of nitric acid and chromic acid together. Again this is heated to quicken the reaction. Franklin [8] proposed mixing together acetic acid and hydrogen peroxide. This method is effective but it can be slow. It is a particularly mild technique that does not damage the fibers appreciably. The Spearing and Isenburg [8] method uses a mixture of sodium chlorite and acetic acid. The Burkhart method [8] uses a mixture of boiling triethylene glycol mixed with a catalyst.

The choice of maceration process ultimately depends on the durability of the wood fibers, the time available and the size of the sample. Large samples of hard and dense timber, such as teak, may require a longer and harsher maceration process than say a soft pine. In the author's opinion it is probably best to start of with Franklin's method or Jeffrey's method as they are both predictable and controllable.

Industrial maceration techniques include Kraft pulping or the sulfate process [9]. The lignin from the wood is extracted by following a cooking process in digesters using caustic sodium hydroxide and sodium sulfide. This process has been designed to produce several useful by-products including the production of steam, electricity, soaps, and turpentine. The sulfite process is an alternative industrial method. Neither industrial method is appropriate for forensic investigations.

The results of the maceration process consist of an opaque liquid containing the separated fibers. This liquid can be washed, dried, and then mounted on a microscopic slide. Staining may sometimes improve clarity. The fibers are then physically separated and the lengths measured.

The objective of the analysis is the examination of fiber lengths. It might be expected that there would be a normal distribution of fiber lengths. Such an event would place great relevance to the mean value. In practice, however, some of the fibers are damaged and do not reflect the original length [10]. In these cases, the distribution is skewed or truncated because of the addition broken fibers. Almost all wood samples contain fibre damage. This could be due to saw damage, the chipping process, and natural fracturing. The maceration process itself could cause fiber damage. A reliance on mean fiber length could be misleading if the distribution is skewed due to damaged fibers. The examiner must take account of broken fibers either by excluding them from further examination or by assessing the actual length distribution for all of the fibers. In the latter case, the analysis is a form of pattern fitting. In effect, instead of comparing two normal distributions, the examiner would be comparing two truncated normal distributions or two skewed normal distributions [10]. The analysis becomes an estimate of fiber length distribution. A typical distribution of fibers and broken fibers can be seen in Figure 3.

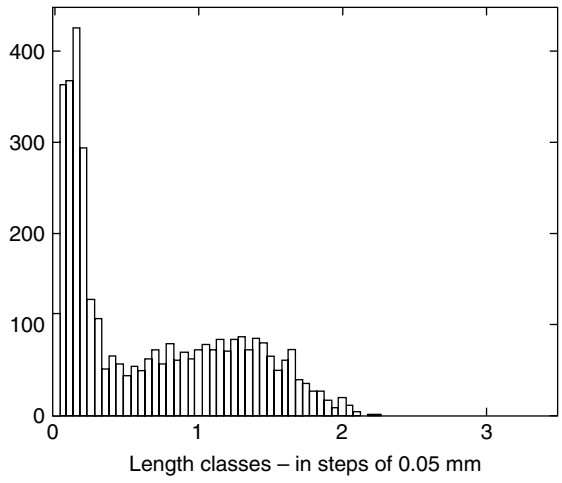

Figure 3 Histogram of fine and fiber length data from a sample from a 22-year-old Scot pine tree from Northern Sweden

It has been found that fiber length distributions have considerable intraspecies variation. Furthermore, variation exists within individuals. Fiber lengths will vary depending on where the sample is taken from the tree. Fibers closer to the core will differ from those nearer to the bark. This need not alarm the investigator because the comparison of fiber length will be between wood that has grown from the same part of the tree as the sample. A recent case in Texas illustrates this point [11]. A splintered pool cue had been used on someone's skull. Samples from the murder weapon were compared with splinters found in the suspect's car. Microscopic analysis confirmed that the splinters in the suspect's car came from a particular type of pool cue found at the crime scene. The microscopic structure of the splinters found in the suspect's car was identical to the structures found on the splintered part of the pool cue.

Good results can be achieved by measuring fiber lengths using a microscope. A less time-consuming method is by the use of an industrial fiber analyzer. Such instruments are designed for the pulp and paper industries. They automatically produce accurate morphological data on all aspects of fibers. They contain statistical analysis software including useful graphical data for distributions. Further research is required to investigate the full range of features that may be useful for forensic investigations.

Dendrochronology

Dendrochronology is the study of tree rings. Tree rings, often known as *annual rings*, mark the passage of growth of the tree throughout the year. They can be seen in the horizontal cross section cut through the tree trunk. Tree rings are common in temperate zones where the seasons are differentiated. They consist of spring wood (early wood) and summer wood (latewood). The spring wood grows fast and tends to be less dense than the summer wood. The comparative widths of both spring and summer wood are determined by the growing conditions existing at the time. Poor summers, for example, are reflected by narrow summer tree rings. All of the trees in a given locality have the same growth patterns. Given a sufficient period of growth, dendrochronologists can estimate variations in past weather by taking timber cores. The use of dendrochronology has expanded in recent years. Climatologists now use tree ring data to monitor changes in climate. Radiocarbon dating is often calibrated by using accurate dating of tree rings sometimes going back 10 000 years. The study of past events such as insect behaviour, wild fires, volcanology, storms, archaeology, and glaciology are all being enhanced by the use of dendrochronology. Tree ring data allows the researcher to cross reference past events accurately. This may have some value especially in the field of forensic archaeology.

External Appearance of Timber

Wood is the secondary xylem of trees. Xylem is used to transport water and nutrients throughout the tree. This is facilitated by transpiration and root pressure. The structure and appearance of xylem are largely determined by ecology and growing conditions. The proportion and density of spring wood to summer wood have already been discussed in relation to dendrochronology. Other aspects of structure such as the appearance of imperfections such as knots and grain effects can also be used for comparison and analysis.

Variations between species and within species pose a problem for the users of wood. Wood is

an heterogeneous material. The natural variation within wood must be accounted for by engineers and other users. Factors such as strength, hardness, modulus of elasticity, durability, tensile strength, and density are variable. Timbers are selected and graded to ensure that specific qualities are selected. For example, structural timbers are produced to meet international standards. Narrows variation down to within acceptable limits. This is usually based on minimum standards. Variation in standards aids identification and differentiation.

The external appearance of timber provides an obvious means of identifying, comparing, and matching. Timber is normally identified by looking at three dimensions or planes. These are illustrated in Figure 4.

The end-on view of a log is referred to as the *transverse section*. The main stem has been cut perpendicular to the grain and the spring and summer wood can be seen as a series of roughly concentric circles. The tangential plane is often found on the surface of veneered timbers. The wavy pattern of annual rings is chosen to enhance the attractiveness or figure of the wood. The radial plane accentuates the grain of the wood that lies perpendicular to the annual rings. The wood is usually very resistant to wear because the percentage of summerwood is maximized in the profile.

Samples of wood may be presented in one or more of these planes. Identification may be enhanced if similar samples that possess matching grain, frequency, and size of knots, as well as imperfections such as regular nail marks and colour are found. Associated paints, varnishes, and oils can be chemically analyzed as can the comparison of tool marks. Splinters of wood that do not conform to species guides because of the smallness of the sample can be identified using microscopic analysis.

The analysis of wood and wood products often requires techniques ranging from DNA profiling to good old-fashioned microscopic observation. Often these techniques must be used together to obtain the maximum amount of identifying information. It is likely that there will be significant growth in this area in the future, especially in civil cases, though one can never discount the need for such expertise in criminal cases.

Wounds: Sharp Injury

Introduction

The term "wounds due to sharp force" comprises injuries that are caused by pointed and/or sharp-edged implements. The main categories are stab wounds, incised wounds (cuts, slashes), and chop wounds.

In stabs, the causative object penetrates along its longitudinal axis producing a wound track that is longer than the skin severance at the entrance site. Incised wounds are inflicted by a cutting edge that slices the affected tissue when the instrument is drawn over the body surface, exerting sufficient pressure onto it; the resulting injuries are longer than they are deep. Chop wounds are caused by heavy metallic implements with a cutting edge such as axes or machetes; their outer appearance resembles cuts, often accompanied by corresponding fractures of the underlying bones.

Epidemiology

Sharp-force trauma is a major topic both in clinical forensic medicine and forensic pathology. In non-fatal bodily injuries, the study material includes a great variety of constellations such as survived knife attacks, attempted suicides (e.g., by wrist cutting), other kinds of deliberate self-infliction (simulation of a criminal offense, self-mutilation for the purpose of insurance fraud, dermal artifacts in patients with personality disorders), and various kinds of accidents.

Fatalities by sharp force account for a considerable part of the forensic autopsy material with a clear predominance of homicidal deaths. In several regions of the world (for instance, in Britain and continental Europe), the use of sharp force, especially stabbing with a knife, is the leading method of killing [1–3]. In most of the cases, the offenses arise from domestic disputes between life partners, interpersonal conflicts, street violence, and brawls associated with alcohol [2, 4]. Apart from this common background, there are also sexually motivated homicides committed by sharp force. In most cases, the perpetrators and the victims know each other.

Cutting the wrists is often seen in attempted suicides, but plays a minor role in suicide acts with fatal outcome. Suicidal stabbing is less frequent than

cutting and is usually confined to the precordial region or the neck. Accidental deaths from sharp force occur sporadically, for instance, when falling into a glass pane.

Stab Wounds

A stab wound is caused by a pointed object that produces a slitlike severance of the penetrated tissues. In most knife stabs, there is a clean division of the skin with sharp, straight, and cutlike edges that usually do not show any abrasions or contusions. Owing to the elastic retraction of the margins, a stab wound will gape, more or less depending on its location and its orientation with respect to the local fiber pattern of the skin. The most gaping wounds are found if the blade hits the skin transversely to the so-called cleavage lines [5, 6]. In contrast to lacerations, no tissue bridges can be seen between the margins of a sharp-force injury. Wounds from single-edged weapons may show one sharply pointed end (corresponding to the cutting edge of the blade) and one rounded, squared off, blunt, or fishtail-like end on the side of the knife's back (Figure 1, [1, 5]). In some types of knives, the back edge is serrated and can be used as a saw.

If a knife is thrust into the body and twisted before withdrawal, the skin wound gets the appearance of a "V", "Y", or "L" (Figure 2, [4, 5]). The wound edges can be considerably longer than the maximum width of the blade, as the stabbing action is often combined with an additional cutting component (incised-stab wounds [5]). The wound may start as a cut, which terminates as a stab wound; on the other hand, stab wounds can turn into an incised wound when the knife is withdrawn at a shallow angle. Stabbing actions do not always result in actual stab wounds but can also produce a cut if the blade contacts a curved part of the body tangentially. In transfixion stab wounds, the weapon may reenter the body after having passed through a limb or a sagging female breast.

Sometimes, the margins show a patterned imprint abrasion from the knife's handle or crossguard if the weapon was vigorously pushed in up to the end of the blade. The details of such contusion marks may allow conclusions as to the respective construction part of the knife [1, 5, 7, 8]. If the plane of the blade enters the skin at an oblique angle, the wound margins are beveled (shelved) on one side and undermined (overhanging, undercut) on the other, thus indicating the direction of the thrust (cf. Figure 1). Knives with serrated cutting edges do not necessarily produce stab wounds with characteristic features. When a serrated blade is drawn over the body surface tangentially, the teeth of the serration scrape across the skin, leaving parallel, linear abrasions [6, 8, 9].

Similar to gunshot injuries, taking X rays of the affected body regions is also advisable in cases of

Figure 1 Stab wound with clean-cut margins and one pointed end (corresponding to the cutting edge) and one fishtail-like end (corresponding to the back of the knife). When the knife enters at an oblique angle, one side is beveled and the other is undermined

Figure 2 Homicide of a 39-year-old man by a stab that penetrated above the right clavicle and severed the brachiocephalic trunk. The V-shaped appearance indicates that the knife was twisted in the wound before withdrawal

stabbing, not only in surviving victims but also in corpses destined for autopsy. Roentgenographs are a valuable means for postmortem documentation of a pneumo- and/or hematothorax, pericardial tamponade, and air embolism [8]; last but not the least, X rays help in recovering broken-off knife blade tips (Figure 3, [5, 8, 10]). Clothing should be examined thoroughly (number, length, and location of perforations and their correspondence to the stab wounds on the body).

In homicide investigations, the question often arises whether the wound dimensions and the other characteristics permit conclusions regarding the size and type of the weapon used. When measuring the length of a gaping surface wound, the edges should be brought into apposition [1]. Even after restoration by approximating the margins, the length of the skin wound need not reach the full width of the penetrating blade (due to the elasticity of the dermis). Moreover, the length of a stab wound also depends on the taper from the tip to the hilt: If only the narrow front section of a tapered blade has penetrated, the size of the wound corresponds to the width at the respective level. As mentioned earlier, a combination of stabbing and cutting may cause a wound slit much longer than the maximum width of the blade.

The length of the entire wound track indicates the depth to which a knife has penetrated. If the whole blade has entered, the depth of the wound may give an estimate of the blade's length. A vigorous stab can indent the body surface (for instance the abdominal wall) and compress the soft tissues so that the depth of the wound track may exceed the length of the causative knife blade [1, 8, 10].

(b)

Figure 3 (a) Kitchen knife with blood-soiled blade. The broken-off tip got stuck in the victim's skin (b). Homicide of a 49-year-old man by multiple stabs to the chest

It is difficult to verbally describe the amount of force required to inflict a given stab wound. For this reason, experienced authors [1] suggest the use of an easily understandable quantification (e.g., "slight pressure", "moderate force", "considerable force", and "extreme force"). There are several factors that influence the force necessary for penetration. An essential point is the sharpness of a knife's tip and cutting edge [4, 11]. (From a scientific perspective, the actual parameter that should be addressed is pressure, which is the amount of force per unit area ($P = F/A$). In this way, it is easy to see how a small force exerted with a pointed weapon causes a penetrating injury, whereas the same force used with, for example, a plank of wood causes only bruising with no penetration of the skin.) A high velocity of the thrust facilitates penetration. Apart from the properties of the weapon and the dynamics of stabbing [12, 13], the resistance offered by clothing, skin, bone, cartilage, and even soft tissue is of major importance [14].

Pointed weapons other than knives are also capable of inflicting stab wounds. Injuries from scissors have a different appearance according to the distance between the two blades: A closed pair of scissors will produce a singular skin wound with abraded margins, the shape often resembling a flat "Z" [1]. Open scissors with separated blades may cause a pair of stabs with one wound above and somewhat oblique to the other [6].

Another stabbing instrument, which can often be identified from the wound appearance, is the blade of a screwdriver. This is especially true for the Phillips screwdriver with its cross-shaped tip resulting in skin wounds consisting of four equally spaced cuts, whereas standard screwdrivers leave slitlike wounds with squared ends and abraded margins [5, 8, 15, 16]. Stab wounds can also be inflicted with a broken bottle or a drinking glass and by falling through a glass door if a pointed sliver enters the body [4, 17, 18]. Other possible stabbing objects include forks, ice picks, pencils, files, screws, and similar instruments with a more or less pointed tip [5, 6].

Analysis of the evidence at scene, the clothes and the injured body, can help differentiate whether

a stab wound was homicidal or self-inflicted [8, 19, 20]. Accidental stabs with a fatal outcome are extremely rare; they may occur in persons working professionally with sharp knives such as butchers when deboning slaughtered animals.

The following signs may be indicators of suicidal self-stabbing [8, 18, 21] :

- localization in the precordial region (Figure 4), sometimes involving the adjacent areas of the upper abdomen and, in rare cases, also stabs to the neck [22] or to the *cubital fossa*, the forearm, or the groin;
- grouping of the stab wounds (in cases with a multitude of individual injuries, Figure 5);
- presence of superficial "tentative stabs" [23];
- additional presence of wrist cuts or hesitation cuts to the neck;
- absence of defense injuries; and
- findings compatible with a retained ability to act up to the last injury.

Many suicides bare the respective body region before stabbing, although this is not true in all cases [24, 25].

In homicides, the fatal injuries are predominantly localized on the chest (Figure 6), neck, and abdomen [3]. The number of wounds is no reliable criterion for differentiation according to the manner of death, as single and multiple stab wounds are seen both in homicides and suicides [19, 26]. Infliction by another person is obvious when the affected body region cannot be reached by the victim's own hand. The additional presence of typical defense injuries proves the homicidal character of stabs.

Incised Wounds

Incised wounds or slashes are characterized by a clean-cut division of the skin and underlying tissues, resulting in a cut that is longer than deep. The wound edges usually do not show any contusion or abrasion, there are no bridges of tissue between the margins, and the wound ends are acute, often forming a superficial "tail" or shallow scratch. Cuts tend to gape in a spindle-shaped way, if they have sufficient depth. When the cutting edge is moved to and fro within one and the same wound, the slash may terminate in a multitude of shallow ends due to the "sawing" effect

Figure 4 (a, b) Suicide of a 55-year-old butcher who used a so-called deboning knife for inflicting two penetrating stab wounds to the precordial region. The wound axes are parallel to each other. The lateral wound ends are squared off, reflecting the back of the blade

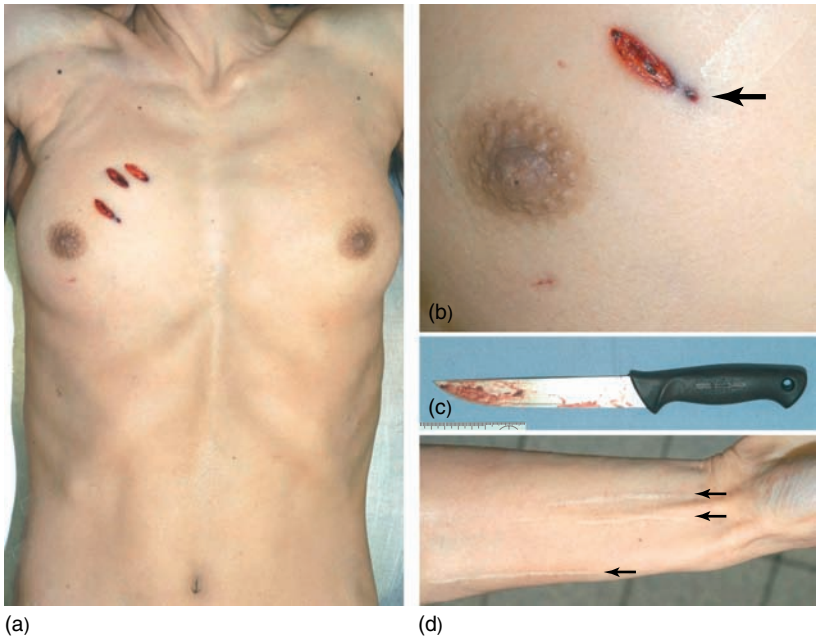

Figure 5 (a) Suicide of a 41-year-old woman by stabs to the chest. Atypical localization of the injuries on the right-hand side. The clothing had been pushed upward and therefore remained undamaged. Beside the wound next to the nipple, there was a punctiform "hesitation" stab (b), and the knife (c) was found close to the right hand. On the left forearm, there were whitish scars from a previous suicide attempt (d)

Figure 6 (a–c) Homicidal killing of a 37-year-old man by singular stab to the chest inflicted with a kitchen knife after a dispute in a state of intoxication. Death from exsanguination into the right pleural cavity [Reproduced from Ref. 21. © Elsevier, 2003.]

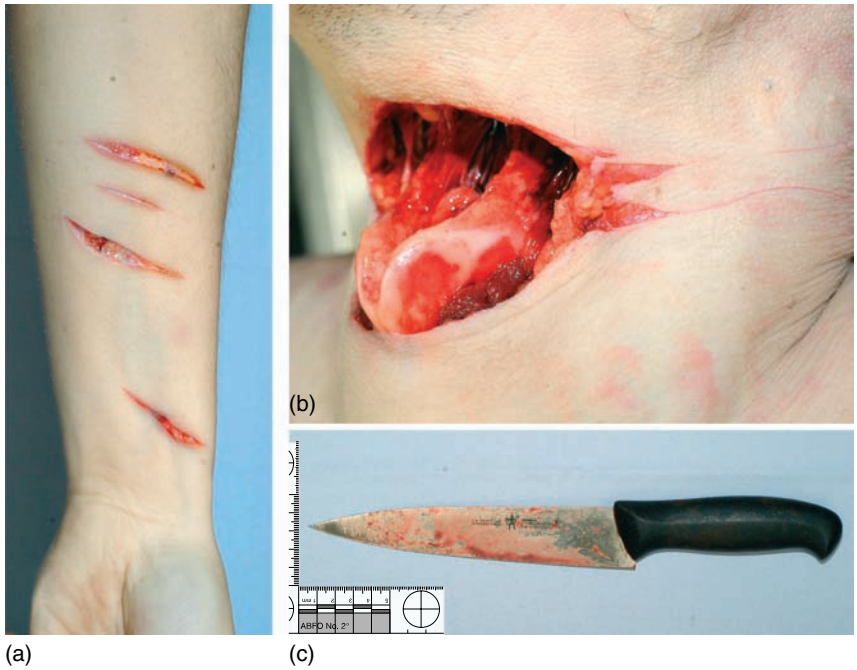

Figure 7 Suicide of a 26-year-old man who suffered from persecutory delusion. On the left forearm, there were four parallel, oblique, shallow cuts (a). Deep incised wound running transversely across the throat, exposing the laryngeal prominence with shallow ends on the left-hand side (b). The tool used was a kitchen knife (c) [Reproduced from Ref. 18. © Elsevier, 2004.]

(Figure 7b). If an edged weapon is drawn across the crests of loose skin or over bony ridges, a singular slash leaves an incised "wrinkle" wound with a linear, but interrupted, pattern of "skipping" cuts [5, 6].

Incised wounds are most often due to knives or other instruments with cutting edges such as razor blades, glass fragments, or pieces of sheet metal.

Cut wounds can occur in homicides, suicides, self-inflicted injuries without suicidal intention, and in accidents. Forensic differentiation between self-infliction and homicide is based on criteria similar to those described in connection with stab wounds [4].

Suicidal cuts are preferably located on the flexor sides of the distal forearms ("wrist cuts" (Figures 8 and 9b)) and on the neck ("cuts of throat" (Figures 7b and 9a)) [18]. In right-handed individuals, most of the wounds are expected to be on the left forearm and *vice versa* in left-handed persons. In most cases, there are multiple injuries, often parallel and arranged in groups, some of them being very superficial and having the character of "hesitation" or "tentative" marks resembling linear scratches (Figure 8b) [10]. Scars on the above-mentioned "sites of election" suggest previous suicide attempts (cf. Figure 5d). If the cuts do not lead to death or do not cause death rapidly enough, the fatal outcome may be achieved by applying another method such as hanging (complex suicide). The implement used to inflict suicidal cuts and/or stabs is typically left at the scene of death, even though the ability to act can be retained long enough to replace the weapon in its usual storage place or hide it [5]. In rare cases, the weapon may be still found in the hand of the deceased. As a rule, suicidal cuts are not accompanied by corresponding damage to the clothing. Unlike homicidal scenes, the place where a suicide is found normally does not show disturbance, especially regarding the distribution and spread of blood stains.

Fatal incised wounds from knife attacks mostly involve the neck [18]. Homicidal throat slashings can be single or multiple: the latter are sometimes in a "crisscross" arrangement with concomitant damage to the clothing. Characteristic hesitation cuts are missing. Additional defense wounds indicate the

Figure 8 (a, b) Suicide of a 54-year-old man by mostly shallow transverse cuts to the flexor side of both forearms. Death from exsanguination due to severance of the left radial and ulnar arteries

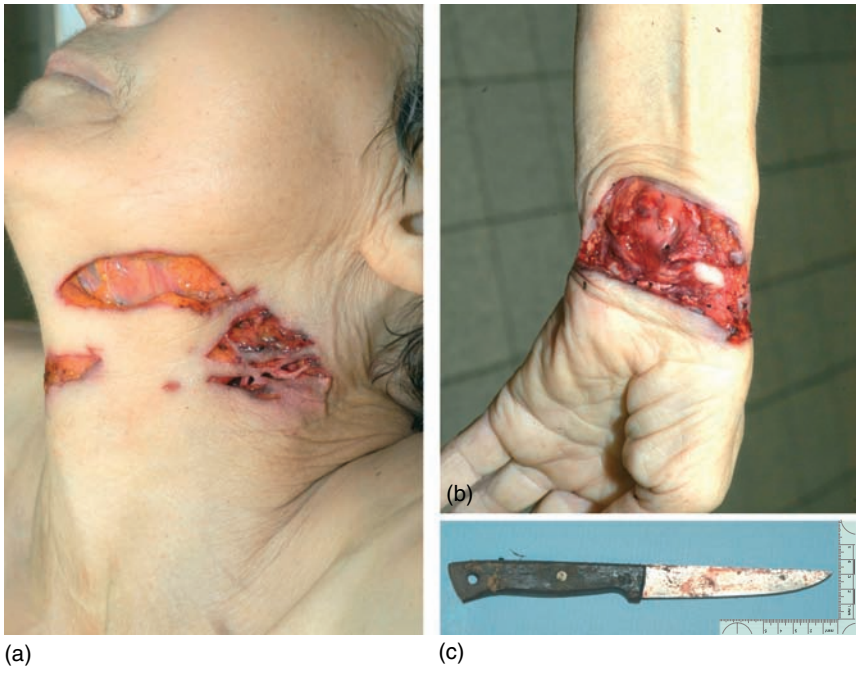

Figure 9 Suicide of a 66-year-old woman with a kitchen knife. Stabs and cuts arranged in groups in the anterior and lateral cervical region. Deep incised wound to the left wrist [Reproduced from Ref. 18. © Elsevier, 2004.]

homicidal manner of death, but they are by no means compulsory. For overall evaluation, it is essential to take into account the case history, the scene (including trace evidence, whereabouts of the weapon *etc*.), and the autopsy findings. Deaths from accidental cuts are occasionally seen after a fall through a sheet of glass or onto fragments of broken glass ware (Figure 10).

In clinical forensic medicine, the physical examination of living persons with stabs and cuts is part of the daily routine work. Apart from victims of assaults (mainly knife attacks), self-inflicted injuries play an important role [1, 4, 27]. A main category of self-induced bodily harm is the simulation of a criminal offense: The alleged victims falsely claim to have been raped or attacked for some fabricated reason (Figures 11 and 12). The primary intention of the informants is mostly to attract attention or affection. Usually, the self-inflicted injuries are caused with the help of pointed or cutting tools. The resulting lesions often consist of either shallow cuts or linear abrasions with the following typical features:

- equally shallow, nonpenetrating cuts;
- multitude of individual lesions;
- uniform shape, linear or slightly curved course of the lesions;
- grouped and/or parallel and/or crisscross arrangement;
- symmetry or preference of the nondominant side of the body (usually the left);
- location in easily reachable body regions;
- omission of especially sensitive body regions;
- no damage of the clothes or inconsistent damage;
- lack of defense injuries;
- sometimes additional presence of scars from former self-injurious behavior.

Some informants simulate a criminal offense by scratching letters, words, or political symbols such as swastikas into their skin [28].

Another category of self-inflicted cuts (including even mutilations) is seen in persons with emotional disturbances or mental diseases. Again, the lesions are typically multiple and located in easily reachable body regions. The coexistence of fresh wounds and

The fatal loss of blood was accelerated by a coagulation disorder due to liver cirrhosis. (b) In the depth of some wound slits, splinters of glass could be detected

Figure 11 Right cheek of a 15-year-old girl with several scratchlike, linear, and equally shallow skin lesions arranged in a group. The girl had initially claimed to have been kidnapped by unknown perpetrators who raped her and caused the injuries on her cheek. Later, she admitted to have simulated the offense in order to justify her late arrival at home. The injuries had been self-inflicted with the tip of a pocket knife

scars of different ages points to repeated episodes of self-cutting (Figure 13).

Chop Wounds

Chop wounds are caused by the impact of rather heavy instruments with a more or less sharp edge, some of them having especially long blades (sword, saber, machete), whereas another group of implements comprises axes, hatchets, choppers, and meat cleavers. The severing of the tissue is effected by pressure and not by a tangential, drawing movement. Powerful blows can not only produce incisionlike wounds of the soft tissues but also notch or break the underlying bone [5, 8, 29]. If the hitting edge is dull, the wound margins show narrow abrasions.

In homicidal attacks with chopping tools, the perpetrators mostly aim at the head (Figure 14), and occasionally also at the neck [18]. Suicides are very rare, but may be committed, for instance, by multiple axe blows to the frontal, temporal, or parietal regions, resulting in parallel wound slits of varying depth. Accidental deaths are seen in persons who sustained injuries from a boat or airplane propeller [8].

In surviving victims, possible self-mutilation for the purpose of insurance fraud has to be considered. In such cases, an accident is simulated in a fraudulent attempt to obtain compensation from an insurance company [27, 30]. Voluntarily inflicted mutilations from axe blows are often claimed to have been caused by a misplaced stroke when chopping wood. Mostly, the thumb or the index finger is cut off close to the proximal joint, whereas in authentic accidents the amputation is usually a distal and incomplete one. A proximal and complete amputation of the index finger in a right angle to the axis is especially suspect of intentional self-mutilation.

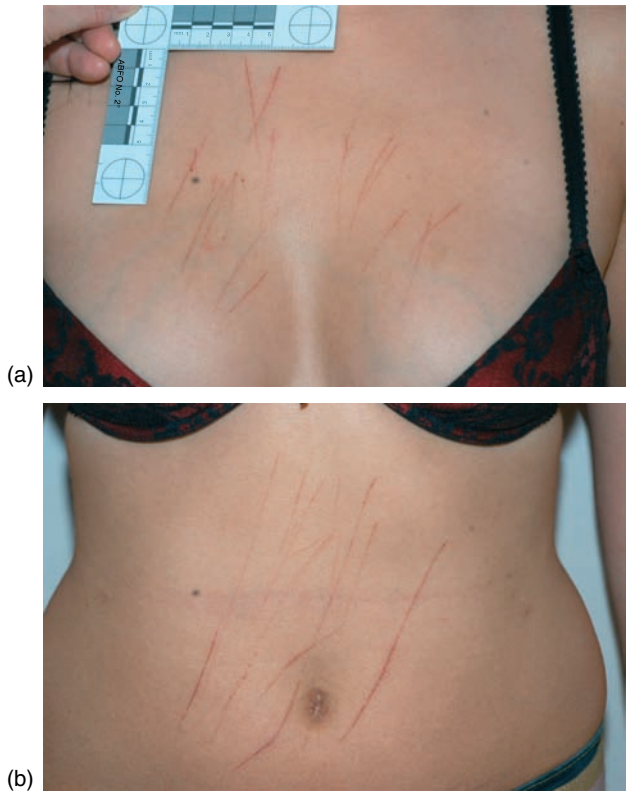

Figure 12 A 17-year-old girl who claimed to have been assaulted by an unknown perpetrator who allegedly injured her with a pointed instrument. The skin of the upper chest region (a) and of the abdominal region (b) showed a multitude of shallow scratchlike cuts, most of them running in parallel and without concomitant damage of clothes. Later, she admitted that she had invented the assault in order to attract attention and to win sympathy

Causes of Death and Ability to Act

A fatal outcome of sharp-force injuries is mostly the consequence of exsanguination caused by lesions to the heart, the great vessels, or the internal organs (*see* **Autopsy** [2, 4, 5, 21]). Penetrating wounds of the chest are often complicated by air in the pleural space (pneumothorax) with consecutive impairment of ventilation, especially when both halves of the thorax are affected. A cardiac tamponade (blood in the pericardial sac) can be caused by stabs to the heart if the blood cannot flow off into one of the pleural cavities. In stabs and cuts to the neck, a so-called air embolism may be the immediate cause of death: Air is sucked into a gaping venous vessel due to a negative intravasal pressure during inspiration. Another possible mechanism in sharp-force injuries of the neck is blood aspiration via the larynx or trachea. Late complications of stabs and cuts are local or generalized wound infections, for instance, peritonitis after injuries of the intestinal tract.

Even penetrating injuries of the heart, the aorta, or other major vessels do not necessarily mean that the ability to act is lost immediately [2, 21, 31, 32]. Incapacitation is to be expected only with the onset of unconsciousness. The duration and extent of the ability to act after stabs to internal organs or great vessels mainly depend on the size of the lesion and thus the amount and speed of blood loss [8].

Defense Injuries

Defense wounds indicate that an individual has been the victim of an assault. They also prove that the

Figure 14 (a) Homicide of an 18-year-old man who was killed with a chopper. Gaping cutlike wounds with severance of the underlying bones and embedding of fragments broken off from the weapon (b). Defense injuries on the extensor side of the left hand with traumatic amputation of the index finger (c)

Figure 15 Defense injury of the flexor side of the left index finger (homicide of a 63-year-old woman being stabbed with a knife)

Figure 16 (a) Defense injuries on the left forearm of a 24-year-old woman, who was killed by several stabs to the chest. In the elbow region, there is a so-called incised-stab wound. (b) The tip of the bloodstained blade is broken off

attacked person was – at least initially – conscious and able to use his or her limbs for protection. When sustaining defense wounds, the victim also must have been aware of the assault. In knife attacks, the victim attempts to ward off the weapon either by seizing it or by raising the forearms and hands in order to protect other body regions such as the head, neck, and chest [1, 2, 4, 5, 8, 18, 33]. "Active" defense wounds occur when the threatened person grasps the knife with the hand so that the palmar surface is exposed to the blade (Figure 15). The "passive" injury type is seen when the raised (upper) limbs are held in front of the attacked body region so that the majority of the wounds is located on the extensor side (Figure 16).

The frequency of defense injuries indicated for homicide by sharp force ranges between 30 and 50% [34]. In victims primarily able to react, the incidence increases with the number of hits placed on the body. The absence of defense wounds in victims with a multitude of stabs/cuts may be an indication that the ability to act was impaired or lost (e.g., in persons who were held, tied, heavily intoxicated, or already unconscious before the knife attack). In rare cases, defense wounds are even localized on the legs: if the victim was in a lying position, the legs may be used to ward off the knife.

Some perpetrators of knife attacks show sharp-force injuries on their hands, which they unintentionally inflicted upon themselves in the dynamics of the offense. If the knife does not have an adequate handguard and the tip of the blade is abruptly decelerated by a solid resistance such as bone, the perpetrator's hand can slip off the hilt and slide onto the blade, causing an injury [35].

Dismemberment

Postmortem dismemberment of a homicide victim is a rare incident and cannot be dealt with extensively in this context. The instruments used comprise sharp-edged tools such as knives, saws, machetes, axes,

Figure 17 Severed left breast of a 25-year-old woman who was killed by blunt force to the head. Subsequently, the perpetrator dismembered the corpse in the bath tub. The upper part of the breast shows shallow parallel cuts

and meat cleavers [36]. The wounds do not show any vital reaction (Figure 17). The main questions to be answered by the medicolegal expert concern the identity of the victim(s) (one person or commingled remains?), the cause of death, and any clues as to the dissecting instrument and possible motives (mutilations for sexual reasons?). Competent disarticulation may be suggestive of a perpetrator with some knowledge of anatomy [21]. A specific search should be made for tool marks, particularly on the articular cartilages and bones [8].

Writing Instruments and Printing Devices

Introduction

Determining the general class of writing instrument or printing device that produced an entry is fundamental to many forensic document examinations. It may be that making the determination is all that is required in a case, or it may be the first stage of a more in-depth examination process.

Some examples of examinations where determining the class of writing instrument may assist are as follows:

- quickly identifying added or altered entries if different types of pen have been used;
- indicating the best method for subsequent chemical analysis, as different classes of pen employ inks with quite different compositions each of which may be more responsive to differing analytical techniques; and
- determining direction of stroke in handwriting examinations.

The detection of counterfeits or fraudulently produced documents is an obvious examination type where determining the class of printing device used is very important. However, this determination is also a basic part of many other examinations as it can allow you, among other things, to

- identify areas of alteration in a document;
- determine whether a document is an original or a copy;
- guide investigators as to what types of device to take samples from; and
- identify the device that produced a document.

Once the general class has been identified, further analysis can be undertaken to assist in identifying possible brands and/or models of writing instrument or printing device. For example, with a typewritten document this analysis may involve consulting a typestyle database to narrow down the possible makes and/or models of typewriter. With a handwritten or inkjet printed document it may involve a chemical analysis of the ink and comparison to an ink manufacturer database.

There are a wide and ever increasing variety of analytical techniques that can be employed in the examination of the output from writing instruments and printing devices. These techniques can be used to distinguish between output from items of the same class, such as thin layer chromatography (TLC) to differentiate between ballpoint pen inks or Fourier transform infrared spectroscopy (FTIR) to distinguish between brands of toner.

In combination with ink libraries and spectroscopic databases, these techniques can be used to

obtain brand and model information. This may allow an investigation to be focused and provide a guide as to what devices to take samples from.

Ultimately, however, the goal of the examination is often to identify the source of a questioned document, using individuating faults to link to a suspect device. Determining the class of printing device allows the examiner to assess the significance of marks and characteristics in terms of their value in linking to a particular device.

This article focuses on the visual examination of the characteristics that allow the different classes of writing instruments and printing devices to be distinguished.

Writing Instruments

Writing instruments constitute a very broad category, which can really include anything capable of visibly recording handwriting on a surface. Obviously there have been, and still are, a large number of devices used for this purpose. This article discusses only pens that are most commonly encountered in document examination cases; that is, nib or fountain pens, ballpoint, porous tip, rollerball, and gel pens. The scope of the article is restricted to the general physical characteristics of the writing line. Ink analysis is covered in **Ink Analysis**.

Nib Pens

Nib pens, such as the steel dip pen or the fountain pen, use capillary action to flow ink down a split in the middle of the nib. Because of the split in the nib, these pens can create double furrows within the ink line (Figure 1). The degree to which this is noticeable depends on the stiffness of the nib and the writing pressure employed.

Dip pens need to be regularly refilled, usually as their name suggests, through dipping in an ink well. Because of this their ink line gradually reduces in intensity between refillings.

Fountain pens on the other hand have an inbuilt ink reservoir. Because of this they generally produce a continuous and even ink line. Fountain pen inks need to be free flowing and are likely to be readily absorbed by paper and bleed into the fibers, causing feathering of the ink line.

The direction of stroke in a nib pen entry can often be determined through the phenomenon of flowback [1], where additional ink flows back down the ink line at the end of a stroke, darkening that portion of the ink line.

Ballpoint

After many early attempts, reliable ballpoint pens became available from around 1950 [2]. The basic writing mechanism of the ballpoint pen is that it has a small steel ball, which is the writing tip, sitting in a housing in which it can freely rotate. As the ball rotates it picks up ink from the reservoir behind it and rolls it onto the page. As the ball keeps rolling it continues to pick up ink from the reservoir, producing a continuous ink line. Because of the pressure applied during writing, the ball generally produces a groove along the middle of the ink line. Ballpoint pen strokes are distinctive owing to the highly viscous, paste-like, ink that is used in them. This ink does not flow, so when writing with light to medium pressure writing the ink often only records on the top surface of the paper fibers, leaving numerous white voids in the ink line.

Stroke direction can be determined in ballpoint pen writing in a number of ways. Two techniques arising from faults are discussed. They also help to characterize the visual appearance of a ballpoint ink line.

Figure 1 A fountain pen entry showing double furrows from the split nib and feathering of the ink line

Figure 2 A ballpoint pen entry showing fine uninked striations and ink "goops"

Firstly, fine uninked striations running through the stroke [3] (Figure 2). These are caused by imperfections, or a build up of debris, between the ball and its housing. As the ball rotates they wipe off the ink, producing fine, uninked lines on the ball, which then transfer to the page. Owing to the rotation of the ball in the housing, as these striations travel along the ink line, they appear to move from the inside to the outside of a curved stroke. This phenomenon very clearly and quickly shows the direction in which the stroke was made. Occasionally these striations occur in sufficiently distinctive patterns to enable the writing from an individual pen to be uniquely identified [4].

Secondly, because of its viscous nature, the ink is prone to accumulating on the lip of the ball housing. These accumulations wipe off onto the ink line appearing as small dark spots and are generally referred to as "*goops*". They tend to wipe off immediately after a change in direction, showing the direction of stroke.

Porous Tip

This class of writing instrument is sometimes also referred to as *fiber tip* as they were the first type of pens in this class, first introduced in the early 1960s [2]. However, the general class of porous tip pens also includes felt tip pens and models with a perforated plastic tip. The two main common features of porous tip pens are that their ink is stored in a saturated fibrous column and that their porous tip works like a wick, allowing the liquid ink to flow onto the writing surface. Because of the very fluid nature of their ink, porous tip pens tend to produce saturated, continuous ink lines, often with feathered edges if writing on paper (Figure 3). Because capillary action is constantly feeding ink to the nib, if the nib is paused during the stroke, ink keeps running onto the paper. This results in a dark dot and/or local thickening of the width of the ink line.

Rollerball

The rollerball pen was introduced in the late 1960s. Like a ball point pen, it uses a rolling ball ink delivery system. However, it has a very liquid ink like a fountain or porous tip pen. Generally, its writing strokes exhibit the groove caused by the rolling ball and seen in ballpoint pen strokes (Figure 4).

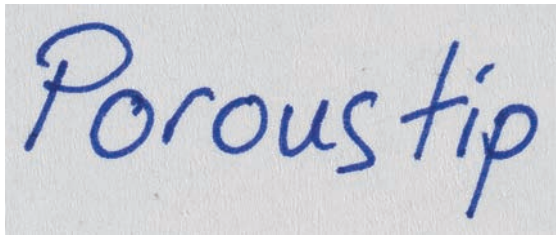

Figure 3 A porous tip pen entry showing feathered ink line and dark dots associated with pauses

However, it can be distinguished from ballpoint pens by the very liquid appearance of the ink line. This has the feathered edge appearance associated with porous tip and fountain pens. Additionally, it sometimes also exhibits the darkening of the ink line at the end of a stroke, reminiscent of the flowback associated with fountain pens.

Figure 4 A rollerball pen entry showing feathered ink line and groove produced by the ball

Gel Pen

The first gel pens were created by Sakura Color Products Corporation of Japan in 1984 [5]. Gel pens utilize a similar rolling ball ink delivery system to rollerballs and ballpoint pens; where they differ is their ink. Gel pen ink is water based and designed to be environmentally friendly with limited volatile components [6]. The ink has a high viscosity, although this is designed to lower when the pen is used. The

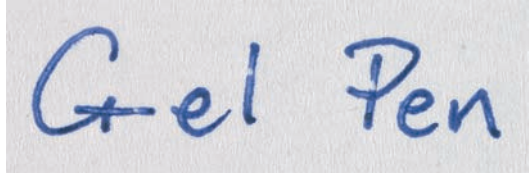

Figure 5 A gel pen entry showing tramline effect and "wiping" of overlapping strokes

appearance of the written line is similar to that from a rollerball. However, the gel-like nature of the ink can become apparent through the tramline effect that can occur along the edges of the stroke [4] (Figure 5). The ink is sometimes forced outward by the ball to the edge of the stroke, creating a dark pair of parallel lines. This, and a lower tendency toward feathering of the stroke edges, enables gel pen writing to be distinguished from that of a rollerball.

Gel pen inks are available in a wide variety of vibrant colors. Those containing reflective particles giving the ink a metallic sheen seem to be particularly popular.

Like rollerballs, gel pens tend to leave a dark dot of extra ink at the end of a stroke. Where two strokes intersect, the tramline edges of the second stroke wipe through and remove those of the first stroke. These characteristics can help determine direction and sequence of stroke in gel pen writing.

Printing Devices

The variety of printing devices and their associated printing technology is something that is constantly evolving. In this article, only the more common printing technologies are covered: typewriting, dot matrix, electrophotographic, ink jet, and thermal printing. Some of the specific issues of photocopier and facsimile machine examination are also discussed.

A discussion of the many different analytical techniques employed to examine the class characteristics of the different inks and toners associated with different printing technologies is beyond the scope of this article. The latter instead concentrates on the likely sources of individuating faults associated with the printing technologies and devices. That is, faults or characteristics that may allow a particular questioned document to be matched back to its source through a comparison with a suspect device.

As rollers or paper grabbers are used to some extent in all printing devices, they are a valuable potential source of evidence. The indented marks they leave on a page can often be visualized with a device such as the electrostatic detection apparatus (ESDA) [7]. While many of the impressions they make may be common to other printers of the same model or make, some rollers may develop individuating characteristics that may link them to their output.

Printing Technologies

The purpose of a forensic examination of a printed document is usually twofold. The first step is to identify the printing process(es) used to produce the document. In some cases, such as general questions of authenticity or counterfeiting, this level of examination is all that is required. Often though, the goal of the examination is to determine whether the printed document contains evidence that positively links it to a particular printing device. That is, the examiner is looking for some form of individual characteristic in the print that is also present on known samples taken from a suspect printing device.

Typewriting. Typewriters differ from the computer driven printing devices more commonly in use now, in that each character or symbol that is going to be typed exists as an examinable physical object. Computer-based printers generate characters and images by creating them from a series of dots; the appropriate placement of which is determined by the computer and printer. However, on a typewriter the individual characters are already there. Pressing a key on the typewriter keyboard causes that character to physically strike the page, generally through a ribbon, forming an image of that character on the page. The distinct advantage this gives an examiner is that if that individual character contains some form of defect or damage that is generally recorded in its image on the page. This is one way for typewritten documents to be identified back to their source.

The two main classes of traditional typewriter technology are the older typebar machines and the electronic single-element typewriters.

Typebar machines are the traditional “basket” typewriters with a row of metal typebars, each of which had a head like a metal stamp with two characters on it. Pressing a key caused an individual typebar to fly forward striking the page through an inked ribbon. Holding down the shift key would adjust the positioning of the typebar so that the other character on the head would strike the page when the key was pressed. Each key press would also move the carriage holding the paper and backing platen one space to the left so that the typed impressions were correctly spaced. In manual typewriters (nonelectric) the pressure with which the typebar hit the page was directly related to the force with which the key was pressed. Accordingly, one of the characteristics of

typing from a manual typebar machine is that overall the typing impression tends to be heavy and the impression of individual characters within a word or line is often uneven.

In addition to developing various alignment and movement faults, this type of machine was particularly prone to developing faults in their type characters. Often when typing it was common to simultaneously hit more than one key, causing two typebars to activate. This often resulted in one head hitting the back of another, causing physical damage to the character. The type characters in a typebar machine are physically part of the typewriter. This means that an individuating fault in a typewritten document positively identifies the machine that typed it. Also, fixing damaged characters requires major repair work; hence, character damage once formed is likely to remain.

This level of certainty was undermined by the development of the single-element typewriters. In these machines the type characters are contained on a removable single element. These elements take the form of either a *typeball* (these machines are often known as *golf ball typewriters*, Figure 6) or a *typewheel* (also commonly referred to as a *daisy wheel*, Figure 7).

Single-element typewriters do not have the direct relationship between typing pressure and the impression on the page that manual typebar machines do.

Figure 6 A typeball or "golf ball" from single-element typewriter

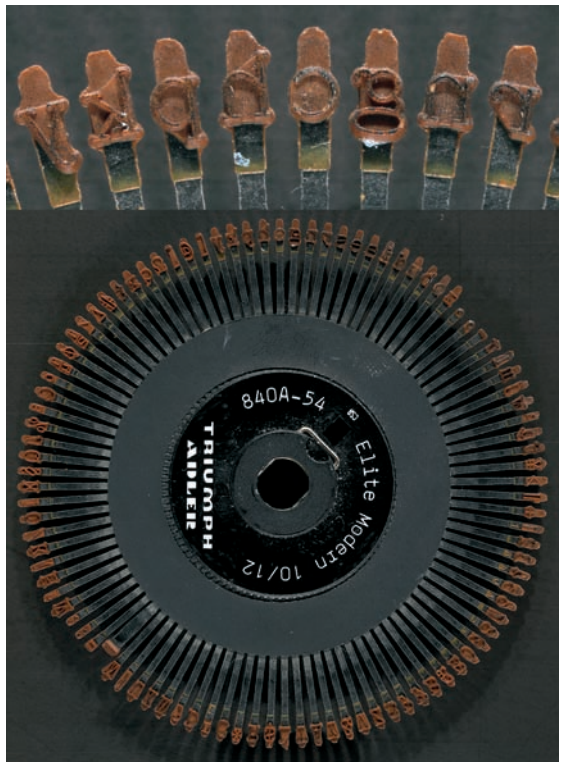

Figure 7 A typewheel or "daisy wheel" from single-element typewriter. The top of the figure shows an enlargement of the characters

The movement of the type element is electronically controlled. Assuming no fault develops in this mechanism, it produces a more even pressure between typed characters. Another major difference is that in single-element machines there is no moving carriage. The platen with the paper is fixed and the type element moves across the page.

The first single-element typewriter was the IBM Selectric, introduced in 1961 [8]. It used a typeball element. The typeball is a sphere (truncated top and bottom) with the characters positioned in rows and columns on its surface. When a key is pressed the typeball rotates and tilts as necessary to move the required character into position. It then moves the entire head forward, impressing the character onto the page through a ribbon.

A typewheel element consists of a central core encircled by radiating flexible spokes, each with a head containing a single character. When a key is pressed the typewheel is rotated to move the spoke

with the required character into position. A hammer then presses the back of the character, pushing it against the ribbon and page to form the typed impression.

Because the elements are removable, a single-element typewriter can produce typing in many different fonts and styles just by changing elements. Changing the elements can also be done without having to remove the page being typed; hence, a page with more than one typestyle can be easily produced. It also means that a character fault can only be matched back to the element, not the typewriter itself.

Individual faults can still develop within the characters on the elements. However, faults found in the characters can sometimes be class faults resulting from the manufacture process. An examination of the actual element, rather than just other typed specimens, can be necessary to more accurately determine the nature of the fault [9]. It has also been noted that once character damage occurs in a typewheel element, the character may continue to break down with use, and the damage becomes significantly worse in a relatively short time [10]. This increases the likelihood of an operator noticing the damage and eliminating it by replacing the type element.

While developments in typewriter mechanics made some aspects of typewriting examinations more difficult, developments in typewriter ribbon technology provided new ways to link questioned typing to its source.

Unlike their fabric predecessors, single strike carbon ribbons were designed to be used only once and then replaced. They consist of a polymer film backing with a coating that is transferred to the paper to form the image when a character strikes the ribbon. This leaves a hole in the coating corresponding to the typed character. With a properly working ribbon mechanism, the next typed character appears one space further on down the ribbon and not overlapping the previous character. A subsequent examination can therefore effectively read back everything typed on the ribbon. Additionally, the pressure of the type element forcing the ribbon against the page causes an impression of the paper fibers at that point of the page to record onto the polymer film backing [11]. This means that questioned typing on a page can be physically matched to the carbon film ribbon that produced it (Figure 8).

Another source of evidence for the document examiner came with the introduction of liftoff correction ribbons by IBM in the Correcting Selectric typewriter in 1973 [12]. This introduced a correction ribbon consisting of an adhesive tape that was used to lift the carbon film impression of an incorrectly typed character off the page. The result is a correction ribbon with a sequential record of the carbon film characters that have been corrected on that typewriter. Unless a significant amount of correction was being done many carbon film cassettes would be used and discarded before the correction ribbon would need replacing. Accordingly, even if the questioned text could not be found on the carbon ribbon currently in the typewriter when located, a fiber impression could be present and a comparison may be possible between any corrections in the questioned text and the images recorded on the correction ribbon [13].

Dot Matrix. The printhead of a dot matrix printer consists of a vertical stack of pins. A variety of printheads with different pin configurations have been used, but the most common are the 9 pin and the 24 pin (two columns of 12 pins) [14]. The name of the process comes from the fact that it uses a set of dots to form characters defined in a matrix form. The vertical columns of the matrix correspond to the printhead's stack of pins. The horizontal rows of the matrix are formed by iterations of the vertical pin stack as the printhead moves across the page.

A standard single pass of a dot matrix printhead produces what is known as "*draft" print quality*. Using a second, slightly offset, pass or a double column printhead produces a more complete image with the individual dots having less gap between them and blending more to look like a solid character. This is often described as "near letter quality" (NLQ) print [15].

With an impact printing dot matrix printhead, the printing controller moves the individual pins in and out, forming the image by striking the paper through an inked ribbon. Because of the impact process, these printers lend themselves to being used in conjunction with self-carbonating forms and this is often where they are used nowadays.

Thermal dot matrix printers also exist, which use individually heated pins to form an image. This can either be directly to darken heat sensitive thermal paper or indirectly using a heat sensitive thermal ribbon to print onto plain paper. Applying heat from

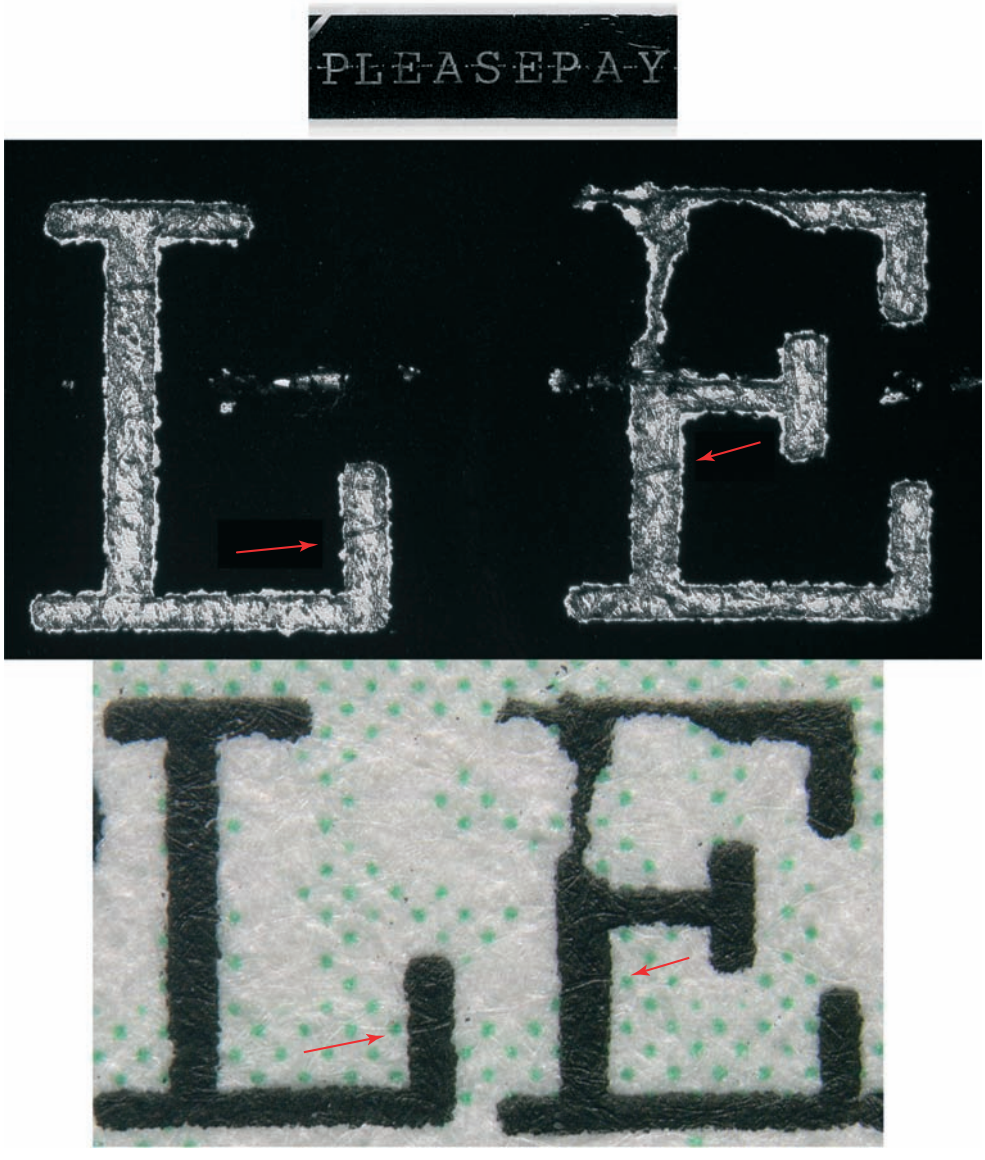

Figure 8 The top of the figure shows a used piece of single strike carbon ribbon. The middle image is an enlarged portion of the ribbon, showing paper fiber impressions that have been formed on the ribbon. The lower image shows the questioned document. The fiber that formed the prominent impressions on the ribbon is arrowed

the pins to the back of a thermal ribbon causes the ribbon to release ink or carbon onto the printing substrate. The process involved in printing with a thermal ribbon is that described in the thermal fusion process in this article.

There are several different types of fault that can develop in the printing mechanism of a dot matrix printer. A combination of some of these in a document may enable the printer that produced them to be identified. Some of the main faults are as follows:

1. Bent pins

A bent pin or misalignment in the firing mechanism that moves it in and out can cause the pin to be out

of alignment with the other pins in the printhead. Generally this is misalignment in the horizontal direction as movement in the vertical direction may result in neighbouring pins colliding, which causes a different fault.

2. Pin wear

Constant impact can lead to wear in the tips of the pins. This could take the form of broadening or "mushrooming" of the pin tip resulting in a larger dot, or uneven wear resulting in a noncircular dot. Significant, sudden damage of this type could occur through an impact with a foreign body, such as a bit of grit in the paper.

3. Weak impression

A pin may record faintly due to a fault in the firing mechanism or a build up of ink and dust that retards its movement. This type of fault can sometimes be intermittent.

4. Print-stack collapse

This is where misalignment in the vertical direction reaches the point of pins collapsing down onto their neighbors. Once this happens to a significant degree it is unlikely that the printer will continue to be used owing to the quality of its output.

When considering pin wear and tear faults it is worth bearing in mind that some pins in the head do considerably more work than others and so could be expected to wear out faster. For instance, in a nine pin head the lower two pins are generally only used (not considering images and vertically enlarged text) for the portions of the image that are printed below the line. Accordingly they get much less use. While the top two pins get more use (capitals, numbers, ascenders) it is the middle five pins that are used constantly. It would be more likely then for a wear associated fault to develop in pins 3–7.

Electrophotographic. Laser printers use the electrophotographic printing process, which is also sometimes referred to as *electrostatic printing* or *xerography*. This is also the process used in most photocopiers and many facsimile machines.

The basic mechanism for this printing process is that light is used to create an electrostatically charged latent image on the surface of a photoconductive drum or belt. Oppositely charged toner is applied to the drum, adhering only to the latent image. The toner image is then transferred to a sheet of paper and fused to it using heat and/or pressure (Figure 9).

There are many variations on this fundamental design.

In traditional photocopiers, the imaging drum is given an initial uniform charge. Light is shone onto the document to be copied and is reflected from the white, nonimage areas of the page onto the photosensitive drum. This reflected light dissipates the charge in these areas of the drum. Accordingly, only the areas on the drum that correspond to the dark, light absorbing image details on the page to be copied are left with charge.

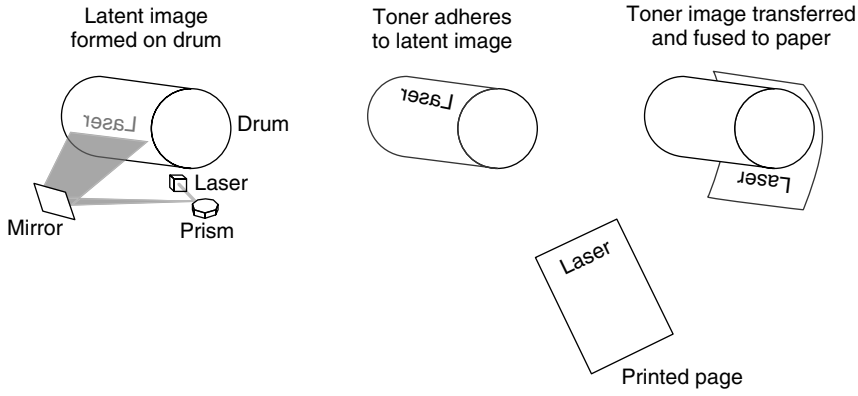

Figure 9 The basic electrophotographic printing process used in laser printers. In this illustration a pulsed laser beam and scanning prism/mirror arrangement are used to from an electrostatically charged latent image on the photoconductive drum. Toner is then applied and adheres to the latent image. This toner image is then transferred to the page and fused to produce the printed document

In a laser printer there is no document for light to be reflected from. Instead, the source of the image is a digital signal sent from a computer. Traditionally, the image is formed through pulsed laser light being scanned across the photosensitive drum. Depending on the printer design, the image can be formed by one of two ways. Either, as with the photocopier design above, the drum is precharged and the laser light is used to dissipate the charge in the nonimage areas that are to be white in the completed print. This is often described as print white. The alternative method is described as print black, where the laser is directed onto the image areas that are going to be black in the completed print. This is the method more commonly used in laser printers today.

A number of laser printers now no longer use the scanning laser beam to create the image on the drum. Instead they use a fixed array of light-emitting diodes (LEDs) positioned in front of the drum. These are switched on and off by the printer controller to selectively expose the imaging drum.

Another alternative technology is the use of liquid crystal shutters. With an electronic signal these shutters can be set to either black (closed) or transparent (open). In this method a constant light source is used, with an array of liquid crystal shutters positioned across the drum. The printer controller opens and closes the shutters to selectively allow the light to the drum to form the image.

There are a number of faults or defects, which can develop in a laser printer that allow documents to be positively matched back to that particular device. However, given the scope of this article, I shall only discuss the two most common faults, those associated with the imaging drum [16] and the fuser roller.

There are many ways damage can occur to the photosensitive surface of the imaging drum, including in the manufacturing process, during installation, from paper jams, foreign objects pulled in through the paper feed, and natural wear. Depending on the nature of the damage these faults can either always attract toner and print black on the page or reject toner and print white (Figure 10). As most documents usually consist mostly of white page with some black text, the faults that print white are often difficult to locate. Accordingly, it is more often the black printing faults that are used for comparison.

A fault on a laser printer imaging drum prints with each revolution of the drum. The circumference of most laser printer imaging drums are smaller than a standard page. Accordingly, a fault on a drum prints repeatedly down the page as a dot in the same horizontal position across the page. A common circumference for a laser printer drum is 94 mm. A fault on a drum of this size prints three or sometimes four times down the page. This makes the marks produced by a drum fault easily separable from the random background scatter that sometimes occurs with laser printers.

When comparing marks on a questioned document back to known samples, the horizontal position of the mark on the page is its initial identifying characteristic. However, given that there are only so many positions that a mark could form in across the page

Figure 10 The top half of the figure shows text from a threatening letter. Faults in the laser printer's photoconductive drum have rejected toner and recorded as white dots. The bottom half of the figure shows the same faults appearing in a sample print from the suspect's laser printer

the possibility that another laser printer could also develop a fault in the same horizontal position is very real and needs to be considered. A repeating pattern of several marks increases the likelihood of being able to positively identify a printer significantly. So too do faults of distinctive size and shape (Figure 11).

The heat and pressure fuser roller mechanism used in laser printers and photocopiers is particularly susceptible to damage [17]. Partly this is through the natural wear that occurs given the twin stresses of heat and pressure. But additionally the fuser is an area often prone to paper jams. This increases the chance of damage when the jam is being cleared. Faults associated with fuser rollers can be extraneous toner marks or smears and heavily embossed patterning of the paper (Figure 12).

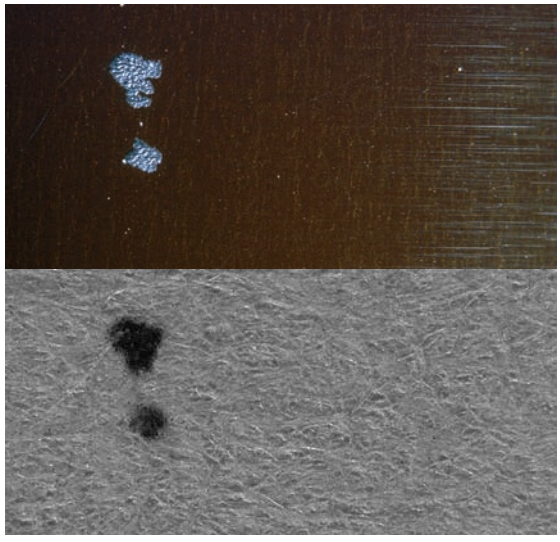

Figure 11 The top half of the figure shows distinctively shaped damage on the surface of a laser printer's photoconductive drum. The bottom half of the figure shows how this damage reproduces as a toner mark on documents printed with this drum. The photograph of the drum has been mirrored to allow for a direct comparison

Inkjet. The output of an inkjet printer is formed from droplets of liquid ink. These are fired at the printing surface through a printhead made up of an array of fine nozzles. The formation of the image is determined by a digital signal.

There are two broad categories of inkjet printing. These are "continuous stream" and "drop-on-demand".

In continuous stream inkjet printing, the printhead produces a constant flow of ink droplets. The droplets that are actually going to be required to form the image are given an electrical charge. By using an electrostatically charged deflection plate, droplets are then deflected, either toward the printing surface if they are to form part of the image or to a waste collection gutter if they are not required. Continuous

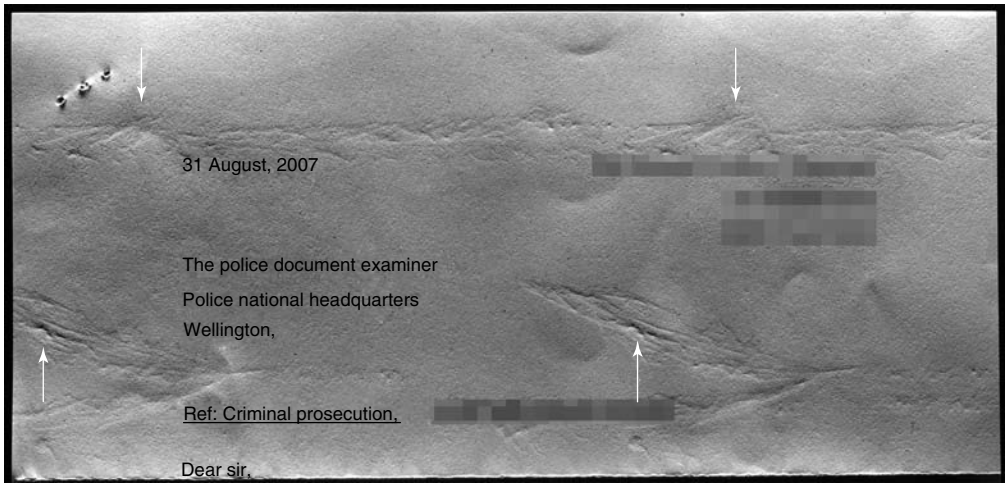

Figure 12 This photograph shows the heavily embossed pattern caused by damage to a photocopier's fuser roller. This pattern is embossed onto all the documents it prints. The arrows highlight repeating marks, demonstrating the circumference of the roller (the pixelization is for privacy purposes)

stream inkjet tends to be utilized in high volume commercial applications such as product dating and barcodes.

As the name suggests, drop-on-demand inkjet printers only produce a droplet when it is required to form the printed image. Drop-on-demand inkjet printing is generally performed using one of three technologies. These are thermal inkjet, piezoelectric, and solid inkjet.

Piezoelectric. The basic principle behind this method is that the application of voltage to a piezoelectric crystal causes it to deform. By alternating the voltage a piezoelectric element can be caused to rapidly flex. This vibration of a piezoelectric element can be used to produce a pressure pulse in a printhead ink chamber, forcing a droplet of liquid ink out of the printing nozzle. Epson is probably the largest user of piezoelectric inkjet printing technology.

Thermal Inkjet. This process uses a heater element in the printhead ink chamber to create a pressure difference to force ink droplets out of the printing nozzle. Rapid heating of the element causes the liquid ink next to it to vaporize, creating a bubble. This rapidly expanding bubble forces a droplet of ink out of the printhead nozzle, firing it toward the page. As the bubble collapses more ink is drawn into the chamber. This process is often referred to as *bubble-jet printing* and tends to dominate the desktop printer market.

Solid Inkjet. Like other inkjet devices, solid inkjet printers have a print head consisting of a series of nozzles through which the ink is propelled to form the printed image. The main difference is the ink itself. This is solid and waxy, rather like crayon. Typically the four process colours cyan, magenta, yellow, and black (CMYK) are used. In the printing process, the ends of the solid ink blocks are melted and the resultant liquid ink is sprayed through the printhead nozzles onto a drum, where the image is formed. The paper is then pressed against the drum, transferring the image to the paper. The ink then cools and hardens into its original solid state. The output from solid inkjet is easily identified by its raised, waxy appearance.

Some printers sprayed the ink directly onto the printed page. However, the interim step of forming the image on a drum and transferring it to the page was introduced as it allowed for faster printing and improved image quality.

Another difference from the majority of inkjet printers is that the solid inkjet printhead is page wide, i.e., the printing nozzles are in fixed positions and the print head does not scan back and forth across the page.

Solid inkjet was originally popular with graphic artists for its saturated colour and as an alternative to thermal wax transfer printers for printing colour proofs. However, Xerox has been developing solid inkjet printing technology and is beginning to market it for general office use. This has included incorporating solid inkjet technology in multifunction devices (all-in-one devices that photocopy, scan, print, and fax).

Positively linking a questioned document to a specific inkjet printer is notoriously difficult. While printers can develop blocked nozzles, this type of fault is often highly transitory as most printers perform regular cleaning cycles to try and eliminate this fault. With colour image printing, a blockage of several nozzles of the same colour often results in a noticeable colour cast, which may well prompt the user to initiate a nozzle cleaning cycle. Stripes through the image that look like blocked nozzles can also be caused through faults with the printhead's electrical contacts. This can sometimes appear quite dramatic with many nozzles not firing. In cases where this is encountered, investigations would need to be made to determine whether that was a common failure in that model of printer.

A not uncommon fault with inkjet printers is paper misfeeds, or paper too small for the image, leading to the printer printing onto the backing platen. Subsequent pages may pick up this ink on their rear providing a possible link to the printer.

With solid inkjet printers the waxy nature of the ink increases the chance that blockages are more persistent. Also, the full page-width printhead means that any nozzle faults occur in the same position on each page, making them much easier to be identified (see Figure 13).

Dye Sublimation. The chemical process of sublimation is where the application of heat transforms a substance directly from a solid state to a gaseous state without an intervening liquid phase. The dye sublimation printing method is also known as *dye diffusion*

Figure 13 This is a print from a solid inkjet printer. The banding seen slightly right of center is caused by blocked cyan ink nozzles

thermal transfer (D2T2), *dye diffusion*, or *thermal dye* [18]. It uses a full page-width print head consisting of a line of heating elements. These elements are heated to transfer sublimable dyes from a ribbon onto the printing substrate. They heat the dye until it sublimates to its gaseous phase and then transfers to the printing substrate. The substrate requires a special coating, which absorbs the gaseous dye, returning it to a solid state and so producing the image. Dye sublimation cannot print directly onto plain paper.

The amount of dye that transfers can be varied by altering the degree of heating of the printhead elements. This means that dye sublimation can print shades of color, producing continuous tone images of near photographic quality.

The ribbon is a clear plastic film coated in dyes. The dyes are in repeating sets of full page sized panels, generally of yellow (Y), magenta (M), and cyan (C). Some ribbons may also include a black (K) panel and/or a protective overcoat (O) panel. The final print is made up through a series of separate passes with each color being printed separately. For example, using a YMC ribbon the yellow component of the image would be printed, then the magenta, then the cyan. At the end of the yellow and magenta passes the printing substrate would be drawn back into the printer to allow for the addition of the next color. All the panels in a set are used to print a single page and cannot (in normal usage) be reused.

The best way of identifying printed output back to a specific printer is through the ribbon. Each panel on a used ribbon retains a negative image (corresponding to the lost dye) of what was printed (Figure 14). A microscopic examination of the ribbon and print often locates areas where a piece of dust or

Figure 14 The image on the left is a print from a dye sublimation printer. The image on the right is from the magenta panel of the printer ribbon, showing a negative image corresponding to the lost magenta dye that has gone to make up the print

other obstruction has affected the transfer of dye and recorded on both the ribbon and print. This allows the ribbon to be "physically matched" back to the print, rather than just on its content.

Failure of heating elements in the printhead results in vertical lines on the printed page and could also be used to link a printer to its output.

Thermal Wax Transfer. This printing process is also known as *thermal mass transfer, hot wax transfer,* or *direct thermal transfer* (D1T2) [18]. The general mechanics of the printing process are sufficiently similar to dye sublimation that many machines are actually sold as dual technology, capable of printing both thermal wax and dye sublimation. The significant difference between the processes is the composition of the ribbon used. Thermal wax transfer uses ribbons coated with a wax layer containing pigments. The heated printhead elements melt the wax and it transfers onto the printing substrate.

Thermal wax transfer can print directly onto plain paper, although it transfers most easily onto a smooth or glossy substrate, working well on transparencies. To improve its performance on rougher papers some printers include a special precoating panel on the ribbon, which lays down a clear wax base onto the substrate before the color printing. Like dye sublimation the thermal wax transfer ribbon is composed of repeating sets of full page sized panels. Generally it consists of yellow (Y), magenta (M), and cyan (C) and sometimes with a black (K) panel and/or a protective overcoat (O).

Because the pigmented wax either transfers from the ribbon or it does not, thermal wax transfer cannot produce the same range of tones and colors that dye sublimation can. The visual appearance of the output from the two processes is very different. Dye sublimation has a distinct grid like appearance, but with blurred individual pixels giving the smooth gradual changes in tone. The output from thermal wax transfer is made up of dots of solid color with distinct edges. Printed text particularly has the characteristic stepped edge associated with low resolution digital printing.

One of the products that dye sublimation and thermal wax transfer are often used to produce is plastic identity cards. These often incorporate dual technology ribbons, where dye sublimation panels are used to print images, such as the holder's photograph, and then text is printed with a thermal wax transfer ribbon. This has the advantage of continuous tone photographic quality images with solid crisp text, all printed in the one machine.

The process of matching thermal wax transfer output back to a specific printer is the same as for dye sublimation. That is, the identification of negative images on a used ribbon and the detection of heating defects with the thermal printhead elements.

Thermal Fusion. Thermal wax transfer is typically associated with color printing using semitransparent pigmented wax. There are other thermal ribbon based printing processes, sometimes grouped under the term thermal fusion, which use carbon or ink rather than wax. They also generally produce only black and white output. The printing mechanics are the same, with a printhead consisting of heated elements being brought into contact with a thermally sensitive ribbon. The heating of individual elements causes the carbon or ink to be released from the ribbon and transfer onto plain paper. The type of devices that use this basic technology can range from small heads and ribbons, such as thermal dot matrix or the IBM Quietwriter, through to page-width printheads and ribbons such as used in some facsimile machines. This technology is also found in specialist devices like labeling machines such as the Brother P-Touch range.

Again, a record of the output from all these devices remains on the ribbons they use and provides a possible avenue for the identification of the printer. Heating element failure, or disruption caused by an accumulation of debris, are the most likely causes of identifiable image faults.

Photocopiers

There have been, and still are, many different print technologies used to reproduce documents in photocopiers [19–22]. The process that became the most successful and widespread is dry toner electrophotographic, described in a previous section. This is still the process used in the majority of photocopiers today, although nowadays the analog photocopiers, which reflected the copied document's image onto the imaging drum, have been largely superseded by digital copiers, which perform the separate action of scanning the document and then sending this information to the printing unit which operates like a laser printer. Many of these devices are designed to also be used as networked printers, scanners, and facsimile machines.

Smaller versions of these devices, often using inkjet rather than electrophotographic technology, are being produced as low cost multifunction devices for the small and home office (SOHO) market.

The faults associated with the print technology used in most photocopiers have been discussed in the appropriate sections earlier. The main device specific characteristic of the photocopier that is of interest to an examiner is the glass platen. Marks on the platen, which may come from such things as scratches, dirt, ink residue, and opaquing fluid can be reproduced on every copy that machine subsequently makes. When they appear on a document they are often referred to as "*trash marks*". If the marks on the platen are noticed, they may be removed by cleaning the glass. But if the glass is not regularly cleaned and the marks are not obtrusive they can remain a feature of the output of that copier indefinitely.

Platen marks occur in the same position on each copied page. Often there are several different marks on the glass platen, which all reproduce onto the copied page as trash marks. Their fixed nature means the spatial relationship between the trash marks remains constant. Some authors liken these patterns of trash marks to constellations of stars. The fixed nature of platen marks helps to differentiate them from imaging drum marks in electrophotographic copiers, as the drum marks repeat along the page with every revolution of the imaging drum. This repeating pattern occurs if the circumference of the imaging drum is less than the length of the page, as is often the case. However, some high volume photocopiers use an electrophotographic imaging belt. The length of some of these belts means that there will be several pages gap between repetitions of a fault on the belt.

The gradual appearance and evolution of platen and drum marks can assist in dating documents. This requires a body of documents of known dates copied on the machine in question.

Duplication of platen marks provide evidence that a document has been copied twice on the same machine. This is sometimes seen in documents created using a "cut and paste" method.

Marks on the underside of the platen's cover can also be reproduced onto copied documents like platen marks. However, their occurrence tends to be unpredictable as it requires that they are not covered by the document being copied.

Another difference between platen and drum marks that is worth noting is what happens when a document is enlarged while being copied. Enlargement works by scanning a smaller than normal portion of the platen and then reproducing that smaller area across the entire normal page size. Hence, platen marks that are outside of the scanned area do not appear on the copy and those that are within the area being reproduced are enlarged. There is no change to the drum marks.

When taking samples from the photocopier you need to remember what you are capturing. Copies taken with the lid down and no paper on the platen capture marks from the underside of the lid, the platen, and the drum. Copies taken with a piece of paper fully covering the platen capture platen and drum marks. This piece of paper should be retained so that it can be determined that none of the copied marks came from a defect in the paper. Copies taken with the lid open and nothing on the platen produce black pages that show up any white faults on the imaging drum. If the copier is also set up as a printer, printing a largely white page captures any drum faults.

The potential for color copiers to be used for counterfeiting purposes prompted some manufacturers to introduce specific anticounterfeiting measures in their color copiers. These included software designed to recognize the patterns from major currencies and prevent the copier from reproducing those patterns. They also created what is in effect a built in drum fault. The copier deliberately prints a pattern of dots, unique to each machine, onto each copy it makes. The machine can then be identified by comparing the dot pattern in the questioned document to that seen on a sample print out from the machine. Through close collaboration with manufacturers, central banks and counterfeiting investigators can also use these proprietary codes to identify a machine from its printed output [23, 24].

Facsimile Machines

A facsimile machine, like a digital copier, consists of a scanner and a printing engine. The print technology employed in them is usually either direct thermal paper, thermal fusion, laser (electrophotographic), or inkjet. Direct thermal paper was the process often associated with facsimile machines with its rolls of shiny thermal paper that quickly faded. After a hesitant start, thermal fusion (using a thermal ribbon to print onto plain paper) took over from thermal paper

because it produced a permanent image and was cheaper than a laser print engine. While the laser print engine facsimiles still seem to dominate the business market, the rise of multifunction inkjet devices means inkjet printed faxes are possibly appearing more frequently.

One of the main differences between faxes and other documents is usually their resolution. While a multifunction device may have a high resolution scanner and printer, the standard protocols that enable different models of facsimile machines to talk to each other mean that transmissions usually take place at around 200 dpi or less. This is what causes the highly pixelated images we associate with facsimile transmissions.

The other distinctive part of the facsimile document is the Transmit Terminal Identifier (TTI) strip along the top of the document. This strip is supposed to carry information regarding the transmission such as the date/time, who from/to, telephone, and page numbers. However, the vast majority of this information can be edited and so cannot be relied on as accurate. Because manufacturers employ different fonts and layouts in these strips, an examination of these aspects may assist in determining the likely make or model of the sending machine. An important point to remember about the TTI strip is that it is generated by the sending machine electronically. That is, it has not been scanned. Accordingly, a TTI on an original facsimile document should be better defined than the body of the fax. If the TTI contains evidence of scanning (not just its normal pixelated appearance), then this suggests that the document has either been copied on a facsimile machine, or is not a first generation fax.

The types of individuating faults generally associated with facsimile machines are vertical black or white lines running through the page. If the line does not extend into the TTI strip, this shows the fault lies with a scanning element in the sending machine. If a scanning element has become obscured (from something picked up off a document), then it reproduces a black line. If there is a fault in the scanning element, it may produce a white or black line, depending on whether it is defaulting to off or on.

If a vertical line extends into the TTI strip, this indicates a fault with the receiving machine.

These faults, along with any print technology faults, can be used to link a document back to a particular facsimile machine. For those machines using a thermal ribbon, a negative image of anything printed on the machine (received faxes, direct copies, and transmission/machine status reports) is present on the ribbon.

GORDON A.I. SHARFE

Y-Chromosome Short Tandem Repeats

Introduction

The physical map of the Y chromosome consists of three distinct regions: the euchromatin, the heterochromatin and pseudoautosomal regions (PARs). The PARs are located at the telomeric ends of the chromosome and constitute ~5% of the Y chromosome sequence. PARs are the only regions of the chromosome to undergo recombination with the X chromosome during male meiotic events. The remaining 95% of the Y chromosome does not undergo recombination referred to as the *nonrecombining region of the Y chromosomes* (*NRY*) and comprises euchromatin sequences (that contain all of the chromosome's known genes) and the functionally inert heterochromatin. Thus, the entire NRY is inherited in a patrilinear manner, with a haplotype of physically and genetically linked genetic markers passed essentially unchanged, barring any rare mutations, from father to son [1].

The unique biology of the genetic markers present on the NRY region has resulted in their widespread use in determining patrilineal relationships within and between populations to aid in understanding of human migration and evolution [2, 3]. Y-chromosome microsatellites or short tandem repeats (STRs) are one class of these genetic markers that have been incorporated into a variety of multiplex PCR assays for potential forensic casework applications [4–12]. Their intended use is not to replace autosomal STR loci but to employ them in casework situations in which the traditional autosomal loci would not be expected to yield sufficient probative information. For example, Y-chromosome short tandem repeats (Y-STRs) are particularly useful for cases involving admixed male and female DNA for which a separation of the male- and female-derived cells is unsuccessful or not feasible [13–15].

Commonly Used Y-STR Markers

A major international multicenter study of 13 candidate Y-STR markers resulted in recommendations for the use of nine core loci for standard forensic haplotyping [3]. These loci are referred to as the *minimal haplotype loci* (*MHL*), and include DYS19, DYS385 (a) and (b), DYS389 (I and II), DYS390, DYS391, DYS392, and DYS393 (*see* **Mini-STRs** for a description of the naming conventions for different loci and alleles). Despite the initial utility of this set of markers in forensic casework, there was a need for additional Y-STR loci to be used in conjunction with these markers to improve the discriminatory capacity of Y-STR testing. In 2003, the use of two additional loci, DYS438 and DYS439, was recommended by the Scientific Working Group on DNA Analysis Methods (SWGDAM) [16]. The MHL loci plus the two additional loci are referred to as the "SWGDAM core loci."

Various combinations of the common Y-STR loci have been incorporated into commercially available multiplex systems (Table 1) [6, 7, 10–12]. The

Table 1 Commercial Y-STR multiplex amplification kits

Commercial kit	Manufacturer	Incorporated loci
Commonly used commercial kits		
PowerPlex® Y	Promega Corporation, Madison, WI, USA	DYS19, DYS385a/b, DYS389I, DYS389II, DYS390, DYS391, DYS392, DYS393, DYS437, DYS438, DYS439
AmpF*l*STR® Yfiler™	Applied Biosystems, Foster City, CA, USA	DYS19, DYS385a/b, DYS389I, DYS389II, DYS390, DYS391, DYS392, DYS393, DYS437, DYS438, DYS439, DYS456, DYS458, DYS448, DYS635(C4), H4
Previously available commercial kits		
Y-Plex™ 5	Reliagene Technologies Inc., New Orleans, LA, USA	DYS19, DYS385a/b, DYS389II, DYS390, DYS391, DYS393
Y-Plex™ 6	Reliagene	DYS389I, DYS389II, DYS392, DYS393, DYS438, DYS439
Y-Plex™12	Reliagene	DYS19, DYS385a/b, DYS389I, DYS389II; DYS390, DYS391, DYS392, DYS393, DYS437, DYS438, DYS439

Promega PowerPlex® Y kit, which contains the SWDGAM core loci plus DYS437, and the Applied Biosystems AmpF*l*STR® Yfiler™ kit, which also contains the SWGDAM core loci plus several additional markers (DYS437, DYS448, DYS456, DYS458, C4 (DYS635), and H4) are two of the most commonly used multiplex kits in the US [6, 7]. Figure 1 gives an example of a 17-locus Y-STR profile from an individual obtained using the Yfiler™ kit. Three additional Y-STR systems were developed by Reliagene Technologies (Y-Plex™5, Y-Plex™ 6, and Y-Plex™ 12) but are no longer commercially available [10–12]. All of these kits have been fully validated for forensic use as required by US national DNA standards and in accordance with SWGDAM validation guidelines [6, 7, 10–12]. They have been optimized to exhibit a high degree of sensitivity and specificity for male DNA, even in the presence of a vast excess of female DNA.

Interpretation of a Y-STR Match

Since the loci in the NRY region of the Y chromosome are inherited as a physical block of physically linked haplotypes, independent assortment does not occur and the loci are in linkage disequilibrium with each other. As a result the product rule cannot be used to determine multilocus Y-STR frequencies. A counting method is commonly employed in order to estimate the frequency of occurrence of a particular Y-STR haplotype. With the counting method, the frequency of the haplotype is the number of times the haplotype is observed divided by the number of samples in the database. Alternative methods for Y-STR haplotype frequency estimates have been suggested including one based upon a mismatch distribution approach that allows the evaluation of the proportion of pairs of Y-STR haplotypes that are prone to become identical by state (IBS), in one generation, by recurrent mutation [17].

To correct for possible sample effects when using databases of limited size, the use of confidence intervals around the haplotype frequency estimate has been recommended. Reporting a haplotype frequency without associated confidence intervals may still be acceptable as a factual statement regarding observations in a particular database. If a confidence interval is applied and the haplotype has been observed in the database, the upper 95% confidence limit would be calculated using the following formula

$$p + 1.96\sqrt{\frac{(p)(1-p)}{n}} \qquad (1)$$

where p is x/n (n is the database size, x is the number of times observed in the database). If

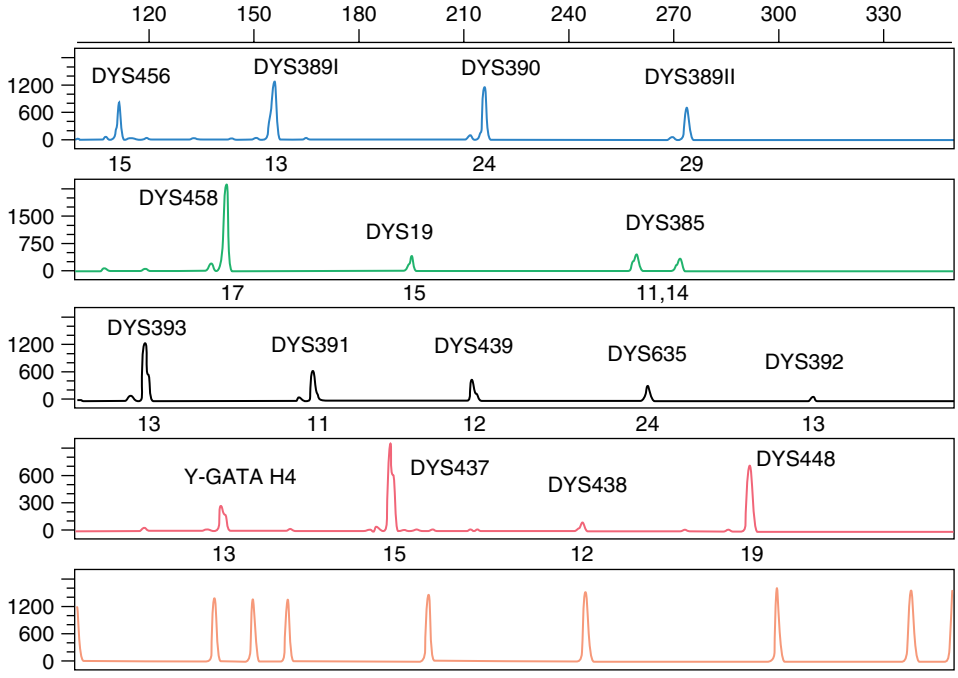

Figure 1 Y-STR profile using the Applied Biosystems AmpF*l*STR® Yfiler™ Amplification Kit. 17 Y-STR loci are coamplified in a single reaction, separated by capillary electrophoresis, and displayed as an electropherogram. The *x* axis represents fragment size (base pairs) and the *y* axis represents signal intensity (relative fluorescence intensity (RFU)). Each locus is labeled with a fluorescent dye: top channel – 6-FAM (blue); second channel – VIC (green); third channel – NED (yellow); fourth channel – PET (red); bottom channel – LIZ (orange) – internal size standard

the haplotype has not been previously observed in the database, the formula used to calculate the upper 95% confidence limit would be the following

$$1 - (0.05)^{1/n} \qquad (2)$$

where n is the size of the database. A simplified alternative formulation can also be used in this instance; $3/n$ (n = size of the database). This value is close to the earlier formula and for 95% of the time the real frequency is less than that estimate. Owing to population differentiation between subpopulations within the broader ethnic groups an appropriate θ (or F_{ST}) correction, akin to the situation with autosomal STRs, may be applicable [18, 19].

Empirical studies have confirmed the nonlinkage of Y-STR haplotypes and autosomal STR profiles [18]. Therefore, in cases with both autosomal and Y-STR analysis performed, it is possible to multiply the autosomal STR profile frequency with the upper confidence limit bounded Y-STR haplotype frequency to produce an overall frequency estimate for the combined profiles.

Casework Applications

Y-STRs can be particularly useful when trying to determine the genetic profile of the male donor in a male/female DNA admixture when the female DNA component is present in vast excess (e.g., ≥100-fold) and when traditional autosomal STR analysis fails or is not well suited for the particular analysis [13–15]. Samples containing a mixture of body fluids other than semen, such as in saliva/saliva mixtures, saliva/vaginal secretion mixtures in cases of oral sodomy, or fingernail scrapings with cells from the perpetrator may not be suitable for autosomal STR analysis. In these types of samples, unlike sperm containing samples, a differential lysis approach to separate the male and female cells is not possible. The minor male component in nondifferentially extracted

samples would often not be detectable with the PCR-based autosomal STR systems routinely used. This is due to the kinetics of the PCR process itself, which does not permit minor components to be detected at low levels (i.e., $\leq 1/20$) because of titration of critical reagents by the major DNA component [20]. Autosomal STR analysis may also fail with some semen containing samples in which few sperms are present, or are present in an extremely fragile state, such as in extended interval (i.e.,>48 h) postcoital samples. Differential extraction of these particular samples may not result in male profile being obtained due to a combination of premature lysis of the sperm's cellular constituents into the nonsperm fraction and to sperm loss during the physical manipulations required of the DNA isolation process. Therefore the use of Y-STR systems can eliminate the need for differential extractions (separating the male and female fractions), thus reducing the potential loss of the small amount of male DNA that may be present in such samples.

Y-STRs are hemizygous in nature, with only one allele being found at each single-copy locus. Therefore, Y-STRs can be useful in determining the number of male contributors in an admixed DNA sample [8, 21–23]. Mixture analysis using autosomal analysis becomes quite complex when the number of donors exceeds two. However, the presence of multiple alleles at each Y-STR locus in a sample can give a more precise indication of the number of male contributors.

Y-chromosome polymorphisms may also be useful in criminal paternity cases, missing persons cases, and in the identification of victims involved in mass disasters where a reference sample from the (male) victim may not be available [24–30]. Y-chromosome markers are inherited as a physical block unchanged from one generation to the next (barring any random mutation events). Therefore, a Y-STR profile obtained by typing a male relative in the same lineage should be the same as that of the victim. Additionally, Y-STR analysis may provide additional discrimination in situations where a complete autosomal profile is not obtained, such as in mixtures or partially degraded samples [20, 31–35].

Y-STR analysis may aid in familial searches, which refers to the use of low stringency autosomal STR matching of a crime scene profile with an offender DNA database to identify possible biological relatives of the donor of the crime scene sample [36, 37]. With the large number of samples present in offender databases, several individuals from different candidate families can arise as potential relatives to the donor of the crime scene profile. Subsequent Y-STR analysis of the crime scene profile and the offenders in the database identified as potential relatives should eliminate most of the adventitious candidates. This not only facilitates the efficiency of the investigative process but also precludes unnecessary invasion of the privacy of noninvolved families. However, coincidental matches between unrelated individuals still occur with the limited number of Y-STR loci typically used in forensic casework. Therefore, it may be necessary to use additional highly discriminating "noncore" Y-STR loci in order to resolve coincidental matches and provide a more accurate indication of true relatedness.

Glossary

AAFS	American Academy of Forensic Sciences, representing over 5000 scientists including physicians, attorneys, dentists, toxicologists, psychiatrists, engineers, and educators, in the application of science to the law.
AAS	Atomic Absorption Spectroscopy.
Accompanying Drop	A small droplet that forms between a larger drop and its blood source when the larger drop breaks away and falls free.
Accuracy	The degree of closeness between a measured or calculated quantity and the actual value, cf Precision.
ACE-V	Analysis, Comparison, Evaluation, Verification; a method used by fingerprint examiners (especially in the United States) to standardize evidence examination steps.
Admissibility	Admissibility of expert evidence in legal proceedings is a matter to be determined by the judge (the finder of law) rather than the jury (the finder of fact). Expert evidence that is deemed inadmissible is excluded from the proceedings.
Admission	(i) The acceptance of a fact in a legal procedure; (ii) A confession of wrongdoing or of guilt; (iii) The acknowledgment of the truth of a fact.
Agonal Respiration	Abnormal breathing, characterized by irregular, gasping, shallow, and slow breaths interrupted by irregular pauses.
Algorithm	Mathematical routine used in computer processing of data to sort or classify information.
Aliquot	A portion of a total amount of solution (e.g., the 10-ml solution was added to the beaker in 2-ml aliquots).
Alkaline Phosphatase	An enzyme produced in the liver, bone, and placenta.

Allele An alternative form of a gene (one member of a pair), that occupies a given locus (location) on a chromosome.

Allelic Frequency The frequency with which a particular allele appears at a specific DNA locus (location) compared with all the possible alleles in a defined population. It is generally expressed as a percentage or proportion of the specified population.

Amplicon Pieces of DNA created by natural amplification processes (such as natural gene duplication) or artificial means (such as a polymerase chain reaction or ligase chain reaction).

Amplification Multiplication of the number of DNA molecules from an initial "template".

Analyte The substance that is being identified or measured in an analytical procedure (e.g., a titration).

Anastomosis An opening between two normally distinct spaces or organs, caused by surgery, pathology, or trauma.

Angle of Impact The internal angle at which blood strikes a target surface relative to the horizontal plane of that target surface.

ANSI American National Standards Institute. This organization promotes and facilitates voluntary consensus standards and conformity assessment systems across a range of areas, and oversees their integrity.

Aptamer Oligonucleic acid or peptide macromolecules whose shape assists in binding to a specific target molecule.

Arterial Spurting (or Gushing) Characteristic bloodstain patterns on a target surface resulting from blood exiting under pressure from a breached artery. Characterized by their size and shape.

ASCII American Standard Code for Information Interchange. A coding system that converts font characters to standard numeric values.

Assay A technique in which an analyte's properties or concentration are measured. Includes immunoassays (e.g., see CEDIA, ELISA), bioassays, stem cell assays, and microbiological assays.

ASTM American Society for Testing and Materials, now ASTM International. A voluntary standards development organization producing technical standards for services, systems, products, and materials across a range of industries.

Atomic Number The number of protons in the nucleus of an atom; generally equal to the number of electrons revolving around the nucleus.

Atomic Weight The relative average weight of an atom of an element, compared to a value of exactly 12 for the principal stable isotope of carbon (carbon-12).

Autosome Any chromosome other than the sex chromosomes (X and Y). Humans have 22 pairs of autosomes.

Back Spatter Blood that is directed back toward its source of energy; often associated with gunshot wounds of entrance.

Bacteria Microscopic organisms in which single cells do not have a membrane-bounded nucleus or any other membrane-bounded organelles like mitochondria and chloroplasts.

Blind Verification The independent application of an accepted methodology to the analysis reached by another examiner-researcher who has no expectation or knowledge of the conclusion of the original examiner. A verification is double-blind when the reviewing examiner is not aware that any analysis has been effected earlier by another person.

Blood The "circulating tissue" of the body; the fluid and its suspended formed elements that are circulated through the heart, arteries, capillaries, and veins.

Blood Clot A blood clot is formed as a result of a complex mechanism involving the plasma protein fibrinogen, platelets, and other clotting factors. It is observed visually as an insoluble network of fibrous material (fibrin and red blood cells).

Bloodstain The resulting transfer when liquid blood comes into contact with a surface, or when a moist or wet surface comes into contact with dried blood.

Bubble Rings Rings in blood that result when blood containing air bubbles dries retaining the circular configuration of the bubbles.

Buccal Swab Device similar to a cotton bud used to obtain a DNA sample from a person by wiping the inside of the cheek.

Buffer Solution that resists change to its pH (acidity/basicity) when small amounts of acid or base are added to it, or when it is diluted.

Burden of Proof The duty to present evidence to support the elements of a cause of action or an asserted legal defense. In criminal cases, the primary burden of proof of guilt of the accused is on the prosecution; in civil cases, the primary burden of establishing the existence of the elements of a cause of action is on the plaintiff. The burden of proof may shift during legal proceedings from one party to another, in accordance with specific rules of procedure. See also Quantum of Proof.

Cast-Off Pattern Blood that has been projected onto a surface as a result of being cast off or flung from an object in motion.

CEDIA Cloned Enzyme Donor Immunoassay. A homogeneous assay used in biochemistry that allows highly sensitive detection of low-molecular-mass analytes without separation steps. The bacterial enzyme b-galactosidase is genetically engineered into two inactive fragments (an enzyme donor and enzyme receptor). The enzyme donor fragment is able to covalently bind to both analytes and ligands, and this binding does not affect the ability of the enzyme donor to then reassociate with the enzyme receptor to form an active enzyme. The amount of enzyme formed is directly proportional to the concentration of analyte in the sample, and is detectable by spectrophotometric methods.

Chimerism Extremely rare disorder in which a single organism has genetically different chromosomes. It can manifest as two sets of DNA, organs that do not match the DNA of the rest of the organism, the presence of both male and female sex organs, or small patches of DNA throughout the body that are different from the DNA of the rest of the body.

Chromatin A combination of DNA and proteins found in the cell nucleus that together make up chromosomes. The name is derived from "colored material" because chromatin can be easily stained and thus visualized.

Chromatography A process of separation of compound materials by percolation through a selectively absorbing medium (paper, liquid, gas-liquid, gas-solid, etc.).

Chromosome A very long DNA molecule with associated proteins that is located in an organism's cells and carries portions of the hereditary information of an organism. Humans have 23 paired chromosomes.

Chronotrope That which affects the heart rate; positive chronotropes increase heart rate and negative chronotropes decrease the heart rate.

Circumstantial Evidence — Indirect evidence. Evidence of one fact from which a different but related fact may be inferred.

CODIS Database — Combined DNA Index System database, funded by the Federal Bureau of Investigation.

Compression Transfer Pattern — A contact bloodstain pattern created when a wet, bloody surface contacts a second surface with minimal lateral motion. A recognizable mirror image, or at least a portion of geometry of the original surface, is transferred to the second surface.

Confession — An admission of guilt or of an incriminating fact following the commission of a crime. In most jurisdictions, confessions that are the product of police questioning can be used as evidence only if it is established that the confession was voluntarily made and not the product of coercive methods, torture, or inhumane treatment. In most countries, there exists a right to remain silent during police interrogation and a corresponding right not to be forced to incriminate oneself.

Confidence Interval — A statistical estimate of an interval that is thought likely to contain the true value of whatever is being estimated or measured. The more confidence sought in the reliability of the results, the larger the interval is likely to be.

Contamination — Error in which unrelated material is introduced into a sample, thus tainting it (e.g., sneezing over a DNA sample to be analyzed in a forensic laboratory, thus contaminating the sample with saliva).

Controls — A set of positive or negative experimental conditions that ensure that a scientific experiment is working correctly. The negative control should always produce a negative result and the positive control should always produce a positive result.

CRFP — Council for the Registration of Forensic Practitioners (UK).

Defendant — The person or entity against whom a legal action is brought by another.

Density — The mass-per-unit volume of a substance, usually expressed in grams per cubic centimeter, under special or standard conditions of pressure and temperature.

Direct Evidence — Evidence that, if believed, establishes a fact without resort to any further inferences of other facts. Example : an eyewitness testimony as to the identity of a perpetrator of an act.

Directionality — Relating to or indicating the direction that blood was traveling in space from its point of origin.

Directionality Angle The angle between the long axis of a bloodstain and a predetermined line on the plane of the target surface taken as 0°.

DNA Advisory Board (US) Appointed by Director of the FBI to set and oversee quality assurance standards in US DNA crime laboratories and for the CODIS database.

Draw-Back Effect Blood in the barrel of a firearm, which has been drawn back into the muzzle of a firearm that was discharged when its muzzle was in contact or near contact with a victim.

Drip Pattern A bloodstain pattern that results from blood dripping into blood.

Drop A volume of blood of sufficient weight to overcome its surface tension and fall free from the mass of blood from which it was formed; typically a volume of 0.05 ml.

Droplet A blood drop volume less than the typical volume of 0.05 ml that was produced by energy exceeding that of gravitational attraction alone.

EAP Extensible Authentication Protocol. Universal authentication framework used commonly in wireless networks and point-to-point network connections.

ECD Electron Capture Detector, used in gas chromatography.

EIA Enzyme Immunoassay. This terms covers a range of biochemical assays in which antigen and antibodies can be quantifiably analyzed. Antigen-antibody reactions are indicated by a color change produced when enzymes react with a substrate (or inhibition occurs). Examples of EIA include EMIT and ELISA.

Electron Microprobe Analysis A research instrument for analyzing any element heavier than sodium in the periodic table.

Electrophoresis Technique to separate charged molecules by migration on a support medium exposed to an electric potential.

ELISA Enzyme-Linked Immunosorbent Assay. A technique used to detect the presence of antigens or antibodies in a sample.

EMIT Enzyme Multiplied Immunoassay Technique.

ENFSI European Network of Forensic Science Institutes. Organizes proficiency tests, seminars, collaborative studies, best practice manuals and glossaries of forensic terms for forensic science organizations throughout Europe.

Enzyme Protein catalysts that speed up the rate of a reaction.

ESDA Electrostatic Detection Apparatus.

Euchromatin A relatively low-density chromatin (i.e., DNA arranged with proteins to make chromosomes), which also has a relatively high concentration of genes.

Expirated Blood Blood that is blown out of the nose, mouth, or a wound as a result of air pressure and/or air flow, which is the propelling force.

Fact Finder In a legal proceeding, the person or persons who determine all disputed factual issues after considering all the evidence. In jury trials, the jury is the fact finder; in bench trials (nonjury) the trial judge is the fact finder.

Familial Search/Kinship Testing Search of a DNA database to identify other people who share a number of alleles or a particular allele (e.g., rare alleles). The search can identify related people or random matches.

Felony Murder A form of common law murder where the killing occurs accidentally while the accused is engaged in the commission of a common law felony. Proof of the intent necessary for the triggering felony substitutes for proof of malice, so that the unintended death can be prosecuted as murder. Even in countries that have the common law as the basis of their criminal justice system, most criminal offenses are today defined by statute.

FEPAC Forensic Educational Program Accreditation Commission. Now a standing committee of the American Academy of Forensic Sciences. FEPAC accreditation is voluntary but is established and standardized. FEPAC deals with accreditation, including external validation, helping students select institutions, and serving as a means for forensic scientists and employers to be able to judge the credentials of graduates. It also can help improve program quality, and it provides a certain demonstrable level of competency to the graduates.

FID Flame Ionization Detector. A type of detector used in gas chromatography, which is particularly useful for the detection and analysis of hydrocarbons and organic compounds with a high proportion of carbon.

Flight Path The path of blood as it moves through space from its origin to the surface it strikes.

Forensic Belonging to, used in, or suitable to courts of law or to public discussion or debate.

Forensic Science The use of scientifically based principles as these principles intersect with and provide evidence for legal proceedings.

Forward Spatter Blood that travels in the same direction as the source of energy or force causing the spatter. Most often associated with gunshot wounds of exit.

FPIA Fluorescence Polarization Immunoassay.

Gas Chromatography Laboratory method and instrument for the separation of complex mixtures to produce a chromatogram, which, by comparison with ASTM chromatogram standards, enables tentative identification of a sample examined.

GC/MS See Gas Chromatography and Mass Spectrometry.

Genotype The specific alleles that make up the genetic code for an individual. Different from phenotype, which refers to the outward appearance of the individual and which is affected by the genotype as well as the environment.

Grain Equivalent to 0.00648 g in weight. Also, Standard American unit of weight for bullet weight and weight of powder charge; 7000 grains per pound.

Gram Metric unit of weight; one gram is the equivalent of 15.4324 grains.

Haplotype A combination of alleles at multiple loci that are transmitted together on the same chromosome, or a set of single nucleotide polymorphisms (SNPs) on a single chromatid that are statistically associated. Can also refer to an individual collection of short tandem repeat (STR) allele mutations within a specific genetic segment.

Harmless Error A technical violation of some procedural rule that does not substantially affect the outcome of litigation and thus does not require a new trial. See also, Prejudicial Error.

Heat of Passion Term used in criminal law and in behavioral science to distinguish intentional killings from murder to manslaughter when the killing occurs in the heat of passion from lawful provocations on the part of the victim.

Heterogeneous Having a diverse, nonuniform composition. See Homogeneous.

Heterozygote Individual with different alleles at a specific locus on homologous chromosomes, one inherited from each parent.

High-Velocity Impact Spatter	A bloodstain pattern caused by a high-velocity impact/force to a blood source of approximately 30 meters per second or greater. (Examples of such impact are gunshot, high speed machinery, or fast moving objects like an airplane propeller.)
Homogeneous	Having a uniform structure or composition (or components of the same or similar kind). See Heterogeneous.
Homozygote	Individual with two identical alleles at a specific locus on homologous chromosomes, one inherited from each parent.
HPLC	High Performance (or High Pressure) Liquid Chromatography.
Hypothesis; Hypothesis Testing	A hypothesis is the postulating of an educated guess that is then tested and compared to experimentally collected data to determine whether the hypothesis can be either proved correct or false.
IAFIS	Integrated Automated Fingerprint Identification System.
Iatrogenic	A disease, disorder, complication, or effect caused by medical treatment.
Impact Pattern	A bloodstain pattern that is created when a blood source receives an impact that results in the random dispersion of smaller drops of blood.
Infrared Spectroscopy	Use of absorption of infrared radiation to obtain the composition of a substance.
Inotropic	That which affects the force of muscle contraction.
Involuntary Manslaughter	A common law felonious but unintended killing.
Isotope	Different versions of the same chemical element, in which the atoms have the same number of protons (atomic number), but different numbers of neutrons (and therefore a different atomic mass).
LASER	Light Amplification by Stimulated Emission of Radiation.
Ligand	An ion, molecule, or molecular group that binds to another chemical entity to form a larger complex. (Latin ligare, to bind).
Liquid Chromatography-Mass Spectrometry	(LCMS) Analysis using a liquid chromatograph instead of a gas chromatograph.

Lividity A sign of death in which the blood in the body causes a purplish red discoloration of the skin in whatever parts of the body are lowest (but not those in contact with the ground or another surface).

Locus A specific position on a chromosome. Plural loci.

Low-Velocity Impact Spatter A bloodstain pattern caused by a low-velocity impact/force of approximately 1.5 meters per second or less to a blood source.

Lumen The SI unit of luminous flux, a measure of the perceived power of light. Also; the central part of a tube.

Lysis The death of a cell by breaking of the cellular membrane. The solution containing the contents of lysed cells is a "lysate".

Major Profile In DNA analysis where there are more than two alleles at a locus (i.e., a mixture of DNA from at least two people), the ratio of peak areas may indicate a distinctive major contributor (larger peaks) and a distinctive minor contributor (smaller peaks).

Malice A mental state in criminal law and in behavioral science that was required in common law jurisdictions for unlawful killings regarded as murder and for the crime of arson. Malice can be either express or implied. Express malice is evidenced by proof of an intent to kill. Implied malice is evidenced by proof that the accused killed another person, either by intending to do great bodily harm to the victim, or by acting with wanton and willful disregard for the safety of the victim or others.

Mark Term commonly used In the United Kingdom and some Commonwealth countries to designate any item of trace evidence found during a criminal investigation and believed to be associated with the crime that can be studied and compared. If the mark is invisible or nearly invisible until revealed by an enhancement method, in the United States and Canada it is more commonly referred to as a latent impression.

Mass Spectrometry (MS) Analytical method usually employed with gas chromatography (GC/MS) to identify materials based upon production and detection of characteristic molecular fragments.

Medium-Velocity Impact Spatter A bloodstain pattern caused by a medium velocity impact/force of approximately 7.6 meters per second to a blood source.

Microtome Instrument used to cut biological specimens into thin transparent sections suitable for microscopic examination.

Minor Profile In DNA analysis, where there are more than two alleles at a locus (i.e., a mixture of DNA from at least two people), the ratio of peak areas may indicate a distinctive major contributor (larger peaks) and a distinctive minor contributor (smaller peaks).

Misting Blood that has been reduced to a fine spray as a result of applied energy.

Modus Operandi (Latin) The manner of operation or the means of accomplishing an act often revealing characteristics and methods peculiar to certain criminals.

Mole Avogadro's number of constituent entities (approximately 6.02214 1023). The 'constituent entities' may be atoms, ions, atomic particles etc.

Multiplex System of testing multiple DNA loci at the same time; for example, SGM+ tests 10 loci, CODIS tests 15.

Murder Under common law, the killing of a human being by another human being with malice aforethought.

Mutation An inherited or acquired permanent change in the DNA sequence of a gene.

Mydriasis Prolonged or excessive dilation of the pupil due to disease, trauma, or drugs and/or failure of the pupil to constrict when exposed to light.

NIST National Institute of Standards and Technology, a U S Department of Commerce division that sets, approves, and maintains measurements standards in the United States. Formerly called the Bureau of Standards.

Nosocomial Any disease contracted by a patient while under medical care, secondary to the patient's original condition. A category of iatrogenic effects.

Offer or Proof The offering of evidence, the admissibility of which is disputed, to permit a judicial officer to render a decision as to its admissibility. Offers of proof may require the presentation of testimonial evidence, or the presentation of documents or physical evidence for the inspection of the judicial officer.

Parent Drop A drop of blood from which a wave cast off or satellite spatter originates.

Passive Drop A drop that is created or formed solely as a result of gravity.

Pattern A form, shape, or outline that is recognized. If comprised of small spots, there must be an adequate number to be classified as a pattern.

PCR Polymerase Chain Reaction. A technique for making multiple copies of DNA from an initial sample.

Peak Height Imbalance In DNA profiling, a peak height imbalance occurs when two peaks that were expected to be the same are more than 30-40 different in terms of their height.

Perimeter Stain A bloodstain that is comprised only of its peripheral outline. (This stain forms when the central area has been removed by wiping after the blood has partially dried, or by its center flaking off after it has completely dried.)

PGM Phosphoglucomutase. An enzyme that facilitates the interconversion of glucose 1-phosphate and glucose 6-phosphate. Variations can be identified from blood tests and used as genetic markers.

Phenotype The outward appearance of the individual, affected by the genotype and the environment. Different from genotype, which refers to the specific alleles that make up the genetic code for an individual.

Plaintiff The person or entity who initiates a legal action against another.

Point (Area) of Convergence A point or area, on a two dimensional surface, from which a bloodstain pattern originated as determined by tracing the long axis of well-defined bloodstains back to a common point or area of convergence.

Point (Area) of Origin The three-dimensional point or area from which a bloodstain pattern originated as determined by projecting angles of impact of individual, well-defined bloodstains back to a common point or area of convergence.

Polarized Light Microscope (PLM) A microscope that is equipped with two polarizing elements that are placed in the optical path of a microscope.

Polymerase An enzyme that catalyzes the polymerization of deoxyribonucleotides into a DNA strand. In DNA replication, polymerase uses an existing DNA strand as a template, and adds nucleotides to create a new strand.

Precision Reproducibility or repeatability, that is, the degree to which further measurements or calculations will show the same or similar results. Different from accuracy.

Prejudicial Error See Reversible Error.

Presumption In law, a device established either by custom, common law, statute, or rule, which requires that the existence of the presumed fact be taken as established when certain other basic facts are established, admitted, or uncontested. The existence of a legally recognized presumption shifts the burden of disproving the existence of the presumed fact to the party who denies or contests its existence. Most legally recognized presumptions merely create inferences, which, in criminal cases, the fact finder is permitted but not required to entertain. "Conclusive presumptions" are not really presumptions, but are rules of substantive law. Example: Asserting that everyone is presumed to know the law merely precludes, as a matter of law, use of "ignorance of the law" as a defense.

Presumptive A presumptive test identifies when something can be excluded (e.g., the sample is not blood) and identifies what it might be (e.g., the sample might be blood).

Prima Facie Case A party who has the burden of proof (plaintiff) has made a prima facie case when he has presented sufficient evidence to allow the tribunal to reasonably determine the issue in his favor, unless or until the opposing party presents evidence to contradict the plaintiff's evidence.

Primer A strand of nucleic acid that is required for the initiation of DNA synthesis (e.g., in PCR). A primer is chosen to be complementary to the DNA region targeted for amplification under specific thermal cycling conditions.

Projected Blood Pattern A pattern created when blood is projected or released as a result of force.

Pull Up Also termed "bleed-through". Occurs when DNA analysis software fails to discriminate between different dye colors, thus creating false peaks. Can be identified by analysis of the position of peaks across the color spectrum. Can be caused by sample overload.

Pyrolysis The chemical decomposition of matter into new compounds through the action of heat or burning.

Qualitative Analysis Determination of the type of material(s) in a sample.

Quantitative Analysis Determination of the amount of material(s) in a sample.

Quantum of Proof — In satisfying the burden of proof in a legal matter, the sufficiency of the evidence depends on the type of legal matter that is pursued. In criminal cases, proof of guilt must be beyond a reasonable doubt. In civil cases, depending on the jurisdiction, the evidence must be proved by a preponderance of the evidence, by clear and convincing evidence, or proved on the balance of probabilities.

Racemization — A racemic mixture, or racemate, has equal amounts of left- and right-handed enantiomers of a chiral molecule (i.e., mirror-image molecules that can not be superimposed, because of their geometry). Racemization is the transformation of one half of the molecules of an optically active compound into molecules having exactly the opposite configuration (thus the compound is now optically inactive overall).

RADAR — Radio Detection and Ranging. Used extensively in speed detection devices that depend on use of the Doppler Effect.

Refractive Index — The ratio of the speed of light in a vacuum to the speed of light through a transparent medium (such as glass).

Relative Fluorescence Unit — A unit of measurement for electrophoreses, which uses a fluorescence detector.

Relevant Evidence — Evidence that tends to make the existence of a fact of consequence to the determination of a triable issue in court more probable or less probable than it would be without the evidence.

Reversible Error — Sometimes also called Prejudicial Error; the erroneous admission or exclusion of evidence or an erroneous procedural that substantially affects the legal or constitutional rights of a party, entitling that party to a new trial or dismissal of prior proceedings. See also: Harmless Error.

RFLP — Restriction Fragment Length Polymorphism.

Ricochet or Secondary Splash — The deflection of large volumes of blood after impact with a target surface that results in staining of a second surface. (Ricochet does not occur when small drops of blood strike a surface.)

Satellite Spatter — Small droplets of blood that are projected around or beside a drop of blood upon impact with a surface. (A wave cast off is also considered a form of satellite spatter.)

Scallop Pattern — A single drop bloodstain pattern that is characterized by a wavelike, scalloped edge. (When scallops appear only on one side they identify the blood drops directionality prior to impact with the surface.)

Scanning Electron Microscopy (SEM) — A microscope that allows for the viewing of samples at much greater magnification (up to 100 000 times) than is possible with a light microscope.

Scientific Method — While there is no standard definition of the scientific method, it is a process of inquiry to explain observational collected data that are critically compared to known information and systematically analyzed so as to lead to a hypothesis, which is then tested, documented, and refined in a manner that minimizes bias and subjectivity. The result is a conclusion that is accepted as reliable by scientists in the same and other fields. The scientific method is marked by strict adherence to observation, objectivity, rationality, testing, and revising (if revision is indicated).

Sensitivity — Measures the proportion of positive results that are correctly identified as such. In other words, it is a measure of the probability of correctly diagnosing a condition/positive result (cf specificity, which measures the proportion of negatives that are correctly identified, i.e., specificity is a measure of the probability of correctly identifying a nondiseased person/negative result.)

Serum Stain — A clear, yellowish stain, usually having a shiny surface, normally associated with a bloodstain after some red cells have retracted following the clotting mechanism.

SGM+ — Second Generation Multiplex Plus (SGM Plus), a DNA profiling package manufactured by ABI (Applied Biosystems), in which 10 STR loci are analyzed.

SLP/MLP — Single Locus Probe / Multi Locus Probe. SLPs are DNA or RNA sequences that hybridize (i.e., form a DNA-DNA or DNA-RNA duplex) with DNA from a specific restriction fragment. MLPs are DNA or RNA sequences that hybridize with DNA at a number of different sites in the genome of an organism.

Smear — A relatively large volume of blood, at least 0.5 ml, that has been distorted to such a degree that further classification is not possible. Similar to a smudge, but a smear is a stain produced by a larger volume of blood. See also Swipe.

Smudge — A small bloodstain that has been distorted to such a degree that further classification is not possible.

SNP Single Nucleotide Polymorphism. A variation in a sequence of DNA that occurs when a single nucleotide (A, T, C, or G) differs between paired chromosomes in an individual.

Spatter Blood that is dispersed as a result of impact.

SPE Solid Phase Extraction (toxicology/drugs).

Spine The pointed, often elongated, linear streaks that radiate away from the center of a bloodstain.

Spoliation The intentional alteration or destruction of documents or evidence.

Spot A spot of blood is not a pattern. It may exhibit directionality, various degrees of size and spatter, and other recognizable characteristics, but a single spot of blood does not constitute a pattern.

Stenotic Narrowed or constricted, as in a stenotic artery.

Stutter Spurious "shadow" bands produced during PCR amplification of STR loci, which manifest as peaks in an electrophoretogram.

Surface Tension Two fluids in contact exhibit this phenomenon due to molecular attractions that appear to arise from a tension in the surface of separation. It is measured in dynes, the force that produces acceleration of 1 cm s?2 in a mass of 1 gram.

SWGDAM Scientific Working Group on DNA Analysis Methods (United States). Falls under auspices of the Federal Bureau of Investigation (FBI) and proposes and recommends revisions to the National Quality Assurance Standards (QAS) and liaises with the forensic DNA community.

Swipe Pattern A bloodstain pattern that results from a lateral transfer of blood onto a surface. (A feathered edge indicates direction of travel.)

Tachycardia Rapid heartbeat.

Tachypnea Rapid breathing.

Target A surface that has become bloodstained.

Tattooing Punctate abrasions, also termed stippling and gunpowder tattooing, are caused by unburned or partially burned pieces of gunpowder impacting the skin upon a weapon being fired in close proximity to the skin.

Teardrop The typical shape of a bloodstain that is produced when a drop or droplet of blood strikes a surface at an acute angle.

Telomere A region of repetitive DNA (TTAGGG) at the end of chromosomes, which stabilizes the chromosomes and protects the ends from attaching to one another. Many cells lose parts of the telomeres during cell division.

Terminal Velocity The maximum speed to which a free-falling drop of blood can accelerate in air. This is approximately 7.7 meters per second for a typical 0.05-ml drop.

TLC Thin Layer Chromatography.

Transfer Pattern A contact bloodstain created as a result of compression and/or lateral movement of a wet, bloody surface against a second surface.

TWGED Technical Working Group on Education and Training in Forensic Science (USA), which addresses qualifications for a career in forensic science, undergraduate programs, graduate programs, and continuing professional training. TWGED guidelines are voluntary and consensus derived.

UKAS United Kingdom Accreditation Service. Sole national accreditation body recognized by the UK government to assess, against internationally agreed standards, organizations that provide certification, testing, inspection, and calibration services. Accreditation by UKAS is intended to demonstrate the competence, impartiality, and performance capability of these evaluators.

Validation Process of checking that a test/process measures what it purports to measure, and performs effectively and reproducibly.

VASCAR Visual Average Speed Computer. VASCAR is used by some law enforcement agencies to measure the speed of vehicles.

Venous Insufficiency Syndrome Small bloodstains can be produced by ruptured varicose veins. These can resemble medium-velocity impact spatter.

Viscosity The internal friction within a fluid, which is described as the resistance to changing the form of the fluid. It is measured in centipoises, which is the tangential force/unit area required to maintain unit difference of 1 cm s?1 between two parallel plains separated by 1 cm of fluid.

Void or Shadow Pattern	Absence of bloodstain in an otherwise continuous bloodstain pattern.
Wave Cast Off	A small blood droplet that originates from a parent drop of blood due to the wavelike action of the liquid in conjunction with striking a surface at an angle less than 90°.
Wipe Pattern	A bloodstain pattern that is created when an object moves through blood that has not completely dried, thereby altering its appearance.
Y Chromosome	The chromosome that determine sex in mammals, including humans. In humans, it consists of approximately 60 million base pairs (G-C and A-T).
